Abecedarian Project

Tasha R. Howe
Humboldt State University, Arcata, CA, USA

Synonyms

Early intervention; Prevention of mental retardation

Definition

The Abecedarian Project was an early intervention project conducted by Craig Ramey and Francis Campbell on a mostly African-American sample of children at-risk for academic failure. The children have been followed from preschool into early adulthood with positive intellectual results.

Description

Ramey and Campbell conducted a prospective longitudinal study on approximately 50 children born between 1972 and 1977 [1]. The children were considered to be at risk for intellectual delays and academic problems because they were born to mostly young single mothers living in poverty. Children were screened for inclusion based on the number of risk factors they faced, including low parental education, father absence, receiving welfare, etc. The researchers randomly assigned 50+ matched children to a no-intervention control group as well. The goal of the preventive intervention was to prevent cognitive delay or non-biologically based mental retardation. Additional areas of interest included academic and social outcomes ranging from preventing grade retention to preventing teen crime.

Interventions for the preschool group included intensive pre-literacy work on language, learning, self-help, and motor skills. The children were also provided medical care at the intervention preschool site. Treatment children were exposed to high quality preschool with low adult/child ratios for the first 5 years of life. Interestingly, at kindergarten, both the intervention and control children were then randomly assigned to a school age (SA) intervention plan. This SA intervention consisted of assigning children to a home/school teacher who helped children with school work at home and at school. They also advocated on behalf of the families for social services, medical care, etc. The SA intervention continued for 3 years. This study design resulted in four groups that could be compared at the study's end: Preschool + School Age Interventions (PSA), Preschool + No School Age (PNSA), No Preschool + School Age (NPSA), and No Preschool + No School Age (NPNSA) intervention.

During preschool, children were assessed on language, cognitive, perceptual-motor and social developmental tasks from 6 to 54 months of age. By 18 months of age, the intervention group had reached national averages on all tests and far surpassed the control group, which declined by 18 months of age to below national averages.

When assessed at 12 and 15 years of age [2], the PSNSA group still showed academic and intellectual advantages over groups that had not received early preschool intervention. For example, IQ scores for PNSA were average 95 points while the NPNSA group averaged 90. The NPSA group had advantages over the NPNSA group, but overall, later school age interventions were inferior to those conducted during the preschool years.

The children were assessed again between ages 16–21 [3] in order to determine whether they had a better quality of life, including fewer criminal behaviors. However, there were no significant differences found between the groups in numbers, types, or severity of crimes committed. The authors suggest that to prevent crime, interventions must

Sam Goldstein & Jack A. Naglieri (eds.), *Encyclopedia of Child Behavior and Development*, DOI 10.1007/978-0-387-79061-9,

involve systematic work with families, not just their children.

The most recent assessment was in 2002 and examined the children at age 21 [4] to examine overall life outcomes. They found that the preschool intervention group versus the control group experienced fewer grade retentions (31 vs. 54% were retained) and was assigned to special education less frequently (24 vs. 47%). The preschool intervention group obtained more total years of education, attended college more, had fewer teenage pregnancies, and were better at reading and math. The NPSA group had better results than the NPNSA group, but weaker than those for children who had received the earliest intervention services. There were no differences between groups for violence and law breaking behavior.

The Abecedarian Project is considered by many to be an exemplary human experiment illustrating the power of brain plasticity in the early years. Their early work set the foundation for current movements like *Zero to Three* (www.zerotothree.org), and *First Five* (http://www.ccfc.ca.gov/default.asp), which provide resources, education, and materials about early brain development and emphasize the need for early stimulation to enhance developmental outcomes.

Abilify

Jeffrey S. Trotter, Andrew S. Davis
Ball State University, Muncie, IN, USA

Synonyms

Aripiprazole (generic name); Atypical antipsychotics; Partial dopamine agonist

Definition

Abilify (Abilify) is an atypical antipsychotic medication indicated for acute and maintenance treatment of adult as well as adolescent (13–17 years of age) patients with Schizophrenia. The medication also is indicated for acute and maintenance treatment of manic and mixed episodes associated with Bipolar I Disorder with or without psychotic features in adult and pediatric (10–17 years of age) patients [1].

Description

Abilify was developed by Otsuka Pharmaceutical in Japan and jointly marketed in the United States with Bristol-Myers Squibb [1]. Clinical trials sponsored by the manufacturer have resulted in the Food and Drug Administration (FDA) approving the use of Abilify as an atypical antipsychotic [1–3]. The FDA first approved Abilify for the treatment of adult Schizophrenia in November, 2002. The medication received additional approval by the FDA for the acute and maintenance treatment of manic and mixed episodes associated with Bipolar I Disorder, with or without psychotic features in adults September 2004 and March 2005, respectively. All of the adult trials were double-blind, placebo-controlled studies of 4–6 weeks' duration. Abilify also was approved by the FDA in November, 2007 for treating adolescents (13–17 years old) with a primary diagnosis of schizophrenia. The efficacy and safety of Abilify for use with this population was based on a manufacturer-sponsored 6-week, double-blind, randomized, placebo-controlled, multi-center study, with 302 ethnically diverse pediatric patients. Patients met DSM-IV criteria for schizophrenia and had a positive and negative syndrome scale (PANSS) $\geq$70 at baseline. In this trial, two fixed doses of Abilify (10 mg/day or 30 mg/day) were superior to placebo in the PANSS total score, the primary outcome measure of the study. The 30 mg/day dosage was not shown to be more efficacious than the 10 mg/day dose. Maintenance efficacy in pediatric patients with Schizophrenia has not been systematically evaluated. In February 2008, following a 4-week, double-blind, placebo-controlled study with 296 pediatric patients from multiple sites, the medication received approval for the acute treatment of manic and mixed episodes associated with Bipolar I Disorder in patients 10–17 years old. Participants in the trial met DSM-IV criteria for Bipolar I Disorder manic or mixed episodes with or without psychotic features and had a young mania rating scale (YMRS) score $\geq$20 at baseline. Both fixed dosages of Abilify (10 mg/day or 30 mg/day) were superior to placebo in change from baseline on the Y-MRS total score. Based on a similarly designed clinical trial (n = 197 pediatric

patients) the FDA approved Abilify in May, 2008 for the maintenance treatment of pediatric Bipolar I Disorder.

The most common side effects exhibited in pediatric clinical trials included somnolence, extrapyramidal problems, fatigue, nausea, akathisia, tremors, and headache [4]. In addition, pediatric patients with Major Depressive Disorder who receive Abilify as an adjunctive treatment may experience initial worsening of their symptoms of depression and/or the emergence of suicidal ideation and behavior [1, 5]. This is particularly problematic with the early use of the medication or during changes in dosage. Abilify is available in 2, 5, 10, 20, and 30 mg tablets and also may be administered as an intramuscular injection or as an orodispersible tablet [1]. The recommended target dose for pediatric patients is 10 mg/day with subsequent increases at 5 mg increments [1]. The medication may be administered without regard to meals and is primarily metabolized by the liver [4].

Similar to other atypical antipsychotic medications (e.g., clozapine, risperidone), Abilify's exact mechanism of action is not fully understood [6, 7]. However, the receptor interactions due to Abilify are understood to be unique and dissimilar to other atypical antipsychotic medications [6, 7]. It has been proposed that the antipsychotic efficacy of Abilify appears to be mediated through either dopamine-serotonin partial agonists and/or by working through the mechanism of "functional selectivity" [8]. Abilify likely exerts its effect by combining a partial agonist of dopamine D_2 and serotonin 5-HT1$_A$ receptors and a potent antagonist at serotonin 5-HT2$_A$ receptors [6, 7, 9]. Two biochemical responses are likely the results of Abilify's partial agonism [10]. First, when postsynaptic dopamine levels are too high, Abilify competes as an agonist thereby dulling positive psychotic symptoms while at the same time avoiding the movement disorders typically associated with nonspecific dopamine antagonism. Simultaneously, Abilify reduces dopamine release and synthesis which produces a neurotransmitter stabilizing effect which blunts excess activity until neurotransmission can be returned to preferred levels. It is hypothesized Abilify's partial agonist activity at 5-HT1$_A$ receptors and antagonist activity at 5-HT2$_A$ receptors contributes to lowered risk for extra pyramidal signs as well as improvements in cognition and negative symptoms [9]. Further reported benefits of Abilify compared to other atypical antipsychotics include a lower incidence of weight gain and sedation, and an absence of elevation in levels of serum prolactin [7].

Ability Grouping

Janet Ward Schofield
University of Pittsburgh, Pittsburgh, PA, USA

Synonyms

Setting (Great Britain); Streaming (Great Britain); Tracking

Definition

Ability grouping is a term referring to a wide variety of school practices that group students for instruction according to one or more measures of academic ability or achievement including their grades, teachers' recommendations, measured IQ, standardized or locally developed achievement tests, etc.

Description

Ability grouping is intended to foster homogeneity in academic ability within educational environments. Ability

grouping can occur within classrooms, between different classrooms or educational programs within schools, or even between schools, as is exemplified in countries like Germany. Sometimes students in different ability groups receive basically the same curriculum, with those in higher-ability groups just moving somewhat faster or covering topics in greater depth. In other situations, classes of different ability levels are presented with very different subject matter, such as math classes covering general math or calculus [5].

In the United States, as well as in many other countries, the nature and extent of ability grouping typically varies with students' age. Specifically, in the U.S. within-class ability grouping is quite common in the early elementary grades. So, for example, students are often placed in small within-class groups, based on their existing skills, to learn how to read. However, as students get older, and most strikingly in high school, between-class ability grouping becomes typical. In the last century, it was quite common for high schools in the U.S. to track students, that is to divide them into completely separate tracks explicitly designed to provide a strong academic focus to academically-talented students, a "general education" for less academically-oriented students, and vocational training for students heading into the workforce immediately after graduation. Now, high school students are more likely to enroll in individual classes that are more or less challenging with other students who are more or less advanced academically, rather than in completely separate tracks or programs, allowing them to match their classes to their individual academic interests and strengths. However, often scheduling and other considerations seriously constrain such choices, creating a situation in which high- and low-ability students are not typically found in the same classrooms.

Although various forms of ability grouping are extremely widespread, ability grouping, especially in its stronger forms, is very controversial. Those favoring ability grouping argue that it allows teachers to target instruction more precisely to students' existing skills than do heterogeneous grouping practices. It is also sometimes argued that students will learn better in academically-homogeneous environments. Specifically, one major concern is that low-ability students in an instructional group will not only limit the kinds of material that can be presented but will slow other students' progress. Arguments favoring ability grouping also sometimes suggest that it will protect the self-esteem of low-achieving students by sparing them constant direct comparison with their academically stronger peers. In addition, ability grouping, combined with the provision of a different curriculum for higher- and lower-achieving students, is sometimes seen as helpful in preparing students who will begin work immediately after school to do so effectively.

In contrast, those opposing ability grouping point out its many disadvantages [2, 3]. For example, they argue that it is not easy to accurately and fairly assess achievement and/or ability and that research shows that factors like socioeconomic background and/or minority group membership sometimes influence placement in ability groups. In addition, they highlight research showing that teacher quality, instructional processes, and the classroom climate are often more favorable to learning in classes containing high-achieving students than in those containing mainly low-achieving students, which means that ability grouping is likely to further impede the progress of initially low-achieving students. They also point out that ability grouping in schools generally increases racial, ethnic, and socio-economic segregation there, due to the consistently found co-variation between socio-economic status, minority group membership and common measures of academic ability and achievement. Thus, they argue that ability grouping undermines the potential of schools to serve a constructive role in preparing students to function effectively in the diverse societies in which many of them will live as adults.

Generally speaking, reviews of the research on ability grouping conclude that *within-class* ability grouping has a modest positive impact on achievement compared to both within-class heterogeneous grouping and whole-class instruction [6]. However, reviews of the research on *between class* ability grouping come to conflicting conclusions. Those focusing on experimental studies, which typically do not involve situations in which higher-achieving groups are presented with very different subject matter than lower-achieving groups, suggest that this practice has no clear overall effect on academic achievement, although one review concludes that it may have a small positive impact on the achievement of initially high-achieving students. In contrast, reviews emphasizing correlational studies, which often are conducted in situations involving some degree of curriculum differentiation, generally suggest that ability grouping at the class or school level has a clear and sometimes substantial negative impact on the achievement of initially lower-achieving students. Some also suggest a modest positive impact of ability grouping on the achievement of initially higher-achieving students.

The fact that many studies of between-class ability grouping suggest either no achievement advantage to it and/or negative effects on initially low-achieving students led to strong calls to abolish such practices, and quite a number of schools and school districts in the U.S. moved in this direction during and after the 1990s.

However, such efforts often meet strong resistance from both teachers and from parents, especially the parents of relatively high-achieving students. Some studies have documented very good results from de-tracking efforts, with markedly improved achievement for many students and no negative impact on initially high-achieving students. On the other hand, it is also clear that such efforts often cause a great deal of strife and they sometimes have unintended negative consequences, such as when the de-tracking of Japanese schools led many high-achieving students to leave the public school system for private schools.

Relevance to Childhood Development

Ability grouping influences students' social and academic experiences. Ability grouping influences their social development by commonly undercutting the potential for students to interact with and develop friendships in school with those from other racial, ethnic, and social class backgrounds. Such a consequence is important because the formation of such friendships appears to have a positive impact on students' intergroup attitudes.

Whether or not ability grouping is practiced also impacts students' academic experiences in predictable ways. Specifically, the research literature strongly suggests that classes with high-ability students tend to be better learning environments than those with large concentrations of low-ability students for a wide variety of reasons related both to the individual characteristics students bring with them and to the kinds of learning environments schools are likely to provide to initially higher- and lower-achieving students [1, 4].

The policy problem posed by ability grouping for those concerned with child development is twofold. First, some forms of ability grouping, such as within-class grouping, appear likely to have modest positive academic effects but negative social effects, because they are likely to reinforce students' predisposition to interact more with those similar to them than with peers from different racial, ethnic or social class backgrounds. Second, some forms of ability grouping, specifically ability grouping with curriculum differentiation, appear to undercut the achievement of some students while possibly enhancing that of others. Even if the negative impact of such forms of ability grouping on lower-achieving students is somewhat stronger than their positive impact on high-achieving students, as sometimes appears to be the case, decisions about whether to adopt such practices are difficult because they often involve trade-offs between losses and gains in different realms and/or for different kinds of students.

Abnormal Presentation

►Birth Complications

Abort

►Abortion

Abortion

Lacy Allen
Floride Institute of Technology, Melbourne, FL, USA

Synonyms

Abort; Dilation and Evacuation (D&E); Miscarriage; Termination

Definition

(1) The spontaneous or induced termination of pregnancy after conception. (2) To miscarry a nonviable fetus [1].

Description

An abortion is a legal, safe, and effective medical method to stop or interrupt the growth and development of a fetus. Even though abortion is a legal medical procedure,

the availability of services has been under political and ethical debate for quite some time [5]. In fact, the availability of abortion services depends on federal and state policies. However, in the United States, abortion has not always been under ethical and political debate. As a matter of fact, up until the second half of the nineteenth century, abortion was not viewed as morally wrong if it was performed before 4–5 months of pregnancy. During the second half of the nineteenth century, abortion was preformed quite frequently using drugs, special potions, and techniques espoused by popular medical guides. Additionally, abortion procedures were often preformed by mid-wives and physicians. The first laws governing abortion were enacted in 1821 and 1841; however, these laws were specifically put in place to prevent women from using unsafe abortion procedures, not to punish women for having abortions [3].

During middle nineteenth century, abortion was a growing trend among white, married, and protestant women. During this time, abortion became commercialized, which worried the new emerging class of predominately male physicians. These new medical professionals expressed concern that the number of abortion procedures in the middle and upper class, protestant, white population would eventually wipe out Catholics, which would ultimately result in whites being outnumbered by the African American and immigrant population. The created an uproar within the medical community. In addition to mid-wives being banned from giving abortions, physicians began to create laws and policies to control abortions. Between the period of 1860 and 1960, stringent laws against abortion and contraceptives were enacted. Women who sought abortions were guilty of murder and were sent to jail. It wasn't until January 22, 1973, that the US Supreme Court ruled 7-2 in *Roe v. Wade* that women have a right to terminate pregnancy based on the constitutional right to privacy established in the 1965 case, *Griswold v. Connecticut* [2].

There are two types of abortion procedures that can be used legally, safely, and effectively. The most common procedure is done in a medical center and is referred to as an aspiration procedure. Another procedure, which is less commonly used, is the D&E procedure (dilation and evacuation). An Aspiration is usually used up to 16 weeks after a woman's last period and a D&E is generally used after the 16th week of pregnancy. An abortion that is carried out beyond the 24th week of pregnancy is likely due to serious health reasons [4].

The following information outlines the specific steps generally covered during an abortion procedure. The following was adapted from [4].

During an **aspiration** abortion:

- Your health care provider will examine your uterus.
- You will get medicine for pain. You may be offered sedation — a medicine that allows you to be awake but deeply relaxed.
- A speculum will be inserted into your vagina.
- Your health care provider may inject a numbing medication into or near your cervix.
- The opening of your cervix may be stretched with dilators — a series of increasingly thick rods. Or you may have absorbent dilators inserted a day or a few hours before the procedure. They will absorb fluid and get bigger. This slowly stretches open your cervix. Medication may also be used with or without the dilators to help open your cervix.
- You will be given antibiotics to prevent infection.
- A tube is inserted through the cervix into the uterus.
- Either a hand-held suction device or a suction machine gently empties your uterus.
- Sometimes, an instrument called a curette is used to remove any remaining tissue that lines the uterus. It may also be used to check that the uterus is empty. When a curette is used, people often call the abortion a D&C — dilation and curettage.

An aspiration procedure takes about 5–10 min. But more time may be needed to prepare your cervix. Time is also needed for talking with your provider about the procedure, a physical exam, reading and signing forms, and a recovery period of about 1 h.

D&E

During a **D&E**

- Your health care provider will examine you and check your uterus.
- You will get medication for pain. You may be offered sedation or i.v. medication to make you more comfortable.
- A speculum will be inserted into your vagina.
- Your cervix will be prepared for the procedure. You may be given medication or have absorbent dilators inserted a day or a few hours before the procedure. They will absorb fluid and grow bigger. This slowly stretches open your cervix.
- You will be given antibiotics to prevent infection.
- In later second-trimester procedures, you may also need a shot through your abdomen to make sure there is fetal demise before the procedure begins.
- Your health care provider will inject a numbing medication into or near your cervix.

- Medical instruments and a suction machine gently empty your uterus.

A D&E usually takes between 10 and 20 min. But more time is needed to prepare your cervix. Time is also needed for talking with your provider about the procedure, a physical exam, reading and signing forms, and a recovery period of about 1 h.

In addition to the two aforementioned abortion procedures, a medical abortion method is also available. A medical abortion is an abortion induced by taking a medication that ends a pregnancy. Mifepristone and methotrexate are the two FDA approved abortion pills available. Mifepristone works by blocking the hormone progesterone, which causes the lining of the uterus to shed (menses). Methotrexate was FDA approved for treating a cancer, but can also be used to end a pregnancy. It can be injected with a hypodermic needle or it can be taken orally. Methotrexate stops the implantation process that takes place during the early weeks of pregnancy. A third drug is indicated and is to be taken in conjunction with one of the above medications. It is called Misoprostol and causes the uterus to contract and empty, which ultimately ends the pregnancy.

- The abortion pill, unlike the aspiration procedure, takes much more time to complete termination. Women who choose the abortion pill will generally have to wait 2–3 weeks before termination is complete. Mifepristone is a quicker method for completing abortion compared to methotrexate. There are several symptoms that are likely to occur after taking the abortion pill that users should be aware of. They include vaginal bleeding after taking the first drug, which may be light or heavy, cramping, which may be light or heavy, and both bleeding and cramping may be more than what a woman may experience on her period. Complication from taking the aforementioned medications include dizziness, strong cramping, nausea or vomiting, diarrhea, temporary fever or chills, and temporary abdominal pain.

Abstract Mapping

Molly Millians
Marcus Autism Center, Atlanta, Georgia, USA

Synonyms

Concept formation; Mental mapping

Definition

Abstract mapping refers to the process of linking the essential conceptual elements from two sets of information to form new knowledge.

Description

Abstract mapping is a psycholinguistic model that attempts to explain the processes needed to form concepts as well as to organize and to integrate information to support memory, reasoning, and learning [1, 2]. Abstract mapping is an extension of models used to describe young children's acquisition of new vocabulary, syntax, and expressive language skills [1, 3, 5, 7].

Mapping refers to the connecting of the underlying elements (abstract) from two sets of information to form a new concept. The connections or correspondences are made between a familiar knowledge base (source) with new stimuli (target). The correspondences are based upon similarities of perceptual features, functions, relationships, and meanings. The process of forming and altering connections contribute to the increase and expansion of knowledge [1, 3, 4, 5, 7].

Correspondences can be created across linguistic and spatial domains [1, 3, 4]. These correspondences influence the development of schema or a framework to organize knowledge domains. Language is used to divide domains into smaller categories to facilitate storage and retrieval of information from memory [1, 3, 4, 6].

Abstract mapping is a model used to depict the intricate network of concept development and learning.

Academic Achievement

Nicholas Bolt
Fordham University, Bronx, NY, USA

Synonyms

Educational; Scholastic; School performance/achievement

Definition

Academic Achievement is the progress made towards the goal of acquiring educational skills, materials, and knowledge, usually spanning a variety of disciplines. It refers to achievement in academic settings rather than general acquisition of knowledge in non-academic settings.

Description

Unlike typical forms of achievement, academic achievement is usually viewed without a definitive endpoint. Rather, the concept is understood as a spectrum along which one can "achieve" certain skills and knowledge, always with the possibility of further developing those skills and increasing the depth, breadth, and specificity of knowledge.

Academic achievement revolves around the central goal of improving the educational knowledge of the students. Because of this goal, the measurement of achievement is often criticized for maintaining a focus on content knowledge rather than problem-solving or product-fashioning skills across a range of materials, which many argue are equally crucial to the definition and measurement. As a result, academic achievement inevitably corresponds with what was taught; students would be unlikely to "achieve" an understanding of material that was not taught, and in this respect, academic achievement is very dependent on teachers and curriculum.

With the overall goal of content evaluation, academic achievement is considered a measure of the educational material that was learned or acquired, with the effort, attitude, motivation, intelligence, or potential of a student having no bearing on the final academic achievement score. While these characteristics may be highly related to the outcome measure, academic achievement itself does not provide a measure of these characteristics. Rather it measures the progress students have made towards the goals set forth by the academic institution and the state-wide or national standards. Academic achievement may measure how well these characteristics have been applied towards acquiring skills and knowledge, but the assessment does not directly factor any of these characteristics into the measure.

Academic achievement is typically measured through two common methods: subject grades given by teachers or professors and standardized test scores, either state-wide or national. While these measures are widely used and may be the best available measures of this concept, obvious criticisms arise in using subject grades and large-scale test scores as a standardized measure of academic achievement. Grades for the same level of achievement may fluctuate widely between teachers and schools based on curriculum and standards, and standardized testing may include a measurement of a student's test-taking ability rather than only measuring the underlying content knowledge.

In addition to these common measures, other assessments have been developed in an attempt to eliminate confounds of subject grades and standardized tests. Various adaptations and revisions of the Woodcock-Johnson psychoeducational battery and the wide range achievement test (WRAT) are two of the more commonly used assessments in this area. However, these tests are administered on an individual basis and can become time-consuming, making them difficult to administer on a large scale.

Relevance to Childhood Development

Academic achievement is widely used as a common outcome measure in the field of child development. School-based and developmental interventions very often target improvement in academic achievement as a main indicator of success, as academic achievement is widely suggested to be an indicator for future success, both academic and otherwise. Research has outlined the direct correlation between academic achievement and many other outcomes of positive development, such as likelihood of college enrollment, quality of future education, prospective careers, and even a decrease in delinquent behavior. In sum, research suggests that academic achievement is strongly related to overall positive development.

In establishing a need for intervention, a student's individual academic achievement scores are compared to the standard scores, both within the school and state or nation-wide, to determine if a student has acquired the academic skills typical of their developmental cohort. In addition, academic achievement scores are often used in conjunction with intelligence testing to determine the presence of a learning disability.

Academic Delay of Gratification

Héfer Bembenutty
The City University of New York, Flushing, NY, USA

Synonyms

Delay of gratification; Reward discounting; Self-control; Self-regulation

Definition

Academic delay of gratification refers to students' postponement of immediately available opportunities to satisfy impulses in favor of pursuing important academic rewards or goals that are temporally remote but ostensibly more valuable.

Description

Bembenutty and Karabenick [4, 5] develop the concept of academic delay of gratification to apply the general construct of delay of gratification to learning contexts. This theoretical approach extends the work of Mischel [6] on delay gratification. Bembenutty and Karabenick [4] demonstrated extensive associations between academic delay of gratification and students' achievement motivation tendencies and use of learning strategies with a scale specifically designed to assess students' tendencies to delay gratification in an academic context (academic delay of gratification scale – ADOGS; [4]). Students reporting greater preference to delay of gratification in an academic context reported also high academic motivation (e.g., higher in self-efficacy and intrinsic interest in learning). They are more likely to use cognitive (e.g., critical thinking, elaboration, organization, and rehearsal), metacognitive, and resource management strategies (e.g., effort management, time and study environmental control, and help seeking). Students' amount of time dedicated to study and the effective structuring of their study environment, as well as their efforts to persist on tasks are directly related to academic delay of gratification. Further, students more likely to delay gratification also reported higher levels of persistence when tasks were less interesting or more difficult [1].

Students' preferences for academic delay gratification are related to self-regulatory processes considered essential to academic success [7]. Self-regulation is an essential component of development. Individuals use diverse strategies to facilitate the implementation of intentions and goals. These strategies may be especially important when alternatives to studying become available. When individuals experience internal or external distraction from enacting intentions, such self-regulatory strategies as selective attention and the control of encoding, motivation, emotion, the environment, and information processing are assumed to help them remain task focused. An example of the relevance of control strategies for delay of gratification is the selective attention that children employ to avoid visual contact with attractive alternatives to the delayed reward [6]. Similarly, the studying student could avoid thinking about the positive consequences of attending the party and, using motivational control, focus on the negative consequences of not studying for the impending exam. Students who delay are also more likely to have available and use self-regulated learning strategies.

Motivational analyses of academic delay of gratification include such factors as the relevance, value, and expectancy for immediate reward versus delayed reward options. Bembenutty [3] found that willingness to delay gratification depends on an individual's expectancies, beliefs, goals, and values. Expectancy and value influence the decisions that learners will make regarding stay home

studying for a test or going out to have fun with their friend even when the homework may not be completed. The expectancy and value placed on the delay task as well as on the nondelay alternative will determine the feasibility of attaining a delayed reward. Students' preference for academic delay of gratification is a function of their expected value of alternative courses of action. Whether the student delays gratification (in order to study) would depend on the likelihood of successful exam performance given that she studies, compared to that of attending the party, and the degree of interest, utility, importance and cost of these alternatives [2].

Relevance to Childhood Development

Children's preference for academic delay of gratification is an essential component of their development and maturity. To be responsible members of the society, children need to acquire the skills and willingness to postpone immediate available reward that are temporarily available but which are less desirable. Learning to prioritize between what is more valuable and conducive to reach long-term goals is a desirable social element that parents and teachers could instill on children. Children needs to learn the necessary self-regulatory skills to learn academic materials, but they also need to develop the ability to engage in goal setting, selecting strategies, monitor goal attainment, engage in effort regulation, time management, and self-evaluation in order to reach their academic potentials. Longitudinal studies have shown that children's ability to delay gratification positively predict adult's self-regulatory competencies.

Academic Readiness

Jordan Luther
Niagara University Academic Complex, Niagara, NY, USA

Synonyms

Learning readiness; School readiness

Definition

Academic readiness is an estimate, based on qualitative and/or quantitative information, about whether a preschool child is ready to handle the various demands of the structured educational environment.

Description

There is no universal definition for academic readiness. Many kindergarten teachers, parents, and early childcare providers believe that academic readiness involves being "healthy, well-fed, and well rested; being able to express their needs, wants, and thoughts; and being enthusiastic and curious about new activities" [10, p. 23]. According to Buntaine and Costenbader [4], developmental age, which is the rate through which a child progresses through developmental stages, is the most commonly used method of assessing academic readiness. Still others believe a more effective way of predicting later academic success is through using psychometrically sound empirical tests which measure specific cognitive, pre-academic, and emotional regulation skills [1]. The Phelps Kindergarten Readiness Scale (PKRS, [9]), for example, measures domain-specific areas which are predictive of later academic achievement [1]. Specifically, the PKRS measures Verbal Processing, Perceptual Reasoning, and Auditory Processing. The Brigance Inventory of Early Development-II (IED-II) is a measure of school readiness which measures skills in motor, language, academic, daily living, and social-emotional domains [3]. The motor section consists of fine motor and gross motor functioning, the language section consists of receptive and expressive language areas, the academic section has a general/cognitive section as well as a prereading/reading section, and the daily living section consists of a self-help and

a prevocational section. All these skills are considered important in terms of success in academic learning environments.

Some believe academic readiness is an ecological construct dependent on a complex combination of a child's skills, their kindergarten teacher, the relationship between the child's family and the school, and the school system [1]. Johnson-Fedoruk [6] believes that even among school readiness assessment tools which are empirically validated, these tools do not consider the various complex "interactions and peculiarities" which occur inside the actual classroom, and therefore even these empirically driven tests may lack validity (p. 2). According to Johnson-Fedoruk, the child's behaviors inside the classroom, and their relationship with their teacher, are the "most obvious attributes" which make a child most prone to academic failure (p. 2). Therefore, although empirically driven tests measure specific skills within domains which are known to be predictive of later academic success, these tests may not have actual predictive validity when it comes to the real classroom. Rather, Johnson-Fedoruk believes school readiness tests should consider variables such as "student behavior, familiar structure, ESL status, age, and personality," which are more predictive of academic success (p. 4).

McClelland and colleagues [8] believe that behavioral functioning is an important factor to consider in school readiness. Children are expected to master specific behaviors before they enter kindergarten, as commonly outlined by early learning standards [7]. For example, when going from preschool to kindergarten, children must be able pay attention, follow instructions, and refrain from engaging in inappropriate behaviors [8, p. 947]. When children control their impulsive behaviors and pay attention, they are better able to perform classroom appropriate behaviors, such as following instructions and completing tasks. According to McClelland and colleagues [8], children in prekindergarten who display higher levels of behavioral regulation also display higher levels of "emergent literacy, vocabulary, and math" (p. 955). Moreover, attention, working memory, inhibitory control, and social-emotional competence were predictive of literacy and math skills from Kindergarten to Grade 6 and predictive of growth in literacy and math skills from Kindergarten to Grade 2. On the other hand, kindergarten children who are rated by their teachers as being disruptive and aggressive are also more likely to be considered at risk for academic failure [7]. Not only are these disruptive children more likely to underachieve academically and score lower on standardized cognitive achievement tests, but they are also more likely to be rejected by their peers [8]. Evidently, students who lack these learning-related skills are at risk for performing poorly in all areas of school performance.

Competence in the use of language is an indicator of academic readiness as well [5]. The Bayley Scales of Infant and Toddler Development: Third Edition [2] as well as the Brigance IED-II [3] both measure expressive and receptive language. Children's success in school depends on their child's ability to verbally communicate with their teachers and peers. Receptive language, which is the ability to comprehend verbal information, is related to the ability to understand directions from teachers. Even the ability to tell stories, which is a form of expressive language, can be used as a measure of school readiness [5]. Narratives reflect how the child conceptualizes their current situation, which is indicative of their level of cognitive and language development. Children who are unable to tell stories in a clear and coherent manner are at risk for development difficulties. These deficiencies in language and intellectual functioning may be exposed in the classroom as difficulties in following and participating in routines, poor early academic performance, and poor social interactions with peers and/or teachers. Furthermore, children who engage in numerous literacy activities in preschool produce higher quality narratives than children who did not engage in such activities [5]. Kindergarten curricula have become increasingly academic, with stronger emphases on literacy skills. Due to this trend, more preschool children are being labeled as academically "unready" to enter the educational world, and are being placed in prekindergarten transitional programs. As a result of this dilemma, some experts argue that kindergarten should be less focused on global academic goals instruction, and instead provide individualized developmental programs within the regular classrooms [4].

Social-emotional skills, such as "self-control, self-concept, social competence, initiative and curiosity, and persistence and reflection" are also important for academic readiness and later academic success [7, p. 38]. According to Logue [7] preschool children should demonstrate the ability to contribute to the overall effort of the group, demonstrate respect and fairness to others, and display effective interpersonal communication skills (p. 40). Many states now have preschool curriculums which teach these social and emotional skills in addition to the academic skills which are taught. For example, the Maine Early Childhood Learning Guidelines are based on the assumption that children will do better academically when they have the "social skills and behavior that enable them to develop meaningful relationships with adults and peers" [7, p. 38]. Without having these appropriate social skills, children miss out on the academic skills being

taught, especially if these children are being removed from the classroom for behavior problems.

Preschool children who come from impoverished home and neighborhood environments are often labeled "unready" for preschool and/or kindergarten. Often these children present with health, behavior, and social problems, which subsequently lead to academic difficulties. In terms of behavior regulation, children who come from chaotic and disorganized home environments have difficulty matching their behavior and temperament to the highly structured environment of the classroom [5]. Children with low socioeconomic status (SES) backgrounds are also less likely to receive adequate verbal stimulation and/or proper materials to play with than their more affluent peers. Children who do not receive adequate verbal stimulation in the home tend to have difficulties functioning at age appropriate levels in "receptive and expressive language, reading ability, and math achievement," which are all important skills later on in school [5, p. 281]. Children who face these multiple risk factors also show lower levels of executive functioning skills, as indicated by lower scores on standardized cognitive achievement tests which purport to measure aspects of executive functioning, such as working memory [8]. These low scores on intelligence tests can be attributed back to the fact that children with low SES are less likely to have quality verbal interactions with their primary caregivers and/or less likely to have intellectually stimulating toys to play with, as mentioned earlier. For example, lack of verbal stimulation from their parent(s) may affect the child's performance on tests measuring Verbal Processing and lack of exposure to proper play materials, such as puzzles, may affect performance on tests measuring Perceptual Reasoning.

Parents have the choice of sending their child to daycare and/or preschool. Day cares tend to focus more on social and behavioral development, as they provide activities such as art, singing, cooking, and gardening; preschools tend to focus more on pre-academic skills. The multiple risk factors which low income children experience are compounded when they receive poor quality daycare. In fact, research has proven that poor quality day care leads to lower intellectual levels and higher behavioral problems, at early and middle childhood, among children from lower socioeconomic groups [5]. According to Logue [7], poor quality preschool programs not only neglect to teach appropriate preacademic, social/emotional, and behavior skills, but actually reinforce negative social behaviors which lead to poor social adjustment and poor academic performance. Conversely, higher quality day care has been shown to lead to higher levels of intellectual functioning and social-emotional development, and lower levels of behavior problems amongst its students [5]. This is especially true for at-risk children who come from impoverished home environments and attend high quality day care facilities [7]. In fact, high quality daycare has been shown to be a protective factor which contributes to the resilience of at-risk children. Unfortunately, disadvantaged children are far less likely to receive quality child care than children from higher SES groups as their parents cannot afford to send them to such programs. In light of the fact that high quality day cares produce positive results and poor quality day care produces negative results amongst at-risk preschoolers, many states are adopting standards for early education [7]. Early child care programs should attempt to increase the overall competence of the child, and increase the amount of support in their lives. For example, the Maine Early Childhood Learning Guidelines requires preschools to address skills related to social development, the learning of literacy, math, science, social studies, health, physical education, and creative arts. The quality of preschool child care is dependent upon the training the child's educator receives and the quality of social interactions the child and educator have with each other [5]. In fact, early childhood teachers should be trained to foster social and emotional development in their students [7].

According to Buntaine and Costenbader [4], nearly half of all children entering kindergarten are at risk of future academic failure because they are not developmentally mature enough for structured classroom instruction. Members of the Gesell Institute believe that learning disabilities, emotional disturbance, and underachievement are due to developmentally immature children being expected to perform at levels outside of their abilities (p. 41). Children in kindergarten or preschool who are believed to be unready for the next level of instruction either stay home an additional year before entering kindergarten, attend a prekindergarten program, spend 2 years in kindergarten, or attend a prefirst grade class after kindergarten. Those who advocate for holding children back a year argue that doing so is a preventive technique aimed at avoiding academic failure before it can occur. They believe that spending an additional year in a learning environment which is less demanding allows a child to become ready for the next level of education. This hypothesis, however, has not been supported by research. In fact, the majority of "prefirst" programs have not been shown to produce significant

advantages in the later academic performance. Studies have found that children who attended "prefirst" programs did not outperform their non-retained counterparts in Grade 1 in areas such as math achievement, social maturity, self-concept, and attention. Additionally, it has been shown that students who waited an extra year between kindergarten and first grade did not perform better academically in Grade 3 compared to their peers who were not held back a year. Students who have been held back a grade also have higher rates of social/emotional problems and significantly higher drop rates compared to their non-retained peers [4]. Plevyak and Morris [10] stress that students who are older than the majority of their peers are more likely to engage in high risk sexual behaviors and use alcohol and cigarettes (p. 24). Therefore, the practice of holding preschool children back a year before entering kindergarten is questionable.

Relevance to Childhood Development

Academic readiness depends on a multitude of child characteristics including pre-academic skills, language competency, behavior regulation, social-emotional development, and the level of development enrichment in earlier home and other care environments. A child's level of functioning in any of these areas will contribute significantly to their later achievement in the actual classroom. Unfortunately, children who come from impoverished environments are at-risk for being underdeveloped in one or more of these areas. Research indicates children who seem to be developmentally unready for the next level of education should not be held back a year, but rather, they should have individualized plans which cater to their strengths and needs.

Acceptance and Commitment Therapy

R. Trent Codd III[1], Steven C. Hayes[2]
[1]Cognitive-Behavioral Therapy Center of WNC, P.A., Asheville, NC, USA
[2]University of Nevada, Reno, NV, USA

Synonyms

ACT (pronounced as one word rather than as individual letters (e.g., "ACT" not "A-C-T"))

Definition

Acceptance and commitment therapy is a third-wave behavioral psychotherapy based on relational frame theory (RFT), a comprehensive behavioral account of language and cognition, whose primary treatment goal is to increase psychological flexibility.

Description

Relational Frame Theory

A comprehensive account of language and cognition from a behavior analytic perspective has emerged: RFT [6]. Several dozen studies have tested the tenants of the theory (see [6] for a comprehensive review), which in brief claims that human beings learn at an early age to derive bidirectional relations among events in certain contexts and

to alter the functions of events due to these relations. For example, a young child may learn that "cat" is the same as "C-A-T" and a small furry animal. With these two trained relations, (a) all bidirectional relations among these three events will probably be derived without explicit training (e.g., "C-A-T"=a small furry animal), and (b) the functions of each related event will alter those of the others. For example, if that child is now scratched by this small furry animal, fear may be shown when the child hears "oh, there's a cat," even though the oral name and aversive events have never occurred together.

RFT leads to important implications for the understanding of language and cognition and thus for psychotherapy. It helps explain why core beliefs or "schemas" tend to be resistant to change, for example, or why suppression and avoidance of thoughts, feelings, memories, bodily states and other private events are both likely to be counterproductive. It also suggests a number of alternatives to currently popular psychotherapy methods: instead of trying to alter negative thoughts, for example, and thus elaborating an already troublesome cognitive network, one might alter the contexts in which these thoughts have behavior regulatory functions. Empirical RFT literature suggests that direct attempts to challenge cognitions may be ineffective or counterproductive [6].

Acceptance and Commitment Therapy

Overview

The Acceptance and Commitment Therapist's main goal is to alter the social/verbal context in which negative private experiences relate to destructive forms of overt behavior [9]. Altering the context is effective because the disruption of the context shows the client that such relationships between stimuli are just talk rather than prescribed realities. In addition, adding more constructive relations to problematic relational networks is more effective than trying to eliminate existing relations.

The goal of altering the context is accomplished in three ways: (a) by reducing experiential avoidance; (b) by reducing excessive literality; and (c) by helping people make and keep commitments to behavior change.

Experiential avoidance is the tendency to attempt to alter the form, frequency, or situational sensitivity of private events (e.g., painful thoughts) even when doing so interferes with valued actions. A vast literature (see [10]) shows that experiential avoidance is among the more pathological psychological processes known to psychology. Yet this process seems virtually ubiquitous [9]. In ACT, the agenda of attempting to control or eliminate negative private events are not viewed as the solution to psychological suffering, but rather they are viewed as a core feature of psychological suffering. They are the problem because attempts to control private events are often unsuccessful, counterproductive, and invalidating [9]. They are also unnecessary. Instead of altering the form of private events (e.g., changing an irrational thought to a more rational alternative), ACT therapists seek to alter the social/verbal context. This is preferred because attempting to control private events is often ineffective and because altering the context is effective in allowing clients to embrace their fear.

Thoughts and feelings emerge from a person's unique history. When a deliberate attempt is made to control these events as a means of behavior regulation, one's history immediately becomes "the enemy." Histories do not change, however, except by the addition of new features. For example, a history of sexual abuse may lead to feelings of vulnerability and a fear of intimacy. A person desiring close, committed relationships may attempt to reduce these feelings so that relationships are possible, but some degree of vulnerability and fear is a natural result of such a history. Unable to make time go backwards, the person may dissociate, drink, or use drugs to "get through" the fear, but this only makes the fear more important, and more linked to overt behavior, while it also reduces closeness – the very goal of relating with others. Furthermore, if fear is something one must not have then fear is something to be afraid of and to focus on – as a result the fear only increases. This provides a concrete example of the reasons why emotional avoidance is likely to be unsuccessful, counterproductive, and invalidating.

In ACT, clients are taught instead to embrace their fear, to defuse from their thoughts, and to focus instead on valued actions that will create a meaningful human life.

Scores of techniques are used, but a few examples can be given. Clients may be asked to say fearsome words (e.g., "I'm bad") out loud rapidly until all verbal meaning is momentarily lost and only the sounds remain. Clients may be asked to watch their own thoughts float by like leaves on a stream, leaving a psychological distance between the person who is aware of these thoughts and the literal thoughts themselves. Clients may be asked to deliberately produce painful emotions in a context of dispassionate observation of their experiential features: where they begin and end in one's body, what words are triggered by them, what memories pop up in association with them, what behavioral urges emerge when they are contacted, and so on. Clients may be asked to label their own ongoing behavioral streams with such phrases as "now I am having the feeling of anger" rather than "I am angry" or "now

I am having the thought that I am bad" rather than "I'm bad." The client may be asked to say negative thoughts very, very slowly, or to sing them, or to say them in a funny voice (see [8] and [9] for more therapeutic techniques).

The purpose of such methods is to reduce the literal importance of thought, but without a direct, literal challenge to thought, and to replace emotional avoidance with acceptance and open exploration. In so doing, the automatic effects of one's history are an interesting focus of observation, not a focus of deliberate change needed in order to produce new behavior. Metaphorically, private events are the exhaust of life, not the engine or steering wheel.

Once this shift has occurred, the focus of ACT shifts to values and overt action. Once one need not accomplish the difficult job of first altering one's insides before beginning to live a valued life, clinical attention can turn to living a valued life itself. Values clarification exercises help focus the client on the life he or she would choose to live if they had a choice. Specific behavioral commitments and exercises then create new behaviors that move in that valued direction, all the while watching for thoughts and feelings that heretofore would have been barriers to movement and now are instead to be accepted and experienced.

ACT is not unique in promoting acceptance. Several traditional methods (e.g., Gestalt therapy) have done so. What is unique is that (a) a scientifically viable theory of language and cognition is now driving and coordinating acceptance based interventions into a new and more coherent whole, and (b) these methods are entering into empirical clinical work, based on clinical manuals and careful experimental research.

The impact of these methods can be significant as controlled empirical work shows that ACT can have a significant impact on many forms of psychopathology (see [7] for a recent review).

The Hexaflex

The ACT therapist directly targets empirically supported processes of change that are grouped into two general categories: mindfulness and acceptance processes and commitment and behavior-change processes. Together, these two groups of processes foster psychological flexibility.

The mindfulness and acceptance processes consist of contact with the present moment, acceptance, defusion, and self-as-context. Contact with the present moment is defined as consciously experiencing internal and external events as they are occurring. Acceptance refers to a behavior, rather than an attitude, of actively embracing feared private events. Acceptance does not mean "white knuckling" or resignation, but rather truly opening up to experiencing what one experiences when one experiences it. Defusion involves experiencing one's thoughts simply as thoughts rather than their referents. Finally, self-as-context is perhaps best understood in contrast to two other common senses of self: the conceptualized self and the self as process of ongoing self-awareness. The conceptualized self is the sense of self one experiences when one experiences oneself as a collection of verbal categorizations (e.g., I'm shy, tall, Caucasian, nice, smart, etc.) whereas the self as process of ongoing self-awareness is conscious awareness of present experiences with mere description and explicitly without judgment (e.g., I'm having the thought that I'm nice). Self-as-context involves ongoing self-awareness with the added awareness of the locus from which one observes one's private experiences (i.e., I/here/now).

The behavior-change processes also consist of contact with the present moment and self-as-context, but include the additional processes of values and committed action. Values are life domains we choose to pursue on a moment by moment basis. They are more like directions in that one can never achieve a value in the way that one can achieve a goal. For example, one may value being a loving spouse, and no matter where one is with respect to this value one can always be more loving. Values are also not feelings. Committed action involves acting toward concrete goals, which are generated based on idiosyncratic valued directions, while simultaneously attending to the other processes of change. Committed action is aimed at achieving larger and larger patterns of effective behavior.

ACT with Children

Empirical work on ACT with children is still in it's infancy, and although several are underway no randomized trials of ACT have yet appeared with children or adolescents. A book-length description of acceptance-based methods for child and adolescent psychopathology recently appeared [4] which summarizes some of this early work.

One empirical reason to believe that the extension of this work to children is warranted is that measures of ACT processes in child and adolescent populations operate very similarly to those in the adult population. For example, age appropriate measures of psychological inflexibility have found positive correlations with measures of child internalizing symptoms and externalizing behavior problems, and a negative correlation with quality of life [5].

A second reason is that early trials have been quite supportive. For example, in an open trial with a group of 14 adolescents with idiopathic chronic pain Wicksell, Melin, and Olsson [13] found improvements follow ACT

in functional ability, school attendance, catastrophizing, pain intensity, and pain interference. These gains were retained at a 3- and 6-month follow-up. Additionally, a small randomized controlled trial [12] compared a brief ACT intervention to multidisciplinary treatment plus amitriptyline for chronic pediatric pain. The ACT group showed substantial and enduring improvement and when follow-up assessments were included the ACT group performed significantly better on perceived functional ability in relation to pain, pain intensity and pain related discomfort.

Parental experiential avoidance has also been examined. The impact of parental experiential avoidance on children's emotional development and behavior has been demonstrated [3] as has it's impact on parenting effectiveness [1]. Parental and child outcomes have been improved as changes in parental mindfulness processes occur [2, 11].

Accommodation

▶Adjustment

Accommodations, Classroom

Elisheva Konstam, Devorah Neuhaus
Pace University, NY, USA

Synonyms

Classroom modifications

Definition

Classroom accommodations are adjustments made in the classroom that allow students with special needs to participate in regular education. These accommodations remove the barriers that would otherwise impede a child's ability to participate due to the nature of the disability. Accommodations and modifications are often used interchangeably. However, they have slightly different connotations. Modifications alter the nature of the

classroom including standards and expectations. Accommodations remove barriers without altering what is expected and being measured.

Description

Who are These Accommodations for?

For students who have disabilities and meet criteria for an individualized education plan (IEP) under The Individuals with Disabilities Improvement Act of 2004 (IDEIA) typically have accommodations written in the IEP. These are individualized accommodations that have been identified as being essential in educating the particular student. For students who do not meet the requirements for classification but still have a disability are covered by Federal law under Section 504 of the Rehabilitation Act of 1973 and can have classroom accommodations written into their 504 plan. Classroom accommodations are individualized based upon the specific disability and needs of the student [3].

What are some of the more Typical Accommodations and how do they Look?

There are accommodations used for making the classroom and school environment accessible for those with physical disabilities. Computers, technology, ramps, and elevators are some accommodations used to allow these students equal access to education. For example, voice recognition software may be used for a student with limited use of his hands.

Accommodations for students with visual or hearing impairments can include Braille, sign language interpreter, computer software, or large print [2].

Accommodations for students with learning disabilities often include testing accommodations such as extra time, the use of a computer, the use of a word processor, the use of a calculator, being allowed to record answers, and having directions and questions read [1].

Accommodations for students with health impairments may include being allowed to eat and drink during class and frequent rest breaks.

Other accommodations that can be used for students with various disabilities include being allowed extended time to complete assignments, breaking down assignments into manageable parts, and giving a student a second set of textbooks to keep at home [4].

Accommodations, Piagetian

Jackie Kibler
University of Montana, Missoula, MT, USA

Synonyms

Adaptation; Adjustment; Change; Modification

Definition

A term coined by Jean Piaget; a cognitive process that involves developing or changing a schema (i.e., mental representation) to fit information encountered in the environment [1].

Description

Jean Piaget's theory of cognitive development includes the concept of accommodation. This cognitive process involves the development and alteration of mental representations, schemas, as individuals encounter new situations. It is the process by which we learn and develop our cognitive abilities. Accommodation, unlike the process of assimilation, requires a great deal of mental energy, thus individuals typically prefer to assimilate (i.e., a cognitive process that involves encountering something in the

environment that fits into an existing mental representation, or schema) more than they accommodate [1].

Relevance to Childhood Development

Children prefer routine in their environment so that they are able to assimilate information that they encounter. When put into a new situation, some children take longer to accommodate to the new environment. For example, when taking young children to a restaurant for the first time, they may have to accommodate their behavior (e.g., lowered voice, staying in their seat, etc.) to fit the expectations of the environment. They are accommodating the information, and as caregivers will attest, some children do it more quickly than others.

Another example of accommodation involves family separation. Some children face separation from family members (due to divorce, military service, relocation, etc.) and are forced to accommodate this information into their schema for daily life. The accommodation process may take children awhile as they seek to understand the change in their environment. Experts typically recommend that caregivers keep children's routine as normal as possible as they deal with this type of separation. Piaget would explain that by keeping their routine normal, you are providing more opportunities for assimilation, so that they are able to use some of their mental energy to accommodate the separation.

Acculturation

Kai Kok "Zeb" Lim
University of Kansas, Lawrence, KS, USA

Synonyms

Adaptation; Assimilation; Cultural transmission

Definition

The term acculturation, used in social science research, was first proposed and defined as a "phenomena which results when groups of individuals having different cultures come into continuous first-hand contact, with subsequent changes in the original culture patterns of either or both groups" by anthropologists Redfield et al. [9].

Description

Acculturation refers to the process whereby the attitudes and behaviors of people from one culture changes when they interact with the people of another culture, typically the dominant or host culture. It is generally accepted that there will be mingling of both cultures as each culture interact and changes one another to a certain degree. Assimilation on the other hand refers to the process where the minority culture will be absorbed into the dominant culture until people of the minority culture adopts the dominant culture completely. Acculturation focuses on the group level rather than at the individual level.

Another term – psychological acculturation, which is termed by Graves [3], refers to the effects of acculturation at the individual level of study. Two dimensions exist at the individual level – behaviors and values. Behavioral dimensions of acculturation involves the choice of language use and participation in cultural activities while values dimensions involves the relational style, person-nature relationships, beliefs about human nature, and time orientation. It is common to observe faster behavioral changes to fit in with the dominant culture within one generation while values changes are slower and occurs across different generational level.

Two model of acculturation exists to explain how groups acculturate. The linear or unidimensional model suggests that acculturation occurs on a continuum where the group either holds strongly to the original culture or adopts the dominant (host) culture. The bidimensional model on the other hand suggests that groups can vary on the continuum of how strongly they hold on to the original culture and simultaneously vary on the continuum of how strongly they adopt the dominant (host) culture. Berry [1] suggests that there are four possible outcomes of the bidimensional acculturation model – assimilation (involves the adoption of the dominant culture completely), integration (involves the synthesis of both cultures), rejection (involves the rejection of the dominant culture), and marginalization (involves the rejection of both original and new culture). While this fourfold model of possible outcomes of acculturation are appealing, other researchers have call this into question (see Rudmin [10] for further reading).

Psychological acculturation is an important construct for physical and mental health professionals because it allows researchers and providers alike to understand the extent to which the minority individual may be receptive to the treatment goals and plan that may be developed for the dominant culture (White, middle class Americans for the most part). To this end, researchers, to understand

better the acculturation process of the ethnic minority individuals, have developed many psychological acculturation measures. Most of these measures were developed with specific ethnic groups in mind, which limit the generalizability of any one instrument across different cultural groups.

Relevance to Childhood Development

The large number of first generation Asian American and Hispanic/Latino/Latina population that are in the United States currently suggests that they may experience psychological acculturation that may influence their mental and physical well-being. First generation ethnic minorities that were born in America or at an early age, came to America would have an easier time acculturating to the dominant (host) culture easier and faster compared to those who immigrate here in their adolescence or at a later age.

At the same time, the parents of the child who immigrate to the United States may have a harder time adjusting to the local culture, custom and norms after they had strongly socialized to the original culture, customs and norms of their place of origin. This may results in conflict between the parents and the child whereby the parents may want the child to hold on to their ethnic/racial, country of origin values, and custom while the child may choose to follow the dominant culture values and customs. The pressure of fitting in with their peers, especially for ethnic minority adolescents, to escape ridicule from peers and be more American is a strong motivator to acculturate quickly. Depending on the resolution of the conflict between the parent and child, professional helpers may need to be recruited to help mediate and educate the family about this struggle to fit in with the dominant culture.

A positive resolution of this conflict between holding on to the values and customs of the country of origin or ethnic background and adapting to the dominant culture values and customs will result in an individual who is biculturally competent in negotiating the intricacies of both cultures. Children who are have the opportunity to learn about their own cultural history and values by their parents and community while at home and to be allowed to learn the dominant culture at school will have a better chance to be a biculturally competent individual than their peers who are forced or choose to adopt one culture over the other.

▶ Validity

Acetylcholine

Tony Wu
Walden University, Diamond Bar, CA, USA

Synonyms

Chemical compound; Neurotransmitters

Definition

A neurotransmitter, $C_7H_{17}NO_3$, that is released at the neuromuscular junctions. It has been associated with learning and memory.

Description

Acetylcholine (ACh) is one of the first identified neurotransmitter in the nervous system. Similar to electrical signals, neurotransmitters are the means by which neurons communicate with each other in biological processes, including sleeping, cognition, emotion, memory, hunger, and movement. Neurotransmitter communication is mediated by several mechanisms that either accelerate or decelerate release of neurotransmitter. It has been documented that coexistence of more than one neurotransmitter in a neuron makes it possible to exert multiple effects simultaneously [4].

Acetylcholine is the most studied neurotransmitter because it is released at the readily observable neuromuscular junctions. Typically, ACh is synthesized and stored in synaptic vesicles that are catalyzed by choline acetyltransferase. Once ACh is released, it is binds to receptors, then is degraded and re-synthesized. Acetylcholine is associated various systems in the body, such as with neurons that excite skeletal muscles, neurons in the autonomic nervous system, and the central nervous system [4].

In addition to stimulating muscle-skeletal movement, researchers have documented that Acetylcholine is linked to brain regions that carry out memory and learning. Injections of cholinergic agent enhance the performance of learning and memory in animal and human experiments. For example, it has been observed that the presence of ACh in the hippocampus increases when rats engage in hippocampus-dependent tasks [8]. Furthermore, the release of ACh has a positive correlation with improved task performances [2]. Studies have provided additional evidence that the release of ACh in the amygdale may enhance memory formation. Studies also suggested that decreased ACh might affect learning. For example, intra-amygdala injections of histamine H_3 receptor antagonists not only reduce ACh release but also impede learning [7].

Finally, studies in Dementia of the Alzheimer type offer further verification that Acetylcholine is related to memory. It is observed that there is a massive depletion of ACh and loss of cholinergic projections in the brain [9]. It is hypothesized that ACh boosts the magnitude of visual search and reduce interference [6]. At the neuronal level, ACh has differential effects on the firing of cortical and thalamic neurons [5], as well as inhibition of distracted variables [1].

Achievement Motivation

Pei-Hsuan Hsieh
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Need for achievement

Definition

Achievement motivation is the need for excellence and significant accomplishment, despite what rewards may be offered after the achievement has been met.

Description

Atkinson and his colleagues formed the concept that achievement motivation stems from two separate needs. One is the motivation to achieve and is related to one's desire to accomplish successful goals and the other is the motive to avoid failure.

Some people may be hesitant to take on the responsibilities of having to accomplish goals or employ in activities

because they are afraid to fail. The motive to avoid failure includes worries about the consequences of failing, self-criticism, and diversion of attention, accelerated heart rate or nervousness, which can all lead to poor performance.

In contrasts, those who feel the need to achieve successful goals are more motivated to persist at goals they know they can accomplish. By doing this, individuals are more likely to avoid running into failure. Most people develop both forms of motivation for achievement. However, achievement behavior is dependent on which need is more dominant.

Individuals high in motive for success are characterized by a tendency to tackle challenging tasks because they have a relatively low motive to avoid failure.

Relevance to Childhood Development

Children can develop high achievement motivation when parents encourage independence in childhood, praise success, and associate achievement with the child's ability and effort.

Recent literature shows that specific tasks, environments, and contexts, influence the development of achievement motivation. In addition, children's need to outperform other students or to avoid negative feedback also influences achievement motivation. As students move up from middle to high school they are expected to accomplish more difficult work while keeping up with their peers. With these expectations, children need to be able to develop the appropriate form of motivation in order to achieve normative success with their peers.

Achievement Testing

Mei Y. Chang, Andrew S. Davis
Ball State University, Muncie, IN, USA

Definition

Achievement testing refers to the practice of using achievement tests to efficiently measure the amount of knowledge and/or level of academic skills an individual has acquired or mastered through the planned instruction that typically occurs in educational settings [1]. The practice of administering achievement tests may take place in the fields of *school psychology*, *clinical psychology*, and *special education* to assist in assessing academic proficiency or diagnosing *learning disabilities*, as well as in the field of *clinical neuropsychology* to assist in detecting individual strengths and deficits in patients with neuropsychological disorders affecting reading, computation, or writing skills [4].

Description

Achievement testing is a procedure of utilizing standardized achievement test batteries to assess the academic skills and abilities acquired from the process of direct educational instruction or intervention. Standardized achievement tests are characterized by being available from large publishers that have sufficient resources to employ professionals and test developers, by including a fixed set of test items designed to measure a clearly defined subject area across a wide span of age and/or grade levels, and by following specific directions for administering and scoring the tests [2]. The procedure of administering and scoring the tests in a consistent manner to nationally representative groups produces a statistical profile composed of data (test scores) that form norms, which enable comparisons between an individual's test score and a large group of individuals at the same age or grade level who have also taken the test [2, 3].

A useful standardized achievement test battery must actually measure what it claims to measure (validity) and give consistent results over time (reliability). Achievement tests may be designed to comprehensively assess skills in reading (e.g., decoding, fluency, and comprehension), mathematics (e.g., reasoning and computation), writing (e.g., fluency, spelling, and prose writing), and language (e.g., receptive and expressive) within one battery, such as two widely used comprehensive norm-referenced achievement test batteries, the *Woodcock-Johnson III Tests of Achievement* (WJ III ACH) and *Wechsler Individual Achievement Test – Second Edition* (WIAT-II) [3, 4]. Achievement tests also may be developed to assess knowledge/skills only in a specific subject area, such as the *Gray Oral Reading Tests – Fourth Edition* (GORT-4), or to be used as a limited screening battery, such as the *Wide Range Achievement Test*-3 (WRAT-3) [4].

Norm-referenced, standardized achievement tests can be designed for individual or group administration. Individually administered standardized achievement tests are used primarily for evaluating individual students who demonstrate learning difficulty in school, as well as students suspected of needing additional support or special

education services [2]. The tests can be administered by a trained school psychologist, clinical psychologist, neuropsychologist, resource teacher, or psychometrician to an individual student in a quiet, confidential setting. Group administered standardized achievement tests can be developed by large national test publishers or state-level testing programs that are typically administered at least once a year to a large group of students, an entire classroom, or across grade level(s) to assess what students are able to do in specific subject areas including reading, mathematics, written expression, and scholastic subjects such as science and history [2, 5]. Student performance that is less than expected of a specific grade/age level is usually characterized as academic underachievement which may indicate a need for additional instruction and/or intervention. Individually administered tests tend to be more comprehensive, reliable, and valid than group-administered tests. Nonetheless, individually administered tests require more monetary costs to administer because of the limitation of working with just one subject at a time by a trained school psychologist or other professionals.

Acne

Joy Jansen
Neurology, Learning, and Behavior Center, Salt Lake City, UT, USA

Synonyms

Blackheads; Pimples; Pustules; Skin inflammation; Whiteheads; Zits

Definition

A skin disease caused by the over activity of the oil (sebaceous) glands resulting in a localized, irritation of the skin at the base of the hair follicles.

Description

The built-up oil than acts as a host to bacteria; thus, creating inflammation of the skin. Types of skin inflammation vary depending on the depth of the blockage. Blockage close to the surface of the skin is a pustule. A papule, commonly known as a pimple, is also near the surface of the skin by a little deeper than a pustule. Cyst is the deepest type of blockage of oil secretion. Skin inflammation can also occur when the oil breaks through the surface of the skin, commonly known as a "whitehead." And, if the "whitehead" becomes oxidized, oil changes from white to black, the result is a "blackhead." The exact cause of the condition is unknown. However, the increase of hormonal levels and heredity are two factors researchers associate to the over activity of oil glands. The condition begins at the age of puberty and decreases or disappears after the early twenties; however, occurrence is not restricted to any specific age range. Areas of the body commonly effected are the face, neck, back, shoulders, and scalp.

Acquired Autism

Judah B. Axe
Simmons College, Boston, MA, USA

Synonyms

Autism; Autism spectrum disorders; Autistic; Autistic disorder; Enterocolitis; Regression; Regressive autism

Definition

The sudden presence of autism at 18 months of age following typical development.

Description

Acquired autism is distinguished from autistic disorder, a neurodevelopmental disorder present at birth and detected through the observation of delays in language, social, and vestibular development. Acquired autism is observed when a child develops normally and then "regresses" or appears to develop autism around 18 months of age. Children receive the measles, mumps, rubella (MMR) vaccine around this age and a small body of

research suggests the disorder is related to the MMR vaccine. However, a larger set of data suggests no correlation between autism and the MMR vaccine. Many factors, such as bowel problems, are thought to contribute to acquired autism, but the specific mechanisms remain unknown. The prevalence of acquired autism has been found to be between 22 and 50% of autism cases.

Acquired Immune Deficiency Syndrome (AIDS)

►Acquired Immunodeficiency Syndrome

Acquired Immunodeficiency Syndrome

Brian P. Daly[1], Cindy Buchanan[2]
[1]Temple University, Philadelphia, PA, USA
[2]Children's Hospital of Philadelphia, Philadelphia, PA, USA

Synonyms

Acquired immune deficiency syndrome; AIDS; Immunodeficiency syndrome acquired; Immunologic deficiency syndrome acquired

Definition

AIDS stands for acquired immunodeficiency syndrome. AIDS is a viral disease that destroys the body's ability to fight infection.

Description

AIDS is the final stage of the human immunodeficiency virus (HIV) infection. HIV finds and destroys white blood cells (T cells or CD4 cells) that the immune system needs to fight disease. HIV disease is transmitted through blood or semen and occurs in three major ways: through sexual activity if the body fluids become exposed to each other, in intravenous drug use if contaminated needles are shared, and from an infected mother to her baby. The diagnosis of AIDS is made when an individual is infected by the HIV, has a CD4-positive T-lymphocyte count under 200 cells/microliter or less than 14% of total lymphocytes, and increased susceptibility to opportunistic infections and malignant neoplasms [1].

Opportunistic infections are common in individuals with AIDS, targeting areas that include the brain, intestinal tract, lungs, eyes, and other organs [2]. Additional health complications include debilitating weight loss, diarrhea, neurologic conditions, and chronic illnesses such as diabetes, heart disease, and cancers like Kaposi's sarcoma and certain types of lymphomas [2].

In the absence of treatment, data from large epidemiological studies in Western countries indicate that the median time from infection with HIV to the development of AIDS-related symptoms is approximately 10–12 years [3]. However, there can be a wide variation in disease progression. The most efficacious treatment for HIV/AIDS is with antiretroviral drugs that fall into four major classes: Reverse transcriptase (RT) inhibitors; protease inhibitors; entry and fusion inhibitors; and, integrase inhibitors. Combinations of these drugs also are employed and can significantly reduce the presence of the virus. Specifically, using a combination of antiretroviral medications and protease inhibitors commonly referred to as highly active anti-retroviral therapy (HAART) has been found to be effective in prolonging the lives of children and adolescents with HIV. Currently, drug treatment does not cure HIV infection or AIDS. Retroviral drugs can effectively suppress the virus, even to undetectable levels, but the drugs cannot eliminate HIV from the body.

Medical advances in the prevention of mother-to-child transmission are particularly encouraging given that fewer than 300 children annually are born infected with HIV in the United States [6]. However, there are still more than 8,500 previously infected children and youth less than 19 years old living with HIV or AIDS [6]. In addition, over 50% of all new HIV infections occur in individuals under the age of 25 [4].

Almost all HIV-infected young children in the United States get the virus from their mothers before or during birth when proper prenatal care is not obtained.

Adolescents become behaviorally infected with HIV through either sexual activity or drug use. Similar to adults, the most effective treatment for HIV-positive children and adolescents is antiretroviral therapy. Antiretroviral treatment reduces illness and mortality among children living with HIV in much the same way that it does among adults. In the United States, all infants with HIV are started on treatment, regardless of CD4 percentage, clinical status or viral load [5]. Adolescents that are behaviorally infected are monitored and generally begin antiretroviral treatment when they present with a history of an AIDS-defining illness or with a CD4 T-cell count <350 cells/mm [7].

Relevance to Childhood Development

Over the course of a child's life, HIV infection results in detrimental effects on the development of the central nervous system (CNS), impairs psychosocial functioning, and ultimately reduces life expectancy. The ramifications of these risks to successful development may occur at any age, and often vary with disease progression to AIDS.

Compromised development of the CNS in children with HIV infection may result in cognitive, social, and/or emotional delays that can become apparent at varying points in the child's life. These deficits vary from acute or specific functioning problems to global difficulties affecting multiple areas of neurocognitive functioning [8]. Impaired functioning is often observed in areas that include social emotional regulation, visual-spatial and perceptual organization, expressive and receptive language development, and attention. Deficits in functioning can be caused by static encephalopathy or by deterioration of the attained brain development by repeated severe infections (e.g., toxoplasmosis, cytomegalovirus).

Additionally, rapid declines in neurocognitive functioning and motor delays often indicate the disease progression to AIDS due to either the failure of the current medical treatment or nonadherence. Disease progression can lead to greater neurocognitive decline and symptoms consistent with AIDS-related dementia (e.g., cognitive, motor, and behavioral slowing, progressive memory impairments, apathy, and deficits in frontal lobe functions).

Similar to other life threatening chronic illnesses, children living with AIDS may experience feelings of sadness, hopelessness, and intense fears of death [9]. Additional internalizing and externalizing symptoms experienced by children with AIDS include depressive symptoms, adjustment problems, feelings of isolation, fear of rejection, and posttraumatic stress symptoms [11]. Psychological and social challenges also may be the result of physical differences from their peer groups such as wasting, descended stomachs, small stature, or atopic dermatitis. Children with AIDS experience repeated and painful medical procedures, recurring hospitalizations and medical visits, frequent school absences, and disruptions in daily routines. However, for children with AIDS, these stressors may be further complicated by feelings of shame about the disease and social stigma.

Psychosocial problems can often hinder adherence to medical care and overall disease progression [10]. Adherence is a primary challenge for children with HIV and nonadherence is a predictor of when children will progress to the final stage of HIV infection. Nonadherence has major consequences in this population including increased viral load, development of resistance to the primary medications, and death.

The neurological, psychological, and social issues faced by youth with HIV disease are complex, requiring careful and supportive assessment and intervention that take into account all of the above influences. Having counseling resources available or making referral to mental health professionals is an important component of providing comprehensive care to children and adolescents with HIV or AIDS.

Active Euthanasia

Lawrence Liggett , Shelia M. Kennison
Oklahoma State University, Stillwater, OK, USA

Synonyms

Assisted suicide; Mercy-killing

Definition

Active euthanasia occurs when one takes active steps to terminate a patient's life, such as administering a lethal dose of medication.

Description

The term euthanasia is derived from the Greek, literally meaning *good death*; *eu* refers to good and *thanatos* refers to death. Active euthanasia refers specifically to the case in which a person's life is ended through a deliberate act, such as the administration of a lethal dosage of a medication. Three types of active euthanasia have been identified. The most common is voluntary active euthanasia in which the person who has a terminal illness asks another person, often a physician, to perform the deliberate, life-ending act. Non-voluntary euthanasia occurs when a person other than the patient acts on the behalf of the patient and asks a third person to perform the deliberate, life-ending act. Lastly, involuntary euthanasia refers to the circumstance in which the patient's death is hastened by a deliberate act without the patient's consent [1].

Active euthanasia that is carried out by a physician is referred to as physician-assisted suicide (PAS). The U.S. Supreme Court has held that there is no constitutional right to PAS [6]. The Court was willing to let the States, not the federal government, regulate PAS. Oregon is currently the only state in the U.S. to have legalized physician assisted suicide. Oregon's Death with Dignity Act is a comprehensive piece of legislation outlining the steps patients and physicians must follow to end the life of a terminally-ill patient. Between 1998 and 2007, 341 Oregon patients have legally ended their lives with prescribed medication [5].

PAS does occur in other countries. For example, in the Netherlands, terminally ill persons have requested and received PAS. In the Netherlands, PAS is permitted when the physician faces an unresolvable conflict between the law, which makes euthanasia illegal, while also facing the responsibility to help a patient whose terminal illness and suffering makes euthanasia necessary [4].

Relevance to Childhood Development

Although the issues surrounding death and death planning may be thought of as affecting older adults more often than younger adults, death and decisions regarding death planning have relevance to all stages of human development. Children may be born with life-threatening conditions or develop terminal illnesses. Parents of such children can face difficult decisions related to the prolonging of life and/or the hastening of death through medical intervention. It has been estimated that approximately 1 in 33 babies born in the United States each year has a physical deformity [2]. Birth defects are a leading cause of infant mortality [3].

In 2002 in the Netherlands, a procedure was developed for the euthanasia of infants. It has been referred to as the Groningen protocol [7]. It requires that there is a joint decision made by physicians, parents and social workers that further medical treatment would be of no use and then a waiting period of several days. During the waiting period, parents may reconsider the decision. After the euthanasia is performed, the records of the case are

submitted to the prosecutor's office for review. Legal prosecution will not occur if the appropriate protocol has been followed. The Groningen protocol remains controversial; however, with the increase in the use of technology that sustains the lives of fragile newborns, the discussion surrounding the care of critical ill children will, no doubt, continue.

Active Exploration

Thomas G. Reio, Jr.
College of Education, Florida International University, Miami, FL, USA

Synonyms

Diversive exploration; Epistemic behavior; Inquisitive behavior; Inspective behavior; Specific exploration

Definition

Exploration refers to the act of gathering information about an environment as result of being curious [1]. The discrepant properties of objects and events arouse curiosity (e.g., in the form of a question), and exploratory responses to satisfy this curiosity expose one to information from the environment that was not previously available [5]. By exploring the environment, new information is acquired and learning ensues. After a child becomes curious about an exciting new computer game, for example, her passive exploration might entail merely observing how a peer plays the game; active exploration would involve actually playing the game to learn its properties. In effect, active exploration of an environment is more likely to result in greater knowledge acquisition than passive exploration [2].

Description

Both animals and humans engage in exploration for the purpose of adapting to environmental contingencies. There are many varying perspectives about exploration, with most embracing the notion that it arises as the result of being curious [1]. Human exploration and exploratory behavior have both motivational and developmental implications that can be useful for guiding educational thinking and practice [4].

Epistemic or knowledge-seeking curiosity results in specific exploration for the answer, for instance, to a child's question. Diversive or experience-seeking curiosity results in diversive exploration of sensory properties, like exploring how it would feel to dive for the first time into a body of ice cold water on a hot summer's day. Specific exploration is motivated by a desire to know a specific answer; diversive exploration is motivated by boredom or a desire to experience a new sensation or experience [1]. Active forms of both types of exploration more likely result in knowledge advances versus more passive forms.

A number of major psychological theories embrace active exploration [3]. Ecological, attachment, psychosocial, and Piagetian theory, among others, each embrace exploration as an integral part of its developmental perspective. The thinking in general is that active exploration is vital for learning, healthy human functioning, and development. In an ecological sense (perceptual learning and development), a child must actively explore to learn about the opportunities for action (affordances) in his environment. Moreover, attachment theorists propose that having a strong emotional bond and therefore a secure attachment with a primary caregiver is essential to active exploration and learning in a toddler's environment. From a psychosocial perspective, identity formation among adolescents is a function of actively exploring to find information about oneself in the context of diverging from parental relationships, and instead making new peer associations and experimenting with new roles in such associations. Finally, Piaget's [4] cognitive theory suggests that active exploration of a child's environment leads to information acquisition, knowledge transformation, and eventual mastery of one's environment. In each of the aforementioned developmental perspectives, active exploration leads to greater learning and more favorable development.

Relevance to Childhood Development

Active exploration is one of the cornerstones of child development [4]. Without sufficient opportunities for actively exploring their worlds, children's cognitive, social and emotional, and even physical development may suffer unnecessarily. Designing learning environments in homes, playgrounds, and schools that motivate active specific and diversive exploratory behavior will promote optimal learning and development [3].

Active Listening

Sandra F. Teniente[1], Norma S. Guerra[2]
[1]University of Texas at San Antonio, College of Education and Human Development, San Antonio, TX, USA
[2]University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Attentive listening; Reflective technique of mirroring what is spoken

Definition

Active listening entails the listener's involvement in hearing for intellectual and emotional messages. The listening focus is with what the person is saying, while confirming the accuracy of the content and affect of the message.

Description

Active listening involves the intent to listen for meaning, in which the listener checks-in with the speaker to verify a correct understanding of the presented message. The listener's attention is to the process: what is heard and what is implied.

Active listening involves identifying explicit and implicit patterns of communication. Verbal communications are received and reflected along with the underlying expression of feelings in an attempt to understand or explain a core message. Active listening is a learned skill and effort to avoid misunderstandings by paying close attention to a speaker. Active listening can be facilitated by creating an environment conducive to listening by eliminating distractions and remaining aware of internal, and physical limitations such as fatigue that may interfere with the listening exchange.

Active Listening Techniques

Active listening can be used to express empathy by using questions and the following techniques: encouragement, restatements, reflections, and summaries.

- The encouraging prompts may include nodding or saying "I see" or "tell me more."
- Restating responses may offer feedback in line with "it sounds like you did not do very well on your test" or "you forgot your homework" which can be used to mirror facts that have been shared.
- Reflecting responses such as "you seem to feel that you are," or "what I hear you saying is that you are afraid of school," can be used to capture the essence of the feelings expressed.
- Summary responses pull important ideas and facts together and can be used to establish the basis for further discussion or help with review of prior gains.

Relevance to Childhood Development

Active listening is a skill for recognizing and exploring a child's pattern of communication. Without active communication skills, a child's concerns often go unrecognized. By the age of 5, children are aware of their power in listening and being heard. They may be able to

demonstrate their ability to speak and hear yet still have difficulty listening. This can be observed in the following example: complying with detailed directions. Differences in children's ability to listen are developmental and may include: attention disorders, emotional disturbances, prenatal drug exposure, and language proficiency. Listening can also be influenced by physiological auditory acuity (ability to hear), and auditory perception (ability to discriminate among sounds).

In the classroom, active listening is the process of summarizing and relaying feedback to the student about expressed feelings and identified concerns. In group, inviting the children to restate what they have heard another child say functions as practice in active listening. Other active listening activities may be introduced with pausing in the middle of a story and inviting the children to tell what they think has occurred; giving directions and having the children repeat what they have heard. Equally important is value of giving feedback to encourage the children's active listening skill development.

Relevance to Parent–Teacher Relationships

Early childhood programs that promote communication between parents and teachers can help to build a strong working relationship to support home – program collaboration. These communications help early childhood professionals to better understand the parent's perception and expectations of their child in relationship to the school program.

The goal in active listening is to develop an understanding of the parent's concern and to clearly communicate the listener's interest in the parent's message.

Through the use of active listening skills, educational professionals can gain important information with which to work with.

In sum, active listening has been described as a process, which includes making empathetic comments, asking appropriate questions, paraphrasing and summarizing for the purposes of verification.

Activities of Daily Living

Norma S. Guerra
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Self-care behaviors; To participate in regular activity associated with independent living

Definition

Activities completed on a regular basis that involve self-management (examples include: bathing and dressing). Daily living activities entail the person's involvement in personal care of intellectual, physical, psychological, and social needs.

Description

Activities of daily living include routines integral to self-sufficiency [4]. Evaluations of daily living activities generally involve psychological and/or medical determinations to understand the person's ability to care for self on a day-to-day basis. Focus of daily living activities becomes a consideration in the assessment of adaptability to determine cognitive function and self-sustainability.

Intellectual and Physical Daily Living Activities

Daily living activities are developmental and are influenced by intellectual capacity.

During infancy and early childhood, daily activities are moderated and managed externally by care-givers. As normal child development occurs, greater levels of autonomy result in increased daily activities. By the age of 7, activities are expressed in physical self-care, some which include: bathing, dressing, toilet management, eating, and sleeping. It is at school age that daily living activities become a decision consideration in assessing normal development. Decisions about normal as desirable or acceptable are frequently assessed in the child's fulfillment of one's own personal daily living needs [1].

Psychological and Social Daily Living Activities

Psychological and social daily living activities increase with maturation and instruction. As the child recognizes and explores immediate environments, appropriate patterns of social communication are reinforced adding to the child's daily living activity repertoire. Some of these

basic daily living activities include: eating, dressing, speaking and interacting with others. The child learns culturally appropriate emotional, psychological and social behaviors, for example: smiling at a friend, shaking hands when meeting someone for the first time, and excusing self when leaving the table. For the child who begins failing to exhibit the appropriate daily living activities, concern arises. Without the demonstrated psychological, emotional and social daily living activities, the child is placed in a vulnerable position that may lead to mistreatment by others.

By school age, children are aware of their ability to self-manage. Teachers are active participants in modeling and teaching appropriate daily living activities. Children learn that school activities of daily living involve self-control, and self-management. Classroom examples may include: sitting behaviors or waiting to be recognized before speaking. While interactive play may involve conflict management using appropriate language rather than fighting. The children learn to develop the social skills and self-managed behaviors that assist with personal development [3].

Relevance to Parent–Teacher Relationships

Early childhood programs working with parents in partnership with teachers to prepare the child for school daily (life) activities have an advantage. These communications help the child better understand the core values and importance of daily living activities as they apply to home and the school environment [2].

In sum, activities of daily living can be described as those critical skills that address self-care in a variety of setting. The goal in teaching daily living activities is individual self-sufficiency.

Adaptability

Octaviana Hemmy Asamsama, Brett R. Nelson, Dudley Wiest, Diana Nelson
CSUSB, San Bernardino, CA, USA

Synonyms

Adaptation; Adaptive; Creativity

Definition

Adaptation is a biological process, which modifies cognitive operations and psychological structures in order to respond to environmental demands and interactions [11]. Additionally, an adaptive person is defined as someone who consistently responds in a positive manner during a stressful situation. An adaptive person's choices and behaviors would not augment the stress. Instead, said choices and behavior would alleviate or at least maintain the original level of stress [1].

Description

Piaget has stated that adaptation is "any modification of an assimilatory scheme or structure by the elements it assimilates" [6]. Adaptation is comprised of two opposing processes: *assimilation* and *accommodation*. *Assimilation* is defined as amalgamation of various external various into "into evolving or completed structures of an organism" [6]. Dichotomously in the operation of *accommodation*, the child will then adapt himself or herself into the specifications of his or her reality. The *plasticity* of said modification exists because assimilation exists in a temporal state. "However much the view of reality is shaped into the form of the child's current form of understanding, there is always an aspect that resists the transformation, in that the assimilating scheme must adapt to the exigencies and particularities of reality" (van Geert, 1998).

Plasticity can be defined as the variability of each individual. Said variability is "an indication of the individual's potential for different levels of functioning or development" [8]. Specifically in the case of psychological and cognitive functioning, plasticity refers to the individual's capability to adapt and be flexible in dealing with various changing environmental factors. It also refers to "an individual's potential (or reserve capacity) to learn new things or increase the level or speed of performance" [8].

There is fluidity in adaptability, where the process of assimilation and accommodation becomes a dynamic process [5]. Piaget defines assimilation as "integration into previous structures" [7]. Despite the integration of new understanding, the structures continue to exist, although, modified by the novel integrations [10]. Accommodation is defined as "any modification produced on assimilation schemata by the influence of the environment" [7]. Piaget views assimilation and accommodation as "functional invariants of life" unchanged as the child develops [10]. "There is no need for them to change, since they only supply the rules for how to accomplish certain tasks independently of what the specific tasks happen to be. The way a mathematician solves a problem really is different from the generalization of the infant. Nevertheless, the difference is not in the processes of assimilation and accommodation but in the schemata or structures used and created in those processes" [10].

Relevance to Childhood Development

In order for adaptation to occur, there must be an accompanying environmental factor. In a face of adversity, having positive adaptation can impact, childhood development specifically sociability, resilience, and social competence. All are interconnected and are integrated in a symbiotic relationship [3].

For example, an aspect of social competence is sociability. Sociability is defined as a "tendency to prefer the presence of others to being alone" [9]. Their definition of sociability is not limited to children's engagement towards strangers but to everyone, such as family members, friends and strangers. They found that shyness is a category of the sociability construct, not a contradictory definition of sociability. Children who are unsociable might not be labeled as shy and vice versa. Children's general sociability can "directly predict the child's tendency to behave prosocially in a given situation. In two observational studies of preschool children, the incidence of children's helping behavior in the classroom was positively correlated with the number of social interactions in which they engaged" [9]. Interestingly enough, even though extraverts offer more "active" help towards others, in comparison to introverts, introverts instead offer a complementary level of "passive" help [9]. Active help was described, as more physical task while an example of a passive help would be offering knowledge in order to help others.

Children who exhibit a high degree of social competence also have a correlating high degree of resilience. Resilience occurred when positive adaptation exists despite the experience of considerable amount of stress and adversity. By definition, it is also "encompasses atypical processes, in that positive adaptation is manifested in life circumstances that usually lead to maladjustment" [3]. Because resilience is a product of two factors, it can never be really measured but instead, its existence can be "indirectly inferred based on evidence of the two subsumed constructs" of positive adaptation and exposure to risky environmental factors [3].

Experiencing a positive adaptation can be best described as an "adaptation that is substantially better than what would be expected given exposure to the risk circumstance being studied. In many studies of resilience across diverse risk circumstances, this has been defined in terms of behaviorally manifested social competence or success at getting stage-salient developmental tasks" [3]. In children who are young, being socially competent can be measured by the security of attachment towards the primary caregiver. Children, who are socially competent or exhibit competence, have secure attachments to their primary caregiver [13]. For older socially competent children their positive functioning can be observed in their positive peer and social relationships and positive academic achievements [4, 12].

In summary, a person who is adaptable or who experiences positive adaptation would be better equipped in several aspects of childhood development. When facing risky or difficult circumstances, a person with a positive adaptation would have a substantially better outcome than those who exhibit maladaptive adaptation. He or she would be more resilient, exhibit higher degree of sociability and would be more socially competent [3].

Discussion

Currently there are several studies researching the various aspects of adaptability in order to provide effective preventive and intervention policies for childhood adversity [2]. The study of the adaptive capability of children is a vast, growing and exciting field of development and further exploration will provide important information about the intricacies of childhood development and its subsequent consequences.

Adaptive Behavior

Emily A. Bullington
Spartanburg School District 6, Spartanburg, SC, USA

Synonyms

Self-care; Self-help skills

Definition

Adaptive behavior can be defined in various ways, the simplest being that it is the performance of daily activities required for personal and social sufficiency [8]. Furthermore, it is how individuals are able to cope with common life demands and how well a person meets the standards of personal independence expected of someone in their particular age group, sociocultural background, and community setting. A persons adaptive functioning could be influenced by a variety of factors, including education, motivation, personality characteristics, social and vocational opportunities [2, p. 40]. For those that may have significant limitations in adaptive behavior, these barriers can easily impact their daily life and affect their ability to respond to a particular situation or to the environment [3].

Description

Adaptive behavior can be difficult to define because it is not independent of intelligence and the number of dimensions associated with adaptive behavior is unknown [8]. The DSM-IV identifies ten areas of adaptive functioning, which include: communication, self-care, home living, social skills, use of community resources, self-direction, academic skills, work, leisure, health and safety [5].

According to Sparrow et al. [8], adaptive behavior is the interaction of personal, cognitive, social, and situational variables. However, there are several important principals that are inherent when using this definition of adaptive behavior. The first is that adaptive behavior is age related, in that it increases and becomes more complex as a person gets older. Second, adaptive behavior is defined by the standards of others. For example, those who live, work, and interact with an individual. Third, adaptive behavior is variable because it can become worse or progress depending on changes in the environment, interventions, or other events. Last, adaptive behavior is defined by typical performance, not ability. It is meant to measure what a person actually does day to day, despite their actual ability to do it [8].

The following is a list of the ten areas of adaptive functioning and their definition, as defined by Harrison and Oakland [4]:

1. Communication: Speech, language, and listening skills needed for communication with other people, including vocabulary, conversation skills, etc.
2. Community use: Skills needed for functioning in the community, including use of community resources, shopping skills, etc.
3. Functional academics: Basic reading, writing, mathematics, and other academic skills needed for daily, independent functioning, including telling time, writing notes and letters, etc.
4. School/home living: Skills needed for basic care of a home, living, school and classroom setting, including cleaning, performing chores, etc.
5. Health and safety: Skills needed for protection of health and to respond to illness and injury, including using medicines, showing caution, etc.
6. Leisure: Skills needed for engaging in and planning leisure and recreational activities, including playing with others, following rules in games, etc.
7. Self-care: Skills needed for personal care including eating, dressing, bathing, toileting, etc.
8. Self-direction: Skills needed for independence, responsibility, and self-control, including starting and completing tasks, keeping a schedule, making choices, etc.
9. Social: Skills needed to interact socially and get along with other people, including having friends, showing and recognizing emotions, assisting others, and using manners.
10. Work: Skills needed for successful functioning and holding a part- or full-time job in a work setting, including completing work tasks, working with supervisors, and following a work schedule.

Relevance to Childhood Development

A child's adaptive functioning will change as the child grows older, and must be considered relative to a child's age. What is expected of a child at age 5 will be quite different from what is expected at age 15. It is therefore very important to maintain a developmental sense of adaptive behavior. Children who have mental retardation are defined as having deficits in their adaptive behavior in at least two areas. Depending on the severity of the mental retardation, adaptive skills can be taught to a child, but may need to be done at a very basic level [5].

Adderall (Amphetamine)

Jana Sander
Texas A&M University Corpus Christi College of Education, Corpus Christi, TX, USA

Definition

A brand name amphetamine used in the treatment of attention deficit hyperactivity disorder.

Description

Adderall is a stimulant drug which contains an amphetamine. It is used to improve attention span and decrease impulsivity. It is available in two different types: Adderall IR (instant release) or Adderall XR (extended release). Generally Adderall XR has only been approved for use in the treatment of attention deficit hyperactivity disorder.

Some of the side effects include: increasing appetite, decreasing appetite, headache, stomachache, trouble sleeping, nervousness, and dizziness. As always, only a doctor can determine if adderall is appropriate for a child to take.

Addictive Drugs

Nicholas J. Balogh
University of Missouri, St. Louis, Columbia, MO, USA

Synonyms

(Superfluous.)

Definition

A drug which, due to its desired, pleasurable effects, has the ability to cause physical and/or psychological dependence to its user. Via the mechanism of positive reinforcement, addiction can develop.

Description

For a drug to be considered addictive, many different factors, both physical and psychological, must be assessed. An educated conclusion can be reached after medical and scientific evaluation, traditionally involving:

1. An assessment of the risk of physical harm: What level of physical harm (if any) is the user placed in, as a result of their use of the drug?

This assessment involves, for example, such varied risks as that of a intravenous drug user contracting dangerous communicable diseases (e.g., HIV, hepatitis C, etc.) through sharing needles; the physical risks of overdose (e.g., severe central nervous system depression); and the relative threshold of how much drug causes an overdose: is a lethal amount of the drug easily obtained, or extremely difficult to obtain? Is a lethal amount 10 pills or 10,000?

2. An assessment of the risk of physical and/or psychological dependence. e.g., What is the likelihood of physical and/or psychological dependence on the drug? Put in other words, does this drug induce feelings of pleasure? If so, how intense are these pleasurable feelings? Is it possible for a habitual user to completely stop their use with no adverse reactions?
3. An assessment of possible social and societal harm. e.g., How does a person's use of this drug affect

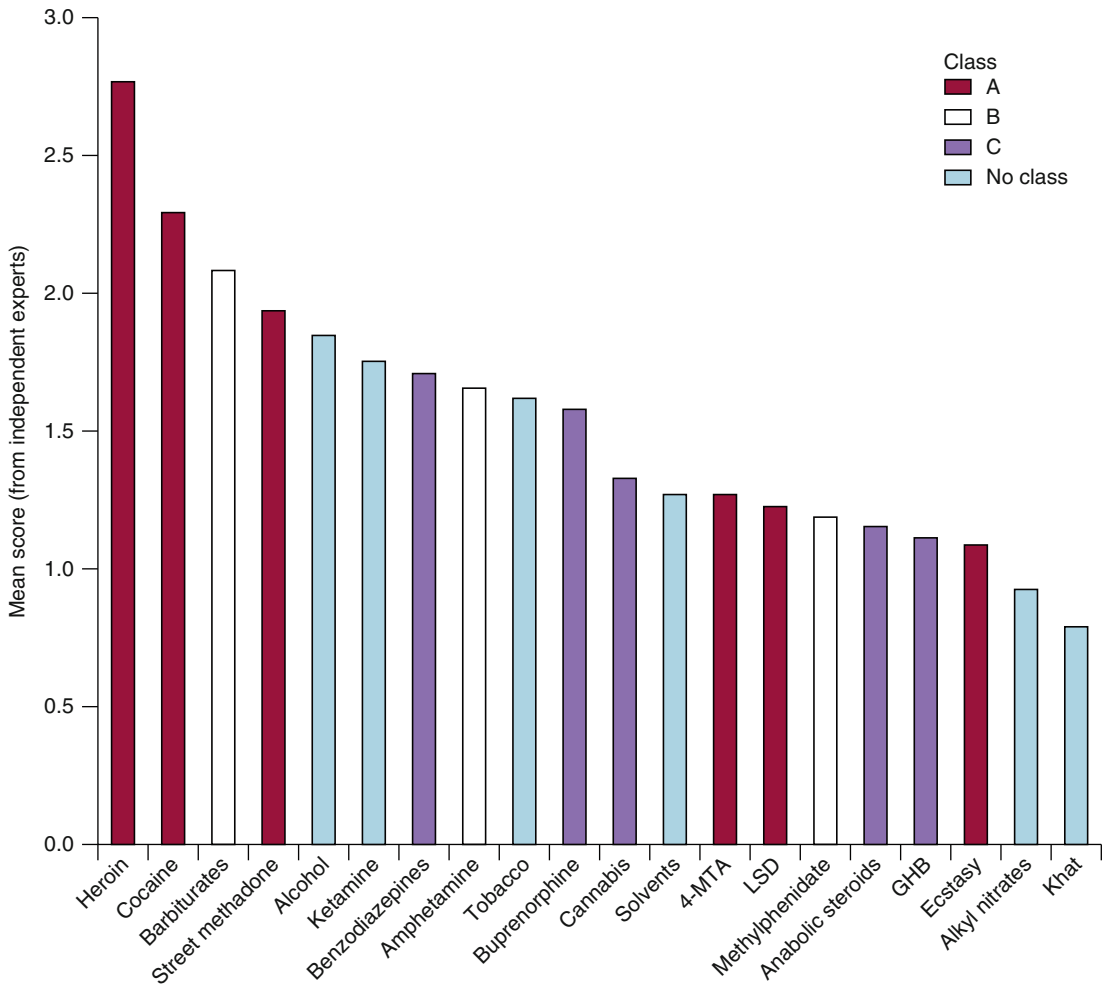
society? Is the highest foreseeable cost to society only a minor nuisance, or a serious and grievous threat to the lives of other members of society? Is it foreseeable that this drug will influence society's health-care costs? If so, will it reduce or raise overall health-related financial expenditures? [1]

[Preceding conditions adapted from Nutt et al.]

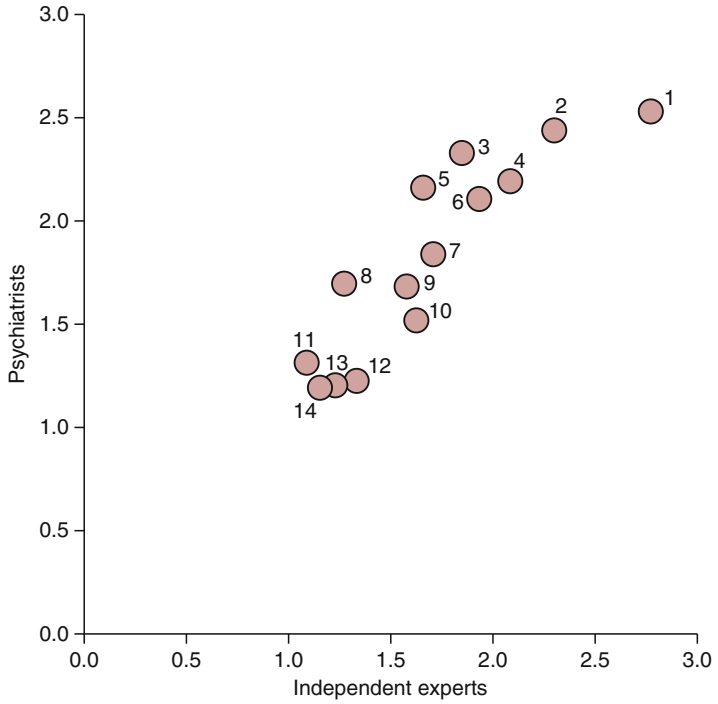
The United States National Institute on Drug Abuse (NIDA) separates "commonly abused drugs" and "drugs of abuse" into the following categories (Figs. 1 and 2):

Alcohol
Nicotine
Cannabinoids, including marijuana and hashish
Depressants, encompassing barbiturates, benzodiazepines, GHB, methaqualone
Dissociative Anesthetics: ketamine, PCP
Hallucinogens: LSD, mescaline, psilocybin
Opioids and Morphine Derivatives: codeine, fentanyl, heroin, morphine, opium, oxycodone (OxyContin), hydrocodone (Vicodin)
Stimulants: amphetamine, cocaine, MDMA ("ecstasy"), methamphetamine, methylphenidate (Ritalin), nicotine
Other: anabolic steroids, dextromethorphan, inhalants [2]

The legality of the use of addictive drugs varies by country, and by specific substance. Efforts to legislate the use of addictive drugs have led to the 1961 United Nations Single Convention on Narcotic Drugs, the creation of the Drug Enforcement Agency (DEA) and declaring a "war on drugs" in the United States. The 1961 convention's



Addictive Drugs. Fig. 1 Mean harm scores for 20 substances. Classification under the Misuse of Drugs Act, where appropriate, is shown by the *color* of each bar. (From [1].)



Addictive Drugs. Fig. 2 Correlation between main scores from the independent experts and the specialist addiction psychiatrists. 1 = heroin, 2 = cocaine, 3 = alcohol, 4 = barbiturates, 5 = amphetamine, 6 = methadone, 7 = benzodiazepines, 8 = solvents, 9 = buprenorphine, 10 = tobacco, 11 = ecstacy, 12 = cannabis, 13 = LSD, 14 = steroids. (From [1].)

preamble stated that its signatory nations are "concerned with the health and welfare of mankind" and are "conscious of their duty to prevent and combat" drug addiction [3].

Especially as of late, there has been a plethora of public discourse on the morality and legality of drug use.

Adjustment

Norma S. Guerra
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Accommodation; Adaptation; Allowance; Alteration; Modification; Piagetian

Definition

Adjustment involves the behavioral process as the person maintains physiological and psychological needs in a response to environmental changes or challenges.

Description

Adjustment involves *the act of making suitable* accommodations in response to a new environment. The act of adjusting connotes adaptation to a particular condition, position or purpose. Implied in its meaning is the act of making it right, to regulate, adapt, or settle. It can be defined as the natural human response to a discrepancy or change in the environment. For instance, consider

a child moving abroad for several years. The challenges the child will encounter throughout the foreign country experience will cause alterations to daily routines and ultimately lead to an ►*adjustment* or accommodation in response to the conditions of that particular country and new environment. This process does not occur rapidly; the child may endure a series of cultural shocks and adjustment phases. These phases include a preliminary stage, initial euphoria, irritability, gradual adjustment, adaptation and biculturalism, an lastly re-entry phase. In considering any new school experience as a condition requiring personal adjustment, the phases of adaptability may proceed as follows.

Preliminary Stage

In the preliminary stage there is excitement and preparation in response to the new challenge. The student prepares for the first day of school. There is a feeling of excitement about beginning a new school year, and setting personal goals. Also facing the student is a sense of uncertainty in response to the new environment. The student will attempt to work out an adjustment either by modifying or changing a position to cope with the new setting. The student may ask for assistance or set up a support system to aid with the transition. In this phase everything is exciting, and the obstacles the student may face have not surfaced. The student may also experience a feeling of fascination and idealism. There are assumptions that are developing; both rational and irrational that may prove to be false with the upcoming change.

Because the student is optimistic, there may be built in negative assumptions that can be detrimental to self-adjustment. The student at this period is not in the classroom environment, and therefore lacks the reality of the experience and any support or motivation the teacher can provide.

Initial Euphoria

In this phase, the reality of the school experience occurs. Anticipations from the previous stage are met with the student's "first day of school" excitement of making new friends, and meeting new people. Unfortunately, as the student becomes more accustomed to school, and things begin to become routine, enthusiasm fades, and the obstacles that were never present before are now prevalent. It is here that if the teacher can execute engaging activities, this phase will last longer, and thus minimize the following phases.

Irritability Stage

The third stage is the most difficult stage. In this stage the student becomes accustomed to the environment, and has adjusted to the new culture that is now becoming more demanding. The student exhibits irritability at having to deal with difficult situations. There no longer is the excitement of new friends, or starting a new school, or even a new phase of life. During this stage, the student begins to make comparisons with previous years' experiences, and sometimes these comparisons can become overwhelming and difficult to deal with. For example, a student may compare how prior teachers allowed them to do things that the current teacher does not allow. Throughout this time, the student becomes irritable with any changes presented. These can be insignificant changes, but can cause the student to become extremely stressed and upset. This stage is the most difficult stage of adjustment because of the comparisons that are made. The changes that face the students make the situation more difficult to accept, because of the student's desire to have things the way they used to be. It is important for students to maintain a positive attitude, and accept the modification(s) as assets instead of hindrances.

Gradual Adjustment

At this point, the student is able to orient and organize self in the school environment. By this time, the student has made new friends, become acquainted with the teacher, and has become aware of any course challenges. The student will be gradually adjusting, and may become aware of the transition. For students who are struggling here to make sense of presented information, it will be important to monitor for a negative attitude toward the obstacles presented. The teacher may consider reaching out to these students before they develop a negative attitude.

Adaptation and Biculturalism

The student is now able to function normally in the new environment. What seemed to be a hardship in the past is now part of the daily routine. School is becoming easier because of the increasing knowledge and ability to apply what has been learned. An important aspect of the student's progress of adjustment is their ability to handle difficult situations. The student generally will no longer let disruptions interfere. It is important for the student to stay active in school, and with the new friendships developed. The confidence level of the student by this time has increased dramatically. The student is no longer fighting challenges to change. Rather the student is more likely to have an optimistic approach to accomplish personalized goals. New insights are being made and the student develops a new perceptive.

Effective Adjustment Phase

The student has completely adjusted to the new culture, and has changed to accommodate a new way of life. The student continues to immerse self in the new (school) culture and is forced to consider deeper cultural issues. This requires self-awareness, study and interaction with the school culture, to ultimately resolve and accept another way of life. Eventually the students begin to respect and enjoy the material being learned, while simultaneously feeling that things are becoming routine and easy. The student is finally comfortable with the new environment, and has reached a new level of maturity.

Relevance to Childhood Development/ Education

There are many ways in which adjustment occurs in childhood and beyond. Facing a new school culture is only one example. It is how the child receives the challenge, and adjusts to it that becomes the largest consideration to the accomplishment of personal goals. Suggested are stages in how the student enters a new classroom, school, or even grade level. Educators should regard the beginning of the school year as a new cultural experience for each student. The suggested phases serve as an insight for the teacher to be able to relate to the students, and overall allow the educator an opportunity to cultivate the best student functioning at their fullest potential. The emotions involved in these adjustment stages can affect the student's performance in school. It is helpful for teachers to understand and find ways to lessen the cultural shock of school in order to attain the highest level of achievement, and to ensure that the students grow in both their acquisition of knowledge and maturity.

Teachers, however, are not the only tools in easing the adjustment (transition) for students. As the students enter new phases of their lives, especially as adolescents, it is not only the culture of school that they have to become acquainted with, but also their own identity and emotional development. Adolescents at the ages of 12–14 are entering a new phase in their lives where they are experiencing new emotions and are in quest for self-identity. Many adolescents are confounded on how best to handle these experiences, causing many to turn to items beyond their maturity level, such as sex, drugs, and other delinquent behaviors. The teacher cannot be the sole initiator of the intervention in the student's lives, and in fact research has proven that quality parent-child relationships can ease the stresses and provide a coping mechanism for adjustment.

Adjustment Disorder in Children

Ginny Kington
Argosy University

Synonyms

Transient situational disturbance

Definition

Adjustment disorder is a diagnosis used to describe emotional and/or behavioral disturbances resulting from exposure to a stressor.

Description

Diagnosis

The Diagnostic and Statistical Manual of Mental Disorders, Second Edition (DSM-II) was the first diagnostic manual to include a diagnosis describing symptoms experienced after exposure to a psychosocial *stressor* [3]. In this version, the diagnosis was termed a *transient situational disturbance*. In the DSM-III, a specific section was created for adjustment disorders which could be classified according to eight different subtypes [4]. After the DSM-III, slight modifications were made, leading to the most recent diagnostic criteria included in the DSM-IV-TR [5].

The DSM-IV-TR defines an adjustment disorder as, "The development of emotional or behavioral symptoms in response to an identifiable stressor(s) occurring within 3 months of the onset of the stressor(s)" (p. 683). According to the diagnostic criteria, an individual's emotional or behavioral difficulties must reach a clinically significant level, as determined by one of two possible factors. The person is responding in either "marked

distress that is in excess of what would be expected from exposure to the stressor" or they are exhibiting "significant impairment in social or occupational (academic) functioning." Additionally, adjustment disorder should not be diagnosed if the symptoms meet criteria for another *Axis I disorder* or if the symptoms are only representing a worsening of a preexisting disorder. This diagnosis should not be used in bereavement situations. Additionally, the symptoms exhibited by the individual should not last for longer than 6 months after the initial stressor occurred or after the consequences of the stressor have ended. The diagnosis of adjustment disorder is unique in that it allows for a focus on the importance of various psychosocial factors and stressors in children's lives [14].

The DSM-IV-TR also provides for the use of several specifiers when making this diagnosis. An adjustment disorder can be described as acute, indicating that the emotional or behavioral disturbance has lasted less than 6 months, or it can be described as chronic. The chronic specifier is used when the emotional or behavioral difficulties last longer than 6 months due to a chronic stressor or a stressor that has lasting consequences. As a requirement of the diagnosis, an individual's symptoms may not last longer than 6 months after the stressor has terminated, meaning that in those instances, another diagnosis must be applied, if warranted.

There are six subtypes of adjustment disorder, chosen based on the most predominant type of symptoms that are displayed. These include: adjustment disorder with depressed mood, with anxiety, with mixed anxiety and depressed mood, with disturbance of conduct, with mixed disturbance of emotions and conduct, and unspecified. Unlike other disorders in the DSM-IV-TR, there are no separate criteria for use with children or adolescents, although some research has found that adolescents are more likely to present with behavioral disturbances. Specifically, one study reported that 77% of adolescents with adjustment disorder presented with behavioral symptoms, in contrast to 25% of adults diagnosed with adjustment disorder [6].

The *International Classification of Diseases*, Tenth Revision (ICD-10) also provides criteria for the diagnosis of adjustment disorder. The ICD-10 diagnostic criteria are very similar to those in the DSM-IV-TR. Specifically, the diagnosis requires that individuals experience "states of subjective distress and emotional disturbance, usually interfering with social functioning and performance, and arising in the period of adaptation to a significant life change or to the consequences of a stressful life event" (p. 121). The manual states that symptoms usually begin within 1 month after the stressor occurs and generally do not last longer than 6 months, except when classified as a prolonged depressive reaction. The diagnosis can be specified as a brief depressive reaction (lasting 1 month or less), a prolonged depressive reaction (lasting up to 2 years), a mixed anxiety and depressive reaction, with predominant disturbance of other emotions, with mixed disturbance of emotions and conduct, and with other specified predominant symptoms [17].

Several authors have described problems associated with the diagnosis of adjustment disorder. These include questionable reliability of the diagnosis and the use of this diagnosis as a way to minimize the stigma associated with mental disorders.

The reliability of the diagnosis of adjustment disorder can be impacted by the fact that there is no specific set level of symptoms required in order to diagnose adjustment disorder or to select the specific subtype of adjustment disorder. Therefore, clinicians are relying heavily on clinical judgment [13, 16]. Authors have recommended that the requirements of the diagnosis be made more stringent in the DSM-V, such as requiring a certain number of criteria to be met, similar to other diagnoses [14]. Reliability can also be impacted by difficulties with the time frames that are required for diagnosis, in that it may be difficult to pinpoint exactly when a stressor began and when it ended [14]. It also can be difficult to distinguish between a "normal" reaction to a stressor versus a "maladaptive" reaction [8].

The diagnosis of adjustment disorder can be problematic when used as a way to avoid the stigma associated with a more severe diagnosis or as a way to avoid more serious diagnoses in children. When clinicians use the diagnosis like this, they may be avoiding the application of a more valid diagnosis, which would impact treatment decisions [12, 16].

Two studies have examined the diagnosis of adjustment disorder in children. One study examined the criterion and predictive validity of the diagnosis of adjustment disorder in a population of 92 children who had recently been diagnosed with acute onset insulin-dependent diabetes mellitus. In terms of the criterion validity, the requirement that the distress develop within 3 months of the stressor was consistent with the experience of 94% of the children. The requirement that the emotional or behavioral disturbance can only last 6 months was relatively consistent with the experience in this population. The average episode of disturbance was 3 months, and 85% of the children's symptoms had resolved after 6 months. In follow up, it was discovered that children who had developed an adjustment

disorder as a result of this stressor were 3.4 times more likely to develop a new psychiatric disorder over the next 5 years [11].

Another study examined the characteristics of adjustment disorder in a group of clinically referred 8–13 year old children diagnosed with this classification. The children were followed over time and it was discovered that during the follow-up period of several years, 29 out of 30 of them recovered. The average length of time the adjustment disorder lasted was 8.87 months, ranging from 2.7 to 24.2 months. Specifically, after 6 months from the onset, 38% of the participants no longer met criteria, and by 12 months, 76% had recovered. When examining other relevant factors, it was found that children who were older when the adjustment disorder began recovered from the diagnosis significantly faster. To examine the predictive validity of the diagnosis, subjects were followed for an average of 7–8 years. There was no indication that the previous diagnosis of adjustment disorder contributed to a decrease in "well time" during the time of the study or to the likelihood of the participants developing new disorders. The results of this study suggest that the diagnosis of adjustment disorder has clinical value and has a good prognosis in children. One implication of this study is that the criteria of adjustment disorder that requires symptoms to dissipate within 6 months may be problematic [10].

Epidemiology

In clinical populations, prevalence estimates of adjustment disorder in children and adolescents have ranged from 6.8 to 42% [12]. Although there is a wide range in the prevalence of this disorder in clinically referred children, it is clear that it is a disorder which is seen frequently in clinical populations.

Unfortunately, not much prevalence information exists regarding the occurrence of adjustment disorder in the general population, especially among children. The large epidemiological studies that have been done in the United States, such as the Epidemiologic Catchment Area study or the U.S. National Comorbidity Study, have not included adjustment disorder among the diagnoses being screened for. One large scale study was done to examine the frequencies of various psychiatric disorders among 5,813 children who were 8–9 years old and living in Finland [2]. Adjustment disorder was diagnosed in 6.8% of these children based on their responses on three screening instruments completed by the child, a teacher, and a parent. Adjustment disorder was diagnosed in 7.7% of the 435 children who completed the second stage of the study, which involved a semi-structured parent interview. The subtype of mixed disturbance of emotions and conduct was the most frequently diagnosed subtype.

Another study examining 386 children living in Puerto Rico found that when children scoring in the mild to moderate range of impairment in academic and social functioning were included, the rate of adjustment disorder was 7.6%. When only those children with severe impairments in functioning were counted, the prevalence rate was found to be 4.2% [7].

Assessment of Adjustment Disorder

The assessment of adjustment disorder is complicated by the fact that there are not specific criteria regarding symptoms expression that are required to make a diagnosis. Since a child could have been exposed to any number of different life stressors to qualify for this diagnosis, the way in which a child is presenting may vary quite a lot. Many different factors can impact how a child responds to a stressor, including the child's cognitive and psychological development, ability to use adaptive defense mechanisms, self-esteem, self-perception of competence, and physiological factors [14]. Several authors provide recommendations for clinicians assessing for adjustment disorder. These include a thorough clinical interview as well as the use of standardized checklists.

A clinical interview conducted with both the child and the parent is a requirement of an effective assessment and an accurate diagnosis of an adjustment disorder. Authors suggest that during an assessment several areas of information be obtained. These include the relationship between the stressor and the current symptoms (i.e., specifically examining the temporal relationship and the symptoms that the child is exhibiting) [9, 13]. It will also help to determine the impact of the stressor on the child's functioning or the presence of a reaction in "marked excess" of that which would be expected [13]. In addition, an effort should be made to understand how the child perceives the stressor, the parents' attitudes about the stressor, and any psychopathology evident in the parents. It will be important for the clinician to assess how the child and parents have coped with stressful events in the past, as well as how they are coping with the current stressor [9].

In addition to the clinical interview, assessment measures may be used. Authors suggest the use of various behavioral checklists including the Child Behavior Checklist, Youth Self-Report, the Children's Depression Inventory, the Revised Children's Manifest Anxiety Scale, the Adjustment Scales for Children and Adolescents, and the Children's Global Assessment Scale (C-GAS) [9, 13].

These are all tools which can assess how the symptoms that are being exhibited by the child compare to behaviors typically exhibited by children their age.

When assessing for adjustment disorder, it is important to differentially diagnose between adjustment disorder and other disorders which may occur following a stressor, or may present with similar symptoms [13, 14]. It is important to differentiate between adjustment disorder and depressive disorders, anxiety disorders, disruptive behavior disorders, *Post-Traumatic Stress Disorder*, and a psychological factor affecting a physical condition [13]. It is also important to keep in mind that adjustment disorder is only used when the criteria for another specific disorder are not met. Therefore, if criteria are met for another disorder, that diagnosis should be given.

Treatment

Given the frequency with which the diagnosis of an adjustment disorder is given, it is surprising that so little empirical research exists about effective modes of treatment [1, 9]. When treating a child who has been diagnosed with an adjustment disorder, it appears that treatment needs to focus on: (1) coping with the symptoms that have resulted from the stressor; and (2) teaching the child coping skills that can be used to deal with future stressors and possibly prevent the future development of emotional or behavioral difficulties in response to stressful events.

In the most simplistic of situations, the stressor could be removed from the child's life or the child could be removed from the stressful situation, thereby resulting in a reduction of symptoms [9, 13]. If this type of simplistic intervention is not possible, other treatment options discussed in the literature include individual psychotherapy, family psychotherapy, or pharmacotherapy. Since parents or caregivers will have a significant impact on the way a child perceives, experiences, and copes with a stressor, the family should be involved in the treatment of the child, even if this does not take the form of traditional family therapy [14, 16].

In terms of individual treatment, authors describe several techniques used to treat symptoms of adjustment disorder in children, including relaxation training and cognitive techniques such as increased problem solving abilities and cognitive restructuring. These treatment techniques would be tailored to the types of symptoms present (i.e., anxiety, depression, or externalizing behaviors) [13]. One author recommends that treatment proceed by acknowledging the stressor, reframing problematic behaviors, teaching emotional vocabulary, focusing on coping skills, and correcting any misinterpretations or misperceptions of the stressor [9].

Although there is a lack of empirical research on the treatment of adjustment disorder, one author presented a case study of a *cognitive-behavioral treatment* with a 10-year-old child diagnosed with adjustment disorder. The interventions that she used consisted of psychoeducation, cognitive restructuring, reframing of situations, validation of emotions, problem solving, and homework. Although no quantitative measures were used, at the end of treatment the client's grandmother reported that the problematic behaviors exhibited at the beginning of treatment had ceased. The client was also able to engage in several behaviors for the first time, including going to camp and staying overnight at a friend's house. The client reported feeling happier, and these gains were maintained at a 6 month follow up [1].

When working with the family, it is important that the parents receive education about how to help their child effectively cope with the stressor [13]. This education could also include information about the cognitive and behavioral techniques being used with their child, and how they can encourage the child to engage in these techniques.

Any treatment with psychotropic medications is recommended only when used as a supplemental treatment to psychotherapy [13]. It is possible that some medications may be helpful in treating the symptoms of adjustment disorder; however, there is no substantial research on the use of pharmacology to treat adjustment disorders [14].

Introduction
Alfred Adler was the first family therapist and the first to do group therapy. Alder established holistic view on a person called Individual psychology, meaning undivided. Adler psychology is the basis of many therapies today.

Alfred Adler was born in Penzing Vienna Austria, February 7, 1870 to parents from Hungry. The family was all musicians at home, and Alfred a tenor, loved to sing attend the opera and the theater. He was the second to the oldest child of six children. Adler's early life he suffered rickets and could not walk until 4 years of age and almost died of pneumonia when a doctor told his family there was no hope for him to live. This statement motivated him to one day become a doctor. Alfred was twice run over by a car on separate occasion, which gave him a fighting spirit. Alfred was a flower lover and felt unhappy because his older brother was favored by his mother and did not feel bonded to her. He was always in completion with is brother and he was able to draw closer to his father with whom he spent much time and saw his father who was a Jewish grain merchant pull himself and his family up through the classes of that time period in Vienna. This brought the family into the Vienna society and was not a part of the Jewish community. Alfred was very friendly and outgoing like his father and felt that mankind was judged by their actions and not by their words alone. Alfred was extremely thoughtful and gained trust by adults and his peers. In school he was faced with a barrier of math and could not resolve it and knew he must try and over come this fear and was able teach himself how to do math.

Educational Information
At age 25 he received his medical degree from the university of Vienna. During that time he met his wife Raissa Timfeyewna Epstein who was a Russian Social activist, and in 1897 they married. Love he felt was a task for two and believed in equal status of women, which in his time was not well accepted. Adler's wife, would become upset because he would not take a political stand and he did not believe in revolution or violence but that better people make better systems. Adler believed in being monogamist and the conflicts of his political beliefs in his marriage was not resolved until a war broke out and his wife was stranded in Russia for 5 months, and she came back from the experience with a different view and never again tried to force the issue of Adler becoming involved in activism again. He never followed or joined in any political groups but followed common sense, fairness, open-mined sane practical ideas. He thought that it was easier to fight for one' principles than to actually live up to them.

They had four children together and he treated all of them equally and his two boys became psychiatrists and his one daughter a scientist and his other an actress.

In the beginning of his career he was an ophanologist and had a firm belief in science. Adler open up his first

general practice in a lower class area of Vienna across from and amusement park and circus where most of his clients were performers. And many of these people remained friends.

There was much political unrest in his country during this time and he was strongly motivated to write and examine personality and became a psychiatrist. Alder in 1907 joined a discussion group with Freud who was 15 years his senior and all went well and, Freud even named him president of Analytic society co-editor of organization newsletter. Adler became very popular and had a great following. Everyone loved him and allowed conversations with all people no matter there class and never tried to make disagreements and if directed to himself he would be truthful in his responses and did not go along with improvable theories. His popularity was growing because he believed that personality problems stemmed from feeling if inferiority deriving from restrictions on the individuals need for self-assertion that maintained people had control of their lives. This went against what Freud's ideas and Adler rejected Freud's theories on sex and he also attacked Freud's ideas over repression. Adler believed that the repression theory should be replaced with the concept of ego-defensive tendencies the neurotic state derived from inferiority feelings and over compensation of the masculine protest, and that Oedipal complexes were insignificant. Freud idea was women had penis envy and Adler's stand was that women where oppressed. Alder abruptly left the Vienna society and formed the Society of Free Analytic Research, renamed the Society of Individual Psychology in 1912 [1].

Adler loved the Café' as a place to chat and express, enjoy social situations with food or drink in a relaxed atmosphere. He was a social being and loved a good joke, humor with a truth injected was his favorite and he lived on humor. He never talked down to people and would talk on their level. No one knew whom his clients were he referred to everyone as his being his friend. Adler had a way of reading people that helped him in his work.

Adler did not delve into any improvable theories and objected to spiritualism, theosophy, astrology and telepathy. These ideas took away our free choice and responsibility and trusted in any real form of religion based on moral principles and thought god was for all people not for a promised few. He also believed in a broken heart and contrite spirit in praying for discretions and thought we all are repentant sinners.

The catastrophe of 1918 also affected the 48-old Adler who was sent to Russian front in the Austrian Army. This time would change his personality from jovial to more of serious in nature. Adler struggled in trying to help young men who were shell shocked (Post Traumatic Stress Disorder) become well enough to go back out to battle field which this tore his heart. He work many long hours with little sleep, and was able to acquire a direct knowledge of war neuroses. He was also called to a work in the hospital with children where he saw the damages of war in the truest form [14].

After the war he began to continue his writing and worked with children in schools and established educational consulting teams in child guidance for the Vienna public school with his ideas to pre-empt the problems in the child by encouraging and promoting social interest and also by avoiding pampering and neglect. This was a time of very little food after the war and a rebuilding was taking place. The advent of the new political regime offered him the possibility of materializing his project. The years 1920–1932 were, in spite of political upheavals, the years of Adler's greatest achievements. A division took place in methods and the Adler published more books and became a professor at Vienna's Pedagogical Institute.

But he did not wait for Hitler to come to power, and immigrated to the United States in 1932. Adler did not know how to speak any English and taught himself by emersion in the language He felt so strongly about his

individual psychology and would prepare his speeches and was able to communicate his messages without any problems because of his passion for his work. Black clouds were gathering over Europe when he suddenly died in 1937 two and one-half years before the catastrophe he had foretold would happen, WW II, and died of a heart attack lecturing tour in Scotland.

Adler influence on psychology would take volumes to write and in summary some of his key points are as follows:

1. That the individual's approach to life is result of early self-training due to his interpretation of his situation. He can change it in later years only if he realizes that his disturbing, conditioned responses are nothing more than inappropriate, inadequate holdovers from childhood. The adult is expected to replace such behavior with more useful responses to be help and not a burden. He should realize it is useless to try to escape the pain he creates for himself in trying to solve adult problems are only situations for which we have not trained ourselves [13].
2. That the problems of behavior, which make us feel and act like inferior second-class passengers in life, are no more than the results of our failure to develop the habit of both emotional and physical self-reliance. We retain from childhood the mistaken expectation that other should "hold up our pants" for us emotionally and physically and be interested in as well as responsible for our welfare.
3. That leaning on others emotionally or physically is a child's way of life. We should not permit this habit to follow us into adult life, since dependency is the root of all feelings of inferiority. Dependency generates the feeling of second-class citizenship. Out of this grows the habit of competition, envy, making comparisons and similar mistaken compensatory strivings we create in our effort to assuage the pain of feeling second class in relation to others. Humiliating feelings of inferiority produce the gnawing, distracting, disruptive, destructive craving for personal recognition and prestige, with its inescapable fear of failure.
4. That unhappiness, loneliness, neurotic symptoms, crime and similar distress arise directly from this unresolved process of learning and depending on others whom we try to control, rule, dominate or exploit for our won benefit, since we cannot otherwise support ourselves physically and emotionally.
5. That only those who are self-reliant emotionally and physically can function as adult human beings able to cooperate with other adults, because life demands that we be useful and productive or as Adler said, to "be a help and not a burden" [17].
6. That the inadequate responses of envy, greed, competition and sabotage-with which we try to solve confronting problems of life-are only reactions which would not arise in the first place if we were in the habit of standing on our own feet and not always trying to find someone on whom to lean and exploit; whom we demand prop us up and hold us there [10].
7. That defects of self-reliance and the inescapable pain that accompanies them can be changed only when we fully realize that the pain we suffer is but the other-end-of-the-stick of our leaning, dependent, subaltern habits of mind. Our problems do not have mysterious, hidden sources in some hypothetical "Id." We do not have to look far or deep to find the source; we keep stumbling, tripping and falling over it all day long, enough though we refuse to identify it as our own childishness [15, 13].
8. That all human beings are the product of evolution, and that we share the inheritance of all human potentialities and are each equally based in evolution. Each can evoke his own reality. Each is his own architect. Whatever one human being has done by others. Creation is a built-in attribute of each of us. It waits, however for the awakening of self-reliance to shape its parts and aspects [3].

View of the Person Holistically

Adler taught that social determinants as goal directedness, or that people are motivated by social forces to achieve certain goals. People are striving for significance, moving forward to fulfill the feeling of belonging [12]. Most people have the need to belong and think they are unique or different [9, p. 16]. This search for significance comes from the feeling of inferiority and is based on our reactions to others. This is the motivational factor as we strive for mastery. Many issues present due to the feeling of inferiority which can create perfectionism, which can become the goal of one's life. Adler stressed that it is self-determination, and our consciousness, that is at the heart of personality, and, that we create our fate by our behaviors and actions. Our choices determine the actions that have purpose and meaning in our lives. In understanding behavior, all actions need to be investigated including the lifestyle development of interactions, experiences and the view one has of the world through living their life [16]. Whatever behaviors are chosen are steps to attain those

goals. Adler calls this approach the movement from "a perceived minus to a perceived plus" [3]. This growth model is used because individuals need to be taught that life has challenges and that there are better ways to handle these "life tasks." Once individuals are provided with a better direction they can change the way they think and replace the negative notions through the encouragement of others.

Holism

Individual psychology was practiced because the term when translated from German to English meant "Holism." The undivided view of a person by their thoughts, feelings, actions, attitudes, and beliefs, uniquely their own by the sum of all parts are united. This holistic approach refers to a person who is part of a larger social system [18].

Environment or Heredity

Adlerians believe that people are not destined because of their environment, or heredity, yet these are the stepping-stones of life. Healthy people can make life what they desire and have the capacity to recognize that the conditions under which they are born is not as important as what they do with life. On occasion conditions can limit what one can accomplish and this then can limit choices. People have a choice in how they react to the way other people behave by either participating or not. The power to change one's own reactions and attitudes gives a person the tools to become master of one's own fate. The key is striving toward perfection yet, not becoming a perfectionist [11]. The role a person plays in their daily life is imparted through the choices they make, like characters in a play.

Germeinschaftsgefühl

The German concept *Germeinschaftsgefühl*, meaning "social interest," refers to a person's attitude in working with other people and the world, humanity within a global future. This attitude is of concern to the happiness and well being of others and the ability ". . .to see with the eyes of another, to hear with the ears of another, to feel with the heart of another" (Ansbacker, 1956, p. 135). Adler [2] wrote how people have a strong need to be accepted and needed in society. One must master three main life tasks: (1) building friendships, (2) establishing intimacy, and (3) contributing to society. Adler affirmed that the degree to which one is successful in working toward concern for the welfare of others is the basis for mental wellness. An individual who willingly demonstrate they have the capacity to give and receive for the benefit of all, understands the key concept of Social Interest. Self-centered behavior goes against the grain and produces the opposite of Social Interest. In group therapy the goal is to increase a person's self-esteem to help them attain social interest [4, 6, 12].

Inferiority and Superiority

Adler believed that most children are born with a degree of inferiority, because of the feelings of helplessness. Inferiority helps us to master our environment by giving one motivation. If the inferiority becomes a problem by restricting our self-worth and growth it can become a negative force. A person moves from the feeling of inferiority to one of superiority as goals are attained in life [5].

Birth Order

The family place or position in which a person is born plays an important part in the development of one's personality. Understanding one's role in the family is important to understanding one's own position regarding relationship with siblings. The family constellation is important to understand how this gives rise to personality characteristics. The child may have characteristics of the parents, yet it is the siblings who the have the most effect on the child's personality. There are specific indicators regarding birth order.

Lifestyle

The individual's family constellation and the family atmosphere promote the lifestyle. The early years, and the reflections of those years in striving for goals, and the formative experiences within the family make up a person's lifestyle. The earliest impressions are the building blocks of lifestyle. How one perceived the experiences becomes personal interpretations of these life events, and is extremely significant. Learning about the experiences of how one interpreted past events can help them to become aware of the patterns that have continued throughout their life. Once an individual is made aware of inaccurate assumptions, changes can then be made. Childhood events create one's personal lifestyle [2].

Contributions

Alfred Adler's career was an example of the social ascension of a man who remained emotionally attached to the lower class of the population and the betterment of all. His idea was "The test of one's behavior pattern: relationship to society, relationship to one's work, relationship to sex" [7].

Several schools dedicated to carrying on the work of Alfred Adler such as The Adler School of Professional Psychology which was founded as The Alfred Adler

Institute of Chicago by Adler's protégé, Rudolf Dreikurs, also, the Alfred Adler Institutes of San Francisco and Northwestern Washington, dedicated to Adler's original teachings and style of psychotherapy. There are also various organizations promoting Dr. Adler's orientation towards mental and social wellbeing. These include ICASSI and the North American Society for Adlerian Psychology (NASAP).

Adolescence

Kendall Cotton Bronk
Ball State University, Muncie, IN, USA

Synonyms

Teenagers; Teens; Youth

Definition

Adolescence is the life stage that bridges childhood and adulthood. This transitional period is characterized by significant biological, cognitive, and psychosocial changes. Although the age range of adolescence varies by cultural and historical circumstance, the beginning is typically marked by the onset of puberty and the conclusion is associated with the full assumption of adult roles. This means that in the United States and most industrialized countries today adolescence roughly describes the second decade of life.

Description

Adolescence is typically divided into two periods. Early adolescence corresponds with the middle school or junior high school years, and late adolescence corresponds with the latter half of the second decade of life. Early adolescence is characterized by the significant biological changes associated with puberty while late adolescence features identity, career, and relational exploration. There is a growing recognition that college aged young people do not resemble adolescents in terms of their developmental activities. Instead, Arnett and a growing group of others in the field refer to young people between 18 and 25 years of age as emerging adults [2].

Historically, adolescence has been viewed as a time of "storm and stress." Early adolescent researchers believed the adolescent life stage was a time of irrationality, moodiness, and turbulence (see G. Stanley Hall). However, little empirical research supports this negative view. While adolescence is a period of significant change, research finds that most adolescents around the world have a positive self-image, are self-confident and optimistic about their future, are happy most of the time, enjoy life, value work and school, have positive feelings toward their families, and demonstrate the capacity to cope with life's stresses [19]. As a result, most psychologists and practitioners today embrace a more positive view of adolescents, and research increasingly emphasizes their hope, optimism, creativity, and purposes in life [5].

Following is a brief discussion of the biological, cognitive, and psychosocial changes that represent the primary areas of growth associated with normative adolescent development.

Biological Development

The onset of adolescence is marked by the physical changes associated with puberty. According to Marshall [18], puberty is characterized by significant height and weight gain, the development of primary and secondary sex characteristics, changes in body composition, and changes in the circulatory and respiratory systems. The endocrine system, which is responsible for producing, circulating, and regulating hormonal levels, plays an important role in triggering and regulating puberty.

Puberty is associated with the most significant increase in growth since infancy. The release of growth hormones, thyroid hormones, and androgens stimulate the rapid increase in height and weight. At least as noteworthy as the absolute increase in size is the rate of growth during adolescence; nearly half of adult weight is gained during adolescence [22]. At the peak of pubertal change boys grow about 4 in./year and girls about 3½ in./year.

The timing and tempo of puberty are influenced by a combination of highly variable genetic and environmental factors. In the United States boys typically start puberty between 9½ and 13½ years of age, and girls typically experience the onset between 7 and 13 years of age. In boys puberty tends to last between 2 and 5 years, while for girls it typically extends between 1½ and 6 years. Over the past 100 years the average age of the onset of puberty has dropped due to improvements in health, nutrition, and living conditions [1].

As young people undergo puberty they often become preoccupied with their changing bodies (Brausch & Gutierrez, 2009). Throughout puberty, boys tend to develop a more positive self-image as their bodies fill out, their faces take on a more angular appearance, and their voices deepen. Girls, on the other hand, are likely to become less pleased with their changing bodies as they gain weight and fat [4]. Changes in self-image affect the way adolescents perceive themselves and the way others treat them. For example, a young person who has recently gone through puberty may feel older and seek to be treated more like an adult, and other people expect more adult-like behavior from a fully mature adolescent.

Cognitive Development

Along with the rest of the body, the adolescent brain experiences noteworthy physical changes. For example, as a result of synaptic pruning – the process through which unnecessary connections between neurons are eliminated – the brain undergoes considerable restructuring during adolescence. Myelination, or the process in which the neuronal projections that connect to form brain circuits become encased in a fatty substance, facilitates the transmission of impulse flow. The combination of myelination and synaptic pruning allows the brain to process information more quickly and more efficiently [13].

It is not just that adolescent's become more efficient at processing information; they also begin to think and reason in qualitatively different ways. Whereas children tend to think in a concrete and absolute manner, adolescents become increasingly able to engage in thinking and reasoning that is abstract and relative. Deductive (reasoning in which one draws logically necessary conclusions from a general set of premises), and inductive reasoning (in which one draws a general conclusion from a set of specific facts) emerge, and adolescents develop the ability to engage in metacognition, or thinking about thinking.

Several scholars, including Piaget and Vygotsky, have offered theories that describe the process of cognitive development during adolescence. Piaget's cognitive developmental theory situates most adolescents in the formal operational stage, which is characterized by the development of abstract, propositional, and hypothetical-deductive reasoning. Idealism and possibilities are the hallmark of formal operational thought. At the same time as Piaget was devising his theory of cognitive development, Vygotsky was engaged in the same task. However, he came to a somewhat different conclusion regarding the nature of cognition. Vygotsky proposed a sociocultural cognitive theory that emphasizes the central role of learning from more skilled others. According to Vygotsky learning is situated in a particular cultural context and collaborative, meaning that social interactions guide development [14].

The more contemporary information processing theory represents a third influential perspective on adolescent cognitive development. Comparing the functioning brain to a computer, this theory emphasizes the way that adolescents manipulate, monitor, and strategize about information in order to make decisions and solve problems [20].

Psychosocial Development

In addition to the biological and cognitive changes that accompany this stage of life, adolescence is also characterized by significant psychosocial development, including growth in the areas of identity, gender, sexuality, morality, and intimacy. According to Erik Erikson [10–12], the

establishment of a coherent sense of self, or identity, is the major task of adolescence. Prior to adolescence, children have a scattered, inconsistent conception of who they are, but during adolescence they develop a more unified and enduring picture of who they are and of who they hope to become. For some adolescents, especially minority youth, integrating a sense of ethnic identity into their overall sense of self is an important part of their identity development.

Like ethnicity, gender represents a significant component of an individuals' identity. From birth, boys and girls are socialized to act in gender specific ways. According to the gender intensification hypothesis [15], pressure to behave in sex-appropriate ways may temporarily intensify during early adolescence.

The development of sexuality coincides with the greater understanding of what it means to be male and female. While much attention is given to adolescent problems in the area of sexuality, most adolescents have healthy sexual attitudes and engage in sexual behaviors that are not likely to have long-term, negative consequences [9]. According to a national survey of adolescents, sexual intercourse is rare among early adolescents but common among late adolescents [8]. For instance, in the United States only 22% of girls and 27% of boys report being sexually active at 15, but 76% of girls and 85% of boys say they have had sex by 19 years of age.

Moral development, another important feature of adolescent psychosocial development, encompasses reasoning, behaviors, and feelings regarding standards of right and wrong. According to Kohlberg [16] most adolescents reason about moral matters at the conventional reasoning level, meaning they abide by standards of right and wrong that they view as external to themselves, typically belonging to either their parents or society. While Kohlberg's theory helps explain how adolescents reason about moral issues, it does not explain why adolescents ultimately act in moral or immoral ways. Instead, Bandura [3] social cognitive theory of moral development is useful in explaining how adolescents learn to enact moral behavior. According to this model, young people learn what is right and wrong through observation. Over time, young people internalize the broader society's standards of right and wrong, and self-sanctions keep their actions in line with their beliefs. In other words, adolescents experience a diminished sense of self-worth when their actions contradict their moral sense. Moral identity offers another perspective on moral action. During adolescence some young people develop a sense of moral beliefs or commitments that are central to their sense of who they are [6]. For these youth, acting in ways that violates their moral sense, or moral identity, jeopardizes the integrity of their sense of self [17].

Balancing a growing desire for autonomy with a continued need for connectedness is another important task of adolescence. As young people mature, they begin to crave the independence associated with adulthood. However, at the same time as adolescents seek more autonomy, they also begin to seek more intimacy in their relations with others. Peer and family relationships during adolescents differ from relationships during childhood in they are more likely to be characterized by openness, honesty, self-disclosure, and trust. While family support and connections remain important to adolescents, peer relationships become increasingly significant. In early adolescence, peer relationships tend to feature same sex friendships, but during middle and late adolescence, they often include opposite sex friendships and sexual relationships, too [21].

Identity, morality, gender, sexuality, autonomy, and intimacy are issues that resurface throughout the lifespan. However, because of the biological and cognitive changes associated with adolescence, they are particularly salient issues during this stage in life. It is also important to keep in mind that each of these aspects of development takes place within a variety of contexts including family, peer, school, and cultural contexts that influence adolescent development in important ways. Bronfenbrenner's ecological systems model describes the way an individual's development is simultaneously influenced by and influences the multiple contexts in which it is embedded [7].

Adolescent Egocentrism

Jeremy Jewell, Nicole Pepin
Southern Illinois University Edwardsville, Edwardsville, IL, USA

Synonyms

Egocentrism; Imaginary audience; Personal fable

Definition

Adolescent egocentrism is generally a heightened preoccupation with the self occurring during adolescence. Specifically, newly developed cognitive abilities give adolescents an exaggerated sense of uniqueness from others and also allows the adolescent to monitor their own thoughts though they do not clearly distinguish their own thinking from the thinking of others.

Description

Egocentrism is generally the tendency to view the world from one's internal point of view with less recognition that others beyond oneself may hold different views, perspectives, and beliefs. Egocentrism is particularly strong during infancy and childhood, though it manifests itself in different ways, while egocentrism to some extent remains throughout adulthood as well. Adolescent egocentrism is defined by the fact that egocentric thought and behavior is heightened in adolescence when compared to typical adulthood, as well as the fact that newly developed cognitive abilities lead to specific manifestations of egocentrism that are distinct to adolescence.

Piaget [3] introduced the concept of egocentrism in childhood through his description of his Cognitive Developmental Theory. Piaget's [3] work for the most part describes the various ways that egocentrism is displayed in infancy and childhood. Piaget explains that infants and young children are unable to differentiate their *self* from the rest of the world in which they exist. Children are also unable to differentiate the possibility that others may view (both literally and figuratively) situations from a perspective other than their own [3]. Piaget also describes the concept that children endow inanimate objects with intention and emotion (known as "child animism") and "...believe that everything gravitates around us" (p. 244). While Piaget describes in detail egocentricity during the developmental periods of infancy and childhood, he gives less attention to egocentricity in adolescence specifically.

Elkind [1, 2] later expounded upon the concept of egocentrism in adolescence in his description of two phenomena he terms the imaginary audience and personal fable. The imaginary audience occurs when the adolescent believes that everyone near them is preoccupied with the adolescent's appearance and/or behavior. Elkind [1] conceptualized the imaginary audience consisting of two parts; the self-critical and the self-admiring. For example, the adolescent may be overly critical of a physical imperfection and views everyone around them as being equally attentive and critical of this imperfection. The opposite is also true in that the characteristics that

adolescents possess during this stage (e.g., loudness, vulgarity) are largely due to the adolescent feeling the need to be the center of attention. This need is driven by the self-admiration an adolescent feels and the belief that everyone around them is also admiring their behavior and appearance. Like other manifestations of egocentrism, the imaginary audience is due to the inability of adolescents to differentiate between the interests of themselves and others [1]. Elkind [2] postulates that the imaginary audience phenomenon declines with age as the adolescent continues to differentiate the self from the rest of the world, thus recognizing that every person has their own preoccupations in life. It should also be noted that there are times throughout an individual's adult life when the imaginary audience can be experienced, though this differs from the adolescent experience because the phenomenon tends to be fleeting and less pervasive in adulthood [2].

Subsequent to the imaginary audience is another form of adolescent egocentrism, which is the personal fable. The personal fable can be defined as a grandiose sense of uniqueness leading to a belief that nothing bad will happen to one personally [1]. The personal fable is established by the failure of the adolescent in differentiating between what is unique to one's self from that which is ordinary to everyone. This exaggerated belief of being "unique" may largely be due to quickly developing cognitive abilities that occur in adolescence. For example, as adolescents begin to realize that they can infer the intentions of others based on subtle nonverbal behavior (part of one's developing social cognition), they falsely believe that they are the only ones with such advanced cognitive abilities. Thus adolescents may believe that they are too important or special to die, get arrested, become pregnant, fail school, etc. [2]. For example, adolescents may engage in risky behaviors such as drinking and driving, believing that this behavior might lead to an accident for others, but that it would not happen to them. Unlike the imaginary audience, the personal fable begins to decrease when the adolescent begins to develop intimate relationships with friends. The participation in intimate relationships by the adolescent helps them understand that their personal thoughts and feelings are not as unique as they original thought [2].

Adolescent Family Life Act (AFLA)

Lynna Lan Tien Nguyen Do
Walden University, Fremont, CA, USA

Description

The adolescent family life (AFL) demonstration and research program, created in 1981 as Title XX of the Public Health Service Act, supports both demonstration and research grants. Within OPA, the Office of Adolescent Pregnancy Programs (OAPP) is responsible for administering the program. The AFL program is funded at $29.8 million in fiscal year 2008.

The AFL program supports demonstration projects to develop, implement and evaluate program interventions to promote abstinence from sexual activity among adolescents and to provide comprehensive health care, education and social services to pregnant and parenting adolescents. The program supports two basic types of demonstration projects: (1) prevention demonstration projects to develop, test, and use curricula that provide education and activities designed to encourage adolescents to postpone sexual activity until marriage, and (2) care demonstration projects to develop interventions with pregnant and parenting teens, their infants, male partners, and family members in an effort to ameliorate the effects of too-early-childbearing for teen parents, their babies and their families. The AFL program also funds grants to support research on the causes and consequences of adolescent premarital sexual relations, adolescent pregnancy and parenting.

The Title XX funds not only help the teens and families they serve directly, but also provide valuable information and evaluation findings that can serve as a basis for future strategies. Every program that receives AFL grant funds is required to include an independent evaluation component. This ensures that the lessons learned by each community will benefit others in the future.

In addition, to ensure that all AFL project staff at the local level have the necessary skills and training to implement these programs, the AFL program has conducted numerous technical assistance workshops annually since 1998 to train front line care and prevention project staff to provide more comprehensive services to their clients.

In 2007–2008, the AFL program is supporting 67 demonstration projects across the country. These projects consist of 36 abstinence education programs and 31 care programs.

Adolescent Mothers

Merith Cosden
University of California, Santa Barbara, CA, USA

Synonyms

Teen mothers; Teenage mothers

Definition

Adolescent mothers are women between the ages of 11 and 19 who become pregnant and parent their children.

Description

Prevalence

While the birth rate for adolescent mothers in the US has declined over the past decade, the US continues to have the highest level of teenage parenting of any industrial nation, with approximately 900,000 adolescent pregnancies each year [7]. Because adolescent mothers are more likely than older mothers to drop out of high school, to require public assistance, and to have children who are at risk for poor birth outcomes and developmental difficulties, adolescent pregnancy and parenting are considered social problems. Although adolescent mothers and their children tend to have special needs, there is heterogeneity within this population with regard to the outcomes for both parents and children.

Risk Factors

The majority of adolescent pregnancies are unplanned. There are a variety of psychosocial risk factors for adolescent pregnancy. Adolescent girls who become pregnant are likely to be poor, single, and to have a history of negative school experiences [4]. A history of childhood sexual or physical abuse is also a risk factor for early sexual activity and pregnancy [6]; children who have been maltreated may be at greater risk of pregnancy due to a lack of parental supervision or a because of sexualized efforts to obtain closeness with others. Finally, risk factors for becoming an adolescent parent include having been born to an adolescent parent, or being part of a cultural group in which younger parenting is common.

While poverty, abuse and lack of parental supervision are risk factors for early sexual activity, not all sexually active adolescents become parents. In some instances, adolescents who are sexually active become parents because they lack awareness of their access to options, including contraceptives, abortion, or adoption. However, it is the case that even when the pregnancy is unplanned, many adolescent mothers chose parenthood as a defining role for themselves.

There is also a high risk among adolescent mothers that they will become pregnant a second time within a few years of their first pregnancy. This second birth is often intentional, reflecting the adolescent mother's goal to focus on parenthood [1]. A primary risk factor for a second teenage pregnancy is not returning to high school within a few months of having the first child. Ironically, having family support with child care, which is associated with better mother and child outcomes, is also a risk factor for a second pregnancy, as is having a stable relationship with the child's father. Finally, cultural norms for young parenting may also support the trend to have multiple children at a young age [7]. Having multiple children as an adolescent decreases the likelihood of the mother completing high school.

Characteristics of Adolescent Mothers

Adolescent mothers face the same stressors associated with child rearing as do older mothers, as well as some that are specific to being a younger mother. Thus, just as some older mothers do, some adolescent mothers experience postpartum depression, while all must address the daily challenges of parenting.

Many of the characteristics specific to adolescent mothers are related to the risk factors for adolescent parenting; thus, a majority of adolescent mothers are poor, single parents. The typical adolescent mother is likely to have had little, if any, prenatal medical care. She is also less likely than an older mother to have poorer prenatal nutrition and weight gain, and more likely to use alcohol, drugs or tobacco during her pregnancy. As a result, adolescent mothers are more likely than older mothers to experience birth-related problems including infant mortality and to have premature and low birth-weight babies [6]. A majority of adolescent mothers have not completed high school, and are not able to support themselves financially. Consequently, many live with extended family and receive public assistance to support themselves and their children.

Nevertheless, adolescent mothers are diverse in terms of their commitment to parenting, their environmental supports, and, consequently, their personal outcomes and the outcomes of their children. Further, it is unclear whether the negative outcomes associated with adolescent pregnancy and parenting are a function of the age and maturity of the mother, or a result of the adverse environments which put them at risk for the early pregnancy. While both appear to have some impact, controlled

studies point to the greater impact of environment over the age and maturity of the mother; that is, many of the problems noted for adolescent mothers and their children, from negative birth outcomes to ongoing maternal stress and financial needs, can be attributed to the circumstances that created the risk for the adolescent pregnancy rather than the age or maturity of the mother herself [5, 7].

Conversely, adolescent mothers who live under less adverse circumstances tend to have better outcomes. Familial support in particular has been associated with positive outcomes for the adolescent mother, including greater likelihood that the adolescent mother will complete high school and less parental stress, as well as better developmental outcomes for the child [2]. A majority of adolescent mothers live with their parents, the child's grandparents, for several years after giving birth, with grandparents providing housing, financial assistance and childcare [3]. This support can be very beneficial, but obtaining this support requires a complex balance of roles and responsibilities for mother and grandmother. For example, while the adolescent mother needs the instrumental as well as psychological support of her family, she may also want to retain parental authority for decision-making, even though she is not the only one taking care of her child. The grandparent, on the other hand, may make sacrifices in order to meet the needs of their grandchild, and may experience some resentment regarding these sacrifices when her authority is usurped. Thus, the roles of all adults in the household need to be negotiated in order to create supportive rather than conflictual relationships with one another.

The impact of the father of the child on family stress and stability is less clear. In approximately half of all cases the father of the child is also an adolescent, while in the remainder the father may be several years or considerably older than the mother. Regardless of age, men who father children with adolescent parents tend to have low income and education [4]. In most instances, the mother and father of the child do not marry or live together. While instrumental support from the father of the child can reduce stress for the adolescent mother, a continued relationship with the father of the child can also be stressful, and, regardless, that relationship is often not available to the adolescent mother [3, 6].

Interventions for Adolescent Mothers and Their Children

In addition to programs designed to help the adolescent mother once she becomes pregnant, there are many programs nationwide with the objective to reduce adolescent pregnancy. Programs that are more effective at delaying pregnancies focus both on early abstinence and using birth control, as well as helping adolescents develop other interests in their communities.

Interventions to help pregnant and parenting adolescent mothers have been implemented in schools, homes and community centers [7]. School-based programs encourage adolescent mothers to complete high school by providing academic programs which they can utilize while they are pregnant as well as post-partum. These programs address the practical needs of the adolescent mother by providing on-site childcare so that the she can attend classes. In addition, these school programs may provide opportunities to learn about infant development or to discuss concerns and questions about parenting. Programs have been successful in helping adolescent mothers complete their high school education and increase the time to their next pregnancy. Home-based and community-based programs have also been implemented. Home-based programs often focus on helping the adolescent mother with her parenting skills, through instruction and in situ modeling of effective infant–adult interactions. Community-based programs typically provide respite for adolescent mothers by providing childcare while the mothers meet to share concerns specific to adolescent parenting as well as those which can occur for any parent, such as post-partum depression.

Other specialized interventions focus on the prevention of developmental delays and improvement of developmental outcomes for the children of adolescent mothers. Because these children are at greater risk for developmental problems, these programs are designed to assess the child's strengths and weaknesses and to provide early intervention to stimulate language acquisition and the development of cognitive skills and social behavior as needed. In addition, programs may help children indirectly by working with adolescent mothers on their parenting skills. These programs increase the knowledge and reduce the stress of the adolescent mother so that she can address the developmental needs of her child.

Relevance to Childhood Development

Adolescent parenting can affect the continuing development of the mother as well as the development of her child. In western industrial societies, adolescents are not expected to assume adult responsibilities, and are still in process of procuring their education and developing the knowledge and interests, skills necessary to function as an adult. Parenting typically interrupts the educational development of the adolescent; unless adolescent mothers return to high school and obtain a diploma they are at a long-term disadvantage with regard to their ability to

become financially self-sufficient. In addition, younger adolescent mothers experience an interruption in the personal exploration of interests and values that is considered part of "normal" adolescent development [4]. The long-term impact of adolescent parenting on one's psychosocial development is unclear, however, as a majority of adolescent mothers live within limited economic circumstances which could limit their options regardless of whether or not they had children.

While some children born to adolescent mothers develop normally, they are still at greater risk than are children of older mothers to have academic, emotional and behavioral problems. These differences in development are attributed to differences in the commitment of adolescent parents to caring for their children, and to diversity in the resources available to the mother and child in the broader social environment. Maternal age may affect mother–child interactions, as adolescent mothers tend to be less patient and provide less stimulation to their children than do older mothers. However, studies find that many of the developmental problems of children of adolescent parents can be attributed to their social and economic circumstances [7]. Child development is more likely to be on track for adolescent mothers who are committed to parenting and have greater support from other adults.

Adult Attachment Interview (AAI)

Raquel Plotka
Fordham University, GSAS, New York, NY, USA

Synonyms

Attachment measures; Attachment patterns; Attachment representations; Attachment styles; Mental models

Definition

The Adult Attachment Interview (AAI) is a method of classifying a current state of mind with respect to attachment in adults.

Description

The AAI is a semi-structured interview, and it is used to categorize adults' state of mind with respect to attachments. These classifications are secure-autonomous (F), dismissing (D), preoccupied (E), and disoriented/ disorganized (U/d). The interview consists of twenty questions focusing on early relationships with parents and the family environment, and takes between 45 and 90 min to administer [4, 6].

The AAI was developed as narrative assessment of an adult's state of mind with respect to attachment figures and reflects patterns of organization of experiences. Some sample questions ask the participant to describe their relationship with one of their parents as young as they can remember, what they did when they would get upset, and how they think their relationship with their parents has affected their adult life. Additionally, participants are encouraged to talk about the feelings of sadness, anger, and loss. This way the interview prompts the description of subjective memories forming an autobiographical narrative [8].

One of the most interesting things about this measure is that in addition to taking the content of the answers into account, the way in which the participant present their story becomes a relevant piece of information. When classifying the interview, the tone of voice, the pauses, the degree to which the participants are self-reflective, and the degree to which they have achieved a coherent interpretation of their lives is taken into account. Additionally, involvement in the narrative, lack of recall, idealization of parents, length, cohesiveness, and coherence of

the arguments are all indicative of state of mind in relationship to attachment [8].

The interview assesses the adult's general orientation and mental model in respect to other attachment figures and intimate relationships throughout life, without giving a specific categorization to the relationship between the participant and a particular parent or person. The classifications take place after extensive analysis of the transcript of the interview giving importance to content and form of the discourse. Grice's [5] four maxims of discourse are guidelines for the coding, and violation in quality (statements supported by evidence), quantity (length and completeness of thought), relation (relevance), and manner (clarity) are recorded. Additionally, the participant's parents or caregivers are scored for the extent to which the rater believes they were loving, rejecting, role-reversing, involved when present, or pressuring. The interview does not claim to be an exact account of the past, but a reflection of the adult's present working models [8].

This measure has been found to be predictive of the quality of attachment between adults and their children. The measure does not correlate with features of adult personality, suggesting that it is actually measuring aspects of the adult life that are highly dependent on experiences with caregivers in the early home environment [2]. Research has also shown that the attachment interview classifications are not related to social adjustment suggesting that the AAI assesses a unique dimension of adults' life that is not better defined as adjustment. Classification in the AAI does not correlate with measures of social desirability, and it appears that subjects are not able to predict what a good AAI answer is. This way, adult's working models seem to be responsible for the biases in the subject's answers [2]. The AAI has shown to be stable across assessments for 4 years, which indicates that it is measuring a construct that is robust, and persists across time [8]. Similarly, the AAI has shown to have good test-retest reliability and inter-rater reliability [1].

AAI Classifications

Adult's Secure/Autonomous State of Mind with Respect to Attachment

The narratives typical of this interview are coherent and consistent, and give ample examples and details to support their description of their parents and relationships. These memories do not always convey ideal parenting and positive feelings, but they express a balanced understanding of the past, fluidity of narrative, and the ability to reflect on early experiences. These adults have secure mental models, can recognize the impact of early relations, and are free to live the present without being impaired by past experiences or worries for the future [8].

Adults Dismissing State of Mind

These interviews, in general, show an overall lack of emotional connections during childhood. This discourse usually lacks details and examples, and the adults in this classification generally insist that they cannot recall specific experiences. The participants fail to support their general ideas about early experiences with evidence, and their responses are generally short. The internal working models of these adults are dismissive, because these adults have developed from a young age adaptive strategies based on the perception of an unreliable world. As a result, they have developed a sense of agency and independence, but a lack of feelings of connection, attunement, and emotional communication [8].

Adult Preoccupied State of Mind

These interviews are categorized by a state of mind that has not solved issues of the past. The past affects the adult's life in the present and prevents him or her from living the present in full. Past fears are expressed in relationships of the present and in worries about the future. These adults have not resolved the question of whether the attachment figure would be available to them. They feel a powerful need for closeness and interrelations, and at the same time, fear of losing these intimate relationships. Relationships in the present are experienced as inconsistent and unreliable and as sources of ambivalent feelings. This discourse is categorized by lack of boundaries between past and present experiences, as the past still has an impact of the present state of the subject, not allowing him or her freedom to experience the present [8].

Adult Unresolved Disorganized State of Mind

These interviews commonly have the underlining theme of lack of resolution of trauma or loss. This discourse is generally categorized by lack of coherence and organization, inability to regulate emotional discussion, disruptive behaviors, shifts in states of mind, and a lack of adaptive strategies. The narrative reflects incomplete processing of past events, usually, as a result of traumatic experiences. These adults typically become confused or disoriented when discussing negative events with parents. In these cases, the mind is impaired by traumatic events from accessing memories and processing these memories in coherent ways. This state of mind is thought to be a result of repeated interactions which a caregiver that was frightening and could not sooth and help regulate

the child's emotions. This categorization is often but not always found among adults whose parents were abusive or suffered from a mental illness [8].

Earned Secure Classification

Researchers had encountered a group of adults that were generally classified as secure even in the face of their descriptions of negative parental care experiences. These adults have the ability to present their story in coherent and congruent ways, and to be emotionally involved as they describe negative memories. In general, these adults are thought to have experience repair of early relationships by finding a secure base in a new relationship such as a caregiver, spouse, teacher, or therapists. They have been able to interpret their life stories in ways that make them tolerable and coherent, achieving resolved states of mind and resilience. This allows them to live the present free from unresolved states related to the past. In general, earned secure adults have rewarding intimate relationships, nevertheless, research points at higher levels of depression in this group compared to the secure autonomous group [7].

Relevance to Childhood Development

The use of the AAI has resulted in a body of knowledge related to the importance of adults' representations of attachment for child development. There is an important association between the classifications in the AAI and the quality of parenting an adult can offer. Research suggests that the way in which a mother recalls her own childhood experiences has a strong association to the quality of her relationship with her children. There seems to exist a transmission of attachment patterns through generations, as the caregivers interaction patterns are internalized in the child and affect his or her behavior as an adult. Interviews of autonomous mothers describe a mother who is free from unresolved experiences and can respond to her children's attachment needs. Dismissing interviews present a mother who is reluctant to admit attachment needs, as her needs have often been rejected, and shows rejection and insensitivity to her infant's needs. Similarly, preoccupied interviews reflect a mother who is still dealing with unresolved concerns about her attachment figures and her need for a secure base. Such mothers are likely to show inconsistent and confused responses to their infants, and still feel the need to be nurtured [8].

Research has shown that the AAI can predict the quality of attachment between the mother and child in the strange situation in 75–80% of the cases, when categorizing into secure and insecure attachments. Additionally, autonomous classification predicts secure attachment, dismissing predicts avoidant, and in many cases, preoccupied predicts ambivalent attachments. Similarly, unresolved-disorganized states predict disorganized attachments in the strange situation. The predictive power of the AAI resides not in the quality of early experiences but in the organization of mental representations of attachment and relationship issues. These mental representations reproduce themselves as the internal working models that infants develop about their caregivers and about themselves [3].

The AAI can enable researchers to learn about the processes that facilitate change in the adult's classifications. This can have an effect on the care that children experience, it could help develop clinical services that improve the quality of the parent-child relationships, and could help interrupt the generational transmission of insecure attachments [3].

Affect

Chris Leeth
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Emotions; Feelings; Mood

Definition

A person's feelings or emotions that can be observed by others based on facial expressions, body language, and tone.

Description

Affect is the display of one's emotions. It is displayed by surface-level behavior and observations such as smiling, laughing, crying, etc. It can be easily influenced by events surrounding the person such as surprises, celebrations, arguing, or violence. Affect should not be confused with mood; affect is a more visible and shorter-term experience of emotion. Affect may be described in many different ways; for example, "flat" (i.e., little or no display of emotion), "labile" (i.e., many changes in mood), "euphoric" (i.e., manic), and "dysphoric" (i.e., down or depressed affect).

Synonyms

Mood disorders

Definition

Affective disorders are otherwise known as mood disorders and include a group of emotional, psychological, and behavioral disturbances. These disorders include major depressive disorder, bipolar I and II disorders, schizoaffective disorder, and seasonal affective disorder.

Description

The DSM-IV-TR (2000) defines mood disorders in distinct groups including depressive and bipolar disorders. Major depressive disorder differs from bipolar disorder

because there is no history of manic episodes, which is a defining characteristic of bipolar disorder [4].

In children, symptoms of a major depressive episode are shown through irritable or cranky moods and academic problems. Also, these symptoms are different from everyday irritability or frustration and are often comorbid with other childhood disorders, such as ADHD [4]. Finally, depressive episodes emerge more during adolescence along with the onset of puberty [1, 4].

Symptoms of bipolar disorder in children are displayed through difficulties with mood regulation, and may be associated with antisocial behavior, academic problems, or substance use [4, 9]. 10–15% of adolescents with major depressive episodes may develop bipolar disorder as an adult [4] and bipolar disorder is the 6th leading cause of disability among adolescents worldwide [7].

Schizoaffective disorder is defined as meeting the criteria for schizophrenia and major depressive episodes [4]. The onset of schizophrenia is usually between the late teens and early 30s, but early onset has been recorded [4]. In children, symptoms include delusions, visual hallucinations, disorganized speech, and disorganized behavior [4].

Another affective disorder is seasonal affective disorder (SAD). This disorder is defined as a negative change in mood when the seasons change. Children suffering from this disorder may not be aware of the mood changes; they begin to feel depressed in the fall and these feelings increase throughout the winter [8]. Symptoms include feeling tired and washed out; feeling cranky and irritable; temper tantrums; difficulty concentrating; physical complaints; and increased cravings for junk foods [8].

Assessment and Treatment

One of the most widely used assessments for affective disorder in children is the Kiddie Schedule for Affective Disorders and Schizophrenia for School Age Children (K-SADS) [6]. This interview asks the child about his/her symptoms and doesn't just rely on the parent to explain the child's behavior [9]. However, this tool is not without criticism because it only rates current affective symptoms and other symptoms are rated for their occurrence over a lifetime [2], meaning that some important symptoms may be overlooked.

Finally, treatments for affective disorders among children are not where they should be due to a lack of controlled studies [9]. At this time, cognitive-behavioral therapy and interpersonal therapy have been identified as effective psychosocial treatment approaches for childhood depression [5], and mood stabilizers and atypical antipsychotic medications are considered first-line treatment approaches for bipolar disorder in children [3].

African American English

Stacy A. S. Williams
State University of New York at Albany, Albany, NY, USA

Synonyms

African American Vernacular English; Black dialect; Black English; Black English Vernacular; Black language; Ebonics

Definition

African-American English (AAE) is the term often used by linguists to define a variety of English spoken by most African-Americans.

Description

AAE has been identified by several idioms in the research literature that are indicative of the socio-political and cultural climate of the time. For example, during the Black power movement in the 1970s, the term Black English or Dialect was often used to describe Black speech. In the nineties, the term Ebonics was used to define the language of some in the African-American community [4]. The thrust of the Ebonics debate in the mainstream media was a by-product of the Oakland School District in California's decision to validate the home language of many of its African American students. The Oakland School District's goals were to increase achievement and to address the media's lack of understanding of the language. The backlash that followed Oakland's decision highlighted the great theoretical divide between bidialectic and bilingualism programs [5].

Geneva Smitherman, in her groundbreaking work in the seventies, defined AAE from a socio-linguistic perspective: "an Africanized form of English reflecting Black America's linguistic-cultural African heritage and the condition of servitude, oppression and life in America" [7, p. 2]. Smitherman further stated that Black speech has two dimensions: language and style. Language refers to the sound and grammatical structure; style refers to the ways in which speakers combine words to communicate meaning in a larger context. AAE may also be defined as "a variety that is used by some African Americans and that has lexical, phonological, and syntactic and semantic patterns that are intertwined with structures in general English" [5, p. 676]. This definition suggests that language production operates on a continuum. At any given time, you may have speakers of AAE at different points on the language continuum. In other words, some may be pure speakers of AAE, others may be bidialectical with proficiency in both, while others may be proficient in Standard American English (SAE) with limited proficiency in AAE [5].

Due to AAE's shared history with SAE, some argue that AAE users engage in a poor version of SAE. However, speakers of AAE do follow a rule-governed pattern. The pronunciation sounds of AAE are very similar to the sounds used in SAE; however, the rules governing the production of sounds have different patterns of distribution [5, 7]. For example, words ending in clusters in SAE do not also end in clusters in AAE; as a result, the final clusters of "st, sk, sp, pt, kt, nd, ld" are often reduced to a single consonant. For instance, the following SAE words "list, desk, wasp and accept" are pronounced in AAE as "lis, des, was, and accep." The omission of the last consonant is not an indication of poor grammar but a rule-governed production. In addition, speakers of AAE tend to do some of the following: pronounce the initial /th/ sound as /d/ (e.g., them = dem; then = den); pronounce the final /th/ sound as /f/ (e.g., south = souf; mouth = mouf); delete the middle and final /r/ (e.g., during = doing; more = mow; star = stah); delete the middle and final /l/ (e.g., help = hep; will = wii); and place primary stress on first syllable and front shifting (e.g., police = PO-lice) [7].

One of the most distinctive and critical features in the structure of AAE is use of the "be" pattern in communicating. This pattern is used to denote a recurring or habitual condition. "Be" is omitted from conversation to describe an action that has happened once. For example, the sentence "The coffee bees cold" means the coffee is cold everyday, versus "the coffee cold" which means that the coffee is cold today. In addition, "be" is often used in conjunction with "do" to convey a recurring behavior expressed in the format of a question (e.g., "do they be playing all day?" which translates as "do they play all day?"). In applying the non-be rule, the AAE speaker communicates with the absence of be before nouns (e.g., he a doctor now), adjectives (e.g., he too tall for me), adverbs (e.g., they shoes right here), prepositional phrases (e.g., my momma in the hospital), and in auxiliary constructions (e.g., they talking about school now) [7].

Speakers of AAE often use "been" to communicate a past action that has recently been completed. The context of the sentence symbols the time past versus the actual amount of time. For example, an AAE speaker may say "she been tardy twice this semester" to suggest that she has been late twice during the semester. In addition, "done" is also used to represent past action that is recently completed (e.g., I done my homework today). The context of the immediate sentence or the entire conversation is used as a time marker. Therefore, AAE speakers do not use the "ed" in past tense or past participle conjunction. Consequently, the same verb format serves for both past tense and past participle (e.g., "the bus pass me up last week" or "the bus pass me up everyday"). Moreover, AAE verbs are not marked for person. Hence, the same verb format serves for both singular and plural nouns. Additionally, AAE speakers tend to use triple and quadruple negatives in their sentence structure (e.g., don't nobody never help me do my homework) and place stresses on the subjects of sentences (e.g., my son, he have a new car). For additional information on AAE structure, the reader is referred to Smitherman's extensive work [7].

AAE and Literacy Development

The association between AAE and early literacy skills is of paramount importance due to the low reading performance of African American students. It was the desire to raise the achievement scores of students in the Oakland School District that prompted the school board to recognize the home language of its students. Based on the examples provided above, it becomes clear how educators may mistake AAE as poor grammar. Recent studies have documented the phonological structure of AAE production in preschool and elementary age students, suggesting that many children enter school speaking some variation of the language [1]. The linear relationship between AAE production and early literacy skills is far more complex than earlier established. In fact, a U-shaped association between preschoolers' use of AAE and their literacy skills was found. The authors found that children who use AAE features more or less frequently in an implicit SAE task (i.e., oral narrative elicitation) demonstrated stronger overall emergent literacy skills than students who produced AAE features moderately. Additionally, in a literacy task which required explicit SAE usage, preschooler used less AAE features in traditional SAE activities. In fact, they appeared to decrease their use of AAE features as the expectations for SAE increased. Hence, even in preschool, students are able to dialect shift between contexts. Moreover, students who produce less AAE features in their speaking demonstrated stronger literacy skills than those students who produced AAE features moderately. Likewise, students who were most prolific and proficient at both languages demonstrated emergent literacy skills [1]. Similar findings were noted in AAE features of middle class elementary age students who were able to code-switch depending on the demands of the activity [6].

In conclusion, students of AAE tend to produce more phonological features at the elementary school level [2]. Phonemic awareness skills are closely aligned with students' ability to read well. As such, programs aimed at increasing the awareness of phonological skills in speakers of AAE need to be attuned to the features of the home language and teach the explicit structure of SAE [3]. Although AAE has been identified as a rule-governed language spoken by many African American children and adults living in low and middle socio-economical environments, educational practitioners continue to struggle with designing language programs to meet these students' needs.

Age Attribution

►Age Bias

Age Bias

Thomas G. Reio, Jr.
College of Education, Florida International University, Miami, FL, USA

Synonyms

Age attribution; Age prejudice; Ageism; Ageist stereotype; Older worker discrimination

Definition

Age bias is the result of prejudicial, evaluative judgments being made toward an individual or individuals merely because of their age [1]. In general, age bias is negative and directed toward those who are older, although age bias is possible toward those who are younger as well [2].

Description

Age bias occurs when age-related stereotyping and prejudice causes one to treat another person or persons with partiality because of their age [3]. Preconceived notions about age then direct biased actions toward that person within the context of the age group in question. For example, age bias tempered by notions of older adults being incurious, resistant to change, technically outdated, and susceptible to physical ailments, might lead a manager to hire a younger job applicant over an equally qualified older applicant. Likewise, possible preconceptions of younger workers as being lazy, less loyal, harder to satisfy, and more likely to miss work because of having young children might bias a manager's decision to hire. To be clear, however, the research demonstrates that age bias is far more prevalent toward those who are older, female, and a member of the non-dominant culture [3, 4].

Age bias is not simply an abstraction to be argued by scholars; it exists and it is pervasive in western cultures [3]. Such bias exists because one's culture supports it in a number of ways, especially through the use of language [4]. Through words like "old," ageist notions are perpetuated. A quick peek at the dictionary yields terms like worn, no longer in use, discarded, tiresome, and obsolete to name a few. Each term has negative connotations that at least unconsciously support age bias. In addition, humor and jokes propagate age bias because age always has been a form of derogatory humor. Modern television, newspaper, and magazine advertisements are notable too in perpetuating age bias in their systematic avoidance of featuring older adults, except when exploiting negative stereotypes such as deteriorating physical appearance (i.e., female beauty is akin to "looking young" and avoiding wrinkling). Similarly, elderly characters on television shows regularly are marginalized into minor roles, poorly developed as characters, and typically described in stereotypical terms (e.g., fading memory, being comical). Indeed, print and electronic media are powerful language forms that continuously inform and shape culturally-accepted ideas of being "older."

In the workplace, age bias toward older workers is problematic, despite laws being passed to lessen its likelihood [5]. In the US, the Age Discrimination in Employment Act (ADEA) was passed in 1967 to promote the employment of individuals on the basis of ability and not age-related stereotypes, with modest success. ADEA permitted exceptions to certain occupations, such as pilots, fire fighters, police officers, bus drivers, air traffic controllers, and others responsible for public safety. The biggest workplace problem associated with age bias is hiring and promotional practices [5]. Older workers in many industries are defined as being 50 or older, but this varies widely. In the computer industry, for example, 35-year-old programmers are considered "old." For fashion models, being near 30 can be a considerable liability; youthful beauty is what sells in this instance. Of course, older workers can be valued for their positive attributes like experience, knowledge, positive attitude, loyalty, and commitment to quality. Yet, organizational research demonstrates that frequently managers have clearly biased perceptions of older workers as being more resistant to change, technology-phobic, less creative, and less capable of handling stressful situations. In study after study, when equally qualified younger and older workers apply for a job or promotion, the younger worker has been more favored in the majority of cases [5].

To combat age bias, people need to be made aware of its insidiousness, pervasiveness, and possible negative consequences. We must be careful to remember that age bias has mostly negative consequences, even more so for females and non-dominant culture members. Those involved in producing print and electronic media could take a leading role in sensitizing its citizens to the issue of age bias and begin addressing it systematically through promoting more positive, but realistic portrayals of older people. In the workplace, conducting intergenerational training and making age a major part of diversity awareness training would be welcome first steps.

Age Equivalent

Laura Tinsley
University of Texas, San Antonio, TX, USA

Synonyms

Age equivalent score; Age score; Developmental norms; Norm-referenced scores; Phylogenetic equivalents; Relative performance indexes

Definition

Age Equivalent is the individual's ability; skill, knowledge, or measurement expressed as the age at which most individuals reach the same level (age norm). The Age Norm is the average score of a particular test completed by children of a given chronological age.

For example, the mental age norm of a 6-year old female is determined by collecting a sample of 6-year old female children's mental abilities, then calculating that average cognitive function as the age norm. This average mental function is the age norm for that group. The cognitive function equivalent of the 6-year-old female will then be compared against this age norm.

Description

Age Equivalents are not only used in intelligence measurement, but also physical development such as physical growth (i.e., height and weight, verbal quantity and quality) and motor skills. There are age equivalents, timetables of development, for both prenatal and throughout childhood.

Some tests which use age equivalents include: WIAT, Oral and Written Language Scales-Written Expression (OWLS WE), Peabody gross motor scale, Mullen Scales of Early Learning for the Assessment of Young Children with Autism Spectrum Disorders, and some early intervention tests. Some tests will use age norms as an additional evaluation tool with standard scores.

Advantages

Age equivalents only report relative standing of different students on the same test and are more intuitively understandable. They give a frame of reference for growth and can provide problem-warning signs.

Disadvantages

Since there is a relationship between maturation and learning, it suggests a timetable. But because individuals are different, they cannot be expected to be in the same place at the same time. Even though two children are the same mental age, they may not both be ready for the same school tasks, such as reading.

Because of comparisons to norms, failing to master developmental tasks as expected may cause unfavorable social judgments and a limited foundation for later tasks. Care should be taken to avoid a negative (self) judgment resulting in feelings of inadequacy.

Age equivalents are ordinal data, which means there are not equal units between scores. The development curves are higher in younger children and plateau with older children and adults. Because of this, there are larger differences between scores of younger as compared to older children. Unless the practitioner understands the difference in the amount of variance, it may cause difficulty with the interpretation; as such, should not be used alone to make decisions.

Standardized tests usually use normative scores, so there is a measurement within an age group. Standard scores provide a more accurate view of an examinee's ability because they are based not only on the mean at a given age level but also on the distribution of scores within the age group. Age equivalents are measured in groups between ages. Age norms are calculated from group scores, not individuals within the group.

Analysis of variance from the mean cannot be calculated with age equivalents. Age norms assume scores are evenly distributed, but there is no way to know how the scores are in actuality clustered. If scores cluster around the top or bottom of the scale it means that change can only be detected in the other direction. This introduces a bias called "ceiling" or "floor" effects. In a ceiling effect, the majority of scores is at or near the maximum possible for the test and is limited by a lack of variability. This presents statistical problems. The test can't measure traits above its ceiling. This violates statistical assumptions and limits reliability results.

Relevance to Childhood Development

Educational Setting

Age equivalents are used to make decisions about intellectual development, academic achievement, and the

discrepancy between them to help identify Learning Disabilities (LD). It also measures comparisons of intellectual ability. IQ is a measure of intelligence calculated by mental age divided by actual age. Even the fact that IQ can change illustrates the problem with analyzing mental age. To minimize this occurrence, it is statistically calculated as a distribution on the bell curve.

Growth and Development

One of the more universally accepted theories is that child development is sequential in nature; that there is often a hierarchy of skills creating milestones or stages. Since all humans go through the same steps, comparisons should be able to be made. Stages are monitored from babyhood on up, observing these steps. The approximate ages at which steps occur are charted on developmental scales. Generally, development is measured in the following areas: fine motor, gross motor, cognitive, self-help, social emotional, and expressive and receptive language. Age equivalents are compared to age norms to determine if development is occurring as expected.

►Age Equivalent

Age of Viability

Carol Patrick
Fort Hays State University, Hays, KS, USA

Synonyms

Fetal survival; Premature infant survival

Definition

The age of viability refers to the period of time when the developing fetus is able to survive outside of its mother's womb.

Description

Generally, the age of viability of a fetus is considered to be between 22 and 26 weeks after conception. Survival of a child born prior to the full gestational age (40 weeks) improves greatly during the third trimester. The survival rates at different times during the age of variability are as follows:

- 21 weeks or less: survival rate is 0%
- 22 weeks; survival rate is 0–10%
- 23 weeks; survival rate is 10–35%
- 24 weeks; survival rate is 40–70%
- 25 weeks; survival rate is 50–80%
- 26 weeks; survival rate is 80–90%
- 27 weeks; survival rate is 90% or more

Neonates born during the age of viability usually need assistance to survive and share some common, but often temporary, disorders. These include seizure disorders, heart defects, blindness, problems controlling body temperature, respiratory difficulties, neurological problems including hemorrhage, among others.

Although some of these issues may persist, the prognosis for the premature children born at the normal weight for their period of gestation is generally better than that of small-for-date children (babies born weighing less than is typical for their gestational age, including children carried full term).

Age-Graded Influences: Cohort

Carol Patrick
Fort Hays State University, Hays, KS, USA

Synonyms

Generational effects

Definition

The term cohort effects refers to traits, attitudes and/or behaviors shared by individuals growing up under similar sociocultural conditions at a particular point in history.

The term age-graded influences refers to effects on development that tend to occur at approximately the same chronological age in most people, and can be either biological effects (e.g., puberty), or environmental effects (e.g., entering the school system, in many countries).

Description

Cohort/History Graded Effects

The developmental researcher Paul Baltes discusses the concept of history graded effects on development. This term refers to the concept that each generation experiences certain historical events, fads, etc. that have a unique effect on their growth and development that other cohorts do not experience in the same way. These effects are thought to be strongest when a cohort is in adolescence or young adulthood; thus, at some level, making them age-graded as well. One example might be how each generation hones its own musical styles and then tends to cling to the music of its youth throughout life. Imagine the effects, particularly in the short term, that the protest music of the 1960s had on the activism of that generation. Another example might be the effect of Watergate on the generation who came of age at in the 1970s. Their attitude toward government and politicians is typically more cynical than that of previous generations, according to some authors. The concept of history graded effects is that, as each cohort experiences the unique sociocultural forces at play during their adolescence and young adulthood, there are some commonalities in their effects on the growth and development of traits, attitudes and behaviors of that cohort.

Cohort effects have been shown to be significant. Research has shown, for example, that the development of personality in teens was affected as much by cohort-related factors as age-related factors. Similarly, it was found that cohort differences in adult intellectual development were as large as longitudinally-studied age differences.

Cohort Effects in Research

Cohort effects can also be important in the study of development and the study of change with age. The two predominant methods for studying change with age are the cross sectional study and the longitudinal study. Cohort effects can be problematic in both types of research.

In cross-sectional studies, researchers study change with age by, at one general point in time, measuring people of different ages on some trait or behavior of interest. For example, a researcher might wish to study the development of memory with age. To do so she loads her test on a computer in her lab, and does a cross-sectional study, testing a group of 20-year-olds, 30-year-olds, 40-year-olds, and so on by decade up through 80-year-olds. Suppose that the researcher finds that 80-year-olds score significantly

lower on the test than 20-year-olds and, at each progressive age tested, that scores are lower. Can we therefore conclude that memory decreases with age? We cannot; one of the major reasons is cohort effects. For example, today's 20-year-olds have much more computer experience on average than today's 80-year-olds. Therefore the differences we see may be attributable to cohort differences in comfort with the method of testing, and not, in fact, decreases in memory with age. It is also true that today's 20-year-olds typically have more recent and extensive experience with memorizing information, given their more recent experience in a school setting memorizing information and using mneumonic strategies. Although this may make it seem as if the younger cohort is more adept at the memory than the older, it may just represent that they have more recent experience and practice in using strategies to memorize quickly. So, once again, cohort effects may make it appear that age-related differences exist when they may not.

Likewise, in longitudinal studies, cohort effects can be an issue. In longitudinal studies, change across age is examined by testing individuals of a single cohort on a trait or behavior of interest, and then continuing to test that group of individuals over time. In this case, a researcher might give a test for a trait like frugality, and follow the members of his original study, testing them every 5 years throughout their lifetimes. The cohort effect issue in longitudinal studies is that only one cohort is studied. The changes across age with the cohort studies might differ if another cohort were studied. Imagine how changes in baby boomers would be different than those of the Depression generation in terms of that trait of frugality.

Typically, cohort effects in research are dealt with by combining cross-sectional and longitudinal approaches in the same study. One might do a series of cross-sectional studies, or a series of longitudinal studies, for example. These are often referred to as sequential designs.

Agenesis of the Corpus Callosum

Brady I. Phelps
South Dakota State University, Brookings, SD, USA

Synonyms

Callosal agenesis

Definition

Agenesis of the corpus callosum (ACC) is a rare congenital defect; it is literally a failure in proper development of the corpus callosum, which is normally the largest commissure or interhemispheric pathway, between the two brain hemispheres of the cerebral cortex. The reported frequency of this condition in the United States is approximately 0.7–5.3% of all births; presumably, the international incidence falls in the same range [5].

ACC may be complete, partial or atypical. In complete ACC, the corpus callosum is totally missing. Such callosal disorders are diagnosed via brain imaging studies such as MRI, CT scan or other technologies [3, 4].

The corpus callosum normally begins to form in the tenth or eleventh week of pregnancy. ACC has no single cause but can be due to genetic factors, prenatal exposure to infectious agents or toxins, among other possible causes; in most cases, the exact cause is unknown. Regardless of the cause, normal formation of the corpus callosum

is disrupted between the fifth and sixteenth week of prenatal development [4].

The symptomology, if any, resulting from ACC varies greatly from one case to another, but includes visual impairments, poor muscle tone and motor coordination, delayed motor milestones, reduced pain perception, and difficulties in chewing and swallowing. Since the emergence of present day brain imaging technologies, it has become known that there are individuals with ACC who do not have any psychological delays or deficits. When psychological symptoms or deficits are apparent, these are either idiosyncratic and or typically difficult to detect in most tasks of everyday life. Subtle difficulties in sensory integration and simultaneous dexterity requiring use of both hands have been observed but distinguishing these from normal inattention or "clumsiness" may be a fine discrimination to make; the individual's IQ is generally normal or in the lower end of what is considered normal [1, 4]. One of the most intriguing aspects of ACC is the lack of symptoms and deficits relative to those observed after ablation of the corpus callosum in a mature brain. Individuals with ACC have been found to have brains with enlargement of what are typically the other minor interhemispheric pathways, namely the anterior and posterior commissures. It is assumed that the enlarged anterior and posterior commissures are a means by which brain or neural plasticity has compensated for the lack of a corpus callosum [1, 2].

Aggression

Janett M. Naylor
Fort Hays State University, Hays, KS, USA

Synonyms

Anger; Antagonism; Assault; Bullying; Hostility; Violence

Definition

Any type of behavior or action that is used to harm or dominate another.

Description

Aggression is part of human nature; therefore, all children must learn to deal with their own aggression and the aggression of others. Even though aggression is an innate component of all human societies, societies vary in degree of acceptance and condemnation of aggressive acts. In addition to variations in societies, individuals vary in their levels of aggression. Great debate surrounds what constitutes aggressive actions. For example, is intention necessary for an act to be considered aggressive? Should the context be accounted for? When does an action change from play to aggression? Aggression is a complex and rather elusive field of study.

Aggression can come in many forms, such as verbal, physical, relational, can be committed by groups or individuals, can be emotional or non-emotional, and can be targeted to a specific person or can be a random act. However, most researchers can agree on the basic distinction between hostile and instrumental aggression. Hostile aggression involves acts that have the goal of hurting others or injuring victims. In contrast, instrumental aggression is acts that are motivated by non-aggressive reason but often harm others as a by-product. The major distinction between hostile and instrumental aggression seems to be intention.

Even with the vague and conflicting definitions of aggression used by researchers, children tend to follow a particular developmental pattern focused on amount, type, causes, and thoughts about aggression. Specifically, the amount of aggression decreases with age. Toddlers use aggression directed at other children about 50% of the time, whereas preschoolers use aggression only about 17% of the time during interactions with other children. Some research does suggest a slight increase in the amount of aggression between ages 9 and 14 years, but this increase is evident in boys only. The gender difference may be due to the expression of aggression. Boys use more overt actions

(e.g., hitting, yelling, pushing), whereas girls use more subtle or covert actions (e.g., exclusion, gossip, name calling).

Another developmental pattern is seen in the type of aggression children use. Given increases in social interactions and language use as children get older, aggression switches from more physical to more verbal actions. Toddlers have limited language skills and have no choice but to express frustration or anger through physical means. However, by middle childhood, children can understand and use language in more complex forms leading to more verbal expression of anger or frustration, such as name-calling, taunting, teasing, joking, and sarcasm. Also, across preschool and middle childhood, instrumental aggression decreases in frequency, whereas hostile aggression remains relatively stable. Change in type of aggression can be attributed to children being able to intentionally use aggressive acts. Rather than aggression being a by-product of actions as is common in younger children, in older children are able to deliberately manipulate aggression toward targets.

Given that social situations change across childhood with children gaining entry into more groups and organized events, the contextual elicitors of aggression also changes with age. For toddlers, aggressive acts are most often directed at playmates and center around possession or lack of possession of toys and play objects. Also, in early childhood, toddlers direct aggressive acts toward parent based on disagreements over daily routine activities like bathing, eating, bedtime, etc. Because children are spending more time in larger group settings like school, older children often use aggression not only for individual gain but for the betterment of the group. For example, children may use aggression to obtain the prime spot on the playground so that the entire group may play together.

The final developmental pattern seen in childhood aggression is due to increased awareness of social situations and interpretation of social events. With age, children are able to better understand their motives and the motives of others. Also, children are able to predict behaviors in social situations and use that knowledge to change social interactions. Older children are better able to take on the perspective of others during social situations and can better anticipate the actions and emotions of others. As a result of children's increased social savvy, aggressive behaviors become more subtle and sophisticated. Older children are now able to control their behaviors and emotional responses to override the impulsive aggressive acts of early childhood and are better able to deliberately plan complex aggressive acts. Intense emotional reactions can still elicit violent behaviors but children are now able to use aggression more effectively to harm others.

Socialization has a large impact on the individual developmental path of aggression. Parental style has been shown to influence aggression in adolescent boys. Specifically, when parents are rejecting or indifferent to their male adolescents, they have little motivation to control hostility. Also, when parents are too permissive and fail to set limits, male adolescents may feel freer to use aggression. Parents may also model the rewards of using aggression. For example, frequent use of physical punishment and repeated demonstration of aggression increases the likelihood of children using aggression as a means to an end. Also, differential rewarding may encourage aggression. Parents of aggressive adolescent males are more likely to punish their sons for aggressive acts directed at parents but rewarded for aggressive acts directed toward peers.

Individual differences in aggression levels are fairly stable across development. Children, who are considered aggressive compared to their peers in toddlerhood, will most likely be considered aggressive compared to their peers in preschool and beyond. Individual differences in aggression are also relatively consistent across situations. Children who are aggressive with peers tend to be aggressive with parents, teachers, and others, as well as across contexts like school and home. However, this does not mean that individual levels of aggression are fixed and cannot be altered. Children can learn the precursors of their aggression and therefore, can learn to control aggressive tendencies. Modeling prosocial actions is another important way to teach children to control their aggression. If children have other more acceptable behavior options, they will be more likely to use positive versus negative actions. Changing children's interpretation of social situations may also help decrease aggression. If children can come to recognize other possible motives for behaviors, they may be able to control their impulsive reactions to potentially threatening social interactions.

Several theories have described possible biological and social determinants of aggression. Freud's instinct theory and Lorenz's ethological theory both characterize aggression as instinctual reactions and therefore an inescapable part of life. For Freud, the death instinct, inborn in every human, was the drive to outwardly destroy property or hurt others. This death instinct builds energy overtime that must be released in socially acceptable ways, via catharsis, or violence is inevitable. According to Lorenz, aggression has adaptive value, like hunger, sexuality, and flight, that ensures the strongest will survive.

Based on learning theories, the Frustration-Aggression Hypothesis and Bandura's Social Learning Theory put

more emphasis on contextual influences on aggression. According to the Frustration-Aggression Hypothesis, aggression is a learned response when faced with frustrating social situations. Children learn that expressing aggression helps to alleviate their frustration when their goals are blocked. Although the link between frustration and aggression makes common sense, research has failed to make a clear and reliable link between frustration and aggression. Being frustrated does not always lead to acting aggressively and aggressive acts are not always caused by being frustrated. Bandura's research explored the link between observing aggression and expression of aggression. Through observational learning, children see the usefulness of aggressive acts for obtaining goals and come to use aggression in similar situations. Bandura's Social Learning Theory is the foundation for the argument that television and other forms of media increase aggression levels. However, a causal link between aggression and media has not been established. Television may increase aggressive behaviors or aggressive tendencies may lead to watching violent television.

Agnosia

David Morrison, Mary Joann Lang
Azusa Pacific University, Azusa, CA, USA

Synonyms

Agnosis Primary; Monomodel Visual Amnesia; Visual Amnesia

Definition

Agnosia is a relatively rare neurological disorder which refers to the inability to recognize common objects, persons, sounds, shapes, or smells, even when basic sensory modalities are intact. An individual diagnosed with an agnosia is able to receive sensory input such as vision, hearing, and touch, yet is unable to understand or recognize what they see, hear or feel. Visual and auditory agnosias are the most common identified in the literature. This inability for recognition is not due to issues with alertness, intelligence and language [3].

Background and Overview

Agnosia, as a term to describe this phenomenon, was first introduced in 1891 by Sigmund Freud (1856–1939). Agnosia comes from the Greek word for "not knowing" or loss of knowledge. Agnosia was described by Teuber (1916–1977) as a "normal percept stripped of its meaning." The phenomenon of agnosia is frequently discussed in the literature but is relatively rare. Due to the rarity of the disorder, there is no standard taxonomy for describing it, which complicates the clinical understanding [4]. Most reported cases have been patient-based of single subject design, with no two cases exactly alike. Limitations of patient-based research have been cited by Farah [2] as not being readily available for replication. The inability to accurately classify the disorder has led some skeptics in the past to question whether or not the phenomenon actually exists. Currently there is a broad consensus that the disorder does exist, in part due to advances in neuroimaging. Additionally, there are many types of agnosia identified in the literature [7]. Each specific type of agnosia affects a specific sensory modality in a specific way. The phenomenon can range from an inability to recognize familiar faces (prosopagnosia), to the inability to recognize familiar voices (phonagnosia). Other types of agnosia identified in the literature include autotopagnosia, the inability to identify the parts of one's own body, and color agnosia, the inability to recognize color despite intact color discrimination.

Agnosia is most commonly seen in persons who suffer from a stroke or from dementia. The inability to recognize sensory stimuli can be partial or complete, depending on the extent of the damage to the brain [8]. For example, an individual suffering from a visual agnosia may be able to visually describe the object that they are seeing, yet is unable to recognize what it is or identify it by name. This curious phenomenon is often confined to a singular sensory area, such as vision, hearing, or tactile (touch), but can manifest concurrent with other sensory areas. For example, a person with a visual agnosia would not be able to identify or demonstrate how to use a common object, such as a hammer, even though they can see it and accurately describe it. They would, however, likely be able to identify the hammer by touch or by sound if they heard it banging on wood, as these sensory modalities would not be affected. Individuals can have a spontaneous recovery, or recovery can be slow and incomplete. Others must learn to cope with their strange disability. No specific treatment exists.

Anatomical Clinical

Gerschwind (1965) published a monograph, "Disconnection Syndromes in Animals and Man"; his primary thesis was that certain types of behavioral deficits were caused by disconnections between hemispheres, within a hemisphere, or a combination of both. Gerschwind advanced the concept that an agnosia was the result of disconnecting the posterior speech area from the visual association cortex, and is caused by dysfunction due to brain damage in the parietal, temporal, or occipital lobes [4]. According to Luria [6], visual agnosias are the result of a disturbance of visual perception that develops as a result of lesions of the secondary visual cortex. Agnosia is a symptom of a brain disorder. The term is most often used when the primary sense organ involving sight, touch, or hearing is involved and is not impaired. Knowledge of the neuropathology of agnosia is currently incomplete. However, there is evidence to suggest that bilateral occipital lobe lesions extending deep into the white matter contribute to this disorder. The parietal and temporal lobes of the brain are implicated, as they are involved with storing memories and the association of objects to those memories. Damage may be due to head trauma, stroke, carbon monoxide poising, anoxia, dementia or other neurological disorders.

There are many different subtypes of agnosia described in the literature, but all generally fall under the three main categories; visual agnosia, auditory agnosia, and tactile agnosia.

Visual agnosia is a neurological disorder confined to the visual modality in which the person is unable to recognize familiar objects despite intact visual processes. Lissauer (1890) was the first to suggest that there was a distinction between a deficit in the ability to perceive stimuli consciously and a deficit reflecting an inability to ascribe meaning to what has been perceived, a disorder that he identified as "soul blindness." He identified two broad classifications or categories for visual agnosia, apperceptive agnosia and associative agnosia. Most neuropsychologists continue to use these broad classifications. While there is a distinction between apperception and associative agnosia, the distinction is not always clear [7].

Apperceptive agnosia is identified when object recognition fails, due to impairment in visual perception. Apperceptive agnosia is the inability to visually assemble incoming information through the visual system and to form an image, while other visual functions such as acuity, color vision, and brightness discrimination remain intact. These individuals have obvious difficulty with visual perception and are unable to process features and, as such, are not able to accurately develop a perception of the overall shape of the object. As a result, they have difficulty recognizing, copying, or discriminating between different visual stimuli. Individuals with apperceptive agnosia are unable to copy images accurately. Simply stated, these individuals cannot see objects normally and, as a result, they cannot recognize them. A review of the literature identifies carbon monoxide poisoning as a known cause of apperceptive agnosia. Damage to the brain caused by carbon monoxide poisoning is frequently profuse and is primarily located in the posterior regions of the brain. The posterior regions of the brain are responsible for the analysis, coding, and storage of information. Lesions in the occipito-temporal and occipito-parietal visual association areas have been implicated in the damage of visual shape or general visual space recognition [2, 4, 5, 7].

Simultanagnosia, also known as Balint's syndrome, named after the Hungarian neurologist (1909) is the inability to perceive more than one object at a time. It is a condition where visual images containing multiple objects cannot be interpreted as a whole. Individuals can recognize single objects or details in their visual field, but only one at a time. They cannot make a coherent picture out of the various images within the scene or make whole images out of details. They literally cannot see the forest for the trees. Instead, individuals with simultanagnosia recognize only portions of the visual scene and fail to describe the overall nature of the scene and comprehend its meaning. Individuals capable of seeing only one object at a time are said to have dorsal simultanagnosia. Individuals with ventral simultanagnosia retain the ability to recognize whole objects, but the rate of recognition is impaired. The left inferior temporo-occipital cortex is generally implicated in the

deficit. This phenomenon has been described as an inability to shift visual attention from one point to another [7].

Associative visual agnosia has been used broadly to describe a heterogeneous set of symptoms, but most often refers to an inability to recognize objects, despite evidence that early stage perceptual processing is intact. According to Farah [2], there are three main criteria that identify an associative agnosia. The first criterion is the difficulty of recognizing a variety of objects, as demonstrated by an inability to categorize these objects by semantic grouping or by gesturing to indicate normal functioning of the object. The second criterion is normal recognition of objects through modalities other than vision, for example, by touching the object. The third criterion includes intact visual perception that seems adequate to the task of recognizing the object [3].

Unlike apperceptive agnosia, these individuals can recognize shapes and objects. However, they cannot access memory or knowledge of what the object is. The object is perceived as an object but has no meaning; therefore it cannot be identified. For example, the individual can describe accurately visual scenes and/or various objects, but they fail to recognize them for what they are. They would be able to copy and reproduce images, but are unable to identify them by name. This has led some to believe that there is damage in the language centers of the brain. Bilateral damage of the posterior cerebral arteries has been frequently identified in associative agnosia. In general, damage to the brain is more localized than in apperceptive agnosia. Reported cases in the literature identify that damage to several different areas of the brain may produce the affect of an agnosia. Associative agnosia is more common than apperceptive agnosia [1].

Auditory agnosia is a deficit in auditory recognition confined to the auditory modality, despite intact auditory sensory function. There are non-verbal and verbal forms of auditory agnosia. Non-verbal auditory agnosia is defined as a failure to recognize nonverbal acoustic stimuli, despite adequate hearing. For example, the individual would be unable to recognize familiar sounds such as bells, whistles, horns, or animal sounds. Like a visual agnosia, this is sometimes described as a disconnect syndrome, meaning that the brain cannot connect the sound to the source of the sound. This disorder is associated with right temporal or parietal lesions or bilateral lesions of the auditory association cortex [4, 5].

Verbal forms of auditory agnosia refer to an inability to comprehend language, despite normal hearing capabilities. These individuals are able to copy and write spontaneously and follow written commands, but cannot write dictation. Auditory verbal agnosia is thought to be produced by damage to Wernicke's area in the left primary auditory cortex, or the tracts leading to it. Lesions leading to the corpus callosum are also implicated.

Tactile agnosia, sometimes referred to as astereognosia, is a deficit in object recognition confined to the tactile modality, and occurs as a result of unilateral damage resulting from lesions of the contralateral inferior parietal cortex. Those with a tactile agnosia have difficulty identifying a familiar object, such as a key or safety pin that is placed in the hand on the side of the body opposite the damaged area of the brain. These individuals cannot recognize an item by touching or holding it, but can immediately recognize the object when they look at it. Like visual and auditory agnosias, this too is sometimes considered a disconnect syndrome between the somesthetic perception area of the brain and the knowledge of what an item is [4].

Aid to Families with Dependent Children (AFDC)

Lynna Lan Tien Nguyen Do
Walden University, Fremont, CA, USA

Description

Aid to Families with Dependent Children (AFDC) was established by the Social Security Act of 1935 as a grant program to enable states to provide cash welfare payments for needy children who had been deprived of parental support or care because their father or mother was absent from the home, incapacitated, deceased, or unemployed. All 50 states, the District of Columbia, Guam, Puerto Rico, and the Virgin Islands operated an AFDC program. States defined "need," set their own benefit levels, established (within federal limitations) income and resource limits, and administered the program or supervised its administration. States were entitled to unlimited federal funds for reimbursement of benefit payments, at "matching" rates that were inversely related to state per capita income. States were required to provide aid to all persons who were in classes eligible under federal law and whose income and resources were within state-set limits.

During the 1990s, the federal government increasingly used its authority under section 1115 of the Social Security Act to waive portions of the federal requirements under AFDC. This allowed states to test such changes as expanded earned income disregards, increased work requirements and stronger sanctions for failure to comply with them, time limits on benefits, and expanded access to transitional benefits such as child care and medical assistance. As a condition of receiving waivers, states were required to conduct rigorous evaluations of the impacts of these changes on the welfare receipt, employment, and earnings of participants.

The Personal Responsibility and Work Opportunity Reconciliation Act of 1996 (PRWORA) replaced AFDC, AFDC administration, the Job Opportunities and Basic Skills Training (JOBS) program, and the Emergency Assistance (EA) program with a cash welfare block grant called the Temporary Assistance for Needy Families (TANF) program. Key elements of TANF include a lifetime limit of 5 years (60 months) on the amount of time a family with an adult can receive assistance funded with federal funds, increasing work participation rate requirements which states must meet, and broad state flexibility on program design. Spending through the TANF block grant is capped and funded at $16.5 billion per year, slightly above fiscal year 1995 federal expenditures for the four component programs. States must also meet a "maintenance of effort (MOE) requirement" by spending on needy families at least 75% of the amount of state funds used in FY 1994 on these programs (80% if they fail work participation rate requirements).

TANF gives states wide latitude in spending both Federal TANF funds and state MOE funds. Subject to a few restrictions, TANF funds may be used in any way that supports one of the four statutory purposes of TANF: to provide assistance to needy families so that children can be cared for at home; to end the dependence of needy parents on government benefits by promoting job preparation, work and marriage; to prevent and reduce the incidence of out-of-wedlock pregnancies; and to encourage the formation and maintenance of two-parent families.

Ainsworth's Procedure

Raquel Plotka
Fordham University, GSAS, New York, NY, USA

Synonyms

Attachment behaviors; Attachment classifications; Attachment patterns; Attachment theory; Exploration; Internal working models; Separation; Strange situation

Definition

Ainsworth's procedure is a method that assesses the quality of attachment between infant and primary caregiver. This procedure takes place in a laboratory, and categorizes infants into secure (B), insecure-avoidant (A) and insecure-resistant or ambivalent (C). Additionally, a forth classification, disorganized (D) is recognized.

Description

Theoretical Background

Attachment theory was first articulated by John Bowlby, who proposed that an attachment is an affectionate tie

that develops between two people, and endures over time [5]. In this relationship one person is viewed as stronger and smarter and takes the role of caregiver and the second person is viewed as needy of care and nurturance. This relationship is based in the etiology and biology of humans, since it served the role of protection and survival of the human infant. This way the relatively helpless infant has innate qualities based in the genetic programming that prompt him or her to form attachments and the human caregiver has innate qualities that facilitate caring and nurturing.

According to Bowlby [6], the attachment figure fulfills two important functions in the development of the child. The first function is to provide the infant with a secure based from which exploration can take place, and the second function is to provide the guidelines for the internal working models. Sensitive and consistent responses from a caregiver constitute a relationship in which the infant feels safe and confident to explore the world. These early experiences form a pattern in the infant's mind and are internalized as internal working models. The experiences of protection, comfort and opportunities for exploration form internal working models of self as independent, lovable, worthy, and self-reliant. In contrast, when an infant experiences the rejection of his or her needs for comfort and exploration the infant is likely to develop internal working models of the self as less worthy, less lovable, and less self-reliant. This way, a child's daily explorations has the function of testing a hypothesis about his or herself and the child's world. The child's learning to attribute meaning to past, present, and future interactions constitutes the basis for the development of internal working models. Therefore, these models can be described as a group of expectation of self and others generated by the attachment relationship [6].

Attachment Behaviors and the Strange Situation

Attachment behaviors are behaviors that aim to promote attachment and survival, and they consist of seeking and maintaining proximity through crying, following, clinging, approaching, smiling, or calling [1]. These behaviors are activated when infants perceive that their sense of safety or integrity is being compromised. These behavior emerge early in development, and they progressively become more directed towards a specific caregiver, usually the mother. Attachment exists even when the behaviors are not present. Hence, once an attachment has been formed, it is believed to be constant even in the absence of attachment behaviors. This way, attachment is considered to be an organization of the behavioral system [1].

Exploratory behavior is also an important element in the attachment system and serves as a period of learning and adaptation. The human infant can adjust to a wide variety of environmental variation, when a balance between the need of proximity to caregiver and opportunity for exploration of the environment is available. Development takes place through the equilibrium between behaviors that draw the child close to the mother for nurturance and behaviors that draw the child away from the mother for exploration and learning [1].

The Procedure

One of the factors that give this theory empirical validity is the fact that these ideas can be measured objectively and reliably. The interaction between exploratory behaviors and proximity-seeking behaviors has been explored in naturalistic settings, bringing Ainsworth and colleagues to develop the Strange Situation. In this procedure, a shortcut to naturalistic observation is proposed as the Strange Situation observes the infant in a variety of situations that prompt both proximity seeking and exploration. These behaviors will take a long time to be observed as activated naturally in the home environment. The procedure was designed to observe the extent to which the infant can use the mother as a secure base from which to explore an unfamiliar environment. This 20-min laboratory procedure constitutes a snapshot of attachment behaviors. This technique exposes the child to a controlled unfamiliar situation with and without the mother and is very effective at evoking attachment behaviors. The balance of exploration-proximity is observed when interpreting the results, as Ainworth's procedure provides the opportunity to observe how exploratory behavior is affected by both the presence an absence of mother and the presence of a stranger [1].

The procedure consists of eight episodes and was described by Ainsworth as taken place in the following way:

"*Episode 1* (M, B, O). Mother (M), accompanied by an observer (O), carried the baby (B) into the room, and then O left.

Episode 2 (M, B). M put B down in the specified place, then sat quietly in her chair, participating only if B sought her attention. Duration 3 min.

Episode 3 (S, M, B). A stranger (S) entered, sat quietly for 1 min, conversed with M for 1 min, and then gradually approached B, showing him a toy. At the end of the third minute M left the room unobtrusively.

Episode 4 (S, B). If B was happily engaged in play, S was nonparticipant. If he was inactive, she tried to interest

him in the toys. If he was distressed, she tried to distract him or to comfort him. If he could not be comforted, the episode was curtailed, otherwise it lasted 3 min.

Episode 5 (M, B). M entered, paused in the doorway to give B an opportunity to mobilize a spontaneous response to her. S then left unobtrusively. What M did next was not specified, except that she was told that after B was again settled in play with the toys she was to leave again, after pausing to say 'bye-bye.' (Duration of episode undetermined.)

Episode 6 (B alone). The baby was left alone for 3 min, unless he was so distressed that the episode had to be curtailed.

Episode 7 (S, B). S entered and behaved as in episode 4 for 3 min, unless distress prompted curtailment (...).

Episode 8 (*M*, *B*). M returned, S left, and after the reunion had been observed, the situation was terminated" [1, p. 54].

The behaviors displayed by infants in the Strange Situation, are the basis for the coding system, and are identified as proximity and contact-seeking, contact-maintaining, contact and interaction resisting, and searching behaviors. Contact-seeking behaviors are behaviors such as approaching, climbing on, and reaching, contact-maintaining behaviors are behaviors such as holding on or refusing to let go, contact and interaction resisting behaviors are behaviors such as attempts to push away or attempts to get down after being picked up, and searching behaviors consist of the infant searching for the mother in her absence, looking at the door or her chair [1].

The Classifications

Classifications are based on careful observation of the child's attachment behaviors in the different composites of the Strange Situation with special attention to the reunion episode [2]. The securely attached child (classified as B) displays the ability to play and explore happily in the presence of the mother and to feel at ease in the presence of a stranger. Securely attached children become distressed when the mother leaves, but they are easily comforted by her when she returns. Children in the anxious-avoidant category (classified as A) are usually indifferent towards the mother and are more interested in toys than in interactions. Such children might exhibit distress when she leaves and might be comforted by the stranger. However, they generally behave with indifference in her return. The insecure-ambivalent children (classified as C) play in close proximity to the mother and exhibit anxiety in her presence. They become very disturbed when she leaves and are not comforted easily in her return. They hesitate between seeking proximity and avoiding the mother during reunion [2].

The behaviors the children exhibit in the Strange Situation reflect on the internal working models of the self, the caregiver, and the world, and are directly related to past experiences with the caregiver. The securely attached infants have developed internal working models of autonomy, confidence, and reliance. Their behaviors reflect on a caregiver who has been consistently available, and an attachment relationship that has served as a secure base for explorations. Insecurely avoidant infants have developed working models of rejection and indifference, and their behaviors reflect a caregiver who has been consistently unavailable. The relationship does not constitute as a secure base, and the infant has developed coping strategies of indifference. Insecure-ambivalent infants have developed internal working models of uncertainty. Their behaviors reflect on caregivers who have been inconsistent in their availability, have not offered a secure base for the child's exploration, and have limited the child's autonomy. Infants are ambivalent about the ability of the caregivers to offer comfort, and therefore they alternate between proximity seeking and resistance [2].

A fourth category has been found through extensive observations of Strange Situations [8]. This category is described as disorganized attachment (classified as D) and portrays a child that lacks an organized strategy to cope with both separation and reunion. This child looks disoriented and confused at reunion and resorts to a mix of behaviors including freezing and stilling. This classification is rare and is mostly present in clinical populations or abusive parents. It reflects a child who has a perception of the caregiver as the source of fear and instability and as unable to sooth the child's emotions (Siegel, 1999). This child's behavior reflects an incoherent working model, and no possible strategy to solve the paradox between seeking protection and avoiding the feared object, as both the fear and the protection are elicited by the same person (Siegel, 1999).

Distribution of Classifications

The Strange Situation has been used in numerous empirical studies in many parts of the world. Attachment classification observed in many U.S. samples have shown a similar distribution to the one proposed by Ainsworth and her colleagues (1978). About 67% of infants observed in the Strange Situation are securely attached, about 21% are classified as insecure-avoidant, and around 12% are classified insecure-ambivalent (Van IJzendoorn and Bakermans-Kranenburg). Cross-cultural research supports

the idea that the B classification is the mode in all countries. Yet, in some cultures some variations of the distribution has been found. For example, in Western Europe and America the avoidant classification is most common among insecurely attached children. However, in both Japan and Israel, ambivalent attachment has been found to prevail, and avoidant attachment is rare [13].

Controversy

Some controversy evolved around the use of the Strange Situation to measure attachment. A central issue in the controversy is the argument that the Strange Situation does not solely measure attachment styles. The behaviors observed in the Strange Situation could easily reflect children's level of arousal and emotionality, distress, fear, and other dimension of temperament rather than past experiences with the caregiver.

However, research points at the role of past experience and caregiver sensitivity to be better predictors of classification in the Strange Situation. For example, in one study level of child fearfulness was associated with the type of insecure classification, as more fearful children were more likely to be classified as insecure-ambivalent and less fearful children were more likely to be classified as insecure-avoidant. Yet, the history of maternal responsiveness was associated to secure or insecure categorizations (Kochanska and Coy, 2002). Similarly, researchers found that categorizations into easy or difficult temperament were not associated with attachment classification [14]. Likewise, a study has shown that insecure-avoidant children were temperamentally easier than both ambivalent and secure children [12].

Moreover, research found that the level of child distress by itself is not related to any attachment classification, although heightened distress is often associated with insecure patterns. However, the level of distresses influences the strategies children adopt during reunion. For example, children who feel higher levels of distress during separation might react in proximity-seeking behaviors and or conflicted behaviors, corresponding to secure or ambivalent classifications. Children who display low levels of distress typically exhibit indifference and less proximity-seeking behaviors, corresponding to avoidant classifications (Kochanska and Coy, 2002).

In one study, children's observations in their interaction with their mothers and level of distress experience in the separation episode were taken into account (Kochanska and Coy, 2002). Children who have shown more anger in their interactions with their mothers were more likely to exhibit resistant behaviors at reunion, and this was unrelated to the level of distress experienced. Similarly, children who expressed less joy in their interactions with their mothers resisted contact most often, and children whose mothers showed unresponsiveness were more likely to exhibit avoidant responses. This study concluded that the child's specific experiences in the mother-child relationship such as anger and joy and maternal responsiveness, were stronger influences on the children's choice of responses at reunion, than levels of distress (Kochanska and Coy, 2002). This supports the idea that the Strange Situation measures a construct that is strongly related to early experiences with the specific caregiver in the procedure rather then irritability or promptness to distress.

Other Methods of Measuring Attachment in Childhood

Since the Strange Situation was established, many new methods have been developed to observe the quality of attachment. However, the classifications remain similar between methods measuring attachment during infancy and childhood [11]. Some of the most common measures employed are the Q-sort, which is an observer's rating system based on home observations. The Q-sort gives a continuous score on attachment security and does not classify between secure and insecure styles. Additionally, there are some variations to the strange situation such as the Cassidy-Marvin system for 2.5–4.5 year-olds, the Preschool Assessment of Attachment, and the Main-Cassidy system for 5 and 6 year-olds. Each of these measures adheres to the categories established by Ainsworth and her colleagues, yet the behaviors used to measure each category vary with the child's age [11]. Lastly, a popular method is the doll-play procedure in which children are asked to use a doll family to complete a set of standardized attachment related stories. This method has many versions and could be used from the age 3 until 7 [11].

Relevance to Childhood Development

The Strange Situation constitutes a reliable method of observing a complex construct such as infant attachment. The availability of this method has enabled theorists and researchers to measure attachment and learn about its crucial role in child development. Additionally, researchers have gathered information about what constitutes an effective intervention that could improve attachment quality. Finally, extensive research has been generated with attention to implications for social policy.

The Strange Situation has enable scientists to show that security of attachment consistently predicts positive emotional development. Securely attached children in general, display pro-social behaviors, competence with

peers, social skills, and empathy (Lamb et al., 1985). Insecurely attached children display higher rates of hostility, impulsiveness, and negative affect [9]. Additionally, secure attachment has shown to be an important factor in resilience and an early predictor of socio-emotional development in the contexts of cumulative risks (Belsky et al., 2000). Attachment security has also proved to have a central role in resilience. In the other had, attachment insecurity has been found to be make children vulnerable to the adverse contextual circumstances [4].

The Strange Situation has enabled scientists to determined whether interventions aimed at improving attachment are efficient and in what way. Researcher have found that interventions are particularly successful if they start when the child is under 3 years of age, they are only a few sessions long, and have clear behavioral focus [3]. Moreover, since attachment is closely related to the quality of the responses from the caregiver to the infant, interventions aimed at refining the quality of these responses are most effective [3].

Finally, the use of the Strange Situation has given room to research relevant to public policy regarding issues such as child care. Studies using this method have shown that children benefit from policies that encourage quality of care during infancy and the preschool period. As more mothers have joined the workforce, and infants experience larger periods of separation these issues become vital. Large controversies remained unresolved in determining what constitute the ideal care for optimal development of infants and young children (e.g., [10]). Nevertheless, research indicates that whether infants experience maternal care, in home care, or center-based care, the quality of interactions and availability of the caregivers, including appropriate adult-child ratio remain as some of the central indicators of optimal care and of predictors of secure attachments (e.g., [7]).

Albinism

Derived from the Latin albus meaning white, albinism is a congenital disorder characterized by the complete or partial absence of pigment in the skin, hair and eyes due to the absence or defect in an enzyme involved in a production of melanin. The condition results from inheritance of recessive gene alleles and affects all vertebrates including humans. Albinism is also associated with a number of visual defects such as photophobia, nystagmus, and astigmatism. A lack of skin pigmentation makes an organism with albinism more susceptible to sunburn and skin cancers.

Alcohol

Nathaniel John Cooney
Oklahoma State University, Stillwater, OK, USA

Synonyms

Depressants; Ethanol; Ethyl alcohol; Grain alcohol

Definition

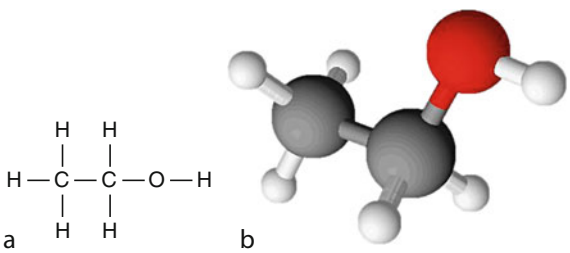
Alcohol is an organic chemical compound that is comprised of an alkyl group (carbon chain) and a hydroxyl group (oxygen–hydrogen bound molecule). More commonly it is used to refer to a class of beverages containing the chemical ethanol, a psychoactive drug that depresses the central nervous system.

Description

The term alcohol can refer to any organic chemical compound that includes one or more aliphatic hydroxyl groups (−OH) attached to an alkyl group (C_nH_{n+1}). While alcohols can exist in many forms, the term alcohol is more commonly used to describe the compound ethyl alcohol (or ethanol, abbreviated EtOH). As its name suggests, ethanol is comprised of an ethyl group (a two-carbon chain) and a hydroxyl group (an oxygen–hydrogen bound molecule), arranged in a straight chain and having the molecular formula C_2H_5OH (Fig. 1). Ethanol is the primary psychoactive ingredient found in most alcoholic beverages, and because of its depressant effects on the central nervous system, it is considered a drug and is regulated in many countries.

Physical Properties of Ethanol

Ethanol is a clear, colorless liquid with a characteristic refined odor. In dilute concentrations it has a sweet taste while in concentrated solutions a burning taste is often observed. It has a density of 0.789 g cm^{-3}, a molar mass of 46.07 g mol^{-1}, and a molar volume of 59 cm^3. It melts at 159 K (−130°C) and boils at 352 K (78°C). It is slightly basic having a pH of 7.33, and is both flammable and volatile [4]. Ethanol is classified as a primary alcohol, meaning that its hydroxyl (−OH) group is attached directly to a carbon atom that has at least two hydrogen atoms attached to it as well. This, combined with its short carbon chain, enhances its miscibility (solubility of one liquid with another to form a homogenous solution) and viscosity (resistance to flow). These properties further enable ethanol to more easily participate in hydrogen bonding with other molecules, being able to accept or donate one hydrogen atom, and also render the ethanol molecule more stable than some other organic compounds of similar molecular weights.



Alcohol. Fig. 1 (**a**) Two-dimensional representation of molecular structure for an ethanol molecule. (**b**) Three-dimensional "ball-and-stick" model of an ethanol molecule.

Metabolism of Alcohol

The primary route of entry for alcohol into the human body is through consumption (drinking) although it also can be absorbed through the skin. Once ingested, alcohol is transported down the esophagus into the stomach. There, it acts as an irritant by increasing the levels of hydrochloric acid (a chemical that aids in the process of digestion) that are secreted from the stomach lining. Approximately 20% of the alcohol consumed is absorbed through the stomach where it is picked up by small blood vessels and transported directly into the bloodstream. The remaining alcohol passes into the small intestine where most of the remaining 80% is absorbed through the intestinal walls into the bloodstream. From there it is carried to the liver and then on to the rest of the body. Because alcohol is water-soluble, it mixes easily with the bloodstream and is quickly circulated throughout the entire body, where it is likely to come into contact with every major organ including the heart, lungs, and central nervous system.

While in the liver, much of the alcohol is broken down by enzymes through the process of metabolism. One of the primary pathways (though certainly not the only one) for this process involves the enzyme alcohol dehydrogenase (ADH), which catalyzes the oxidation of ethanol into acetaldehyde (CH_3CHO). While ethanol itself is not a carcinogen, acetaldehyde is mutagenic, which means that it is very often toxic and carcinogenic as well. It is this chemical that is largely responsible for many of the physiological consequences alcohol exerts on the body. This compound is eventually broken down further by aldehyde dehydrogenase 2 (ALDH2) in the cell's mitochondria where it is converted into the acetate: acetic acid (CH_3COOH), whose effects include depression of the central nervous system. The acetate is eventually metabolized to form either carbon dioxide (CO_2) in the heart, skeletal muscle, and brain cells; or to form acetyl CoA ($C_{23}H_{38}N_7O_{17}P_3S$), which plays an important role in the production of energy and the neurotransmitter acetylcholine [7].

The rate at which alcohol is eliminated from the blood has been found to be on average 0.015% per hour, but as high as 0.06% per hour. Given that most standard drinks contain approximately 0.06% alcohol by volume, this estimate suggests that the body can eliminate up to one

alcoholic beverage each hour. However, a number of factors influence the rate of metabolism, including a person's genetics, gender, ethnicity, types and levels of enzymes present in the metabolic system, amount of food present in the stomach, and other variables as well. Recent research has suggested that the rate at which alcohol is absorbed and metabolized can vary by as much as three to four times across individuals. However, new research methods that allow precise dosing and specially grown cultured cells show promise in improving our understanding related to alcohol metabolism [6].

Effects of Alcohol on the Human Body

The effects of alcohol on the human body are numerous. Perhaps the area most widely studied with respect to the physiological effects of alcohol concerns its impact on the brain. Research has demonstrated that different regions of the brain vary in their levels of sensitivity to alcohol. Unlike other psychotropic drugs, which tend to target the receptors for specific neurotransmitters, alcohol appears to exhibit an influence over a number of areas and in variety of ways. Receptor sites for the neurotransmitters gamma-aminobutyric acid (GABA, implicated in inhibition of anxiety), *N*-methyl-D-aspartic acid (NMDA, which may be implicated in the physical dependence of alcohol), and serotonin (implicated in mood regulation) are just a few examples of those that have been shown to be specifically influenced by the presence of alcohol [1].

It has already been noted that alcohol is quickly and easily mixed with the bloodstream and distributed throughout the body. In fact, this process occurs so quickly that alcohol carried by the circulatory system can reach the brain in less than 1 min after consumption. Because of the way the vascular system is structured in relation to the brain, the blood (and consequently the alcohol) reaches the outer cortical areas first, before making its way inward and downward through the brain structures. This pattern suggests that the first areas of the brain to be affected by alcohol are those responsible for higher order processing (affecting such domains as judgment, decision making, and inhibition), followed by lower order processing centers (affecting coordination, memory, emotion, and sensory processing), and finally reaching the more primitive areas of the brain (affecting levels of consciousness and life functions such as breathing and heart rate).

While the initial impact of alcohol on the brain may be immediate, the consequences of prolonged use have longer-lasting effects. Many of these effects are not seen during the childhood or adolescent years (i.e., liver cirrhosis, hepatitis, etc.) because their onset and course generally require longer periods of development than adolescence affords. Despite this, recent studies have begun to demonstrate the negative impact of moderate to heavy alcohol consumption among adolescents. These findings include lower levels of sex hormones (estrogen in females, testosterone in males), lower levels of growth hormones, increased levels of liver enzymes typically identified as indicators of liver damage, and lower bone mineral density [3]. Further, alcohol use in adolescence is associated with decreased hippocampal volume (associated with memory impairment), abnormalities in the corpus callosum, and overall smaller brains when compared to control groups of adolescents who did use alcohol [5].

Beyond the problems already discussed, there also exists growing evidence that alcohol use during adolescence may further lead to long-term physiological consequences. One suggestion is that because of the rapid growth and development taking place during adolescence, exposure to alcohol during this critical period may disrupt cognitive development in such a way that it may predict future psychological and physiological concerns [3]. There remains much to be learned with respect to the short- and long-term impact of alcohol consumption among adolescents. Moreover, the preliminary findings already discussed, along with the recently observed trends in adolescent alcohol consumption (see "Drinking," this volume) underscore the need for continued investigation into this important area of research.

One final area that must be addressed concerns the impact of others' alcohol consumption on child and adolescent development. Children can experience the effects of others' alcohol use both directly and indirectly. For example, the social environment plays a significant role in adolescents' decisions to consume alcohol, particularly with respect to the influence of parents and peers [2]. Further, among the more notable examples of direct consequences to childhood development are the fetal alcohol spectrum disorders, including fetal alcohol syndrome.

Fetal alcohol syndrome is one of the leading causes of birth defects as well as a leading cause of mental retardation. The disorder is believed to develop prenatally as a result of heavy drinking by the mother during pregnancy. Because alcohol is distributed so easily throughout the circulatory system and because the developing fetus receives its blood supply from the mother, the mother's alcohol consumption can have a direct and negative impact on the fetus's development. The problems associated with fetal alcohol syndrome are many. Children with this disorder tend to exhibit retarded growth; cognitive, neurological, and motor deficits; learning difficulties, and social and behavioral problems. They may also display a number of permanent physical abnormalities, particularly

with respect to craniofacial malformations. These can include widely spaced eyes, small eye openings, and skin folds at the corners of the eyes; a short nose and lower nasal bridge; small head circumference, small midface, and receding chin; thin upper lip and a groove between the nose and upper lip. Often brain development is also impaired, with a number of brain structures including the corpus callosum, cerebellum, and basal ganglia showing decreased volume and size.

Summary

In summary, alcohol represents a significant problem for children and adolescents throughout their development. The consequences associated with exposure to alcohol during critical developmental periods accentuate the severity of this problem. While a majority of the available research has focused on the effects alcohol has on the brain and central nervous system, it is clear that the consequences are many and far reaching. Many questions still remain regarding the extent to which the chronic and severe alcohol-related problems observed in adulthood will also be observed in adolescence. However, the relationship between early alcohol use and later alcohol-related problems has already been established. Despite the magnitude of the current problems associated with alcohol and adolescent populations, new technologies and research methodologies suggest our understanding of these important issues will continue to improve as future investigations are undertaken.

Alcohol Exposure

Lisa Kilanowski-Press
Niagara University, Niagara, NY, USA

Synonyms

Alcohol exposed; Alcohol related neurodevelopmental disorder (ARND); Fetal alcohol effects; Fetal alcohol spectrum disorder (FASD); Fetal alcohol syndrome (FAS); Prenatal alcohol exposure

Definition

The term alcohol exposure is used to denote the adverse effects of maternal alcohol consumption on the developing fetus. Alcohol exposure is a general term representing the wide spectrum of physiological, cognitive, and behavioral difficulties resulting from varying degrees of alcohol use during pregnancy.

Description

The term alcohol exposure is used to denote the wide spectrum of difficulties that may arise from maternal consumption of alcohol during pregnancy. Conceptually, alcohol exposure serves as a broad umbrella encompassing the multitude of physiological, neurological, behavioral, emotional, social, and academic deficits resulting from the teratogenic effects of alcohol in utero. Fetal alcohol syndrome (FAS), fetal alcohol spectrum disorder (FASD), and

alcohol related neurodevelopmental disorder (ARND) are specific terms used to characterize the varying degrees of impairment that result from maternal alcohol consumption. Alcohol exposure serves as a general term used to indicate exposure to alcohol during pregnancy without describing the degree of resultant fetal impairment. Historically, FAS has been viewed as the form of alcohol exposure resulting in the most severe physiological, cognitive, and behavioral impairments in children.

Contemporary base rate estimates suggest that between 9 and 10 per 1,000 live births or 40,000 children are diagnosed with alcohol exposure each year, with relatively fewer (2.8 per 1,000 live births) diagnosed with FAS [1, 2, 4]. Diagnostic criteria for FAS is well defined and includes the presence of facial dysmorphia (lack of philtrum or ridge between mouth and nose, widely set eyes or small eyes, and thick upper lip), growth deficiency (low body weight and height), and central nervous system dysfunction (structural brain damage and/or cognitive impairment). However, whereas criteria for FAS is definitive, criteria for alcohol exposure, also referred to as FASD, is often vague, and may only include only one or two of the aforementioned genres of impairment or impairments in behavioral, emotional, and social functioning [1, 4].

Holistically, those diagnosed with any form of alcohol exposure may experience a plethora of impairments ranging in severity from mild to severe. The most common cognitive impairment resulting from alcohol exposure is a reduction in overall IQ, with reductions ranging from 7 to 35 points below the mean; alcohol exposure, specifically FAS, is the most common cause of mental retardation in the Western hemisphere [1]. Other cognitive deficits common among those with alcohol exposure include reduced verbal comprehension ability, memory deficits, and difficulties in social learning and applying social norms. Executive function deficits, including difficulty sustaining attention, planning, organizing, and inhibiting are exceedingly common. Those diagnosed with alcohol exposure are particularly prone to emotional and behavioral challenges, including hyperactivity, aggression, oppositional behavior, stereotypical behavior, and inappropriate sexual behavior, among others [1]. Both externalizing difficulties, as previously mentioned, and internalizing difficulties, such as depression, anxiety, and low self-esteem, are common, although some have asserted that continued parent alcohol use in the home, as opposed to the effects of alcohol exposure in isolation, is to blame for many behavioral challenges [3].

In sum, it has been estimated that between 84 and 94% of those diagnosed with alcohol exposure experience behavioral and emotional challenges. Common diagnoses found among the alcohol exposed population include ADHD, depression, oppositional defiant disorder, conduct disorder, and bipolar disorder [1, 3, 4]. Cognitive, behavioral, and physiological difficulties have been found to persist into adulthood, with some dissipation in the appearance of physiological symptoms. Many of those diagnosed with alcohol exposure have been found to become dependent on alcohol use in adulthood [4].

Relevance to Childhood Development

Alcohol exposure, whether mild or severe, often leads to pervasive and persistent cognitive and behavioral difficulties influencing the individual throughout the lifespan. Early detection and intervention has been cited critical first steps toward mitigating the influence of alcohol exposure on overall well-being [1]. Previously cited cognitive and behavioral sequelae manifest during childhood and stand to greatly impede academic performance. Those working with children affected by alcohol exposure must be attuned to the unique presentations of the disorder and resultant academic difficulties should proper intervention ensue. Given the breadth of challenges and needs that may arise as a result of alcohol exposure, comprehensive academic and behavioral intervention plans and supports are frequently warranted as part of both general and special education programming. While consideration for special education programming is not necessary in all cases of alcohol exposure, design of appropriate Individual Education Plan goals and objectives, including consideration of behavioral and social/emotional supports, is integral in cases where special education is required. Careful attention should be paid to student needs surrounding attention, planning, organization, and self-regulation. Completion of functional behavior assessments (FBA's) and resultant behavior intervention plans (BIP's) should occur in cases where behavior is found to impede learning and social functioning, regardless of eligibility or need for special education supports. School based counseling can prove helpful in assisting students struggling with issues related to peer interaction, self-esteem, and other internalizing or externalizing behaviors.

Allele

Definition
One member of a pair located on the same points of a pair of chromosomes.

Description
Individuals inherit two alleles for each gene. One allele is inherited from each parent. Various alleles produce variations of inherited characteristics. For example, if both alleles are the same, the person will inherit dark hair. However; if each allele is different, the dominant gene will override the recessive gene. If one allele has the characteristic of dark hair and the other allele has the characteristics for light or blonde hair, the dominate gene for dark hair will override the gene for light or blonde hair.

Allport, Gordon Willard

Jim Anderson
Oklahoma State University, USA

Life Dates
1897–1967

Educational Information
After graduating second in a class of 100 from Glenville High School in Cleveland, Gordon Allport attended Harvard beginning in the fall of 1915 [7]. By 1919, he had earned his bachelor's degree majoring in psychology and social ethics [10]. After graduation, Allport spent a year teaching English and sociology at Robert College in Constantinople. During this time Allport was offered a graduate fellowship at Harvard, and so he returned to earn a Ph.D. in psychology finishing in 1922 at the age of 24 [6, 7]. His dissertation, *An Experimental Study of the Traits of Personality: With Special Reference to the Problem of Social Diagnosis*, reflected his dual interests in psychology and social issues [10].

After completing his Ph.D., Allport was awarded the Sheldon Travelling Fellowship and spent the first year of the fellowship in Germany and the second at Cambridge

University. At the end of the fellowship Allport was offered an instructor position in social ethics at Harvard [6]. He remained there for 2 years and then accepted a position as assistant professor in psychology at Dartmouth. In 1930, after 4 years of teaching at Dartmouth, he returned to Harvard and would finish his career there [10].

Accomplishments

Allport's early focus was on personality. He stated that "No other psychologist, at least at Harvard, seemed to be interested in social values as an academic problem nor in developing a lifelike psychology of personality" [7]. He is generally thought to have been the first person in North America to teach a college level course on personality [10]. As a faculty member, he helped to establish at Harvard the Society for the Psychological Study of Social Issues, the Department of Social Relations, the Department of Sociology and served 18 years as the chair of the Committee on Higher Degrees of the social relations department.

The book *Personality: A Psychological Interpretation* [1] was an important introduction of his theory of personality [6]. Gordon would continue to write a proliferation of articles and books. Among his more influential books are: *The Nature of Prejudice* [2], *Becoming: Basic Considerations for a Psychology of Personality* [3], *Pattern and Growth in Personality* [4], *Letters from Jenny* [5], *The Person in Psychology* [7] and *The Psychology of Rumor* [8].

Contribution

Allport argued that psychology should use both idiographic and nomothetic methods. It was his assertion that the discipline focused too much on nomothetic approaches and he insisted that if you wanted to know something about an individual you should ask that individual first [10]. He believed every person was unique and that the best way to study psychology was to evaluate the healthy person [9]. Perhaps his most radical and best known concept is that of functional autonomy. Allport believed that while adult motives developed out of childhood drives, adult motives become independent. In other words, motivation occurs independently from past experiences.

Allport's personality theory asserted that within individuals were real traits that helped guide behavior. He classified these traits into two major categories: (a) common traits, traits that may occur among a group of people in any culture, and (b) individual traits, traits that are uniquely expressed within the individual. He further divided these traits into three levels. The first was what he referred to as cardinal traits. These were traits that were so dominant that the bulk of a person's behaviors could be linked directly to them. The second level was central traits. These referred to characteristics that were easy to detect and each person possessed an average five to ten. The third level was secondary traits. He believed these were harder to detect and only persons who were close friends of the individual may even be aware of these traits. While Allport attempted to identify each type of trait, he believed they acted in an interdependent way. None of the traits were separate from the influence of the others, and the trait that exerted dominance was highly dependent on the situation.

Altricial

Merry Sleigh
Winthrop University, Rock Hill, SC, USA

Synonyms

Neoteny; Nidicolous

Definition

An immature state of development following birth or hatching that necessitates care by others.

Description

Altricial animals are born in an immature state and unable to care for themselves. Owls, kangaroos, cats, dogs, and humans are examples of altricial species. In contrast, precocial organisms are mobile and independent within hours or days following birth or hatch (e.g., ducks, zebras). Because of the extensive care altricial organisms require, they are usually born as singletons or in small numbers into social groups where there is the opportunity to have more than one caregiver.

Humans require care for a long period of time and reach sexual maturity and adulthood after a long period of postnatal development. The benefit of this lengthy period of immaturity is that the nervous system has an extended period to develop, ultimately resulting in more complexity and greater cognitive ability. Infancy, childhood and adolescence provide humans with a range of experiences, each of which have the potential to shape the nervous system and the organism's capabilities [1].

Relevance to Childhood Development

At birth, the human brain is not fully developed and has great plasticity. The vast majority of neurons (i.e., nerve cells) are created during the prenatal period; however, the brain continues to grow and reconfigure throughout the lifespan. The most dramatic postnatal changes occur during infancy and childhood [4]. As the young organism experiences the world, neurons that are activated will form communication pathways with other active neurons. These pathways become stronger with continued use. At the same time, unused neurons die off, allowing room for the communication network and increasing the brain's efficiency [2]. Proper nutrition, a stimulating environment, and positive social interactions facilitate this development and are necessary for the brain to reach its full potential [3].

Ambien (Zolpidem)

Nicholas J. Balogh
University of Missouri, St. Louis, Columbia, MO, USA

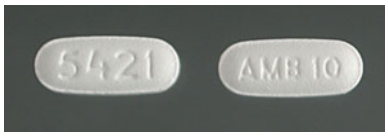
Synonyms

Hypnogen; Myslee; Nimadorm; Nitrest; Sanval; Stilnoct; Stilnox; Z drug; Zoldem; Zolfresh; Zolpidem; Zolt

Definition

A nonbenzodiazepine (imidazopyridine structure) hypnotic drug utilized mainly with insomnia and other sleep disorders, but also used in patients with brain injury. It is chemically distinct from previous generations of

Ambien (Zolpidem). Fig. 1



Ambien (Zolpidem). Fig. 2

hypnotics such as the barbiturates (e.g., Seconal) and benzodiazepines (e.g., Halcion, Restoril). It potentiates (increases amounts of) GABA, an inhibitory neurotransmitter. It was introduced to the public in the early 1990s by G.D. Searle & Company, and is a controlled drug (U.S. Schedule IV).

Description

Ambien mainly affects the benzodiazepine (GABA-A) receptor site, and at high doses, possesses anticonvulsant, myorelaxant, and anti-conflict effects, but nearly all doses possess rapid-onset, short duration hypnotic properties [1]. Its safety and effectiveness in children has not been confirmed, and should be used only under "extreme caution" [6]. In a meta-analysis of newer hypnotic drugs published in JAMA [2], only minor differences were evident between Ambien and other hypnotics such as benzodiazepines, both classes of drugs produced reliable improvements in sleep parameters of patients with chronic insomnia. Previous studies involving 1,894 patients had a median treatment duration of 7 days [2], however, a study of intermittent (when deemed necessary by the patient) use of 10 mg Ambien indicated effectiveness, with no evidence of dose dependency, discontinuation syndromes, or dose escalation [3]. A 1997 study found a lack of re-bound insomnia with Ambien, unlike Halcion (triazolam) [5].

Adverse effects such as Ambien-induced psychosis are rarities. Nonetheless, there have been cases of psychotic reactions in Ambien patients without a history of psychosis. A 1996 study of these reactions discovered all the patients who experienced psychotic reactions with the drug were female, criterion for Ambien dose dependency were met, and the adverse reaction quickly resolved once the drug was no longer administered [4]. As with most sleeping pills, Ambien should not be used in conjunction with alcohol or other depressants, which tend to have a synergistic effect on the central nervous system.

Ambivalent Attachment

Raquel Plotka
Fordham University, GSAS, New York, NY, USA

Synonyms

Anxious attachment; Attachment classifications; Attachment patterns; Attachment styles; Insecure attachment; Insecure-resistant attachment; Resistant attachment; Strange situation

Definition

Ambivalent attachment is a form of insecure attachment characterized by inconsistent responses of the caregivers and by the child's feelings of anxiety and preoccupation about the caregiver's availability.

Description

Ambivalent attachment is one of the attachment patterns categorized in the Strange Situation, and it is classified

as C. This type of attachment is characterized by caregivers who respond to the infant's needs in inconsistent ways, sometimes being neglectful and sometimes responsive. The infant develops an anxious and preoccupied pattern of attachment in which he or she is not sure when the caregiver will respond to his or her needs. As a coping mechanism, the infant develops two strategies, one of clinginess and proximity seeking, and one of avoidance, indifference, or resistance [5]. In the Strange Situation ambivalently attached infants display puzzling behavior. They are extremely distressed by the departure of the parent, yet, they are not easily soothed by the parent's return. At the reunion they alternate between seeking proximity and avoiding or resisting contact, and do not return to play quickly [1].

This group of infants is the least understood, because they constitute a small percentage of the non-clinical population, and approximately 7–15% of United States infants fit this classification. The Strange Situation behavior of these infants reflects internal working models of the caregiver, the self, and the world as inconstant and unreliable. These infants are different than insecure-avoidant children, as insecure avoidant children have developed working models of consistent unavailability of the caregiver, and have developed a strategy accordingly. However, insecure-ambivalent children have inconsistent models of both availability and unavailability. These multiple contradictory mental models of attachment create insecurity in the child and do not leave cues for a clear approach to regulate emotions. Because of the deficit in the internal self-regulatory capacities, the child's sense of uncertainty gives him or her an urgent internal need for comfort of others [2].

The inconsistency of responses forces these children to develop a strategy in which they focus their attention in the attachment figure, centering their efforts in predicting or influencing the caregivers' attitude and states of mind. This way, both the clinging and resisting behaviors are aimed at attempting to attract the caregivers' attention and responses. Furthermore, infants feel the need to monitor their caregivers and stay close to them to assure access. This heightened attachment behavior limits the opportunities for exploration [2].

Home observation of maternal behavior of ambivalent infants has shown low levels of availability. This relation was observed in Ainsworth's Baltimore study, as during the last 4 months of the first year mothers showed deficits in affection, responsiveness to the infant's crying, sensitivity to infant's signals, cooperation, and acceptance. At the same time, these mothers offered some level of physical comfort, yet inconsistently [1]. Similar results were found in subsequent studies, where ambivalent infants have been observed to experience the least amount of reciprocal interactions and involvement with their mothers at 1, 3, and 9 months compared to infants in other classifications. Additionally, this group of infants experienced a disproportionably frequent number of occasions in which mothers did not respond to their vocalization. Similarly, mothers of ambivalent infants have shown to initiate the least amount of interactions with their babies at 6 months compared to both other groups of infants [4].

Although mothers of ambivalent infants show a pattern of inability, this is not the case when it comes to infant explorations. Studies have shown that these mothers are characterized by intrusion and interference with the infant's attempts to explore the environment. This way, they are less involved in situations in which their infants want their attention and more involved in situation in which their infants do not want their attention. These mothers were observed to initiate interactions when their infants were involved in other activities or were not willing to interact. This maternal behavior seems to contribute to the infant's behavior in the Strange Situation, as maternal interference of the infant's exploration forces the child to redirect all the attention towards the mother. Both the mother's low availability and her intrusion contribute to a single outcome, the development of a child who is extremely dependent and lacks autonomy [2].

Both the child's and mother's behavior are viewed as adaptive strategies. The immaturity and clinginess of the child serves the function of maintaining proximity to the caregiver. However, this relationship places most of the responsibility for maintaining proximity on the infant. The child has developed a strategy of emphasizing immaturity to increase care. This strategy is often used by children when they feel their care is reduced, for example, after the birth of a sibling. In addition to immaturity, the ambivalently attached child has developed an increased monitoring of the mothers, because the child perceives the mother as inefficient and weak. In a way, the infant feels the need to care for her, because if something happens to the mother the infant will lose his or her only sense of a secure base. On the other hand, maternal behavior is interpreted as part of a maternal copying strategy. In the mother's mental model, this pattern of interactions assures her that she is central in her child's life. She denies attention to feel needed and to make the infant feel dependent. Similarly, she interferes with exploration to limit the child's autonomy, and to ensure the child remains available as an attachment figure. The heightened dependency of the child is viewed as reassurance to the mother

that she will be wanted and that the child will remain close. Consequently, the mother's working models present the infant with a situation of inversed roles in the mother-child relationship [2].

It has been argued that the temperament of the ambivalently attached child contributes to the behavior of the Strange Situation, since in general ambivalently attached children display the highest level of irritability and distress during separation. Yet, infant temperament has shown low association with Strange Situation classification. The argument of temperament affecting classification is weak, since the biggest determining factor is not the level of distress but the behavior at reunion, and the combination of proximity-seeking and resisting behaviors is characteristic of ambivalent children with diverse temperaments [2].

Relevance to Childhood Development

Attachment style in general, and ambivalent attachment in particular, are central organizers of experiences and personality throughout development. Ambivalent attachment seems to affect the way the child generates expectation about the self, the environment, and close relationships. This type of attachment puts the child at risk of developing difficult patterns of socialization exhibiting ambivalence and insecurity in intimate relationships through life [5].

Ambivalent attachment has a great impact on the amount, and quality, of explorations of the infant. Research has shown that ambivalent infants play with less toys and objects than infants in the other classifications. As toddlers, they engage in significantly less symbolic play, and as preschoolers they are less likely to initiate social offers to their peers and they are more likely to ignore social offers from their peers compared to children in other classifications. Additionally, they are viewed by other children as more helpless and dependent, and they elicit nurturance from securely attached children and exploitation from avoidant peers. At ages 5–7 children who were previously categorized as insecure ambivalent, have reported to experience the highest level of loneliness. Similarly, ambivalently attached children have shown to be less dominant, less goal oriented, less achievement oriented, and less independent than children with secure attachments at age five [2].

As a result of early patterns of interactions, children who had been characterized as ambivalent tend to place this ambivalence in romantic relationships and to reverse role with their children, using their children as a safe base. Research has shown that parents of ambivalent children generally behave very similar to mothers classified in the Adults Attachment Interview as preoccupied [2]. Mothers classified as preoccupied usually limit children's autonomy and exploration. Additionally, they seem to respond with acceptance most often to infant's expression of fear, and infant's fear usually results in limited exploration [3]. These mothers also ignore or invalidate their infant's expression of initiative during play. Similarly, preoccupied mothers were observed to express greater anxiety when preparing their adolescents for stressful events, directing the conversation towards their own feelings, and expressing lack of confidence in the adolescent's ability to be independent [2].

Children of mothers classified as preoccupied are frequently classified as ambivalent, this seems to be explained by the fact that an ambivalent attachment style results in an adult who is preoccupied, confused, angry and ambivalent in their state of mind in relation to attachments and in turns, reflects that ambivalence in his or her responses to the child. The preoccupied state of mind does not allow the adult to respond affectively to the infant's cues, maintaining a generational cycle of ambivalent attachments [2].

American College of Obstetricians and Gynecologists (ARCOG)

Lynna Lan Tien Nguyen Do
Walden University, Fremont, CA, USA

Description

The American College of Obstetricians and Gynecologists (ACOG) is a professional association of medical doctors specializing in obstetrics and gynecology in the United States.

The mission of ARCOG is to facilitate and promote professionalism, affirm dedication to the educational

process for women's health, and to foster the development of standards for residency coordinators in conjunction with CREOG.

References

American Psychiatric Association

Lynna Lan Tien Nguyen Do
Walden University, Fremont, CA, USA

Description

The American Psychiatric Association (APA) is a medical specialty society recognized world-wide. Its over 38,000 U.S. and international member physicians work together to ensure humane care and effective treatment for all persons with mental disorder, including mental retardation and substance-related disorders. It is the voice and conscience of modern psychiatry. Its vision is a society that has available, accessible quality psychiatric diagnosis and treatment.

Members

The APA is an organization composed primarily of medical specialists who are qualified, or in the process of becoming qualified, as psychiatrists. The basic eligibility requirement is completion of a residency program in psychiatry accredited by the Residency Review Committee for Psychiatry of the Accreditation Council for Graduate Medical Education (ACGME), the Royal College of Physicians and Surgeons of Canada (RCPS (C)), or the American Osteopathic Association (AOA). Applicants for membership must also hold a valid medical license (with the exception of medical students and residents) and provide one reference who is an APA member.

Vision

The APA is an organization of psychiatrists working together to ensure humane care and effective treatment for all persons with mental disorders, including mental retardation and substance-related disorders. It is the voice and conscience of modern psychiatry. Its vision is a society that has available, accessible quality psychiatric diagnosis and treatment.

Mission

The mission of the APA is to:

- Promote the highest quality care for individuals with mental disorders (including mental retardation and substance-related disorders) and their families.
- Promote psychiatric education and research.
- Advance and represent the profession of psychiatry.
- Serve the professional needs of its membership.

Values

- Best standards of clinical practice
- Highest ethical standards of professional conduct
- Prevention, access, care and sensitivity for patients and compassion for their families
- Patient-focused treatment decisions
- Scientifically established principles of treatment
- Advocacy for patients
- Leadership
- Lifelong professional learning
- Collegial support
- Respect for diverse views and pluralism within the field and the association
- Respect for other health professionals

American Psychiatric Association Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)

Lynna Lan Tien Nguyen Do
Walden University, Fremont, CA, USA

Description

The *Diagnostic and Statistical Manual of Mental Disorders* (DSM) is the standard classification of mental disorders used by mental health professionals in the United States. It is intended to be applicable in a wide array of contexts and

used by clinicians and researchers of many different orientations (e.g., biological, psychodynamic, cognitive, behavioral, interpersonal, family/systems). The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (DSM-IV) has been designed for use across clinical settings (inpatient, outpatient, partial hospital, consultation-liaison, clinic, private practice, and primary care), with community populations. It can be used by a wide range of health and mental health professionals, including psychiatrists and other physicians, psychologists, social workers, nurses, occupational and rehabilitation therapists, and counselors. It is also a necessary tool for collecting and communicating accurate public health statistics.

American Psychological Association (APA)

Lynna Lan Tien Nguyen Do
Walden University, Fremont, CA, USA

Description

Based in Washington, DC, the American Psychological Association (APA) is a scientific and professional organization that represents psychology in the United States. With 148,000 members, APA is the largest association of psychologists worldwide.

Mission Statement

APA Bylaws I.1

The objects of the APA shall be to advance psychology as a science and profession and as a means of promoting health, education, and human welfare by

- The encouragement of psychology in all its branches in the broadest and most liberal manner
- The promotion of research in psychology and the improvement of research methods and conditions
- The improvement of the qualifications and usefulness of psychologists through high standards of ethics, conduct, education, and achievement
- The establishment and maintenance of the highest standards of professional ethics and conduct of the members of the Association
- The increase and diffusion of psychological knowledge through meetings, professional contacts, reports, papers, discussions, and publications

thereby to advance scientific interests and inquiry, and the application of research findings to the promotion of health, education, and the public welfare.

American Sign Language (ASL)

Lynna Lan Tien Nguyen Do
Walden University, Fremont, CA, USA

Description

American Sign Language (ASL) is a complete, complex language that employs signs made with the hands and other movements, including facial expressions and postures of the body. It is the first language of many deaf North Americans, and one of several communication options available to deaf people. ASL is said to be the fourth most commonly used language in the United States.

Thomas Gallaudet, founded the first school for the deaf in Hartford, Connecticut.

Americans with Disabilities Act (ADA)

Lynna Lan Tien Nguyen Do
Walden University, Fremont, CA, USA

Description

The Americans with Disabilities Act (ADA) is a federal mandated law that prohibits discrimination on the basis of disability in employment, State and local government, public accommodations, commercial facilities,

transportation, and telecommunications. It also applies to the United States Congress.

To be protected by the ADA, one must have a disability or have a relationship or association with an individual with a disability. An individual with a disability is defined by the ADA as a person who has a physical or mental impairment that substantially limits one or more major life activities, a person who has a history or record of such impairment, or a person who is perceived by others as having such impairment. The ADA does not specifically name all of the impairments that are covered.

There are five titles within the ADA that covers specific topics: ADA Title I: Employment; ADA Title II: State and Local Government Activities; ADA Title II: Public Transportation; ADA Title III: Public Accommodations; and ADA Title IV: Telecommunications Relay Services.

Amniocentesis

Robert Sean Bannon
Emporia State University, Emporia, KS, USA

Synonyms

AFT; Amniotic fluid test

Definitions

A common, prenatal medical procedure usually conducted about the 16th week of pregnancy in which a needle is inserted into the uterus through the abdomen and a small amount of amniotic fluid is withdrawn from the amniotic sac surrounding the developing fetus. The fluid, which contains fetal tissues, is examined to determine the presence of genetic disorders and birth defects.

Description

Amniotic fluid, a substance with a consistency similar to water, contains live fetal skin cells and additional chemicals that can be examined during the prenatal period for genetic defects and chromosomal abnormalities possessed by a developing fetus. During the procedure amniocentesis, a small sample of amniotic fluid is withdrawn from the amniotic sac surrounding the fetus. During the analyzation period of 10–12 days, the live fetal skin cells are separated from the amniotic fluid and grown in a laboratory prior to examination. Additionally, levels of *alpha-fetoprotein (AFP)*, a protein found in amniotic fluid, are measured and used to determine the presence of neural tube defects (NTDs). Amniocentesis is not offered to all pregnant women due to the low risk of miscarriage that follows the procedure. Medical professionals offer amniocentesis to those that are considered to have an increased risk for genetic birth defects, chromosomal birth defects or certain malfunctions. Disorders that amniocentesis can be used to screen for include down syndrome, NTDs, cystic fibrosis, fragile X syndrome, sickle cell disease, muscular dystrophy and tay-sachs among others. Side-effects and risks of amniocentesis include mild pain or cramps, period pain, spotting (light vaginal bleeding), fetal injury from the needle (reduced by the use of ultrasound guidance), puncture of the placenta (most common injury, self-healing), bacterial infection, Rhesus disease and in rare cases miscarriage.

Amygdala

Nava R. Silton[1], Ariel Brandwein[2]
[1]Fordham University, New York, NY, USA
[2]Long Island Jewish Medical Center, New Hyde Park, NY, USA

Synonyms

Amygdaloid nucleus; Basal ganglion; Corpus amygdaloideum

Definition

The amygdala is an almond-shaped structure located at the anterior medial portion of the temporal lobe of the brain. It is involved in the perception of emotional and affective stimuli and is therefore considered to be a part of the limbic system.

Description

The word "amygdala" derives from the Greek word for almond, the most common description given to the shape of this structure. Anatomically, the amygdala is a mass of gray matter composed of a collection of nuclei located anterior to the hippocampus and medial to the hypothalamus in the temporal lobe of the brain.

The amygdala receives input from various senses: olfactory, visual, somatosensory and gustatory. It then relays information to other areas of the brain such as the frontal and prefrontal cortex, orbitofrontal cortex, hypothalamus, hippocampus and brain stem nuclei. These connections help control the emotional and physiological responses to perceived stimuli. Some of the physiologic responses induced by the amygdala include vasodilatation of vessels in skeletal muscle, tachypnea, elevated body temperature, localized sweating, bowel hypomotility, sphincter constriction and piloerection. Neurotransmitters involved in the amygdaloid pathways include norepinephrine, serotonin, acetylcholine and dopamine.

In general, the amygdala is considered to be an inhibitory center that prevents response to irrelevant stimuli and allows habituation to repeated stimuli. More specifically, it has been theorized that the amygdala is involved in the inhibition of the activity of the periaqueductal gray (PAG), one of the major structures involved in the interpretation of fear. Normally, the PAG results in protective and defensive reactions. The amygdala suppresses these actions resulting in freezing, a manifestation of learned fear.

It has been suggested that there are two pathways directing input to the amygdala. Both pathways traverse the thalamus prior to reaching the amygdala. However, while one path courses directly from the thalamus to the amygdala, the other path is first diverted to the cerebral cortex. The purpose of this dual pathway is thought to allow two reactions to emotional stimuli to occur. The first reaction is an immediate reaction (the direct path); it allows the body to produce a quick response to potentially harmful stimuli. The delayed reaction travels through the cortex first, allowing the brain to analyze stressful situations in more detail to determine the most appropriate response. Through this combined process, the body can instantly prepare itself for potentially dangerous stimuli. Then, if the stimuli are judged to be less harmful, the initial response can be curtailed.

One of the most well-known functions of the amygdala is its involvement in the perception of fear. By incorporating input from a number of sources the amygdala is able to modulate the physiologic and emotional responses to fear. Moreover, the amygdala maintains a certain degree of plasticity which aids in the creation of short- and long-term memory for those situations. In this way, the amygdala is able to control future responses to those same fearful stimuli. In fact, it is postulated that this idea is, in part, responsible for the extinction of phobias through proper conditioning.

Research has suggested that the short- and long-term memory created by the amygdala is done so in an indirect manner. The amygdala secretes neuromodulatory substances in response to emotional situations. Adrenergic, cholinergic and glucocorticoid transmitters are thought to enhance the memory created by those situations. Gamma aminobutyric acid (GABA) and opioids tend to impair these memories. Once GABA and opioids are secreted by the amygdala, these substances influence the memory centers of the brain to either strengthen or weaken the memories for those events.

In addition to fear, the amygdala has also been implicated in the processing of stimuli involved in eating, drinking, sexual desires, aggression, reward and punishment. Unfortunately, in contrast to what is known about its function in the perception of fear, the involvement of the amygdala in other emotions has been less well studied.

According to LeDoux [4], the amygdala begins storing information relating to the body's physical state as early as three months of gestation and as late as five years old. For

example, if a pregnant mother became frightened from a house fire and experienced an appropriate physiologic response (i.e. tachycardia, tachypnea, muscle tension, etc.), the fetus would experience the same physical state which would be stored as a memory by the amygdala. In the future, if that person were to be confronted with a similar situation, the frightening experience would be re-triggered.

Changes in the amygdala have been associated with a number of conditions such as post traumatic stress disorder (PTSD), attention deficit and hyperactivity disorder (ADHD), phobias, panic disorder, schizophrenia, depression and autism. More generally, it is thought that the involvement of the amygdala in these situations is related to an increased level of fear and anxiety that is often found to be a comorbidity of those disorders.

There are theories that have suggested that the involvement of the amygdala in some of the above conditions is related to its initial overactivity. The result is an overexcitation of neurons that causes the death of cells in the amygdala and a reduction in its size. As an example, this theory has been proposed as part of the mechanism in the development of depression. In fact, some researchers have postulated that anti-depressant medications may serve to reduce overexcitability thereby preventing the destruction of neurons.

Lesions of the amygdala, such as in Kluver-Bucy syndrome, have been associated with changes in emotion and appetite. Patients exhibit hyperorality, bulimia, hypersexuality and aggression. These lesions may be due to insults such as trauma, infection, seizure activity and tumors. Depending upon the cause of the lesion, the presentation of these symptoms may last only a few days or may be more permanent.

Relevance to Childhood Development

The intact functioning of the amygdala is crucial to the proper development of emotional states and their physiologic manifestations. The memories created by the amygdala early on in life allow the body to react appropriately at a later stage when posed with similar situations.

Changes in the amygdala have been linked to the development of autism in childhood. More specifically, it has been hypothesized that the amygdala plays a role in the recognition of facial expressions. Experiments focusing on monkeys with lesioned amygdalas have shown impaired social interactions in those monkeys, one of the key features of autism. However, others have argued that the lack of social interaction in these monkeys is not due to autism, but rather to a greater degree of fear which is no longer inhibited by an intact amygdala.

Additionally, Bauman et al. [1] conducted a study in which a group of juvenile monkeys had their amygdalas lesioned. They demonstrated that following one year of typical development, these monkeys began to develop stereotypical behaviors, another defining characteristic of autism. However, given the delay of one year in the development of stereotypies, it has been suggested that it is not a lesion to the amygdala itself that induces this behavior, but rather an alteration in the neural circuits involving the amygdala.

ADHD, a relatively common condition in children, has also been associated with changes in the amygdala. A study conducted by Plessen et al. [8] demonstrated that although the size of the amygdala did not differ between control and experimental subjects, the size of individual sub-regions was found to be smaller in children with ADHD. Moreover, morphologic disturbances in the amygdala may interfere with normal processing of fearful situations which may disrupt emotional learning and the drive to sustain attention to otherwise mundane stimuli.

Research has also indicated that there may be alterations in the pathways between the amygdala and the orbitofrontal cortex in children with ADHD; these pathways normally support decision-making and reward reinforcement. The disturbed connectivity of these two areas in children with ADHD may result in more impulsive behaviors and in preferences for smaller immediate rewards. Some of these pathways involve noradrenergic and dopaminergic activity. Therefore, stimulant medications which potentiate noradrenergic and dopaminergic transmission may help to enhance the cognition of children with ADHD.

Anabolic Steroids

Steuart T. Watson, Tonya S. Watson
Miami University (OH), Oxford, OH, USA

Synonyms

Medical terms: Anabolic-androgenic steroids (AAS); Street terms: Gas, Gear, Juice, Roids

Definition

Anabolic steroids refer to a broad class of drugs that have both anabolic and androgenic properties that can be administered either by injection, taken orally, or via a transdermal patch.

Description

Anabolic steroids have two primary properties: (1) anabolic, which refers to an increase in protein synthesis which results in increased muscle tissue, and (2) androgenic, which refers to promoting the development of masculine sexual characteristics (e.g., deep voice, body hair).

Anabolic steroids were "invented" in the 1930s by chemists seeking to isolate the powerful male hormone produced by the testes. This hormone became known as testosterone, a combination derived from the words testicle, sterol, and ketone. Perhaps the first reference to using testosterone for muscle building purposes appeared in *Strength and Health* magazine in 1938. The use of injectable anabolic steroids to enhance performance was vigorously pursued by the Soviet Union and other Eastern bloc countries, beginning in the 1940s. Due to the success of athletes from the Soviet Union and, primarily, East Germany, the U.S. Olympic team physician Dr. John Ziegler helped to develop a steroid for use by American weightlifters (Dianabol). Dianabol was approved by the FDA in 1958 [3].

The medical establishment seriously harmed its credibility over the issue of steroids by asserting that they were ineffective for promoting gains in muscle mass or for enhancing athletic performance. Their position was based on a number of flawed studies conducted over the course of two decades. Literally thousands of athletes were aware of the effectiveness of steroids. More recent studies confirm what athletes have long known; mainly that steroids increase muscle mass, decrease fat mass, and generally improve athletic performance [4].

Relevance to Childhood Development

There are a number of adverse side effects noted with the use of anabolic steroids. It is important to note that many of these effects are only seen when steroids are taken at extremely high doses and/or for extended periods of time. Some of the most common side effects in males include increased acne, enlargement of breast tissue (gynecomastia), testicular atrophy, and premature baldness for those who are genetically predisposed. In females, the most common side effects include increased acne and body hair, enlarged clitoris, and disruptions in the menstrual cycle. Less common, and sometimes debated, side effects may include high blood pressure, liver damage (primarily associated with high doses of oral steroids), cardiac problems, structural changes in the heart (especially thickening of the ventricle) and behavioral/personality changes (increased aggression, psychosis). For the adolescent user, one of the main concerns is the premature closure of the epiphyseal fusion which would shorten the length of bones, and increased frequency and duration of erections [1].

Anabolic steroid use among adolescents is estimated by various studies to range from about 1–4% [2]. Most of the adolescent users, who tend to be male, participate in some type of competitive sport. Thus, they are using steroids primarily to enhance performance as opposed to augmenting the appearance of their physique. Although some believe there is a link between suicide and adolescent use of steroids, there are no data confirming this supposition. In addition, despite the popular notion that steroid users experience "roid rage," there are no data demonstrating that steroid use actually causes one to behave more aggressively [1].

Analysis of Variance

Elizabeth G. E. Kyonka
West Virginia University, Morgantown, WV, USA

Synonyms

ANOVA

Definition

Analysis of variance (ANOVA) tests the null hypothesis that there are no differences in the means of measurements from two or more different groups.

Description

Suppose you are interested in determining whether different groups score differently on a particular continuous dependent variable. Calculating the differences between mean scores of each group is straightforward but gives no indication whether the differences are reliable or meaningful. The statistical technique analysis of variance (abbreviated ANOVA) determines whether differences in the average measurements of different groups are meaningful by comparing the variability between groups to the variability within groups.

Assumptions of Analysis of Variance

As with other null hypothesis significance tests, the assumptions of analysis of variance are normality, homogeneity of variance and independence of observations. The assumption of normality simply states that each measurement is sampled from a population that is normally distributed. Generally, this is a reasonable assumption for naturally occurring random variables. Sometimes it is possible to transform distributions that are not normally distributed by taking the logarithm, square root or reciprocal of each measurement. The assumption of homogeneity of variance is that all of the populations observations are drawn from have identical amounts of variability. ANOVAs are generally robust to violations of normality and homogeneity of variance. Independence of observations simply means that there are no confounds, that is, no systematic relationships between different measurements from the same group. Good experimental design can address many potential confounds. If a particular confound is unavoidable, factorial analysis of variance or analysis of covariance (see "*other experimental designs*" below) may be more appropriate.

The Null Hypothesis

The standard hypothesis in analysis of variance is that observations from each group are drawn from populations with the same mean. Because it is assumed in analysis of variance that all distributions are normal with homogenous variance – the same standard deviation – if they also have the same mean, the distributions are assumed to be identical. In other words, if distributions of observations from all groups are normal with the same mean and standard deviation, there is no evidence the observations from each group are not drawn from a single population.

Calculating an F Ratio for a One-Way ANOVA

Four numbers are necessary to calculate an F ratio for a one-way analysis of variance:

1. The total sum of squared residuals represents the total amount of variability:

$$SS_{\text{Total}} = \sum_{i=1}^{n} \left(X_i - \overline{X_{GM}}\right)^2$$

   For each of n observations, the statistical analyst (or, usually, her computer) calculates the difference between the observation (X_i) and the grand mean, the mean of all observations in all groups ($\overline{X_{GM}}$). All of those differences are first squared and then added together.
2. The sum of squared residuals under the treatment effect represents the total amount of variability remaining, or error, when different values are used in estimates for each group:

$$SS_{\text{Error}} = \sum_{i=1}^{n} \left(X_i - \overline{X_{Gi}}\right)^2$$

   For each of n observations, the statistical analyst calculates the difference between the observation (X_i) and the mean of all observations in the same group ($\overline{X_{Gi}}$). Those differences are squared and then added together.

	Sums of squared residuals	Degrees of freedom	*MS*	*F*
Treatment (variability between groups)	$SS_{Treatment} = SS_{Total} - SS_{Error}$ $\sum_{i=1}^{n}(X_i - \overline{X_{GM}})^2 - \sum_{i=1}^{n}(X_i - \overline{X_{Gi}})^2$	$df_{Treatment}$: $N - 1$	$MS_{Treatment}$: $\frac{SS_{Treatment}}{df_{Treatment}}$	$F = \frac{MS_{Treatment}}{MS_{Error}}$
Error (variability within groups)	$SS_{Error} = \sum_{i=1}^{n}(X_i - \overline{X_{Gi}})^2$	df_{Error}: $n - N$	MS_{Error}: $\frac{SS_{Error}}{df_{Error}}$	

3. Treatment degrees of freedom is one less than the number of different groups; if there are N groups, $df_{Treatment} = N - 1$.
4. Total degrees of freedom is one less than the number of observations; if there are n observations (preferably with exactly n/N observations per group), $df_{Total} = n - 1$. The difference between df_{Total} and $df_{Treatment}$ is df_{Error} – the degrees of freedom unaccounted for by differences between groups. $df_{Error} = n - N$.

These four numbers are combined to derive average estimates of variability between and within groups. Those estimates are compared as the F ratio.

An estimate of the total amount of variability accounted for by the treatment effect, or $SS_{Treatment}$, is derived from the total amount of variability and that remaining when the treatment effect is assumed: $SS_{Treatment} = SS_{Total} - SS_{Error}$. Mean squared residuals for the treatment effect, or $MS_{Treatment}$, is an estimate of the average amount of variability between groups determined by $SS_{Treatment}/df_{Treatment}$. Mean squared error, or MS_{Error}, is an estimate of the average amount of variability within groups. It is determined by SS_{Error}/df_{Error}. $MS_{Treatment}$ and MS_{Error} are the numerator and denominator of the F ratio, respectively:

Rejecting the Null Hypothesis

Statistical analysts assess the null hypothesis by comparing the average amount of variability between the different groups with the average amount of variability within groups. The resulting F ratio, named for Ronald Fisher, indicates the probability of obtaining results as extreme as or more extreme than the observed results if the null hypothesis were true. By convention, psychologists usually reject the null hypothesis if that probability is less than one in twenty. That is, they conclude that observations from different groups were not drawn from a single population if the probability of identical or more extreme results (an F ratio as high as or higher than the obtained) is $p < 0.05$.

Other Experimental Designs

One-way analysis of variances compare differences in means of two or more groups, for example, the heights of children in grades 1, 3 and 5. Suppose someone wanted to compare heights of boys and girls separately. They would have six different groups (grade 1 boys, grade 1 girls, grade 3 boys, grade 3 girls, grade 5 boys, grade 5 girls), but those groups would not be completely independent (although the observations would be); grade 1 boys have something in common with grade 1 girls and grade 3 girls have something else in common with them. There would be two factors – sex and education level – involved. In factorial analysis of variance, separate F ratios are calculated for each factor as well as for all possible interactions. If someone wanted to compare heights of the *same* children in grades 1, 3 and 5, he would probably use repeated-measures analysis of variance or multivariate analysis of variance, which are different ways of comparing means when observations are not independent. If someone else was interested in comparing heights of boys and girls of different ages rather than grade levels, she would use analysis of covariance. Analysis of covariance tests the null hypothesis that there are no differences in the means of measurements from two or more different groups, after the variability attributable to a different variable (a covariate, in this case age) has been removed. These variations on analysis of variance allow statisticians to apply the general technique to a wide variety of data.

Analytic Intelligence

Nava R. Silton
Fordham University, New York, NY, USA

Synonyms

Academic problem-solving skills; Componential knowledge; Fluid intelligence; Implicit knowledge

Definition

Analytic intelligence relates to the mental mechanisms individuals utilize to plan and undertake academic and problem-solving tasks, which are often measured in traditional intelligence tests. Analytic intelligence relies on applying internal mental knowledge to solving novel problems rather than on explicit or learned knowledge from prior experience and/or schooling.

Description

Analytic intelligence tasks typically require an individual to provide a single-correct response to well-defined questions involving new information without utilizing crystallized knowledge, or explicit, declarative knowledge from schooling or prior experience. In this manner, analytic intelligence is similar to Cattell's (1963) notion of *fluid intelligence*. Like fluid intelligence, analytic intelligence challenges an individual to contend with novelty, and to adapt one's problem-solving to a new cognitive problem rather than relying on crystallized skills from one's prior education and experience.

The Ravens Progressive Matrices Test (1962), a classic test of analytic intelligence, consists of a set of visual analogy problems. Each problem presents a 3×3 matrix, wherein the bottom right entry is absent and must be designated from eight response alternative entries which lie below the matrix. Each of these entries normally contains one to five figural elements including geometric figures, lines, or background textures. The test-taker is asked to examine the rows and columns in order to determine which rules will be relevant towards identifying the missing entry. This test benefits from strong stability of individual differences, a relatively large number of items for sufficient theoretical and experimental analysis of problem-solving behavior and correlations with measures of general intellectual achievement.

Sternberg's Triarchic Abilities Test (2003) is a more recent test which delineates analytic intelligence, corresponding to his earlier *componential intelligence*, as one of the key forms of intelligence and as imperative for success in academic pursuits. According to Sternberg, analytic intelligence describes the standard psychometric definition of intelligence as measured by academic problem solving tasks like analogies and puzzles. Sternberg asserts that analytic intelligence is comprised of the joint operation of *metacomponents*, *performance components* and *knowledge acquisition components* of intelligence. *Metacomponents* refer to the higher-order processes which utilize executive functioning skills to order, organize and devise which strategy to use to solve performance components. *Performance components* are the basic operations and cognitive processes which afford test-takers the ability to encode stimuli, store information in short-term memory, formulate calculations, perform mental calculations, and mentally compare diverse stimuli and retrieve information from long-term memory. Finally, *knowledge acquisition components* are used to acquire and store new information as in the process of memorization.

Moreover, analytic intelligence can be divided into three subtypes: verbal analytic intelligence, numeric analytic intelligence and spatial analytic intelligence. Verbal analytic intelligence includes *lexical intelligence*, *phrasiologic intelligence*, *narrative intelligence and conceptual intelligence*. *Lexical intelligence* refers to responding quickly to word problems, for instance determining the anagram for inntlelgiece (intelligence) or completing the following word, "l_ngua_e" (language). *Phrasiologic intelligence* refers to sequencing words in a correct order to form sentences while *Narrative intelligence* relates to sequencing sentences in the appropriate order to form a short story. Finally, *Conceptual Intelligence* involves determining which word does not belong and to evaluate the values and attributes of concepts.

Numeric analytic intelligence relates to arithmetic and the completion of a sequence or matrix of numbers since it is the ability to determine the relations between numbers. For instance, a numeric analytic test question may ask an individual to combine 6, 2, 3, and 4 to form 24. A spatial intelligence IQ is essential to complete larger complex formulas. Spatial analytic intelligence encompasses mental rotation, mirroring, translation, comparing shapes, estimating angles and relative distances. For instance, this ability requires one to observe the relationships between complex formulas in mathematical analyses and shapes in geometry. Spatial analytic intelligence is related to both verbal (words, sentences, text and meaning) and numeric (meaning of numbers) analytic intelligence. Spatial intelligence is considered the most pure intelligence despite including some aspects of numeric intelligence (calculating and comparing numbers of lines or dots).

Finally, with regard to gender distinctions in analytic intelligence, Anastasi (1958), Lynn (1962) and Milton (1957) reviewed findings which suggested that males demonstrate superior performance on spatial and analytic tasks but are less successful on measures of verbal ability as compared to females. These findings suggested that while boys and girls may perform equally on social interaction or communication tasks, boys would rely more on analytic abilities while girls would rely more on verbal skills to successfully complete the tasks. While later studies including Coie and Dorval [2] dispute these gender findings, future research will help divulge these distinctions.

Relevance to Childhood Development

Due to the strong correlation of analytic intelligence to general intellectual achievement, analytic intelligence is an important construct for cognitive development in childhood. Furthermore, since the fluid (cognitive mechanic) abilities of analytic intelligence are thought to constrain or support the acquisition or expression of crystallized abilities (cognitive pragmatics) in later life, it is critical to examine various features of analytic intelligence in early life in order to target the full scope of intelligence and intellectual achievement during the life-span.

Anastasi, Ann

Daniel Patanella[1], Chandra Ebanks[2]
[1]New York City Department of Education, New York, NY, USA
[2]Florida International University, Miami, FL, USA

Life Dates

1908–2001.

Educational Information

Anastasi studied at Barnard College, and then earned her doctorate at the age of 21 from Columbia University under supervision from Henry Edward Garrett (1894–1973).

Accomplishments

Anastasi taught at Barnard College and Queens College, where she would be the psychology department's chairperson, before joining Fordham University in 1947. It was at Fordham where she would spend the remainder of her long and successful academic career. Anastasi's early mathematical aptitude translated easily into the world of psychological measurement and, influenced by the work of both Leta Stetter Hollingsworth (1886–1939) and Charles Spearman (1863–1945), she developed a nationwide reputation as an expert – as well as a critic – regarding standardized testing.

Anastasi cautioned against the interpretation of test scores as indicative of primarily genetically-based ability and stressed the importance of environment, nurturing, and learning as components of intelligence testing. Long before the boom in test-prep courses for standardized educational assessments, Anastasi wrote of the dangers coaching presented to the integrity of all standardized tests. Anastasi's conception of test validity as a living document of sorts stands in sharp contrast to how tests are often presented to the public. Anastasi was also an early advocate for the cultural relativism of intelligence, arguing that since different cultures value different aspects of the global concept of intelligence, the very concept of a "culture free" intelligence test is a misleading one.

A prolific author with more than 150 publications to her name, Anastasi's most indelible contributions outside of Fordham University were two influential textbooks, *Differential Psychology* (first published in 1937), and *Psychological Testing* (first published in 1954) [2, 3]. These works have appeared in multiple editions, been translated in several languages, and have been used around the globe. References to them still appear in testing literature, and Anastasi's colleagues remember her as an author with justifiable pride in her meticulous attention to both detail and style [1, 4, 5].

A leader as well as an influential author and scholar, Anastasi's multiple professional presidential positions were capped with her 1972 presidency of the American Psychological Association. She was an avid consultant and committee member for both government and private industries, and received honorary doctorates from Villanova University and University of Windsor, among others. The recipient of multiple awards from both academia and professional organizations for her work in testing

and education, Anastasi also received the National Medal of Science in 1987 from President Ronald Reagan.

Contribution

Anastasi enriches psychology with multiple legacies. On the one hand, her important literary contributions to the textbooks of testing and assessment are reminiscent of William James' (1842–1910) contributions to general psychology in that her books are well-written, definitive, and influential upon both practitioners and students alike. Her well-reasoned arguments regarding the misinterpretations of test scores are still timely, continuing the resonance her works still possess. Her many dignified leadership positions provide powerful models for other leaders of professional organizations to emulate, and her list of accolades is astonishing. It is even more astounding that for much of Anastasi's early life, women in the USA faced extreme barriers in pursuing careers in mainstream academic psychology. Anastasi's exemplary accomplishments are even more inspirational within this context.

Anderson-Fabry Syndrome

►Fabry Syndrome

Androgyny

Angela D. Mitchell[1], Lacy Allen[2]
[1]Texas Woman's University, Denton, TX, USA
[2]Florida Institute of Technology, Melbourne, FL, USA

Synonyms

Blended gender; Hermaphrodite; Hermaphroditic

Definition

The presence of a high degree of desirable masculine (instrumental) and feminine (expressive) traits in the same individual. A person who does not fit into the stereotypical masculine and feminine gender roles of their society.

Description

Gender roles have traditionally been well-defined constructs with masculinity being synonymous with aggression, independence, and power; and femininity being associated with nurturance, dependence, and an indifference to being in power [8]). However, in the 1970s, alternatives to the "masculine" and "feminine" sex roles were explored [7]. The concept of androgyny emerged as one of these alternatives – showing that as opposed to the stereotyped gender roles of masculinity and femininity being expressed on a continuum, one individual could present with the most desirable traits from both genders. An androgynous individual might be a male who is assertive while being sensitive to the feelings of others, or a female who is dominant but caring [8].

Psychologists have been fascinated with the gender spectrum; thus, shaping the approach to the study of men and women. In fact, psychologists have developed tests to measure the dimension of masculinity and femininity. However, results and the interpretations of Masculinity–femininity measures (M–F) were based on value judgments, such as it is "better" to be on the feminine side if you are female [5]. In other words, the aforementioned tests base measurements of M-F on assumptions, which decreases the validity and reliability of the tests. However, after 1974, scales were developed to measure masculinity, femininity, and androgyny; thus, expanding the perspective of gender identity [4]. One measure that was developed to assess androgyny is the Bem Sex-Role Inventory [7]. Based on one's responses to the items of the measure, an individual could be classified as having one of four gender-role orientations: masculine, feminine, androgynous, or undifferentiated. According to Bem, men and women who are androgynous are more effective, flexible, well-functioning, and mentally healthy than individuals who present with either masculine or feminine traits alone. Additionally, Stake [10] found that androgyny is linked to lower levels of stress and well-being; and Shifren et al. [9] found that emerging adults who were androgynous reported having better health practices such as using seat belts and not smoking than any other gender role classification.

Using a revised version of the BSRI, Hyde and Phillis (1979), as referenced by [4], tested androgyny across a life span. They discovered younger women and older men were more androgynous; therefore, suggesting that

androgyny is a result of developmental changes rather than do to cohort effects. [4] decided to replicate Hyde and Phillis' study, and in doing so, they found contrasting results. [4] found that both men and women were more feminine in older age, which may have to do with increased dependency and unemployment. Many women were also more androgynous in both young and old ages and more masculine between the ages of 21 and 40. On the other hand, men tended to be more androgynous and feminine at all ages than what was previously thought.

Overall, many gender researchers suggest that, as people age, they respond to life more androgynously. In other words, androgynous people do not restrict their gendered behavior to conform to societal expectations. In fact, the older an individual gets, the more flexible, adaptable, and reliable they tend to be [6].

Anencephaly

Brady I. Phelps
South Dakota State University, Brookings, SD, USA

Definition

Anencephaly taken literally, means without a brain but this is too broad of a definition to be accurate. "Cephaly" as in "cephalic" is term referring to the "head" or the "head end (or head most end) of the body." Anencephaly is a congenital disorder in which the cephalic end of the prenatal neural tube, the antecedent structure to the brain, fails to close early in pregnancy [5]. Individuals born with this cephalic disorder are absent a significant portion of the brain, skull and possibly scalp. The brain that is present is missing the cerebral cortex (the neocortex) of the cerebral hemispheres, the mass of the cerebral hemispheres, the subcortical structures of the cerebral hemispheres (the telecephalon and diencephalon) and most if not all of the structures that normally compose the midbrain (the mesencephalon); the brain tissue is often exposed to the environment. The development abnormalities occur very early in pregnancy, typically between the twenty-third and twenty-sixth day of gestation [2]. For instance, an encephalic infant may have a partially developed medulla oblongata to enable respiration [4].

A website maintained by the National Institute of Neurological Disorders and Stroke [3] (the NINDS) describes anencephaly in the following:

> A baby born with anencephaly is usually blind, deaf, unconscious, and unable to feel pain. Although some individuals with anencephaly may be born with a rudimentary brain stem, the lack of a functioning cerebrum permanently rules out the possibility of ever gaining consciousness. Reflex actions such as respiration (breathing) and responses to sound or touch may occur.

This disorder is one of the most common congenital disorders of the prenatal central nervous system (CNS), with about 1,000–2,000 such births occurring annually in the United States, according to the National Institutes of Health. The exact causes of anencephaly are not known but the variation in the sex ratio of affected embryos seems to suggest that there are perhaps two causes of anencephaly, one of which is environmental and predominantly afflicts female embryos. The other causes may be environmental or genetic, and seems to attack different sex embryos in roughly equal numbers [1]. Possible environmental causes are thought to be high levels of exposure to mercury, chromium, nickel and lead.

At present, there is no therapy or treatment for anencephaly and the prognosis for afflicted individuals is poor. Most infants born with anencephaly do not survive birth; individuals who are delivered alive typically die within a few hours or, at the most, a few days after birth, most often from cardiorespiratory crises [2]. The typical clinical response is to offer nutrition, hydration and other palliative measures. Anencephaly can often be diagnosed prenatally via ultrasound examination [4].

Angelman Syndrome

Samantha M. Nelson, Maria G. Valdovinos
Drake University, Des Moines, IA, USA

Description

Angelman syndrome (AS) is a neurogenetic disorder caused by an abnormality to the maternal chromosome 15. Specifically, the region of 15q11-q13 is mutated or deleted causing the lack of expression of the UBE3A gene. The prevalence for the disorder ranges from 1/12,000 to 1/20,000 births across races and genders [28]. Information about AS has been emerging since the first description in 1965 by Dr. Harry Angelman. In a paper, he described three children having similar symptoms which included abnormal development of the skull, language delay, spurts of uncontrollable laughter, seizure disorder, and jerky movements [1]. Since its first description, over 300 cases of AS have been diagnosed [5].

Genetics

Angelman syndrome is caused by the lack of expression of the UBE3A gene which is located on the critical area (15q11-q13) of the maternal chromosome. This region on the 15th chromosome is called the PWS/AS critical region. Interestingly, another disorder called Prader-Willi Syndrome (PWS) is caused by the same abnormality, but on the paternal chromosome 15 [6]. However, Prader–Willi syndrome has a very different phenotype than Angelman syndrome (see Chapter Prader–Willi Syndrome).

UBE3A is a gene that encodes for a protein that enables an enzyme that facilitates protein turnover. Typically, this gene is expressed on both maternal and paternal chromosomes except in the brain. In the brain, the UBE3A gene is typically activated on the maternal chromosome and inactivated by imprinting on the paternal chromosome in this critical region [29]. This process, genetic imprinting, occurs when genes are expressed differently, depending on whether the genes are inherited paternally or maternally [31]. The absence of the maternal critical region is responsible for Angelman syndrome. Generally, AS is found to occur when there is an abnormality in the critical region on the maternal chromosome and the UBE3A gene function is disrupted. There are four ways the critical region on the maternal chromosome becomes impaired which include: deletion to the critical region, paternal uniparental disomy (PUD), an imprinting defect, and a mutation in the UBE3A gene [32].

The most common genetic cause for Angelman syndrome is a molecular deletion of the critical region on the maternal chromosome and which occurs in 70% of cases [9, 14] This deletion results in the UBE3A gene to be deleted along with four million base pairs [17]. The gene is silenced because it is maternally deleted and paternally inactivated. Individuals with this deletion have the more severe phenotype than their counterparts with AS not due to deletion. Imprinting defects account for 6–10% of AS [17]. Imprinting defects cause a maternal imprinting error. Specifically, the maternal gene assumes the role of the paternal gene and becomes inactivated. Some imprinting defects, specifically imprinting maintenance defects, result in somatic mosaicism [22]. Paternal UPD occurs when the child inherits two copies of the paternal chromosome. UPD is less prevalent and only makes up 3–4% of individuals with AS [7]. In addition, a genetic mutation or partial deletion of the maternal UBE3A gene may cause AS. This only makes up 4–6% of individuals with AS [19]. Lastly, 10–20% of individuals have no signs of genetic mutations to 15q11-q13, but instead have been diagnosed with AS based on presenting clinical features [7, 10, 24, 29]. However, it is possible that some of these individuals may be diagnosed improperly due to shared symptoms with other syndromes. For example, a similar phenotype is observed between those with a deletion of 22q11.3 and a duplication of 15q11-q13 [33].

Diagnosis

A diagnosis for Angelman syndrome is not usually given within the first year because infants are typically born with average birth weights and score within typical development ranges, which obscure other signs of AS. As previously mentioned, the first sign of AS tends to be an unusual electroencephalogram (EEG) reading (diagnostic criteria) [25]. Research has shown 47% of individuals had an EEG before the diagnosis of AS [20]. Angelman

syndrome can be diagnosed 80% of the time with genetic tests such as a high resolution test, fluorescence in situ hybridization (FISH), and methylation analysis. The first test usually done is a methylation analysis because of its ability to give a positive result for a deletion, UPD, or imprinting error. However, the test is unable to detect which of these is the genetic cause. Next, a FISH test or high resolution test will be given to detect any deletions of the critical region on chromosome 15. The high resolution tests are prone to false positives and false negatives, which shows the importance of getting two positive laboratory tests for a genetic diagnosis of AS. The DNA polymorphism test is able to determine if either the paternal or maternal critical regions are deleted. If positive, a second test would need to be done in order to determine whether the diagnosis is Prader–Willi syndrome (deleted maternal critical region) or Angelman syndrome (deleted paternal critical region). In 10–20% of AS cases, there is no evidence for a genetic based diagnosis [10, 24]. In this case, the laboratory tests appear to be typical and evidence for a diagnosis has to come from the clinical features of AS. In addition, an EEG can help diagnose the individual because of its characteristic pattern.

Overall, the diagnosis of AS is important to parents as the genetic basis determines the risk of occurrence of AS in a sibling. There is a 2% risk of reoccurrence with deletion AS and a low risk of reoccurrence for uniparental paternal disomy AS. There has not been a case of recurrent AS due to a typical AS deletion or UPD. In the 10–20% of individuals with AS who do not have a genetic cause, there is the highest chance of reoccurrence and some report a 50% chance [7, 24]. There is one case in which three siblings all inherited the same mutation to chromosome 15 resulting in AS. However, the mother was unaffected as she inherited the mutation from her father and the paternal gene is naturally silenced. Within this scenario, she had a 50% chance of passing that gene on to her children [10, 16]. Given that 5% of the time, it is the mothers who are carriers of the genetic mutation, it is important for parents to get a chromosomal analysis to determine their status [11].

Characteristics of Angelman Syndrome

Individuals with Angelman syndrome display a range of characteristics that differ in severity which is influenced highly by the genetic basis for the disorder [2]. Due to the broad-spectrum of symptoms, characteristics of AS have been split into three categories based on their consistent presentation in individuals with AS: consistent, frequent, and associated. Diagnostic criteria for AS was first produced in 1995 and were updated in 2005 by Williams and colleagues.

Consistent (100%)

- Developmental delay, functionally severe
- Speech impairment, none or minimal use of words; receptive and nonverbal communication skills higher than verbal ones
- Movement or balance disorder, usually ataxia of gait and/or tremulous movement of limbs. Movement disorder can be mild. May not appear as frank ataxia but can be forward lurching, unsteadiness, clumsiness, or quick, jerky motions
- Behavioral uniqueness: any combination of frequent laughter/smiling; apparent happy demeanor; easily excitable personality, often with uplifted hand-flapping, or waving movements; hypermotoric behavior

Frequent (More Than 80%)

- Delayed, disproportionate growth in head circumference, usually resulting in microcephaly by age 2 years. Microcephaly is more pronounced in those with 15q11-q13 deletions
- Seizures, onset usually <3 years of age. Seizure severity usually decreases with age but the seizure disorder lasts throughout adulthood
- Abnormal EEG, with a characteristic pattern. The EEG abnormalities can occur in the first 2 years of life and can precede clinical features, and are often not correlated to clinical seizure events

Associated (20–80%) [32]

- Flat occiput
- Occipital groove
- Protruding tongue
- Tongue thrusting; suck/swallowing disorders
- Feeding problems and/or truncal hypotonia during infancy
- Prognathia
- Wide mouth, wide-spaced teeth
- Frequent drooling
- Excessive chewing/mouthing behaviors
- Strabismus
- Hypopigmented skin, light hair and eye color (compared to family), seen only in deletion cases
- Hyperactive lower extremity deep tendon reflexes
- Uplifted, flexed arm position especially during ambulation
- Wide-based gait with pronated or valugus-positioned ankles

- Increased sensitivity to heat
- Abnormal sleep–wake cycles and diminished need for sleep
- Attraction to/fascination with water; fascination with crinkly items such as certain papers and plastics
- Abnormal food related behaviors
- Obesity (in the older child)
- Scoliosis
- Constipation

Neurological Features. Individuals with AS have a distinct electroencephalogram (EEG) patterns. Although EEG patterns are not all the same for individuals with AS, the characteristic pattern includes rhythmic spiking patterns mainly occurring in the frontal region [20]. Seizures develop 80% of the time in individuals with AS and have been noted to originate in infancy or early childhood [8]. The onset of seizures tends to be earlier, more severe, and occur more often in individuals with a deletion. However, seizures occur in those with both deletion and nondeletion forms of AS. Furthermore, seizures can range in severity from physical trembling of hands and legs to momentary absence seizures. During childhood there are several different types of seizures that can happen which include tonic–clonic seizures, atypical absence seizures, myoclonic seizures, tonic seizures, and status epilepticus. However, myoclonic and atypical absence seizures are most prevalent in adulthood [20, 25] Typically, the seizures tend to subside by age 7–10 [8], but some research reports adults will still likely have reoccurrences of seizures [20, 25]. Regardless of the genetic cause of AS, seizures tend to occur in bursts followed by seizure-free periods that may last months. Seizures are thought to occur spontaneously, but may be elicited by physical activity, fatigue, excitement, infection, and fever [20, 25]. Seizures are hypothesized to occur due to abnormalities of the $GABA_A$ receptor system for which coding lies in the critical region of chromosome 15 [25]. The diagnosis of epilepsy can be difficult due to abnormal jerky movements displayed by individuals with AS. Furthermore, it is possible seizure disorders may be unnoticed or over diagnosed [25]. Additionally, brain development seems to be altered as recent MRI data show that there are delays in myelination and abnormalities in cortical development.

Physical Features

The most prominent physical features of individuals with AS include the inability to manage muscle movements (ataxia), lack of physical development, distinguished facial features, delayed walk, and hypopigmentation. The physical features of AS differs according to the genetic cause of the disorder. Individuals that have a deletion have more severe physical symptoms of AS, while individuals with an imprinting error or UPD tend to have a later onset and less severe physical features.

Physical Development. In almost every case, a child with AS has typical fetal movements, normal levels of amniotic fluid, with a typical birth weight and head circumference. However, parents note the infant tends to be 7–10 ounces lighter than siblings without AS [10]. Although there are no signs of developmental delay at birth, in 100% of cases there is a visible developmental delay between 6 and 12 months [32]. Overtime the child's growth slows and a child may have a smaller head, which may result in microcephaly. Research reports 90% of children with the deletion have microcephaly, compared to 33% of individuals with nondeletions [21]. In addition, it is common for the back of the individual's head to be flattened [21]. Growth retardation is found in 50% of individuals with deletion AS and only in 10% of nondeletion cases [8]. However, height is not severely affected as many adults will be in the normal height range.

Walking. Physical functioning can be highly affected due to a movement disorder found in individuals with AS which constitutes of tremor-like movement of the arms and the legs. These tremor movements likely impact some daily functions such as eating, reaching for objects, and walking. Significant developmental delays are observed in children with AS. On average, children with AS sit at 12–20 months of age and crawl at 22 months [5, 8]. Individuals with nondeletion form of AS start walking, on average, at 2½ years, while individuals with deletion form of AS begin to walk, on average, at 5 years of age [21]. Approximately 10% of individuals with AS never learn to walk [10]. For those individuals who are able to walk, walking is characterized by a distinct gait. Specifically, the arms are lifted, elbows are bent, and hands are turned downward [8, 24]. It is this gait that resulted in the use of the antiquated term "happy puppet syndrome" [14].

Facial Features. Facial features include a pointed jaw, large mouth, spaced teeth, deep set eyes, thin upper lip, and a protruding tongue which is more noticeable when children laugh and may cause excessive drooling. Individuals with deletion AS can have hypopigmentation which includes lighter hair, skin, and eyes. This feature is only found in those with the deletion because the pigment gene, which causes the melanin synthesis, is also deleted [18]. In addition, infants may have a hard time sucking and coordinating tongue movements, which may inhibit infants from getting the nourishment needed [8]. In some instances, infants are diagnosed with failure to thrive.

Beyond infancy, obesity may be problematic. Obesity rates rise from 15% in deletion cases to 50% in nondeletion cases [21].

Behavioral Characteristics

Happy Demeanor. One distinct behavior individuals with AS display is an uncontrollable laughter and an excessive happy demeanor. Many times this "burst" of laughter may be at an inappropriate time and research has shown laughter and smiling occurs more than their counterparts [15, 23]. This excessive happiness can be detected as young as 4–6 weeks as infants smile frequently, with laughter outbursts starting at 10 weeks [8]. There have been mixed reports about the frequency of excessive laughter and smiling (range of occurrence in 57–96% of individuals) [8, 28] Laughter has been noted to occur more frequently before and after seizures and may not always be contextually relevant. Nonetheless, this level of laughter may be heightened by social interaction [15]. Interestingly, research has found that adults with AS smiled and made eye contact more with individuals also diagnosed with AS than individuals diagnosed with other developmental disabilities [23]. Laughter is a behavioral characteristic that has an unknown cause and more research needs to be done to explain why this behavior may occur.

Hypermotoric Activity. Hypermotoric activity is a very common characteristic displayed by children with AS and may be noted as early as infancy and toddlerhood. This activity may manifest as rapid activity change and continuous mouthing of toys [5]. When children are engaged in these activities, they appear to have difficulty attending to social and environmental cues. Consequently, this creates a lack of social interaction which may contribute to language deficiencies associated with AS and may create barrier to learning alternate forms of communication such as sign language, or gestures. Other behaviors such as hand flapping, biting and grabbing others tend to increase as hyperactivity increases. However, hyperactivity seems to decrease with age [9]. Many children with AS do not need medication for these symptoms as they will subside, but behavioral modifications may help reduce unwanted behavior.

Sleeping Problems. Sleeping disturbances are considered an associated characteristic in individuals with AS and have shown to affect between 20 and 80% of individuals with AS. Sleeping disturbances have been speculated to be caused by disruptions in the GABAergic system (see seizure section) [26]. Research shows individuals with AS get a reduced total amount of total sleep (5–6 h), take longer to fall asleep, have frequent night awakenings, and experience less REM sleep with more leg movements than those without AS [4, 8, 26]. The delayed onset of sleep may be due to night rythmias, unstable circadian cycles, and jerky movements before falling asleep [26]. Sleeping disturbances may come in spurts followed by a period of relief from these abnormal sleeping patterns. Despite, these sleep characteristics, some research reports those with AS do not experience drowsiness throughout the day suggesting that individuals with AS may need less sleep than their counterparts. Additional sleep difficulties include problem behaviors such as destroying bedroom furniture [8]. Sleeping problems tend to be worse in childhood and may diminish as adolescence or adulthood approaches [8]. Although decreasing severity and presentation of symptoms are reported as those with AS age (e.g., sleep difficulties, behavior problems), there has not been research to support that increased sleep is responsible for the reduction of these and other characteristics of AS [26].

Activities Enjoyed. Individuals with AS tend to have a heightened attraction to water. Research shows individuals with AS have a higher preference for water than individuals with Down syndrome and other developmental disabilities [13]. Those with AS are often observed jumping in water fully-clothed and going into bodies of water, such as swimming pools and lakes whenever there is an opportunity [8]. In addition, individuals with AS tend to have a love for any shiny or reflective objects. Finally, individuals with AS are reported to also enjoy social activities, humor, and television [9, 29].

Cognition and Language

Speech and language development is contingent upon the genetic basis of AS. Many individuals with AS are not able to speak or may have up to four words [5]. Research has shown that out of 83 individuals with AS, 30% could not speak and 70% were able to speak 1–6 words [8]. However, in some atypical AS deletion cases, those individuals with AS are able to speak 20–30 words. Few individuals with mosaic form of an imprinting center have been noted to speak in simple sentences and over 50 words [22]. This language deficit is apparent early in development (lack of cooing and babbling in infancy and decreased crying and vocalizations in toddlerhood). Toddlers with nondeletions may begin to use nonverbal communication to indicate wants, but hyperactivity creates teaching alternate ways to communicate difficult. Individuals with AS use nonverbal skills mainly for manding (requesting and refusing items) and individuals with AS have a significantly lower ability to tact (label) items, echo and imitate other individuals nonverbal cues compared to other individuals with severe and profound mental retardation [12]. Some less severe cases of AS may learn how to use visual aids and some sign

language, but this is very difficult for children who are more severely affected and unable to establish eye contact with another. Individuals with AS have more success with receptive language and commands [9].

Developmental tests show individuals with AS have a limited range of functional abilities with a developmental level between 24 and 30 months and are often diagnosed with severe to profound mental retardation [27]. Determining the developmental level of individuals with AS is a complicated task due to the lack of speech, hyperactivity, and movement disorders. Furthermore, test scores may be lower than actual functioning and cognitive levels. Adaptive skills are limited as individuals with AS need assistance when taking a bath and getting dressed. Some individuals can be toilet trained, but rarely toilet trained at night [9]. Individuals with AS require supervision at all times given their compromised ability to appreciate danger [9].

Treatment

Angelman syndrome does not have a cure, but many of its symptoms can be treated. One of the most commonly treated symptom of AS is seizure disorders. Seizures can be treated with medications such as valproic acid, topiramate, levitiracetam, and clonezapam. However, carbamazepine has been shown to have paradoxical effects. Many times seizures will decrease with age due to correctly identifying the most effective medication for that particular individual. In addition, a ketogenic diet, which includes consuming four times more fat than protein or carbohydrate at each meal, has been noted to help with refractory epilepsy [30].

Melatonin has been shown to help individuals with sleep disturbances. Research has found melatonin helped eight children with AS start sleeping sooner, decreased sleep latency, and increased the total amount slept. In addition, the number of times individuals woke up during sleep was reduced [3]. However, melatonin has also been ineffective in some individuals [24]. It is important to note the use of melatonin is still a debated issue and more research needs to be done in order to understand the best candidates for melatonin and specifically, the sleeping problems melatonin will help alleviate. In addition to melatonin and medication use, behavior therapy may aid in addressing sleep disorders. Behavioral therapy includes establishing a bedtime routine, finding alternate appropriate activities for the child to engage in while the family sleeps, and finding environmental connection for each individual's sleeping characteristic.

Language development can be difficult and there has not been a specific therapy that has shown to produce effective increases in language. In a few cases of AS, individuals are able to use Picture Exchange Communication System (PECS) or augmented communication devices. Individuals can understand commands given to them and are most successful at this type of communicative approach. Barriers such as hypermotoric activity can cause difficulty when teaching language and new skills making language acquisition easier for older patients with a higher ability to sustain attention [9]. There is some suggestion that massage and aromatherapy can help reduce hypermotoric activity. It is also important to continuously reinforce individuals for gaining new skills and for appropriate behavior [9].

Physical therapy can help the development of walking and other gross motor skills. This further helps individuals from having obesity and creates a healthier lifestyle. In addition, braces can help individuals walk. Other treatments include simple changes that can have a large impact. Bottle feeding can be more effective than breast feeding due to the sucking and difficulty in coordinating mouth movements [8]. In addition, individuals with hypopigmentation have a high risk to sunburn and sunscreen should always be used.

Definition

The angular gyrus is a convolution of the inferior portion of the Parietal lobe that plays an integral part in aspects of language, cognition and achievement, including reading, writing, and mathematical calculations [6].

Description

The Angular Gyrus is a convolution of the inferior parietal lobe that presents as a connecting point of a Parieto–Occipito–Temporal origin. As such the Angular Gyrus represents a cortical association area that provides cross-modal integration of visual, tactile, and verbal information [7]. From a functional standpoint, the Angular Gyrus has been shown to play a vital role in reading, writing, and mathematical calculations [6]. Linkage of the Angular Gyrus with such specific abilities has been best exemplified through lesions analysis. For example, lesions in the dominant hemisphere (i.e., that hemisphere in which language is predominantly housed) that impact the Angular Gyrus may result in alexia (i.e., impairment in reading) and agraphia (i.e., impairment in writing) [4]. This is due to the fact that transmission of neuronal impulses that allow such abilities to be carried out must pass through the Angular Gyrus. For example, reading requires information to be sent from visual areas in the Occipital lobe through the Angular Gyrus and from there to Wernicke's area, which allows one to read silently or, through anterior transmission by way of the Arcuate Fasciculus and in conjunction with Broca's area, which allows one to reads out loud [5]. In regards to writing, the transmission is carried out in a more anterior to posterior direction in which Broca's area works in concert with temporal regions to decipher what is to be written then by transmission through the Angular Gyrus as well as motor systems involved in writing, involvement of the Occipital and Parietal regions allows for the process to be carried out [7]. Given its' involvement in reading and writing, the Angular Gyrus has been proposed as an essential component of the holistic domain of language. One of the most accepted models of language is the Wernicke-Lichtheim-Geschwind (WLG) model, which is an expansion of the WLG. Although the Wernicke-Lichtheim model accounted for oral (i.e., spoken) and aural (i.e., heard) language it could not account for visual language, which involves reading and writing. The model was expanded by Geschwind to include the Angular Gyrus which was proposed to provide the basis for visual language, as its location at the junction between the Temporal, Parietal, and Occipital lobes allows the Angular Gyrus to efficiently receive projections from primary and secondary visual areas, while also providing a region in which associations with anterior circuits may be made [2]. While the Angular Gyrus is mostly related to reading and writing, lesions of this region have been linked to a cluster of symptoms together referred to as Gerstmann Syndrome, which not only involves agraphia and acalculia but also right–left confusion/ disorientation, and finger agnosia [6]. While Gerstmann Syndrome and the idea of it originating from isolated lesions of the Angular Gyrus have received a fair amount of attention, an array of newer research suggests these four symptoms do not occur together as a unitary syndrome, although large lesions of the posterior Parietal lobe, not the Angular Gyrus specifically or singularly may produce such an arrangement of symptoms [1]. While the idea of Gerstmann Syndrome has proposed an extension of the functions the Angular Gyrus plays a role in (i.e., reading and writing) anomic aphasia and alexia with agraphia have also been associated large left-sided lesions in the Angular Gyrus with, in addition to those symptoms associated with Gerstmann Syndrome [3].

Anhedonia

Kristine Augustyniak
Niagara University Academic Complex, Niagara, NY, USA

Synonyms

Dysphoria; Melancholy; Unhappiness

Definition

The word anhedonia acquires its meaning from the Greek works *an-*, without, and *hedone-*, pleasure. Anhedonia is

an inability to experience pleasure from normally pleasurable life events (e.g., eating, social interaction, sexual activity, etc.).

Description

People who suffer from anhedonia may feel an intense sadness for no apparent reason. Furthermore, an individual may lack motivation, become more apathetic, feel tired and display feelings of irritability. In more severe incidences of anhedonia, individuals may develop a feeling of helplessness and/or hopelessness. Anhedonia is recognized as a core clinical feature of the mood disorder Major Depressive Disorder according to both the *Diagnostic and Statistical Manual of Mental Disorders* (4th ed., text revision) (DSM-IV-TR, [1]) and the International Statistical Classification of Diseases and Related Health Problems, Tenth Revision (ICD-10, [7]). As criteria for the diagnosis of Major Depressive Disorder, anhedonia is described as a significant reduction in a person's level of interest in or pleasure derived from most activities, nearly every day for a 2-week period of time (DSM-IV-TR, [1]). It is important to note that not every individual who experiences anhedonia suffers from Major Depressive Disorder or another mental health disorder. Anhedonia is also seen in Schizophrenia, Schizoid Personality Disorder, individual's experiencing substance abuse withdraw, and other mental health disorders [5].

Current research has linked anhedonia to a break down in the brain's Central Reward Pathway. The brain is divided into several distinct regions that are each responsible for performing different functions. The brain can perform highly specialized functions in these regions due to cells called neurons. Neurons are the cells responsible for passing chemical and electrical signals along the pathways of the brain. Of these specialized regions, the ventral tegmental area (VTA) and the nucleus accumbens (NAc) play central roles in the processing of rewarding environmental stimuli and in drug addiction through the release of a neurotransmitter (chemical) called dopamine [5]. Furthermore, in the mesolimbic region of the brain, dopamine-sensitive neurons project from the ventral tegmentum into the medial prefrontal cortex, amygdala, and ventral striatum regions. Reduced activity in the striatum may lead to a failure of the prefrontal cortex to process rewarding experiences due to a decrease in the release of dopamine or an increase in neurons tolerance for dopamine. It is thought that disruption in these areas inhibits the brain from positively reinforcing typically pleasurable life experiences, thereby forcing the brain to interpret characteristically pleasurable experiences as neutral experiences [6].

Relevance to Childhood Development

Anhedonia is typically seen in children who also meet the criteria for Major Depressive Disorder and other affective mental health diagnoses. After years of controversy, professional consensus supports the notion that young children can indeed suffer from depression. Moreover, they tend to exhibit symptoms that are strikingly similar (although not identical) to those of older adolescence and adults with depression. Several empirical research studies of depressive phenomenology have subsequently provided evidence that depressed prepubertal children could be identified using the adult *DSM* classification criteria [3]. However, depression can be difficult to diagnose during prepubertal years, because these children cannot yet verbalize their feelings or inner experiences. Although researchers have noted that children can "mask" their depressive symptoms, the majority of children suffering from Major Depressive Disorder present with an anhedonic affect [2].

Anhedonia in the early elementary school years is often expressed through behavior problems, whereas older preadolescents and adolescents may begin to verbalize feeling of hopelessness and decreased enjoyment from previously enjoyable activities. Additionally, school and peer relationship problems are more commonly seen after the age of six. Children with anhedonia are more likely to be rejected by their peers, be perceived as less likable, and have more negative social behaviors than their peers who do not display anhedonia. Anhedonia can interfere with the formation and maintenance of healthy friendships and further solidify the child's depression and/or anhedonia [4].

Animism

Brian Vandenberg
University Missouri, St. Louis, MO, USA

Definition

Animism is the belief that biological and physical phenomena in the natural world possess conscious intentions and purpose. Thunder, for example, is considered to be the voice of a god, or the moon is a conscious being whose movement is animated by its personal intentions.

Description

The term was popularized in 1871 by E.B. Tylor in his work, *Religion in Primitive Cultures* [4]. Taylor is considered one of the founders of the discipline of anthropology who, following the impetus of Darwinian theory, sought to provide an account of the cultural evolution of religion. Animism, he argued, represents the first, earliest stage of religion, which is found in "primitive peoples" who have no systematic religious doctrine or scripture, who believe that the universe is alive with spirits, souls and supernatural intentions. From this primitive beginning, later, more sophisticated religious beliefs derive. He also argued that animism is the antithesis of materialism, which is a much later developed form of thought that recognizes that biological and physical factors, not spirits, are responsible for the causes and consequences found in the natural world [4].

The investigations by Tylor and other early anthropologists in the nineteenth century influenced the psychological theorists of the twentieth century, notably Freud and Piaget. Freud argued that thought consists of primary processes, which are id driven, seek immediate gratification, and are instinctual; and secondary processes, which are ego driven, seek rational accommodation with objective reality, and develop later. Animism and magical thinking are characteristics of primary process thinking, as id driven wishes and desires are projected onto external reality. These distortions of reality are mitigated and overcome with the development of secondary process characteristic of rational thought. Freud argued that this ontogenetic developmental trajectory parallels the phylogenetic evolution of cultures, from animism to rationalism, described by anthropologists [1].

Piaget addressed animism in his early book, *The Child's Concept of the World*, which has had the most significant impact on developmental research on this topic [2]. Piaget argued that young children are egocentric in their thinking and therefore presume that the world, like themselves, is animated by conscious will and intentions. All things are endowed with life, and movement or activity of any kind necessarily entails purposefulness. As children develop, Piaget asserts that their thought becomes more decentered, and the boundaries between their own experience and that of the world become more differentiated. With development, children's thinking becomes less animistic, more reasoned, and they appreciate that the physical world is governed by material principles, not conscious purposes. Piaget leaves open the question of the relation between the anthropological cultural-evolutionary accounts of animism and his own investigation of ontogeny, but he does consider it an issue worthy of scrutiny [2].

These early social scientists shared a presumptive progressive-evolutionary framework, and considered animism a quintessential expression of primitive thought that is overcome and replaced by more advanced critical, rational processes. Contemporary research, however, no longer shares this framework and animism, thus, no longer serves as a theoretical cornerstone. Consequently, the topic has received much less research attention. Recent research, however, suggests that animism is less pervasive and profound than originally proposed by Freud and Piaget. Young children do, indeed, possess animistic thinking, but they are less egocentric, are capable of much more sophisticated understanding of causality at an early age, and develop sophisticated reasoning skills much more quickly than previously believed [3, 5].

Anorexia Nervosa

Jenna J. Barry
Humboldt State University, Arcata, CA, USA

Synonyms

Anorexia; Anorexic; Eating disorder; Emaciation; Malnourishment; Starving; Without appetite

Definition

Anorexia Nervosa (AN) is an eating disorder primarily affecting adolescent girls and young women (although anorexia in adolescent boys and young men is becoming more prevalent), characterized by pathological fear of becoming fat, distorted body image, emaciation, and excessive dieting.

Description

Anorexia Nervosa (AN) is a form of self-starvation to the point of emaciation. A person must maintain a significantly low body weight (15% below normal body weight for height and age) in order to be diagnosed with AN. He or she must also be continually preoccupied with food and its nutritional values (i.e., calories, fat grams) for fear of gaining weight. This irrational fear of weight gain may cause the person to control his or her eating by skipping meals and starving his or herself, which can lead to hospitalization and sometimes death. Another key symptom of AN is a distorted body image manifested through thoughts, feelings, and perceptions of being overweight, when in reality, the person is extremely thin. A person with anorexia does not see an accurate picture of him or herself when looking in the mirror. Rather, they see themselves as overweight, regardless of their appearance. Amenorrhea, or the absence of at least three menstruation cycles, is also a symptom of AN, but does not apply to males, prepubescent females, or females on birth control.

A common index used to diagnose AN in adults is the Body Mass Index (BMI), a measure of body fat estimated by an individual's height and weight. A BMI of 17.5 or below is a common guideline used for diagnosis. However, this same BMI is translated into percentiles for diagnosing and assessing children and adolescents [1]. AN can affect all parts of a person's life, particularly their social relationships, school performance, and family relationships. Without treatment, it is likely a person with AN will suffer from medical and psychological consequences throughout his or her life. Deaths related to AN are most often due to medical complications (about 50% of cases) compared to suicide (30%) and unknown causes (20%) [3].

There are currently two subtypes of AN, the binge/purge subtype and the restricting subtype. The binge/purge subtype is characterized by episodes of overeating followed by purging behaviors, whereas the restricting subtype severely limits his or her intake of food. However, this classification is controversial as it has not been proven by empirical research. Instead, it is based on expert agreement regarding what is known about the disorder [5]. Researchers have also found the classification system limiting because it restricts the ability to examine the AN spectrum [5].

Physical repercussions of the binge/purge subtype include malnutrition, dehydration, ruptured stomach, organ damage (including heart, kidney, and liver), tooth/gum erosion, and esophageal tears. Psychological consequences for both subtypes include depression, low self-esteem, guilt, shame, impaired family and social relationships, mood swings, and thought disturbances [4].

AN is a serious disorder, affecting nearly seven million women and one million men in the United States alone [4]. About 86% of people with AN report an onset of symptoms prior to the age of 20 whereas about 10% report an onset at age 10 or younger. Approximately 16% of people with AN report having symptoms that last between 10 and 15 years, whereas 30% report symptoms lasting between 1 and 5 years. Six percent of serious cases end in death and 50% of cases report being "cured" [4].

Relevance to Childhood Development

Childhood anorexia is uncommon, as about 4–8% of all cases reported an onset in early childhood with an incidence of 0.15 new cases in 100,000 per year in 2000 [2]. Anorexia in male children (prepubescent; 26–28%) is significantly higher than anorexia in male adolescents (postpubescent; 4–6%). Childhood AN can be difficult to diagnose because children are at a much different

developmental level than adolescents and adults. A child may lack a full understanding of what it means when he or she does not eat. Even while a child's current weight may appear to be proportionate to his or her current height, he or she is still physically developing, so stunted growth is a possibility, especially if the child is suffering from anorexia. In this situation, the child would need careful monitoring by a pediatrician using a growth chart. Children with AN also tend to present physical symptoms such as nausea or feeling full more often than adolescents and adults [4]. With the exception of amenorrhea, children generally exhibit similar symptoms as adults and adolescents with AN.

Major life events, such as the birth of a sibling, moving, or death, are often precursors to the development of childhood AN. These events might lead the child to feel a loss of control or sense of safety, to which the child may respond with food refusal, weight loss, and, possibly, Anorexia Nervosa [2].

Anosmia

Brady I. Phelps
South Dakota State University, Brookings, SD, USA

Definition

In general, the term anosmia is used to refer to the inability to discriminate or detect qualitatively different olfactory sensations, or in simpler terms, an absence of one's sense of or ability to smell [6, 19]. Related terms include partial or specific anosmia, which refer to deficient ability to detect a specific odorous stimulus or a limited class of odorous stimuli [6, 10, 19]. A fairly large number of specific anosmias have been identified [1, 10]. The terms hyposmia or microsmia have also been used to label instances of decreased sensitivity to odorous stimuli [19, 22].

As with most any trait or ability, individuals show variability in their capacity to smell [9]. Some deficits in our olfactory sense are probably normal [4] and it is generally agreed that females report more acute sensitivity to odors than males [3, 12]. It is also reported that a likely majority of humans will experience measurable deficits in their olfactory sense as a function of aging [6]. The ability to smell can be impaired or disrupted by a number of conditions, such as lesions to the brain, particularly of the orbitofrontal cortex area [11, 13]. Blows to and injuries of the head are often followed with deficits in olfaction as the olfactory nerve is easily lacerated [19]. Severe sinus infections can result in total or partial anosmia, as can exposure to some chemicals [6, 8, 19]. An impaired ability to identify odors has been found co-occurring with disorders such as Alzheimer's disease, Huntington's disease, Parkinson's disease, Korsakoff's psychosis, chronic alcoholism, HIV infection and schizophrenia [2, 7, 17, 18]. It is clear that the vast majority of anosmia cases are acquired deficits [6]. The incidence rates of these olfactory deficits range from an estimated 1 to over 50% of the population under and over age 65, respectively [19]; other published reviews reported 67% of some population samples displaying measureable disruptions of the ability to smell, with slightly over 31% showing a complete loss of smell [6].

There is sparse information regarding any genetic or ►congenital basis for anosmia; the main genetic syndrome associated with anosmia is Kallman's syndrome in which there is either a disruption of the requisite prenatal migration of ►neurons from the brain to olfactory structures and or insufficient or absent neuronal synapses

in the olfactory structures and pathways [6]. Kallman's syndrome is a rare condition, with incidence rates found to range between 1 in 10,000 and 1 in over 80,000 persons [21].

The research connections between olfactory dysfunction and the putative effects of as yet to be identified human pheromones have been termed provocative [7] as well as disputed [14]. Despite studies showing evidence of a physiological effect [15, 16, 20], there is little evidence for any actual changes in human behavior resulting from alleged pheromones [14]; although humans do possess most of the same structures involved in the actions of pheromones in other mammals [5], the human circuitry has sparse neurons, few if any neuronal connections to the brain and is likely more vestigial than functional [5, 7].

►Anovulatory Cycle

Anovulation

►Anovulatory Cycle

Anovulatory Cycle

Merry Sleigh
Winthrop University, Rock Hill, SC, USA

Synonyms

Anovular cycle; Anovulation; Estrogen breakthrough bleeding; Estrogen withdrawal bleeding

Definition

A menstrual cycle during which no egg (ovum) is released.

Description

In an anovulatory menstrual cycle, a woman does not release an egg (ovum), resulting in an infertile cycle. The subsequent release of the uterine lining is known as anovulatory bleeding, rather than menstruation. This condition may happen for many reasons, all of which are linked to atypical levels of estrogen, luteinizing hormone (LH), or follicle stimulating hormone (FSH).

The first half of a normal menstrual cycle is concentrated around increasing the uterine lining (endometrium) and releasing an egg. FSH enables immature eggs housed in the ovary to develop. As these eggs mature, estrogen is released. The rise in estrogen triggers the pituitary gland to release LH rather than FSH. The LH surge causes the most mature egg to be released from its ovarian follicle. The empty follicle is now known as the corpus luteum and releases progesterone, a hormone that will be necessary to maintain a pregnancy. The subsequent series of events depend on whether the released egg is fertilized or not.

In an anovulatory cycle, there is enough estrogen to build the uterine lining, but the hormone ratios necessary for ovulation are absent. Anovulatory bleeding occurs because of a drop in estrogen or because the endometrium is no longer self-sustaining. Although the flow is irregular, a woman may not be able to tell the difference between an ovulatory versus an anovulatory cycle.

Anovulatory cycles happen to every fertile woman at some point in time; however, there are developmental periods when such cycles are more frequent. During early adolescence, anovulatory cycles are very common as the young girl's body slowly develops its ability to regulate hormone levels and maintain predictable menstrual cycles. Anovulatory cycles also are experienced by women who are pregnant or consistently breastfeeding, as both activities suppress the release of estrogen. In later years, anovulatory cycles can precede menopause, a period when estrogen levels drop and a woman's body is less responsive to LH and FSH.

In addition, any behavior or situation that impacts hormone levels can result in anovulatory cycles. For example, stress, illness, strenuous exercise, and travel have been linked to anovulation. Being underweight or overweight can interfere with estrogen levels and thus cause anovulatory cycles. Women who stop using a hormone-based birth control method (e.g., birth control pills) may experience anovulatory cycles as their body works to resume control of the natural feedback system that regulates hormone levels. Last, anovulatory cycles also may result from serious medical conditions, such as polycystic ovarian syndrome (PCOS) or thyroid disease.

Depending on the cause, anovulatory cycles may be a temporary or lasting condition. Most cases can be diagnosed by a health care provider and are treatable.

Anoxia

Laura Bruder
Nova Southeastern University, Davie, FL, USA

Synonyms

Anoxic episode; Anoxic ischemia

Definition

Anoxia is the termination of the oxygen supply to an organ's tissues despite sufficient blood flow to the tissue.

Description

Anoxia is a condition that occurs when there is a loss of oxygen to the organ's tissues despite the tissue receiving adequate blood flow [4]. Oxygen depriving conditions include smoke or carbon monoxide inhalation, cardiac and respiratory failure, complications with anesthesia or exposure to high altitudes, poisoning, near-drowning, and survival following an attempted hanging or strangulation [4, 5].

The brain is more dependent on oxygen than most other organs and also lacks the ability to regenerate cells after cell death. Therefore, brain damage can occur if an anoxic episode lasts longer than 5 or more minutes. An airway must be established immediately to continue supporting the individual's respiratory and cardiovascular systems and to prevent fatality. If these systems are supported, recovery is possible [4]. During the recovery process, a patient may experience psychological and neurological symptoms including dementia, psychosis, confusion, personality degeneration, amnesia, hallucination,

parietal lobe syndromes, and memory loss [4, 5]. Persons who endure less severe anoxia may experience impaired learning ability and challenges with the retrieval of previously stored information. Severe anoxic episodes can result in a permanent comatose state or fatality.

Relevance to Childhood Development

The period surrounding birth holds the greatest risk for an anoxic episode. Anoxic episodes can occur during the gestational, parturitional, and neonatal stages [5]. Gestational causes of anoxia include maternal cardiac arrest, infectious disease, diabetes mellitus, pre-eclampsia, toxemia, and severe anemia or bleeding by the mother. Parturitional causes include an abrupt fetal separation from the placenta, placental compression, birth trauma, cord accidents (e.g., cord wrapped around neck) or placenta previa. Neonatal conditions include perinatal brain trauma, traumatic injury to the lungs, and pneumonia. Fortunately, most infants survive an anoxic episode with few neurological complications [5]. Level of impairment and survival is dependent upon the amount of time the infant experiences the anoxic episode. The most severe consequences of anoxia include the motor features of cerebral palsy, mental retardation, and seizures.

Sequelae of an anoxic episode early in life may be expressed in later childhood. Effects can include deficits in cognitive, executive, and physical functioning depending upon the region of the brain affected and the extent of the oxygen deprivation. For example, damage to the basal ganglia can produce motor slowing [1], while damage to the hippocampus can cause impaired memory for new information as well as attentional difficulties [1]. Severe damage to the brainstem can result in visual and auditory disorders [2, 5, 6]. While research has suggested that anoxia can place an infant at risk for a wide range of deficits, an anoxic episode alone is not a strong predictor of later childhood disability [5].

Antecedent Management of Behavior

James K. Luiselli[1], Derek D. Reed[2]
[1]The May Institute, Inc., Randolph, MA, USA
[2]University of Kansas, Lawrence, KS, USA

Synonyms

Preventive intervention; Stimulus control

Definition

Antecedent management is a type of therapeutic intervention that changes child behavior by manipulating conditions that precede such behavior.

Description

Antecedents to child behavior include the physical environment, such as the arrangement of desks in a classroom, and interactions with other people, such as a parent giving an instruction or making a request. When behavior

that occurs in the presence of antecedent conditions is reinforced or punished, these conditions become a source of control. Referencing the preceding examples, children may be disruptive in the classroom if they sit at a desk in close proximity to other students who do not pay attention. Similarly, children may respond inappropriately when their parents present instructions that are unclear or stated harshly.

A first step toward antecedent management is verifying a predictable antecedent-behavior relationship. Consider a situation in which children have difficulty playing together when they have access to certain toys or games. It may be that these objects foster aggressive actions because they are associated with violent themes. Or, there may be little to no adult supervision of the play activity. If the children's negative play behavior occurs consistently under such conditions, several antecedent management procedures may be indicated. To illustrate, the children could be given toys and games that facilitate cooperative social interactions. Another option would be having an adult watch the children intermittently and praise them when they play positively.

Compared to other operant procedures, antecedent management has a prevention focus because it does not rely on imposing consequences when children demonstrate problem behaviors. That is, the basis of intervention is to eliminate the conditions that historically provoked or set the occasion for the problem behaviors.

Relevance to Childhood Development

Children learn quickly the conditions that predict the consequences of their behavior. A disdaining look from a teacher may indicate that there is too much commotion in the classroom. At home, a parent may post notes specifying chores that need to be completed. These and similar antecedent conditions acquire stimulus control over behavior because they "signal" events that children desire and wish to avoid. Furthermore, antecedent influences affect children's motivation. For example, permitting a child to watch a favorite television show upon completing homework assignments is more likely to function as an incentive if she/he did not watch television previously during the day. The concept of *establishing operations* explains a type of antecedent management that affects motivational states.

Anthropology

Norissa Atingdui
Fordham University, NY, USA

Definition

Anthropology is a social science that studies the human being; involving itself with such things as the origin, behavior, language, physical characteristics, culture, social organization, development and interrelations of mankind.

Description

Anthropology concerns itself with many aspects of the human being. It is interested in the earliest forms of mankind and its evolutions. Evolutionary facets of interest include such things as language, behavior, physical characteristics, culture, government, social organization, etc. Context is very important to the anthropologist as it influences these changes in mankind; such as the way in which environment plays a role in the types of food eaten by a particular people, which in turn influences nutrition and physical growth outcomes.

Anthropologists espouse an approach of study that involves in-depth analysis of subjects such as ethnography. Researchers often become participant observers. Studies in the social sciences, especially anthropology, strive to rid itself of ethnocentric views (ethnocentrism) through the practice of cultural relativism, a concept defined by Franz Boas. In this regard, aspects of your own culture are to be judged or understood only in regard to one's own particular culture. Different ways of being are to be respected and valued, rather than judged. Cultural relativism suggests that is to be understood that there is no universal culture and/or way of doing things.

Anthropologists have contributed a lot to our understandings of the various ways in which cultures vary.

Anticipatory Bereavement

►Anticipatory Grief

Anticipatory Grief

Rachel Hibberd, Rachel Wamser, Brian Vandenberg
University Missouri-St. Louis, St. Louis, MO, USA

Synonyms

Anticipatory bereavement; Anticipatory mourning

Definition

Anticipatory grief encompasses the emotional, psychological, and interpersonal processes of confronting the imminent loss of a terminally ill loved one. Some authors argue that the term anticipatory *grief* should be reserved for the acute emotional and cognitive reaction to loss, while anticipatory *mourning* is more appropriately used to describe the larger processes of confronting the loss, including grief, coping, planning, and psychosocial reorganization [6]. The term "anticipatory grief" will be used here in a broad sense, referring to all aspects of an individual's response to impending loss.

Description

Erich Lindemann introduced the term "anticipatory grief" in his seminal 1944 article "Symptomatology and the Management of Acute Grief." Since then, the concept has generated considerable controversy – whether it exists, how it differs from post-loss grief, and whether it impedes or facilitates the post-loss mourning process [3, 6]. Anticipatory grief *is* grief, in that it occurs in response to loss. However, it is different from post-loss grief and mourning in several respects. The death being grieved is not in the past, but the abstract (and possibly unimaginable) future. Furthermore, the person being grieved is still present and active in the interpersonal relationship, engendering tension between the normal grief process of decathexis (separation) and the need to remain close. Because of these unique characteristics, anticipatory grief is fertile ground for exploration of key questions about bereavement in general: the nature of "grief work" and when it begins, how and when mourners separate from the dying, and the effects of interpersonal, psychological, and physical pre-loss experiences on post-loss adjustment.

Findings have been mixed regarding the effects of anticipatory grief on post-death mourning [6]. Many studies of the families of terminally ill patients point to the benefits of forewarning and the opportunity to engage in anticipatory grieving, suggesting that awareness of impending loss allows mourners to cherish the remaining time with the patient, assist with care, facilitate a good death, and gradually make cognitive adjustments necessary to navigate the world without the patient. According to these authors, individuals may be able to accomplish some "grief work" before death occurs, easing the burden of post-loss grief. Other studies indicate little or no effect of anticipatory grief on later mourning. Finally, some studies (including Lindemann's original description) warn of possible harmful effects of anticipatory grief. Mourners may prematurely detach from the patient or become emotionally exhausted by alternating grief and hope, thus losing the opportunity to deepen relationships and participate in patient care [4]. Other life responsibilities, such as parenting healthy children, may suffer during the anticipatory grief period, requiring additional reconstruction during post-loss grief [10]. Some studies suggest that a moderate amount of forewarning is ideal, providing mourners enough time to engage in some anticipatory grief tasks but limiting the burdens of extended caregiving [6].

Relevance to Childhood Development

Although some authors have described "anticipatory grieving" of one's own death, typically the individuals of interest in anticipatory grief research are the (adult) family members of terminally ill patients. Fewer studies have examined anticipatory grief in children, but the extant research suggests that important differences are present in the way children and adults understand and prepare for

loss. Young children lack the cognitive ability to understand death; belief that death is final and universal, and ability to imagine a future without the dying person, do not emerge until middle or late childhood [5]. Young children's views of death may be further complicated by well-meaning caregivers who use euphemisms such as "sleeping" or "on a trip." Some young children may even believe they or a sibling are causing the patient's death by wishing he or she would "go away." Older children are able to more fully grasp the abstract meaning of death, but may still differ from adults in their emotional readiness to confront the death of an actual person they know and love.

Given this uncertainty over whether and how children anticipate loss, few studies have compared children who did and did not have an opportunity for anticipatory grief before the death of a family member, and no studies exist which directly measure anticipatory grief in children. However, several authors point to the potentially negative effects of forewarned (as compared to sudden) loss on the later adjustment of bereaved children [7–9]. Many of the benefits of adult anticipatory grief are unavailable to children, including the ability to plan and reorganize in preparation for life without the deceased, the opportunity to deepen relationships through caregiving, and the solace in facilitating a good death. Children are also uniquely vulnerable to the prolonged traumatic effects of forewarned loss: exposure to death, graphic stimuli associated with illness, and the fear and anxiety of caregivers [9]. Furthermore, children's distress during the anticipatory period tends to be underestimated by their parents, resulting in isolation and confusion [7].

Perhaps even more than the direct effects of anticipatory grief, healthy children in a family with a terminally ill member can be negatively affected by the anticipatory grief processes of adult family members. Parents in such a family are overwhelmed with a variety of financial, emotional, and interpersonal stressors, and may have fewer resources to allocate to the needs of their children. In survey research, these parents identify particular concerns in the areas of emotional sensitivity and maintaining consistent discipline for their children while coping with anticipatory grief [10]. When the patient is one of the children, parents' anticipatory grief may be particularly intense and distressing [1], thus further impairing their ability to maintain a stable environment for healthy siblings.

Anticonvulsants

Mark Pennick
University of Alabama, Birmingham, AL, USA

Synonyms

Antiepileptic drugs; Antiseizure drugs; Depressants

Definition

Anticonvulsants are a clinically defined class of medications used to treat various forms of convulsions or seizure disorders. Some of these medications have also been shown to be useful in treating mood disorders, migraine headaches and neuropathic pain.

Description

Anticonvulsant medications are a diverse class of drugs and so we will focus on the general mechanism of action for the majority of the drugs. Seizures are uncontrolled

and rapid brain activity that causes various symptoms which will be discussed in further detail later. This rapid and unrestrained neuronal activity is reduced when ions such as calcium, potassium, and sodium, are stopped from entering the neuron and when the inhibitory neurotransmitter gamma aminobutyric acid (GABA) acts on the cell. By blocking the flow of positively charged ions into the neuron the chances of an action potential are reduced. Similarly, increasing the amount of inhibitory neurotransmitter such as GABA also has a calming effect on neural activity. Another common neurotransmitter is glutamate. This is the primary excitatory neurotransmitter and it is implicated in seizures. Some of the anticonvulsants act to block this neurotransmitter's action at the synapse. Anticonvulsant medications work by these or similar mechanisms and many operate in combination with one-another. It is also important to note that scientists do not fully understand the mechanisms of action for all of the anticonvulsant drugs.

In order to understand the use of anticonvulsant medications one must first comprehend the salient features of a seizure. This is because the child who suffers from a seizure will be treated according to the particular symptoms of their seizures. For this purpose there are classification criteria for seizures. For those who are likely to be around persons who may experience seizures these classifications are important in that they can be reported to the child's physician to treat the seizure with the utmost efficacy. The following descriptions are taken from Weinstein and Gaillard [5].

Absence Seizures These seizures are characterized by a brief behavioral arrest with impaired consciousness. There is no postictal (time immediately following the seizure) period of confusion. The onset for this type of seizure is typically 3–12 years of age. During the seizure the child may continue to perform the task that they were engaged in before the seizure; however, the child will not responds to new information. It is common to notice a glazed eye appearance, abnormal eye blinks, and possible changes in head and extremity tone. The implications for a child suffering from absence seizures are that they may be in danger if they need to react to something in the environment during a seizure, and it may be very hard for the child to learn because of interruptions of consciousness.

Partial Seizures These are the most common type of seizure. They are typically preceded by an aura which is an altered state of consciousness or perception of something in the environment that does not exist. These seizures are usually located at a certain point in the brain and so the child with this type of seizure will usually have the same symptom presentation from episode to episode. The part of the brain affected can include areas of motor control, sensation, behavior and cognitive functions. If the seizure spreads and alters consciousness it is called a complex partial seizure.

Myoclonic and Atonic Seizures These are the briefest types of seizures that alter motor control. Myoclonic seizures are motor attacks that cause a sudden bending backward of the head and torso. These seizures and any other seizure that cause a loss of muscle tone combine to form the class of drop seizures. The person suffering from a drop seizure will suddenly lose consciousness and abruptly fall, without any attempt to protect oneself. It is recommended that people with these types of seizures wear a helmet to protect their head from falls.

Tonic–Clonic Seizures This is the most frightening seizure to observe. It is commonly referred to as the grand mal seizure. These types of seizures may begin focally and then spread to other parts of the body. They can also begin as generalized seizures. The body experiences both clonic motor activity, which is characterized by repetitive jerking, and tonic activity, which is expressed as stiffening of the body. If the clonic activity generalizes to multiple parts of the body then the person is experiencing a Jacksonian seizure. Other common observations of tonic–clonic seizures are irregular breathing, unusual vocalizations, cyanosis, and incontinence.

Febrile Seizures These are seizures that are caused by fever and they are the most common seizure for children to have. Febrile seizures are generally seen when a child's temperature goes above 102°F. They are usually brief symmetric tonic or clonic–tonic events that occur once during an illness.

As referenced in the *Tarascon Pocket Pharmacopoeia* [4], there are no fewer than 20 recognized medications for use in treatment of convulsions. Another pragmatic description of current pharmaceutical interventions for persons having seizures is Simon Shorvon's, *Handbook of Epilepsy Treatment 2nd Edition*, [2]. This text describes no fewer than 25 medications and is complete with information regarding pharmacokinetics, adverse effects, antiepileptic effect, and clinical uses in epilepsy. The reader is referenced to Table 1 for a brief over view of some of the common drugs that are considered safe to use with children who are suffering from seizures. It is not intended for use to prescribe medications and does not included any advanced medical information, it is intended for persons in the field of child development to understand treatments being prescribed by physicians and some side-effects that must be closely monitored.

The *Tarascon Pocket Pharmacopoeia* [4], indicates carbamazepine, lamotrigine, topiramate, and valproic acid as

Anticonvulsants. Table 1 Common medications for treating children with seizures

Medication	Indications	Adverse events	Advantages	Disadvantages
Carbamazepine (Tegretal)	Partial and generalized seizures	Drowsiness, fatigue, dizziness, ataxia, diplopia, sedation, insomnia, tremor, weight gain, rash	Highly effective and usually well tolerated	Adverse effects, especially on initiation of therapy. Possibility of toxicity
Clobazam (Frisium)	Partial and generalized seizures	Sedation, dizziness, weakness, blurring of vision, restlessness, ataxia, aggressiveness, behavioral disturbance	Effective for patients with epilepsy that are resistant to first-line therapy. Considered safer than other benzodiazepines.	Tolerance develops in up to 50% of patients
Clonazepam (Klonopin)	Partial and generalized seizures, neonatal seizures, status epilepticus	Sedation, cognitive effects, drowsiness, ataxia, personality and behavioral changes, hyperactivity, restlessness, aggressiveness, psychotic reaction, seizure exacerbations, hypersalivation, tone changes, leucopenia	Useful action, especially in children	Side-effects, sedation is common, tolerance and withdrawal symptoms
Ethosuximide (Zarontin)	Generalized absence seizures	Gastrointestinal symptoms, drowsiness, ataxia, diplopia, headache, dizziness, hiccups, sedation, behavioral disturbances, psychotic reactions, EPS, rash	Effective for generalized absence seizures; No risk of hepatic toxicity carried by the alternative treatment of valproate	Common side effects
Gabapentin (Neurontin)	Partial or secondarily generalized epilepsy (for children over age 6)	Drowsiness, dizziness, seizure exacerbation, ataxia, headache, tremor, diplopia, nausea, vomiting, rhinitis	Lack of side effects; Good pharmacokinetic profile	Lack of therapeutic effect in severe case; Possible increase in seizures
Lamotrigine (Lamictal)	Partial and generalized epilepsy (for children over age 2)	Rash, headache, blood dyscrasia, ataxia, asthenia, diplopia, nausea, vomiting, dizziness, somnolence, insomnia, depression, psychosis, tremor, hypersensitivity reactions	Moderate effectiveness; Well tolerated	High incidence of rash, commonly severe; Complicated pharmacokinetics
Oxcarbazepine (Trileptal)	Partial and secondarily generalized seizures	Somnolence, headache, dizziness, diplopia, ataxia, rash, hyponatraemia, weight gain, alopecia, nausea, gastrointestinal disturbance	Similar to carbamazepine, but with a different adverse effect profile and less drug interactions	Higher incidence of hyponatraemia than carbamazepine
Phenobarbital (Luminal)	Partial or generalized seizures (including absence and myoclonus seizures), childhood epilepsy syndrome, febrile convulsions, neonatal seizures	Sedation, ataxia dizziness, insomnia, hyperkinesis, mood changes, aggressiveness, cognitive dysfunction, impotence, reduced libido, folate deficiency, vitamin K and vitamin D deficiency, rash, risk of dependence, risk of abuse	Highly effective and low cost	CNS side-effects-especially for children; Controlled drug in many countries

Anticonvulsants. Table 1 (Continued)

Medication	Indications	Adverse events	Advantages	Disadvantages
Phenytoin (Dilantin)	Partial and secondarily generalized seizures (excluding myoclonus and absence seizures), status epilepticus, childhood epilepsy syndromes	Ataxia, dizziness, lethargy, sedation, acute encephalopathy, hypersensitivity, rash, fever, blood dyscrasia, mood changes, myopathy, connective tissue alteration, hepatitis, vasculitis, coagulation defects	Highly effective and low cost	CNS and systemic side effects, non-linear elimination kinetics, drug interactions
Primidone (Mysoline)	Primary and secondarily generalized seizures	Sedation, ataxia dizziness, insomnia, hyperkinesis, mood changes, aggressiveness, cognitive dysfunction, impotence, reduced libido, folate deficiency, vitamin K and vitamin D deficiency, rash	Not a controlled drug, less risk of abuse than Phenobarbital	Side effects
Topiramate (Topamax)	Partial, secondarily generalized, Idiopathic generalized epilepsy (for children over age 2)	Dizziness, ataxia, headache, parathesia, tremor, somnolence, cognitive dysfunction, confusion, agitation, amnesia, depression, emotional liability, nausea, diarrhea, diplopia, weight loss	Powerful antiepileptic action, weight loss common	Potential for CNS and other side effects
Sodium valproate (Depakote)	Primary and secondarily generalized seizures (including myoclonus and absence), partial seizures, indiopathic generalized seizures, childhood epilepsy syndrome, febrile convulsions	Nausea, vomiting, metabolic effects, endocrine effects, hepatic toxicity, pancreatitis, drowsiness, cognitive disturbance, aggressiveness, tremor, weakness, encephalopathy, weight gain	Treats a wide spectrum of seizure activity, drug of choice for those with idiopathic generalized epilepsy	Weight gain, CNS side-effects, possibility of hepatic disturbance in childhood, teratogenicity
Zonisamide (Zonegran)	Refractory partial epilepsy, progressive myoclonic epilepsy	Somnolence, ataxia, dizziness fatigue, nausea, vomiting irritability, impaired concentration, mental slowing, itching, diplopia, insomnia, abdominal pain, depression, skin rashes, hypersensitivity, renal calculi, weight loss, oligohidrosis and heat stroke	Effective in a broad spectrum of epilepsies, has indication for infantile spasms, and myoclonic epilepsies	Side-effect profile

treatments for bipolar disorder. Stahl [3] reports that the initial logic of using anticonvulsant medications to treat bipolar disorder was that seizure activity, if left untreated would result in increased seizure activity. This same pattern of neural activity becoming more pronounced with repetition was seen as similar to manic activities in people with bipolar disorder. The mechanism of action for these drugs in bipolar disorder is poorly understood. It is assumed that the same calming of neural firing are at work with people who have bipolar disorder.

Relevance to Childhood Development

The impact of having seizures during child development is different for children than for adults. The formation of personality and the special need for acceptance in the peer group to the developing child will impact development.

It is common for the parents of children with seizure disorders to protect their children and this should be avoided to allow for the least restrictive environment for the child to be safe in. Children who do have seizures will benefit from their peer group and adults who are involved in their life to have education about seizures. This will help mediate the possibility of being viewed as strange by their peers and keep them safe.

Antidepressants

Erin Shae Johns
Nova Southeastern University, Davie, FL, USA

Synonyms

Paxil (Paroxetine)

Definition

Antidepressants are the class of drugs prescribed primarily to treat symptoms of depression. They are also indicated for the treatment of ADHD, separation anxiety disorder, obsessive-compulsive disorder, eating disorders and sleep disorders.

Description

Antidepressant medications are prescribed primarily for the treatment of depression in children and adolescents, but are also used in the treatment of other common childhood disorders including ADHD, separation anxiety disorder, obsessive-compulsive disorder, eating disorders and sleep disorders. These include six classes. Tricyclic antidepressants (TCAs), Monoamine Oxidase Inhibitors (MAOIs), Selective Serotonin Reuptake Inhibitors (SSRIs), Selective Serotonin and Norepinephrine Reuptake Inhibitors (SSNRIs), Selective Norepinephrine Reuptake Inhibitors (SNRIs), and Others. In 2002, 11 million prescriptions for antidepressants were written for children under the age of 18 years [1].

Tricyclics Antidepressants (TCA's)

Tricyclic antidepressants (TCA's) are the oldest class of antidepressants and include such medications as *Elavil* (amitriptyline), *Norpramin* (desipramine), *Anafranil* (clomipramine), *Sinequan, Adapin* (doxepin), *Tofranil* (imipramine), *Pamelor* (nortriptyline), *Vivactil* (protriptyline), and *Surmontil* (trimipramine). Tricyclics block the reuptake of neurotransmitters such as norepinephrine and serotonin. These medications are used for the treatment of depression in children who are at least 12 years of age [2], although these medications have been prescribed to children younger than 12 years of age for evidence-based reasons. For example, *Tofranil* (Imipramine) is approved for the treatment of enuresis in children; however it is also used off-label for the treatment of attention-deficit/hyperactivity disorder (ADHD), school phobia, separation anxiety disorder, sleep disorders, and major depressive disorder (MDD). *Anafranil* (clomipramine) has been approved for obsessive-compulsive disorder (OCD) in children. *Tofranil* (imipramine) and *Anafranil* (clomipramine) are the two TCA's most frequently studied and utilized in the pediatric population.

Due to the rapid metabolizing of TCAs, discontinuation of these drugs may produce withdrawal symptoms including: nausea and vomiting, abdominal discomfort and pain, headache, and fatigue. Other side effects of TCAs include: drowsiness, increased heart rate, seizures, anxiety, insomnia and nightmares, confusion, delusions, blood dyscrasias, dry mouth, blurred vision, constipation, changes in libido, and psychotic episodes [2]. There have been eight reported cases of sudden death of children and adolescents taking TCAs [2]. TCAs are also fatal in overdose and should not be prescribed to children and adolescents with suicidality.

Selective Serotonin Reuptake Inhibitors (SSRI's)

The following medications are classified as selective serotonin reuptake inhibitors (SSRIs): *Prozac* (Fluoxetine), *Luvox* (Fluvoxamine), *Celexa* (Citalopram), *Lexapro* (Escitalopram), *Paxil* (Paroxetine), and *Zoloft* (Sertraline). As their name suggest, SSRIs work by blocking the reuptake of the neurotransmitter serotonin from entering the cell. *Prozac* (Fluoxetine) is the only SSRI approved for the treatment of major depressive disorder (MDD) in children and adolescents older than the age of 8. While no other SSRI has FDA approval for MDD in children, *Prozac* (Fluoxetine), *Luvox* (Fluvoxamine), and *Zoloft* (Sertraline) all have approval for the treatment of obsessive

compulsive disorder (OCD) in children older than 7 years, 8 years, and 6 years respectively. SSRIs also have approval for the treatment of panic disorder, social anxiety disorder, posttraumatic stress disorder (PTSD), bulimia nervosa, premenstrual dysphoric disorder, and generalized anxiety disorder (GAD) in adults only.

SSRIs are better tolerated and have less severe side effects than TCAs. Moreover, SSRIs do not have the lethality in overdose and cardiac toxicity that is associated with TCAs. Therefore, SSRIs have become the most frequently prescribed antidepressants for children and adolescents. The most common side effects of SSRIs include: headache, nausea and vomiting, diarrhea, nervousness, sleep disturbance (insomnia), and sexual dysfunction [2]. Furthermore, behavior changes, such as restlessness, hyperactivity, internal feelings of excitation and impulsivity have been noted with some SSRIs in the pediatric population [2]. SSRIs are longer lasting than TCAs which lends to once a day dosing and less withdrawal side effects. Regardless, discontinuation and withdrawal from SSRIs can lead to dizziness, headache, nausea and vomiting, diarrhea, movement disorders, insomnia, irritability, visual disturbances, lethargy, anorexia, tremor, electric shock sensations and lowered mood [2].

Others

Deseryl (Trazodone) and *Wellbutrin* (Bupropion) are not chemically related to other antidepressants and are classified as others. *Deseryl* (Trazodone) acts as antagonist at serotonin receptors, blocking serotonin from entering new cells. This differs from reuptake inhibitors which block the neurotransmitter from re-entering the cell it was previously released from. *Wellbutrin* (Bupropion's) mechanism of action is to inhibit the reuptake of the neurotransmitters dopamine and norepinephrine. Neither drug has indication in the pediatric population nor has the safety and efficacy of these drugs been established for children and adolescents younger than 18 years old. However, *Deseryl* (Trazodone) has been studied in children demonstrating aggressive behaviors and *Wellbutrin* (Bupropion) has been utilized in children and adolescents with ADHD. Furthermore, *Wellbutrin* (Bupropion) has been used for the treatment of smoking cessation. The most common side effects of *Deseryl* (Trazodone) include drowsiness, dizziness or lightheadedness, dry mouth, and nausea and vomiting [2]. Unlike the other antidepressants, *Wellbutrin* (Bupropion) has been linked to increased memory and concentration [2]. However, Bupropion has also been linked to seizures, agitation, dry mouth, insomnia, headache, nausea and vomiting, constipation and tremor [2].

Selective Serotonin and Norepinephrine Inhibitors (SSNRIs)

Selective serotonin and norepinephrine inhibitors (SSNRIs) include: *Effexor* (Venlafaxine), *Remeron* (Mirtazapine), and *Cymbalta* (Duloxetine). *Effexor* (Venlafaxine) works by inhibiting the reuptake of the neurotransmitters serotonin, norepinephrine, and occasionally dopamine. *Remeron* (Mirtazapine's) mechanism of action includes blocking alpha-2 receptors, which in turn inhibits the release of norepinephrine and serotonin. *Cymbalta* (Duloxetine) works by blocking the reuptake of norepinephrine in the synapse. Similar to *Deseryl* (Trazodone) and *Wellbutrin* (Bupropion), these medications have not been approved for the treatment of children and adolescents. *Effexor* (Venlafaxine) is indicated for adult depression in the immediate release formula and for MDD, GAD and social anxiety in the extended release formula. *Effexor* (Venlafaxine) has been studied in the pediatric population for MDD and GAD but no significant treatment effects were found. However, *Effexor* (Venlafaxine) was shown to negatively affect weight and height in the pediatric population. Other side effects of *Effexor* (Venlafaxine) include anxiety, nervousness, somnolence or insomnia, nausea, anorexia, weight loss, constipation, increased sweating, dry mouth, dizziness, abnormal ejaculation/orgasm, and impotence [2]. *Remeron* (Mirtazapine) and *Cymbalta* (Duloxetine) only have indications for MDD in adults. Common side effects of these medications include somnolence, increased appetite, weight gain, dizziness, dry mouth, increased sweating and constipation [2].

Selective Norepinephrine Reuptake Inhibitors (SNRI)

Strattera (Atomoxetine) is a selective norepinephrine reuptake inhibitor (SNRI) and is indicated for the treatment of ADHD in children and adolescents. SNRIs work by blocking the reuptake of norepinephrine. Side effects include dyspepsia (indigestion), nausea and vomiting, fatigue, decreased appetite, dizziness and mood swings [2].

Monoamine Oxidase Inhibitors (MAOIs)

Monoamine Oxidase Inhibitors include: *Nardil* (Phenelzine), *Parnate* (Tranylcypromine), and *Eldepryl* (Selegiline). MAOIs have a complex mechanism of action. These drugs block the chemical monoamine oxidase, which inhibits the breakdown of monoamine neurotransmitters. These neurotransmitters are responsible for breaking down other neurotransmitters, such as dopamine, serotonin and norepinephrine. Because these neurotransmitters are not

being broken down, there are more of these neurotransmitters available in the body. *Nardil* (Phenelzine) is approved for MDD in adolescents at least 16 years of age and *Parnate* (Tranylcypromine) is only indicated for adults. Due to the severe food and drug interactions of MAOIs, they are primarily used in adults who have failed to respond to other antidepressants. Ingesting foods containing Tyramine (such as cheese, wine, beer) and other drugs (such as caffeine) can lead to hypertensive crisis. Other significant reactions of these drugs include orthostatic hypotension, dizziness, headache, sleep disturbances, sedation, fatigue, weakness, hyperreflexia, dry mouth, and gastrointestinal disturbances [2].

Black Box Warnings on Antidepressants

In October 2004, the Food and Drug Administration (FDA) ruled to label antidepressants used in the treatment of children and adolescents with a black box warning. According to the black box warning, use of antidepressants within this population may lead to increased risk of suicidal thinking, suicidal gestures, and death by suicide [4]. This warning also specifies that children, adolescents, and young adults taking antidepressants should be closely monitored following the initiation of the medication. Despite the recommendation for follow-up and increased monitoring, the majority of pediatric patients treated with antidepressants have no contact with mental health providers [3, 6]. Since the commencement of this black box warning, antidepressant prescriptions have dropped by 54% for all antidepressants that are not FDA approved for use in children and adolescents, while the rate of prescriptions for Fluoxetine, the only FDA approved antidepressant for use in children, increased by 60% [5].

Antiepileptic Drugs

▶Anticonvulsants

Antipsychotics

Synonyms

Depressants

Description

Antipsychotics, or neuroleptics are medications used in psychiatry to manage delusions and hallucinations particularly individuals suffering from schizophrenia or bipolar disorder. These medications were first discovered in the 1950's. The original drugs were referred to as typical antipsychotics. The newer drugs in this category are referred to as atypical antipsychotics. Both generations of medications interact with a wide range of receptor targets in the brain. A number of adverse side effects have been observed with these medications including lower life expectancy, weight gain, tardive dyskinesia, diabetes, and sexual dysfunction. The development of new antipsychotics and the relative efficacy of different ones is an important ongoing field of research.

Antisocial Behavior

Mysti S. Frazier
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Physical aggression

Definition

Antisocial behavior describes disruptive, external behaviors and actions of a child, in which the rights and norms of others or society are violated. These undesirable behaviors are influenced by many, if not all, aspects of the child's

life (school, community, physical, emotional, parental, etc.). Furthermore, these behaviors are often involved in attention deficit-hyperactivity disorder, conduct disorder, and oppositional defiant disorder.

Description

For decades research on antisocial behavior (ASB) has expanded to detailed research examining the root causes of these disruptive behaviors starting as early as conception. Understanding the development of ASB in children is important to researchers as they try to uncover objective reasoning behind the harmful actions of these individuals. Furthermore, acknowledgment of related disorders such as attention deficit-hyperactivity disorder (ADHD), conduct disorder (CD), and oppositional defiant disorder (ODD) by the American Psychiatric Association has led to great demand for such research. The creation of assessment instruments to measure ASB also has allowed for a greater understanding of the behavior and provides insight on possible prevention and intervention strategies.

Research has found that there are many types and forms of aggression in children, making it a complex construct to study. Early in the research history of ASB antisocial activity was divided into two categories, undersocialized and group-delinquent [4]. Today, aggressive behaviors can be classified as verbal, physical, goal-directed, proactive, reactive, direct, indirect, relational, overt, or covert [4]. Moreover, antisocial aggression can be further broken down in terms of when and how onset began.

Bloomquist and Schnell [2] discuss the pathways of ASB in terms of early-onset continuously adaptive, early-onset continuously maladaptive, the resilient pathway, and the late-onset maladaptive pathway. These four pathways seek to explain the social, emotional, cognitive, and physiological functioning of the child at various stages of ASB development. ASBs fall on a continuum from mild to severe behavior problems, depending on factors such as intensity, frequency, and impact on the environment [4, 6]. Therefore, diagnostic measures are multimodal in nature. This has led researchers to link such behaviors to other disorders that are better understood and clearly defined as a means to quantify them.

DSM-IV and ADHD, CD, and ODD

ADHD, CD, and ODD have both similarities and differences as they relate to antisocial behavior. ADHD is commonly comorbid with CD and ODD, though not as persistent with CD [4]. ADHD is defined as developmentally inappropriate inattention and/or hyperactivity-impulsivity that results in significant impairment [1]. Research suggests that early aggressive behavior combined with ADHD symptoms are precursors for the development of ASB [4].

ODD is defined as a chronic pattern of disobedient, defiant, and hostile behaviors [1]. These behaviors include: losing temper, arguing, defying or refusing to comply with rules or requests of adults, deliberately annoying others, blaming others, anger and resentment, and spiteful or vindictive actions [1]. ODD includes a variety of covert and overt behaviors, and there is evidence to indicate that ODD serves as an antecedent to CD. CD is defined as a chronic pattern of behavior in which the rights of others are violated and societal norms are disregarded [1]. Categories of behavior include aggressive conduct, nonaggressive conduct, deceitfulness or theft, and serious violations of rules. In general, the behaviors required for diagnosis of CD are more antisocial in nature and more severe than those involved in ODD.

Development of ASB

It is widely agreed throughout the literature that while ASB has various root causes, overall it is learned behavior that is highly influenced by early development. The development of ASB begins early and grows through adolescence and adulthood. However, it is not to be assumed that all children displaying symptoms of ASB will go on to develop CD or ODD; a substantial number of them develop normally [4].

The development of ASB begins with the caregiver unknowingly conditioning maladaptive behaviors such as impulsivity, negative temperament, and sensation seeking from infancy [2, 4]. Usually, environmental factors contribute to the caregiver's lack of knowledge and parenting skills to combat such conditioning, including health of the mother, low socioeconomic status, family size, and involvement of both parents [5, 6].

According to [2], the development of ASB follows stages. Beginning at birth through age 2, children may develop a difficult temperament portrayed by irritability, anger, and frustration. At ages 3–5 this temperament is displayed through tantrums, argumentativeness, and defiance. In elementary school years covert aggressive behaviors (stealing, lying, sneaking) begin to develop. This is followed by more frequent and substantially delinquent behaviors, such as skipping school, vandalism, experimentation with drugs and alcohol, and fire setting, from ages 9–14. Once in adolescence there is a crystallization of such behaviors that escalate to violence, gang affiliation, promiscuity, and more serious substance abuse. It is estimated that 1 in 3 children with early onset ASB will develop adult antisocial personality disorder; the others may have functional problems throughout adulthood, including trouble keeping a job, violence, relationship difficulty, and criminality [2].

Assessment

Rating scales are commonly used to identify externalizing behavior patterns including impulsivity, overactivity, aggressiveness, and tantrums [6]. Furthermore, observations of the behaviors and related family interaction have led to better diagnostic validity, as have family history interviews, self-reports, and evaluations of environmental causes of ASB patterns [6].

The use of rating scales to assess ASB has positive and negative aspects. Behavioral checklists, such as the Child Behavior Checklist and the Revised Child Behavior Profile, require an adult informant's view of the child's behavior. Though these instruments are easy and quick, they require adults close to the child to judge behavior, which may compromise objectivity. Another shortcoming of rating scales is that in many cases they do not parallel diagnostic criteria for ASB [6]. Overall, these scales do provide some insight into the behavior problems with a child, but should be utilized with other assessment tools in order to gain a multidimensional understanding of the child's behavior so that an appropriate intervention can be designed.

ASB Prevention and Intervention

Research conducted by [5] outlines targets for prevention and early intervention for children at risk for ASB, a term they call "preventative intervention." They begin by discussing the learned maladaptive behaviors and negative reinforcement patterns unknowingly taught by the caregiver. For example, when a demand is placed on the child the child has learned that if he/she displays an undesirable behavior, such as a tantrum, the caregiver will withdraw the demand to keep the peace. The interventions work to disrupt these negative reinforcements through consistent and long term reconditioning of the behavior.

Furthermore, preventative intervention aims to teach the caregiver how to set appropriate limits and utilize appropriate discipline techniques. It also teaches him/her how to reward positive interactions and encourage positive behavior and social interaction. These skills are then intended to be used outside of the home at the playground, in the classroom, and throughout the community [5]. Overall, preventative intervention may not be the only way to reconstruct a child's behavior, but it does work to reduce risk factors in the short and long term [6].

Anxiety

Dominic A. Candido
Dartmouth College, Lebanon, NH, USA

Synonyms

Apprehension; Autonomic arousal; Fear; Fight or flight; Hyperarousal; Revised children's manifest anxiety scale: second edition; Stress; Sympathetic activation; Threat response

Definition

Anxiety is a basic emotion best described as a state of vigilant apprehension whose function it is to prepare for a response to a perceived threat. Anxiety has several associated, though not necessarily correlated, dimensions: phenomenological, emotional, cognitive, behavioral and physiological [3]. The state is characterized by a narrowing of attention [10], a sense of dread [27], ruminative worry [25], a perception of vulnerability [33], an inhibition of behavior [15] and a heightened state of sympathetic arousal. It is generally experienced and classified as a negative emotional state, along with anger and sadness.

Description

Clinical Significance

Anxiety becomes clinically significant, reaching a level of diagnosable disorder, when there is a resulting impairment in one's ability to function (i.e., when the state no longer assists the organism in dealing effectively with threat) and/

or when the associated subjective distress is marked and debilitating [43]. Other clinically significant features of anxiety include a threat response system that becomes too inflexible, too easily and inaccurately triggered and too slow to return to baseline once initiated [7].

Diagnosis

Diagnosis across all mental disorders including anxiety disorders has been historically categorical. There are currently twelve separate anxiety disorders identified in the Diagnostic and Statistical Manual of Mental Disorders IV-TR, including Separation Anxiety Disorder, and at least 23 other anxiety-related conditions [1].

Emerging trends alternatively suggest models of disorder that are dimensional assessing aspects of experience along continua as opposed to meeting criteria for a certain number of present features [21]. High co-morbidity rates across disorders with regards to a ubiquitous anxiety presence (as much as 42% in a recent epidemiological study of anorexia nervosa adolescent patients [35], 29% in autism-spectrum disorders [37] and 25% in a study of ADHD children as examples [19]) has furthered a change in conceptualization away from a categorical view of anxiety to one of general distress.

As diagnosis is inextricably tied to treatment, categorization, an emphasis on randomized control experimental studies as the gold standard for determining efficacy and a general movement toward evidence-based treatments led to a proliferation of protocols and guidelines for first-line interventions for anxiety (and other) disorders. Newer, unified protocols, however, attempt to address the essential maintaining elements of distress and dysfunction across disorders such as threat appraisal, experiential avoidance and emotion-driven behaviors [4].

Anxiety Disorders in Children

Children experience the full range of anxiety disorders similarly to adults. Life stage differences can yield categorical variations (e.g., separation anxiety, selective mutism and some types of school refusal) but the overall form, experience and impairment that results is frequently similar and equally distressing and limiting [14]. Developmental and socialized differences between children and adults can give rise to differences in the surface features of expressed anxiety such that these represent interesting and important clinical intervention markers rather than substantive differences in the function or dysfunction of anxiety.

Prevalence of Anxiety Disorders

The National Institute of Mental Health puts best estimate 1-year prevalence rates for anxiety disorders among 18–54 year olds at 16.4% of the population [28]. For children and adolescents aged 9–17 years, that figure is 13.0%. The rates for any (mental) disorder, however, are 21.0% for adults and 20.9% for children. While the definition and subsequent nature and distribution of mental disorders can be slightly different in children and adolescents, overall levels (accounting for dissimilarities and difficulties in categorization) suggest quite similar rates of disorder across ages.

From Child to Adult Anxiety Disorder

At question is the developmental course of anxiety disorders in children and whether their presence indicates risk for related, though not always the same, adult onset disorders [16]. Separation anxiety disorder, for example, appears related to the onset of panic disorder, agoraphobia and other conditions yet may simply represent the culmination of processes such as an early sense of low perceived personal control experienced within the critical mammalian context of attachment that, by itself, may be a vulnerability to anxiety disorder onset at any age [13]. Further, with the added interaction of physiological and possibly genetic propensities for heightened nervous system sensitivity to perceptions of unpredictable, uncontrollable environments, the stage is set for the development of a variety of threat-related disorders of hyperarousal [2].

With these issues at hand, researchers have turned to identifying the transdiagnostic processes and perhaps even the transprocess variables that endow vulnerability to disorder [23] where risk factors suggest correlation between a characteristic and an outcome and vulnerability connotes more causal factors to onset.

Key Dimensions

Key dimensions of anxiety worth measuring are: allocated attention to threat [34], appraisal of the degree of danger posed by threat [11], appraisal of one's abilities and resources to handle threat, anxiety sensitivity (AS) [41], emotional, cognitive and behavioral avoidance [26] and inflexible response strategies often characterized by escape, these strategies termed safety maneuvers for their misattributed role in the perceived result of lack of harm [36].

Physiological indices of anxiety have frequently been examined but have been shown to be inconsistently correlated with emotion. Homeostatic measures such as heart rate, blood pressure, cortisol levels and amygdala activation can be difficult to interpret when detected coincident to anxiety [12].

Allostatic models of physiological function, on the other hand, emphasize change as critical to stability and purport that healthy organisms are free to vary to a much greater degree than unhealthy ones and lead to perhaps more reliable measures of anxiety. Heart rate variability is one such measure where decreased variability is suggestive of increased pathology [24].

Genetic models are advancing that elucidate mechanisms and processes related to anxiety disorder onset. Neurotransmitter efficiency, receptor site affinity and pre and post synaptic activity are all promising but as yet not well understood variables leading to particular behavioral outcomes. The picture is further complicated by epigenetic factors, such as shared familial environment or an early learning history of low perceived control, that moderate the effects of dysmorphic architecture on the etiology of anxiety disorders in children and adults alike [38].

Coping with Anxiety

To reiterate, anxiety is a useful, purposeful emotion whose function it is to prepare and motivate an organism to effectively respond to threat. When the anxious response begins to become problematic, as noted previously, there arises a need for additional resources within the individual to handle the response itself. Anxiety management [39] thus became an important area of research and intervention for clinical reasons, where anxiety rose to a level of diagnostic significance, and for non-clinical reasons as in performance enhancement in areas such as sports or educational psychology [40].

Early models of anxiety management, particularly behavioral models, stressed maneuvers aimed at stopping or limiting the anxiety response. Progressive muscle relaxation or PMR is one such early attempt to "reciprocally inhibit" anxiety [42]. In this procedure, an individual volitionally and progressively tenses then relaxes various muscle groups. Later refinements added programmed monitoring of discrete changes in muscular tension through focus on perceived changes in blood flow and strain as well as on the difference between tension and relaxation. PMR became a standard component of most anxiety management packages both clinical and non-clinical [17].

Systematic desensitization or SD extended this line of reasoning with a procedure that attempted to pair relaxed states with stimuli that previously elicited states of anxiety thereby neutralizing a sympathetic response [44]. Based on classical conditioning theory, the SD strategy tried to break the associational bonds between stimuli and responses. Later theoretical explanations looked to the modulation or contextual effects of new learning upon old [6].

Cognitive-behavioral models that followed were quick to adopt a similar anxiety-stopping philosophy. Thought suppression, distraction and substitution of positive imagery were developed as methods to temper unhelpful feelings by directing attention and cognition away from presumed triggers of distress [30].

Exposure was another technique aimed at eliminating a particular response developed in behavioral theory. Based on extinction concepts, exposure was later applied to anxiety and has since proved to be among the most robust and potent interventions of all. Exposure in a strict behavioral account of fear learning refers to exposure to stimuli in the absence of previous reinforcement whose effect is explained by a passive process where a response to a stimulus is extinguished or sometimes explained by a passive physiological process known as habituation [32].

The advent of two-factor learning accounts of fear acquisition and maintenance joined classical with operant conditioning principles [44]. Where classical accounts stressed associations between stimuli and elicited responses, operant principles stressed the organism's emitted behaviors that changed the contingent consequences. Simply put, in the presence of stimuli signaling a feared outcome, the emission of a response such as escape or avoidance that changes an expected outcome is said to have reduced anxiety and reinforced the tendency to flee on subsequent encounters with similar stimuli. Escape response prevention became an important addition to the exposure technique [5].

Pharmacological models, likewise, have focused on management and treatment strategies aimed at attenuating or terminating anxiety. While precise mechanisms of action are frequently unknown and to a great extent involve a significant placebo component [31], the use of benzodiazepines and other agents to depress sympathetic activation have become widespread. Several theoretical mechanisms attempt to account for their therapeutic effect including, but not limited to, enhancing the activity of inhibitory central nervous system neurotransmitters such as gamma amino butyric acid or GABA [31]. Still other pharmacologic interventions aim to attenuate anxious symptoms directly by the use of agents such as beta-blockers to suppress cardiac response and stem sympathetic arousal. Even anti-depressant agents known as selective serotonin-reuptake inhibitors or SSRIs also have significant adrenergic effects and have been shown to reduce anxious symptoms such that they are independently indicated for use in various anxiety disorders [18]. This general strategy of stopping anxiety perpetuates notions of "protecting" the patient as well as the view that anxiety is dangerous and a threat in itself.

The reader will note that certain medical conditions can be exacerbated by sudden sympathetic activation and possibly trigger events that are in fact dangerous to the individual. Medical management strategies in this case often involve limiting sympathetic arousal through chemical and sometimes surgical means [8]. The importance of a complete medical examination to rule out any underlying possible medical conditions that can either cause or be exacerbated by sudden anxious response cannot be underestimated. Individuals may have anxiety disorders prior to onset of medical conditions or may develop such conditions coincident to them. While the vast majority of anxiety disorders occur in individuals where medical status is not a significant or complicating factor, careful collaboration between physicians and other treating professionals is, nonetheless, important if not essential.

In the absence or presence of medical conditions, individuals vary in their degree of anxiety sensitivity (AS) defined as the general sense that, when experienced, anxiety is harmful to the self. This concept has been shown to be predictive of development of anxiety disorders [41]. The individual high in AS is seen as more vulnerable to misinterpretation of the benign physiological sensations associated with sympathetic arousal in a healthy person. These individuals are hypervigilant to anxiety symptoms, have a propensity to view these symptoms in harmful terms, overestimate the likelihood that the worst possible outcomes will happen and underestimate their ability to cope.

Cognitive models have more purely retained a focus on the active process of relearning about danger signals and coping capacities through the actual experience of anxiety not its suppression [36]. These cognitive accounts emphasize cognitive reappraisal through confronting fears by choice and prediction testing while dropping maneuvers that contribute to false attributions of safety. These approaches also often utilize imaginal or visual channels to achieve changes in threat assessment and self-efficacy. The desired end of such procedures is not to stop anxiety but to restore its accurate and purposeful function in an effective response to threat.

More recent cognitive models termed mindfulness-based approaches have begun to move away from notions that emphasize management or regulation of anxiety to awareness and acceptance of the response largely based on findings demonstrating increases in anxiety directly due to attempts at control [9]. Unfortunately, these models fail to acknowledge both the exposure component inherent in their procedures and the likely explanation of cognitive reappraisal as the mediating variable of change. These approaches have, however, furthered a functional, purposeful view of anxiety, and all emotion for that matter, in a healthy person's search for a full and valued life.

Future models, whether psychological, physiological or pharmacological, may very well relinquish attempts at anxiety control and may focus instead on techniques that enhance learning [20]. New paradigms are beginning to emerge such as the use of the antibiotic d-cycloserine to augment exposure [29] or transcranial stimulation [22] of neocortical regions with projections to the limbic system that may improve the ability to benefit from experience or chemical agents such as dopamine reuptake inhibitors that may boost the efficiency of the brain's reward system and aid the organism in profiting from the contingencies which their behaviors actually produce. The focus of the future may not be to counter disorder and disease but rather to create the conditions within individuals which promote the great inherent potential of the human being to grow and to heal.

Anxiety Disorders

Synonyms

Generalized anxiety disorder; Obsessive–compulsive disorder

Definition

Anxiety is a usual reaction to everyday life stress; however, when anxiety becomes excessive and irrational it can interfere with an individual's life and reach the level of disorder. Severe anxiety can manifest through disturbance of mood, behavior, thought, and other psychological activities. Anxiety disorders are the most common mental disorders and are highly comorbid with a number of other psychological disorders.

Description

There are a number of anxiety and anxiety related disorders, they are as follows:

- Generalized Anxiety Disorder (GAD)
- Obsessive-Compulsive Disorder (OCD)
- Panic Disorder
- Post-Traumatic Stress Disorder (PTSD)
- Social Phobia (Social Anxiety Disorder)
- Specific Phobias

Treatment

Generally, anxiety disorders can be treated with medication, psychotherapy, or a combination of medication and psychotherapy. The typical medications used to treat anxiety are antidepressants, selective serotonin reuptake inhibitors (SSRIs), monoamine oxidase inhibitors (MAOIs), tricyclics, benzodiazepines, and beta-blockers (for physical symptoms). The most prominent and evidence-based psychotherapy treatment for anxiety disorders is cognitive-behavioral therapy (CBT) that can be used with a number of anxiety disorders to help alleviate both the thought and behavioral disturbances caused by anxiety disorders. There are also exposure therapy for OCD and phobias, acceptance and commitment therapy (ACT), dialectical behavior therapy (DBT), interpersonal therapy (IPT), and eye movement desensitization and reprocessing (EMDR) for post-traumatic stress disorder, panic attacks, and phobias. A combination treatment of medication and psychotherapy has been shown to yield best treatment outcomes. However, note that treatment options should be considered on an individual case basis.

Relevance to Childhood Development

Many children will have appropriate fears and anxieties that correspond with their developmental age. It is important for parents to monitor their children's fears, and to see if the child out grows their fears at an appropriate age. Anxiety can interfere with children and adolescent's social, school, and everyday life functioning. Further, excessive anxiety at an early age may suggest future anxiety problems or be factors in the formation of other mental health disorders. Parents need to play an active role in seeking treatment for their child and can discuss treatment options with their child's physician.

Anxiolytics

►Depressants

Anxiolytics/Hypnotics

Kristine Augustyniak
Niagara University Academic Complex, Niagara, NY, USA

Synonyms

Anti-anxiety medications; Depressants; Sleeping pills; Soporifics; Tranquilizers

Definition

Anxiolytics are agents used to decrease emotional tension or anxiety. Hypnotics are drugs used to induce drowsiness or sleep or to reduce psychological excitement or anxiety [17].

Description

An anxiolytic is a drug prescribed for the treatment of symptoms of anxiety.

Hypnotic drugs induce sleep and are typically used in the treatment of insomnia and in surgical anesthesia.

Sedative–hypnotic, is a substance that depresses the central nervous system (CNS) resulting in calmness, relaxation, sleepiness, slowed breathing, and reduction of anxiety.

Types of Anxiolytics (Partial List)

1. Benzodiazepines (BZDs)
   - Alprazolam (Xanax)
   - Bromazepam (Calmepam)
   - Chlordiazepoxide (Librium)

- Clonazepam (Klonopin/Rivotril)
- Clorazepate (Tranxene)
- Diazepam (Valium)
- Halazepam (Paxipam)
- Lorazepam (Ativan)
- Medazepam (Nobrium)
- Nordazepam (Stilny)
- Oxazepam (Alepam)
- Prazepam (Centrax)

2. Azaspirodecanediones/Serotonin 1A agonists
   - Buspirone (BuSpar)

Types of Hypnotics (Partial List)

1. Barbiturates (Sedatives)
   - Amobarbital (Amytal)
   - Phenobarbitol (Luminal)
   - Pentobarbital (Nembutal)
   - Secobarbital (Seconal)
2. BZDs commonly prescribed to treat insomnia
   - Estazolam (ProSom, Eurodin)
   - Flunitrazepam (Rohypnol)
   - Flurazepam (Dalmane)
   - Temazepam (Restoril)
   - Triazolam (Halcion)
3. Nonbenzodiazepines commonly prescribed to treat insomnia
   - Zaleplon (Sonata)
   - Zolpidem (Ambien)
   - Eszopiclone (Lunesta)
4. Antihistamines
   - Diphenhydramine (Benadryl)
   - Doxylamine (sedating ingredient of NyQuil and used in over the counter sleep aides such as Somnil, Dozile, Donormyl, Restavit and Unisom-2)
   - Hydroxyzine (Vistaril)
   - Promethazine (Phenergan)
5. Other
   - Gamma-hydroxybutyric acid, GHB (Xyrem, Illegal use: aka "date-rape-drug")
   - Glutethimide (Doriden)
   - Melatonin, a hormone, can work as a hypnotic if taken 30–90 min before usual bedtime. Ramelteon (Rozerem), a relatively new drug, stimulates melatonin receptors in the brain
   - Alcohol is also used as a sedative–hypnotic drug, though not medically

BZDs: BZDs, though used for a wide variety of conditions, are most commonly prescribed for short-term relief of severe and disabling anxiety such as panic disorder, generalized anxiety disorder (GAD), and social phobia. Long-term use is typically not recommended because they are habit forming and there is a risk of withdrawal symptoms and rebound syndrome after continuous usage past 2 weeks. Common withdrawal symptoms include anxiety, insomnia, restlessness, agitation, muscle tension, and irritability. Seizures and depression may also sometimes occur. To attenuate adverse effects such as drowsiness, cognitive impairment, disinhibition, depression, motor impairment, and rebound anxiety, BZD dosage should titrated slowly and tapered gradually [5, 19].

Due to their low toxicity and rapid and effective action, BZDs may be indicated to cover the latent periods associated with slower onset medications, such as selective serotonin reuptake inhibitors (SSRIs) and Serotonin 1A agonists, now commonly prescribed for long-term treatment of anxiety. BZDs are also often a first choice when rapid control of acute symptoms is needed [11]. Longer term uses include treatment for severe anxiety and psychosis. BZDs are also potent anticonvulsants and have life-saving properties in the acute management of status epilepticus. The most commonly-used BZDs for seizure control are lorazepam and diazepam.

The pharmacological actions of BZDs are believed to enhance gamma amino butyric acid (GABA-A) function and therefore are referred to as GABA-A agonists. BZD agents bind to unique portions of GABA receptors that exist as large protein complexes located on neurons in the CNS. This protein serves as the major inhibitory neurotransmitter in the brain [19]. By enhancing GABA's inhibitory actions, brain cells are unable to be stimulated by excitatory neurotransmitters, and this inhibition alleviates symptoms of anxiety. The impact of BZD agents on particular regions of the CNS appears to determine the clinical effect. BZDs impact on the cortex and limbic system is associated with their anxiolytic properties. The effect on the brain stem and reticular formation appears to induce a sedative effect. The impact on the striatum, globus pallidus, and substantia nigra is associated with anticonvulsive effects, while the effect on purkinje cells in the cerebellum is implicated in their anti-ataxic effects [7].

Azaspirodecanediones/Serotonin 1A agonists: Azaspirodecanediones are a class of drugs with both antidepressant and anxiolytic effects. Azaspirodecanediones have fewer side effects than most BZDs, are not habit forming and do not exacerbate the effects of alcohol. Azaspirodecanediones are thought to agonize serotonin (specifically the 5-HT1A receptor), primarily in the

hippocampus. Buspirone (BuSpar) is the most commonly prescribed serotonin 1A agonist for the treatment of GAD. Reportedly, like SSRIs, BuSpar works gradually, reaching therapeutic levels in approximately 2–6 weeks. BuSpar has not been supported as a highly effective broad spectrum anxiolytic in adults [4]. However, there is some evidence of effectiveness with children presenting with both anxiety and depression [8, 13] or to augment the effects of SSRIs [2].

Barbiturates: Barbiturates, such as pentobarbital and phenobarbital, were the first agents to treat anxiety disorders in adults and children. Barbiturates exert a sedating effect linked to their ability to reduce physiological symptoms of anxiety. Barbiturates and BZDs act similarly to produce depression of CNS function and behavior. Both classes of drugs enhance the ability of the inhibitory neurotransmitter, GABA. BZDs, however, have largely supplanted barbiturates because BZDs have less potential for abuse, addiction and lethal overdoses [14]. Many experts consider barbiturates obsolete, although they may be valuable for the short term treatment of severe insomnia, only after BZDs or non-benzodiazepines have failed. They are contra-indicated for use children or adolescents [4].

Antihistamines: Antihistamine drugs exhibit anticholinergic (drying) and hypnotic–sedative properties and are most commonly used to treat allergic reactions. The body releases histamine during several types of allergic reactions and, to a lesser extent, during some viral infections such as the common cold. When histamine binds to its receptors on cells, it causes the cells to release chemical messengers that lead to sneezing, itching, and increased mucus production. Antihistamines, like histamine, bind to the histamine receptors, but when they bind to the receptors they do not stimulate the cells to release chemical messengers. In addition, they prevent histamine from binding and stimulating the cells. As mild sedatives, antihistamines are also sometimes prescribed to calm sporadic anxiety and combat insomnia [4].

Relevance to Childhood Development

The primary indications for use of anxiolytics and hypnotics in children and adolescents are anxiety disorders, sleep disorders, seizures, psychosis, aggression, and preparation for medical and dental procedures [19]. Affecting 6–18% of children and adolescents, anxiety disorders are among the most common mental health conditions and can impair social and academic functioning to the same extent as disruptive behavior disorders [3, 16, 18]. Moreover, childhood anxiety disorders have been associated with vulnerability to a number of adult mental health challenges [1, 9, 12]. Thus, childhood anxiety disorders represent a significant public health concern and mandate efficacious and early intervention. Best practices in childhood mental health professions assert a multimodal approach where psychotropic medication is considered only one aspect of a comprehensive treatment program. Ideally, psychopharmacological interventions should be combined with others interventions such as social skills training, special education, psychoeducation and/or individual and family psychotherapy as determined through systematic assessment of individual needs [10, 13].

Though touted for their quick action, low toxicity, and relatively safe side effect profile in use with adults, the literature on the efficacy of BZDs in children and adolescents with anxiety disorders is scant and inconsistent. In addition, the potential for abuse, dependence, and adverse events limits their use of first line agents in childhood psychopharmacotherapy. Side effects such excitement, rage, anger, or hostility occur more frequently in children and adolescents. Because anxiolytics typically result in calming effects, these are coined "paradoxical reactions." These reactions may occur secondary to the relief of anxiety and usually occur within the first two weeks of therapy. In contrast to the literature on BZDs, substantial evidence supports the use of SSRIs in the treatment of pediatric anxiety disorders. Although treatment with SSRIs may lead to a small increase in the risk for suicidal ideation in children and adolescents, they are most frequently favored for the treatment of childhood anxiety by prescribers [5, 6, 14, 15, 19].

Apgar

Laura Bruder
Nova Southeastern University, Davie, FL, USA

Definition

The Apgar test is a quick and efficient system used to assess the physical condition of a new born child at birth and to determine the need for immediate medical care.

Description

The Apgar test is a quick and efficient system used to assess the physical condition of a new born child at birth and to determine the need for immediate medical care. The scoring system was developed by Virginia Apgar, M.D in 1952 to rapidly determine the medical condition of an infant immediately following delivery [1]. The Apgar test is based upon five objective signs present at birth. Each condition is evaluated on a scale from zero to two with a total Apgar score ranging from 0 to 10. Total scores earned on all five criteria of 3 and below are considered critically low; scores between 4 and 6 are fairly low, while scores between 7 and 10 are within normal limits [4]. The Apgar test is conducted at 1 and 5 min after birth. If the first two Apgar scores are low or if there are concerns regarding the baby's overall condition, an Apgar test may be given at 10 min after birth as well [4].

The letters of Dr. Apgars' last name have become an established acronym for the conditions of the test and are as follows: **A**ppearance, **P**ulse, **G**rimace, **A**ctivity and **R**espiratory (see Table 1) [2]. A newborn's appearance is based upon their color and the presence of cyanosis [1]. Pulse is based upon heart rate and is the most important condition of the five areas assessed [3]. A heart rate of 100–140 is scored a 2, a rate under 100 is scored a 1, and the absence of heart rate is scored a 0. Grimace is based upon reflex irritability to some form of stimulation. The stimulation is usually the placement of a rubber catheter inside the infant's nostril. A score of 2 is assigned if the infant pulls away, sneezes or coughs, a score of 1 are assigned if the infant only provides a facial response such as a grimace, and a score of 0 is assigned if there is an absent response to stimulation. Activity is based upon muscle tone. A score of 2 is assigned to an infant who spontaneously flexes their arms and legs with active movement. A score of 1 is assigned to an infant who flexes their arms and legs without movement, while a score of 0 is assigned to an infant who remains completely flaccid. Lastly, respiratory effort is based upon breathing rate

Apgar. Table 1 Apgar test

Acronym	Sign	Score 0	Score 1	Score 2
A	A. Appearance (skin color)	Blue, pale	Body pink, limbs blue	All pink
P	P. Pulse (heart rate)	Absent	<100	>100
G	G. Grimace (reflex irritability)	None	Grimace	Sneeze, cough, cry
A	A. Activity (muscle tone)	Limp	Some flexion of limbs	Active movements
R	R. Respiratory effort	None	Slow, irregular	Effortful, good strong cry

Source: [2]

and effort. An infant who breathes at a normal rate and provides an effortful cry receives a score of 2, an infant with slow and irregular breathing and a weak cry receives a score of a 1, while an infant who has absent breathing receives a score of 0 [1, 4]. Low Apgar scores, particularly at 1 min are commonly seen following a high-risk pregnancy, cesarean section, complicated deliveries and among premature infants. By 5 min, scores frequently improve. Critically low scores suggest that the neonate is in critical condition and requires immediate medical attention [4].

Apgar Score

Lydia Aydlett
Western Carolina University, Cullowhee, NC, USA

Definition

The Apgar score is a measure of the infant's condition immediately after birth.

Description

The Apgar score is the most well-known representation of the newborn's risk status administered immediately after birth. Because newborns may have suffered distress prior to or during birth or may have difficulty transitioning to life outside the womb, the Apgar is used to quickly screen newborns to identify infants who need immediate attention. The screening is administered at one minute after birth and if any difficulties are noted the baby is screened again at five, and sometimes at ten minutes after birth. The additional Apgars are administered to assure that infants who show distress at first have recovered by the 5 or 10 min measure.

In 1952, Virginia Apgar, M.D. presented "A proposal for a new method of Evaluation of the newborn Infant" to the Twenty Seventh Annual Congress of Anesthetists. The purpose of her proposal, published with supportive data in 1953, was to provide a practical, clear evaluation of the condition of the newborn infant. She recommended that the scale be used to compare "the results of obstetric practice, types of maternal pain relief and the effects f resuscitation."

The criteria for her assessment are:

	Score of 0	Score of 1	Score of 2
Heart rate	Absent	Slow (<100 beats/min)	>100 beats/min
Respiratory effort	Apneic (no breathing)	Weak cry, hypoventilation	Good strong cry
Reflex irritability	No response to stimulation	Grimace, feeble cry when stimulated	Grimace, sneeze, cough
Muscle tone	Limp	Some flexion	Active movement
Color	Blue or pale all over	Blue at extremities, body pink	Body and extremities pink

As displayed in the table, a 0, 1, or 2 rating is made for each of 5 functions: heart rate, respiration, reflex response, muscle tone, and color. A score of 2 for a particular function is the best possible sign indicating no cause for concern.

A score of 0, 1, or 2 for each sign indicates whether the sign is absent or present. The highest possible composite score is 10 and indicates that the baby is in the best possible condition. An Apgar score of 7 or better means that the infant needs little medical intervention and is successfully adapting to the postnatal environment. A score of 3 or lower means emergency medical attention is needed.

Because the Apgar scale is such a clinically useful screener of newborn risk status, hospitals around the world use it daily. Findings from follow-up studies indicate that the Apgar has survived the "test of time." In an analysis of more than 150,000 infants researchers in Texas found a strong correlation between infant mortality and the 5 min Apgar score. The 1 min score continues to focus attention on the infants' condition immediately after birth.

Relevance to Childhood Development

The Apgar score at one minute after birth focuses on the infant's need for resuscitation. Without a quick, easy to administer assessment of infant status, infants in the past were less supported medically and more poorly monitored. An Apgar score of 0–3 at 5 min predicts infant mortality within the first 28 days of life. Although the Apgar alone does not predict cerebral palsy, uses in conjunction with other measures it can contribute to the prediction of developmental difficulties.

Aphasia

Anna Mazur-Mosiewicz, Raymond S. Dean
Neuropsychology Laboratory, TC 904 Ball State University, Muncie, IN, USA

Synonyms

Impaired language; No language; Reading impairment

Definition

Aphasia is a disorder of language most often secondary to brain damage (as opposed to *dysphasia*, which is a congenital or developmental language disorder and not partial or incomplete aphasia). Aphasia is usually caused by lesions, or dysfunction, in the region of the sylvian fissure of the dominant hemisphere of the brain. The sylvian fissure comprises the opercular and insular areas, which are supplied by branches of the left sylvian artery. The upper division of the sylvian artery supplies the insula and the upper regions of the sylvian fissure, and the lowed division supplies the posterior parieto-occipital regions. Most commonly, aphasic disorders arise from arterial disease in the two divisions.

Description

Aphasia has several clinical types that are related to the site of the brain damage. Systematic clinical examination is necessary to decide whether the patient has *motor*, or *Broca's aphasia*, which is sometimes called *expressive*, *anterior*, or *nonfluent aphasia*; a *sensory* or *Wernicke's aphasia*, which also is referred to as *receptive*, *posterior*, or *fluent aphasia*; a *total* or *global aphasia*; or one of the *dissociative language syndromes* that include *conduction aphasia*, *word deafness* (*auditory verbal agnosia*), *word blindness* (*visual verbal agnosia* or *alexia*), and several types of *mutism*. *Mutism* does not permit to predict the exact site of the lesion. *Anomia*, which is also called *nominal* or *amnesic aphasia*, and *agraphia*, which is impaired ability to communicate by writing, are often found to some degree in all types of aphasia. Additionally, agraphia is rarely to be found alone [1, 5].

Motor aphasia (*Broca's aphasia*): Broca's aphasia is a primary deficit in language output or speech production. This type of aphasia has a wide range of variation in motor deficit, from the mildest type known as cortical dysarthria, which is characterized by intact comprehension and ability to communicate through writing, to a compete loss of all means of communication through any lingual, phonetic, and manual action [1, 5].

In the most advanced forms of motor aphasia, patients are unable to speak, read, or repeat words aloud. Yet, the lingual and phonatory apparatus is not paralyzed, and patients retain their ability to chew, swallow, and even vocalize without words. Occasionally, the words *yes* and *no* can be produced, and used within the context. Sometimes, patients can repeat several stereotypic words or phrases over and over again, as if compelled to do so, which is a symptom of *monophasia* (*recurring utterance*, *verbal stereotypy*, or *automatism*). If speech is possible,

certain habitual expressions, such as "Hi," and "Good morning," seem to be the easiest to produce. In the milder forms of the disorder, spontaneous speech is nonfluent, mute or telegraphic. Naming is impaired. The normal melody of speech is entirely lacking, and words are produced slowly and laboriously. The dysfluency takes the form of improper accent or stress on certain syllables, incorrect intonation and phrasing of words in a series, and pacing of word utterances. Speech is often sparse and consists only of nouns, transitive verbs, or important phrases. Length of phrases and sentences is reduced and many of the short words (articles, prepositions, etc.) are often omitted [4]. Repetition of spoken language is as abnormal as the patient's own speech. Language comprehension is intact with the exception of mild difficulties with grammatically complex phrases. Additionally, repeated patients usually recognize their errors and failures in speech, which may cause exasperation and despair [1].

Associated signs are right hemiparesis, right hemisensory loss, and depression. Most patients with Broca's aphasia have correspondingly severe difficulty with writing. If the dominant hand is paralyzed, the patient struggles with printing and writing with the non-dominant; letters are often malformed and words misspelled. Broca's aphasia is caused by lesion in the Broca's area in the posterior part of the inferior frontal gyrus, along with damage to adjacent cortical areas and subcortical white matter. Motor speech disorders, including severe motor aphasia and transient types, are generally due to vascular lesions. The most frequent type of vascular lesion that results in an abrupt onset or rapid regression is embolic infraction in the territory of upper main (rolandic) division of the middle cerebral artery [1, 4].

Aphemia: Aphemia is a rare variant of the Broca's aphasia. It is a nonfluent syndrome characterized by initial mutism followed by retaining ability to speak. However, the speech is characterized by phoneme substitutions and pauses. All other language functions are intact including the ability to communicate through writing. Aphemia is usually transitory and results from small lesions to the Broca's area or its subcortical white matter or the inferior precentral gyrus [1, 2].

Wernicke's aphasia (*sensory aphasia*): Wernicke's aphasia consists of two main elements: (1) an impairment in speech comprehension, or the inability to differentiate spoken and written word elements or phonemes, which reflects involvement of the auditory association areas or their separation form the primary auditory cortex; and (2) fluently articulated but paraphasic speech. Therefore, in Wernicke's aphasia speech is fluent with paraphasic errors. Naming is impaired and is often characterized by bizarre paraphrasic misnaming. Oral comprehension and repetition are impaired. Wernicke's aphasia is characterized by a visual language deficit that is reflected by the inability to read, *alexia* [1, 4].

Speech is produced without effort, and phrases and sentences are of normal length and are properly intonated and articulated. Despite normal articulation and prosody, the speech is meaningless, and the words do not convey any communicative value. Words themselves are frequently malformed or inappropriate, which is referred to as *paraphasia*. There are several types of paraphasias, depending on the type of paraphasic error: *literal paraphasia*, in which the patient substitutes phoneme or syllable within a word (i.e., "The apple is greel") and *verbal paraphasia* or *semantic substitution*, which is characterized by substituting one word with another (i.e., "The apple is blue"). *Neologisms*, or words that are not part of the language may also be observed (i.e., "The apple is prums"). Fluent paraphasic speech is often entirely incomprehensible, which is called *gibberish* or jargon *aphasia*. In Wernicke's aphasia patients seem to be unaware of the deficit. Although the motor apparatus required for the expression of language may be intact, the patients are unable to function socially due to communication difficulties. They are deprived of any means of linguistic communication. They cannot express themselves through language, and language comprehension is often limited to several simple commands. Writing is well formed and may contain some correct words; however, a majority of written words are meaningless. All these impairments are present in varying degrees depending on the exact site and size of the brain lesion. Right hemianopsia is sometimes associated with Wernicke's aphasia, but motor and sensory functions in the limbs are typically normal. Wernicke's aphasia is associated with the posterior perisylvian region (comprising posteriosuperior temporal, opecular supermarginal, and posterior insular gyri), and usually is due to embolic occlusion of the lower division of the left middle cerebral artery [1, 5].

Global aphasia (*total aphasia*): Global aphasia is the summation of Broca's and Wernicke's aphasias, in which all aspects of speech and language are affected. Speech is nonfluent or mute, but comprehension is also impaired. Naming, repetition, and writing are poor. At the most, patients are able to say only a few words, which are limited to cliché and/or habitual words or phases. They may understand several words or expressions; however, they fail to carry out a series of simple commands and name a series of objects. They cannot read written text or

repeat oral language. The patients often use meaningful gestures (i.e., greeting), avoidance reactions, and self-help activities [2, 4].

Most patients also present with dense right hemipharesis, hemisensory loss, and often, hemianopsia. The syndrome is due to lesion that affects a major part of the language area and the major cerebral hemisphere. The lesions are usually large and involve both the inferior frontal and superior temporal regions and often much of the intervening parietal lobe. The lesions are usually due to occlusion in the left internal carotid or middle cerebral artery, but it also may occur as a result of hemorrhage, or tumor [1, 5].

Dissociative syndromes (*disconnection syndromes*): Dissociative syndromes do not result from lesions to the cortical language areas but from the interruption of association pathways joining the primary receptive areas to the language areas. This category includes aphasias that are due to lesions separating the strictly receptive parts of the language mechanism form the motor ones and to lesions separating the perisylvian language areas from the other parts of the cerebral cortex [1, 5].

Conduction aphasia: Many features of conduction aphasia resemble these of Wernicke's aphasia. Similarly to Wernicke's aphasia, conduction aphasia is characterized by literal paraphasic errors. Naming is impaired; yet, contrastingly to Wernicke's aphasia, auditory comprehension is normal. Writing also is impaired. Patients have severe difficulties with repetition and reading aloud. Dysarthria and difficulties with prosody may also be present. Spontaneous speech is usually normal; however, some patients may presents with fluency difficulties and frequently hesitate due to self-correction. Hemianopsia and hemisensory loss are sometimes observed, but motor ability is preserved. Conduction aphasia is usually due to lesions that are located in the upper bank of the sylvian fissure and involve the supermarginal gyrus and, occasionally, the most posterior part of the superior temporal region [1, 2, 5].

Pure word deafness: This is an extremely rare syndrome characterized by an impairment of auditory comprehension and repetition and the inability to write words that are dictated. However, the abilities to read, write, name, and spontaneously speak are preserved. Hearing for pure tomes and non-linguistic noises (i.e., anime cries) are intact. Mild aphasic deficits, mostly paraphasic speech, are not uncommon. Pure word deafness is associated with lesions isolating the Wernicke's area from both Heschl's gyri (*disconnection syndrome*; [1, 2]).

Anomic aphasia (amnesic aphasia, nominal aphasia): The most frequent aphasic disturbance is word finding difficulty or anomia. Yet, anomic aphasia is diagnosed only when the anomic disturbance is the most prominent feature of the language difficulty. Anomic aphasia is characterized by the impaired access to the internal lexicon, which results in ability to name objects or phenomena. Simultaneous speech is normal with the exception of pauses, groping for words, circumlocution, and substituting word with another word or phrase that conveys the same meaning. Oral and reading comprehension and writing are intact. Isolated, severe anomia may be related to lesions in different parts of the language area [1, 2].

Transcortical aphasia: Transcortical aphasias are a result of lesions that separate cortical centers form the language circuit. There are three main transcortical aphasic syndromes: (1) Isolation Syndrome, in which patients have fluent and echolalic speech and present impaired oral comprehension, naming, reading and writing skills despite normal repetition ability; (2) Transcortical Motor Aphasia, which is characterized by nonfluent speech, impaired naming, and intact reading and repetition ability; and (3) Transcortical Sensory Aphasia, which is associated with fluent and echolalic speech with intact repetition and impaired naming, oral comprehension, reading, and writing abilities [1, 4].

Subcortical aphasia: Subcortical aphasias are caused by lesions that are localized in the basal ganglia or deep cerebral white matter of the dominant hemisphere. Subcortical lesions cause aphasia less commonly than cortical lesions, and the language functions affected are often atypical. Depending on the exact site of lesion, the symptoms may include anomia, dysarthria, lost capacity to speak while retaining the ability to write, understand spoken words, and comprehend written text. Generally, subcortical lesions are associated by syndromes that are difficult to classify and occur along with right hemipharesis [1, 4].

Alexia with agraphia: *Alexia* refers to the inability to read, and *agraphia* describes the inability to write despite previous literacy skills. Thus, alexia with agraphia is often referred to as "acquired illiteracy," in which previously educated patient loses the ability to read and write. Alexia with agraphia is generally observed along with a right hemianopsia and elements of the Garstmann syndrome: agraphia, acalculia, right-left disorientation, and finger agnosia. This type of aphasia is due to lesions in the inferior lobule, particularly the angular gyrus [2, 3].

Alexia without agraphia (*pure word blindness*, *visual verbal agnosia*): This is a rare syndrome, in which a literate person loses the ability to read, comprehend written script, and, often, to name colors. Patients are able to write; however, they are not able to read their own written productions. Speech, oral comprehension, and repetitions are normal. Naming, especially for colors, may be impaired. The disorder s commonly associated with right hemianopsia or upper quadrant defect. Alexia without agraphia is usually associated with a stroke in the territory of the left posterior cerebral artery, with infraction of the left visual cortex, particularly the geniculocalcarine tract, the connections of the right visual cortex with the intact language areas of the domain hemisphere [1, 2, 5].

Aphasia Screening Test

Matthew J. Holcomb[1], Raymond S. Dean[2]
[1]Ball State University, Muncie, IN, USA
[2]Neuropsychology Laboratory, TC 904 Ball State University, Muncie, IN, USA

Definition

"Aphasia screening test" is a broad term applied to a variety of short screening measures which address potential language disorders related to aphasia and are employed by a variety of mental health professionals including neuropsychologists. Some of the tests go beyond language, such as the Aphasia screen test of the Halstead reitan neuropsychological test.

Description

The term aphasia means literally "without language" and is one of the most common consequences of a stroke [5]. When a patient presents with aphasia, it is important that clinicians be able to differentiate between different types of aphasia. Typically this involves differentiating between various types of aphasia. For more information about types and causes of aphasia go to *aphasia*.

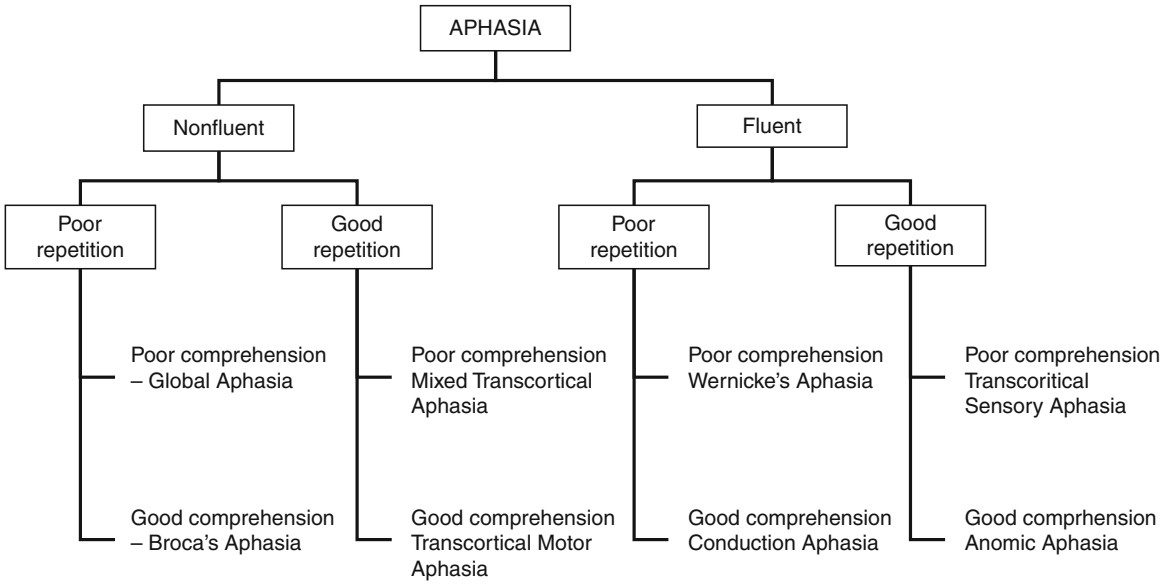
Examination

The examination of aphasia can take on a number of different looks and there are a number of accepted aphasia screening tests which are available. There are however some basic components which most aphasia screening tests will examine with the patient to help in diagnosis. Lezak (2004) suggested that when evaluating aphasias a review of language and speech functions will help an examiner to determine whether or not problems are present. The areas that Lezak suggests should be covered with verbal ability are:

1. Spontaneous speech
2. Repetition of words, phrases, sentences
3. Speech comprehension
4. Naming
5. Reading
6. Writing

The following examination is a common form of an Aphasia screening tests and is known as the Bedside Language Exam.

1. *Spontaneous speech* – observation of patient's speech and comprehension. The most important aspect of spontaneous speech is the fluency of the individual being tested, as well as attention and articulation.
2. *Naming* – naming is a test which asks patient to name objects, object parts, colors, pictures, of other items. In most aphasia screenings it's important to differentiate between recognition of objects and the ability to actually form and articulate the name of the object being presented.
3. *Auditory comprehension* – patients are asked to follow simple commands which are presented auditoorally. In many circumstances the tasks are presented as multistep commands that require the examinee to understand directions and then motorically carry out the commands.
4. *Repetition of words and phrases* – it is common to find difficulty with rapid consonant articulation and speech in rapid sequences.



Aphasia Screening Test. Fig. 1 Differential diagnoses for aphasic syndromes [3, 6].

5. *Reading* – examinees are asked to read aloud and then is tested on comprehension.
6. *Writing* – obtaining a writing sample provides a sample of expressive language but also allows the examiner to analyze spelling. Writing also tends to be seen as sensitive to the degree of aphasia.

Apnea

Anne Fierro Vanderlaan
Saybrooke University, Meridian, ID, USA

Definition

An impermanent interruption of breathing during sleep.

Description

Apnea is a reoccurring obstruction of air from the lungs or a problem in the brain that controls respiration. This is a sleep disorder that can cause sleepiness during the day because of the disruption of sleep. Some times an individual can stop breathing during sleep and then struggle for air. This constant struggle for air affects the quality of sleep often leaving the person feeling drained. This condition has been found in infants, children and adults.

Relevance to Childhood Development

Sleep apnea in children can affect cognitive and behavioral difficulties. Often, sleep disorders in children have been over looked. Current research shows a relationship of sleep disorders with Attention Deficit Disorder.

Applied Behavior Analysis (ABA)

Shelly Harker
Georgia School of Professional Psychology, Argosy University, Atlanta, GA, USA

Synonyms

Applied behavioral assessment; Behavior analysis

Definition

Applied behavior analysis (ABA) is a scientific approach in which procedures based on the principles of behavior are systematically applied to identify environmental variables that influence socially significant behavior and are used to develop individualized and practical interventions [2–4].

Description

Rooted philosophically and theoretically in the science that informs the practice of Behaviorism, behavior analysis is an umbrella term that encompasses three interrelated branches including applied behavior analysis (ABA), experimental analysis of behavior (EAB), and behaviorism. ABA involves experimental single-subject designs used to demonstrate the functional relationship between environmental variables and socially significant problem behavior. Findings derived from ABA research embody the breadth of literature behavior analysts use to guide their professional practice. EAB also involves single-subject laboratory research; however, it is aimed at examining the effects of independent variables (i.e., treatment) on dependent variables (i.e., target behaviors) to clarify the basic principles of behavior further.

Although proposed nearly 40 years ago, Baer et al. coined seven dimensions that are still regarded as the primary criteria for defining and reviewing ABA as a science today [2, 3]. Foremost, they stated that a study must be *applied* or, in other words, socially significant to the individual and all related parties (i.e., parents, caregivers, teachers, etc.) and aim to improve the lives of others through meaningful interventions. Secondly, they claimed that studies must also be *behavioral*, in that the target behavior should be measurable, chosen based on importance and not convenience for others, and be closely monitored to insure that change is attributable to the individual and not external factors (i.e., the behavior of the researcher). A study in ABA must also be *analytic*, or demonstrate experimental control between the manipulated events, or the treatment, and the behavior of interest. In other words, the experimenter is able to demonstrate control over the occurrence and nonoccurrence of the target behavior. Another hallmark of an ABA study is that it must be *technological*, or provide sufficient detail to allow for replication of the behavioral procedures to produce similar results. Additionally, the behavioral procedures described should be *conceptually systematic*, or described using the basic ►behavioral principles from which they were derived, to facilitate and promote a cohesive discipline. Lastly, an ABA study must also be *effective* in deriving socially significant results for the

behavior under investigation and be *generalizable* longitudinally, across different contexts, and different behaviors. Additional ABA criteria were later proposed by Heward who suggested that the science was also accountable, public, doable, empowering, and optimistic [8].

There is an abundance of literature supporting the use of ABA in treating a wide topography of behaviors and related diagnoses. Much of the research produced in the field of ABA has been conducted with individuals diagnosed with developmental disabilities due to the severe behavioral excesses and deficits that commonly co-occur with these disorders. To name a few, Hagopian and Boelter cited studies in which ABA has been successfully used to treat aggression, self-injurious behavior (SIB), stereotypic behavior, and pica [6]. Furthermore, once the function of an aberrant behavior is identified, ABA-based procedures are then used to teach adaptive behaviors, such as communication, academic skills, and self-help skills, to replace behavioral deficits. ABA has been used to address behavioral excesses and deficits in individuals with the following diagnoses: ▶autism spectrum disorders (ASD), schizophrenia, mental retardation, attention deficit hyperactivity disorder, stereotypic movement disorder with self-injury, Down Syndrome and pediatric feeding disorders [6]. Lastly, ABA has also proven effective with typically developing populations to address more benign behavior issues, such as controlling personal habits, increasing athletic performance, and promoting a healthy lifestyle [4].

The field of ABA is broad and has been implemented in a wide range of settings and across a variety of behaviors. ABA procedures are commonly implemented in homes, schools, and hospital settings but have also been generalized to the community to address such issues as littering, recycling, unsafe driving, seatbelt use, and speeding [4, 15]. ABA is also implemented in businesses, industries, and in human services, to improve employee and supervisor performance, to address job safety, and to promote business productivity. Although procedures used in these types of settings are generally derived from basic behavioral principles and procedures, study in this setting is typically subsumed under industrial organizational psychology (I/O Psychology) or organizational behavior management (OBM).

Although it is often assumed that ABA is only one standardized treatment approach, there are a number of different applications used to address a variety of socially significant behaviors. There is a large body of empirical support for the use of ABA-based skill acquisition techniques and behavior reduction interventions. The UCLA Young Autism Project, or early intensive behavioral intervention (EIBI), developed by Ivar Lovaas is one of many applications of ABA used to optimize children's functioning [12]. Lovaas' method employs a standardized set of procedures, otherwise known as discrete trial training (DTT), which consists of one-to-one interaction with a therapist, delivery of clear and concise instructions, the use of three-step prompting procedures (i.e., "tell, show, do"), and the delivery of immediate and consistent reinforcement (see [11] for more information). Lovaas' early research was not only monumental in advancing the field of ABA and in facilitating a greater understanding of autism in preschool children, but it also emphasized the necessity of early and intensive intervention using behaviorally-based procedures to increase both language and academic skills [19].

Skinner's analysis of verbal behavior is yet another application of ABA that has been extensively reviewed and disseminated to a growing number of families of individuals with autism and other developmental disabilities. In his book, *Verbal Behavior*, Skinner provided a conceptual framework of what he termed to be controlling variables of language [18]. Unlike traditional linguists who generally conceptualize language based on meaning or syntax, Skinner examined language as verbal operants, which were each defined by their functional relationship to environmental events [17]. For instance, a child who learns to vocally request a toy would not be conceptualized as understanding what that word means or the timeliness of its use in a social context. Rather, through Skinner's analysis of verbal behavior, one would examine the antecedents, or motivating operations, that elicited the child's request, or mand, for the item and the consequences that maintain this verbal behavior across social environments. Therefore, the speaker and listeners' behaviors and the use of basic verbal operants are seen as the foundational building blocks for more sophisticated language. Typically, information about a child's pre-existing language repertoire, if any, is assessed using the assessment of basic language and learning skills (ABLLS). Information derived from this assessment is then used for establishing language or target goals that are then taught using intensive language training [17].

Another application of ABA that capitalizes on a child's motivation in the natural environment is Incidental Teaching. This procedure entails the instructor manipulating or structuring the learning environment so that preferred items and activities are used to create learning opportunities [13, 14]. This list of commonly used skill acquisition procedures is not exhaustive; however, it does represent the diverse ways in which ABA, namely the principles of behavior, are used to teach or improve behavior.

Behavior reduction interventions and techniques used in the field of ABA focus on the operant functions of

a target behavior as opposed to attributing its occurrence to an underlying pathology [1]. Specifically, ABA focuses on antecedents and consequences that can be used to alter or reduce problem behavior [10]. Antecedents are stimuli, settings, and contexts that occur before a target behavior; consequences are events that follow a target behavior. Furthermore, consequences for behavior rely heavily on positive and negative reinforcement and positive and negative punishment [10]. Behaviors become associated with and highly influenced by certain types of consequences or antecedents that can either increase or decrease the likelihood of the occurrence of that behavior.

One of the most common ABA-based procedures for identifying operant functions of problem behavior involves a unique assessment technique known as a functional behavior assessment (FBA). This comprehensive assessment method is designed to systematically identify variables responsible for maintaining problematic behavior through record reviews, indirect assessments or interviews with caregivers, direct assessments through observations, and a functional analysis (FA), which involves the experimental manipulation of environmental events. Based on the results of the indirect and direct assessments of the FBA, hypotheses regarding the variables maintaining problem behavior are formulated and tested during the FA. The results from this analysis yield information pertaining to the maintaining variables of problem behavior, which are then used to identify and test probable intervention(s) through a treatment analysis (TA). Because there are many different approaches one can take in reducing problem behavior (e.g., reinforcement-based treatments, such as differential reinforcement, and punishment-based treatments, such as time-out procedures), a TA is typically conducted in an analog setting to ensure the effectiveness of the treatment selection prior to generalizing it in to the natural environment.

Seminal Figures

Although a complete historical account of the evolution of ABA is beyond the scope of this reference (see [2–4, 10], suggested resources for more information), a review of some of the early seminal leaders and the revolutionary work upon which the scientific principles of ABA are based is both noteworthy and warranted. The foundation of ABA began with the early proclamations of Charles Darwin (1809-1882), who focused his research efforts on evolution and the continuity among species. Specifically, he recognized that humans and infrahumans, although different, were subject to similar influences and principles based on survival. This declaration by Darwin spawned the importance of the study of animal behavior in order to gain a greater understanding of human behavior.

Animal research continued to serve a prominent role in the study of behavior through the work of Ivan Pavlov (1849-1936), who unveiled the processes of respondent conditioning, and Edward Thorndike (1874-1949), whose experiments with felines led to the development of the Law of Effect. John B. Watson (1878-1958), who was a seminal leader in the movement towards behaviorism, is recognized for his development of stimulus-response (S-R) psychology, which focused solely on direct observation of environmental stimuli (S) and the responses the stimuli evoked (R). B.F. Skinner (1904-1990) later expanded the work of Watson and the field of behaviorism through the publication of his book, *The Behavior of Organisms* (1938/1966). In this great work, he recognized Pavolv's S-R psychology as respondent behavior and, because he found that it was unable to explain the mechanisms responsible for spontaneous or voluntary behavior, Skinner coined what he called operant behavior or operant conditioning. His discovery of the three-term contingency (Antecedent-Behavior-Consequence) and his successful account of these basic principles in identifying a functional relationship between human behavior and one's environment marked the beginning of experimental behavior analysis and behavior modification. Skinner is also well known for his extensive writings on the philosophy of this science, which later came to be known as "radical behaviorism" [4]. In 1968, the publication of the *Journal of Applied Behavior Analysis* (JABA), which was the first journal in the Unites States to address applied behavioral problems, marked the formal beginning of contemporary ABA [4]. To date, this publication continues to provide researchers with new methodological variations on the assessment and treatment of aberrant behavior and serves as a launching ground for the publication of current trends and novel work.

Despite its growth within the past 40 years, ABA is still a new science with much to be researched and explored. Ongoing trends in ABA research are its continual efforts to examine variations in the use of basic behavioral principles and methods, focusing on the overall effectiveness of treatment methodologies, and evaluating the social validity of treatment interventions. In a report analyzing current trends in presentations at annual conferences for the Association of Behavior Analysis (ABA), Kangas and Vaidya [9] reported that the number of registered attendees has increased from 21 to 346% since its original inception in 1974. Furthermore, they found that applied research, or ABA presentations generally outnumbered both basic and conceptual research and have concentrated more on topics related to autism, developmental disabilities, and education. Another trend in the field of ABA is

the increasing number of researchers seeking certification as board-certified behavior analysts (BCBA) or board-certified associate behavior analysts (BCABA) since its initiation in 1998. The growing popularity of obtaining certification would suggest that many researchers are now eager to put the empirically-based behavior analytic procedures they have investigated into practice.

Relevance to Childhood Development

As noted previously, many of the research efforts in the field of ABA have focused on individuals diagnosed with ASD [15]. From the behavioral analytic perspective, autism and ASD are characterized as syndromes of behavioral deficits and excesses [5]. Behavioral deficits of children with autism include language or communication impairments, failure to develop peer relationships, and an inability to engage appropriately in reciprocal social interactions. Behavioral excesses may take the form of aggression, self-stimulatory behaviors, or SIB. ABA has been used to treat these behavioral deficits through skill acquisition techniques, such as those mentioned previously, and behavioral excesses through a variety of differential reinforcement interventions paired with extinction. The individualized procedures of ABA that are systematically applied to behavior not only help to bring about change, but ultimately alter the developmental trajectory of children with autism [7].

ABA-based procedures used for assessing and treating comorbid behaviors related to this diagnosis and for teaching these children have been extensively researched and empirically supported [6]. Furthermore, based on the empirical evidence produced by ABA interventions, many professional and government agencies have recognized treatments derived from these principles as both highly effective and as best-practice procedures. Specifically, a report published by the National Research Counsel of the National Association of School Psychologists (NASP) summarizing necessary components of effective interventions for children with autism recommended active participation in intensive ABA programming for a minimum of 25 h per week, which is equivalent to a full school day for 5 days a week [16]. Additionally, the Surgeon General of the United States recognized ABA as the treatment of choice for children diagnosed with ASD: "Thirty years of research demonstrated the efficacy of applied behavioral methods in reducing inappropriate behavior and increasing communication, learning, and appropriate social behavior" [20].

Applied Behavioral Assessment

Mary Ann Zipprich
Texas A & M University – Corpus Christi, Corpus Christi, TX, USA

Synonyms

Applied behavior analysis (ABA); Operant learning and applied behavior analysis (ABA)

Definition

Applied behavior analysis (ABA) is the branch of psychology that is devoted to understanding and improving socially important human behavior ([1], p. 63). Furthermore, it involves the scientific study of behavior through the use of techniques underlying positive behavior support. ABA uses the principles of operant psychology to reduce problem behavior or increase positive behavior ([2], p. 321).

Description

Practitioners who use operant learning and applied behavior analysis principles as a part of their practice believe that behavior is learned and therefore can be unlearned, or that the individual involved can be taught new behaviors ([3], p. 32.) Using an ABA approach, the teacher or therapist analyzes an observable behavior and the antecedents and consequences which seem to support the behavior. An antecedent is defined as "an environmental event or stimulus that precedes a behavior and influences the probability that it will recur in the future" ([3], p. 32); therefore, it is imperative to identify antecedents. Additionally, an analysis of behavior consequences is equally important because behavior is controlled by the consequences that follow it ([3], p. 33).

Following the analysis of a behavior in the context of antecedents and consequences, a behavior intervention plan can then be designed to manipulate them so that a new behavior can be taught or an undesirable behavior can be eliminated. There are specific principles and practices which promote the increase of desirable behaviors, and different principles and practices are available to decrease undesirable behaviors. Appropriate principles/strategies are incorporated into the behavior intervention plan depending upon the objective derived from the target behavior.

Relevance to Childhood Development

Typically, children learn developmentally appropriate academic and social skills without direct instruction or intervention; yet some children, including individuals with special needs and those specifically with emotional and behavior disorders, require a structured environment designed to provide the conditions to learn appropriate academic and social skills. Applied behavior analysis is used by learning therapists, teachers and other professionals as a systematic and data driven approach to the teaching and charting of academic and social skills. The methodology is frequently used to understand and plan interventions which address the inappropriate behaviors of students with emotional and behavior disorders (EBD) [4].

Typical ABA Training Assignment

Learning therapists, teachers and other professionals who are interested in the role of environment in behavior change are taught to use ABA principles in a systematic manner as a teaching and assessment tool leading to data-based teaching and charting of academic and social behaviors. The following set of training instructions written in a step by step format serves as typical assignment given to behavior interventionists to help them design a behavior intervention plan to be implemented in an applied setting using ABA principles.

Applied Behavior Analysis (ABA) Behavior Intervention Plan

An ABA behavior intervention plan will be required in this course on *one student* or a *small group of students* in a classroom or other approved setting concerning an *academic* or *social behavior* you feel needs to be addressed through an intervention. If you choose to address *an academic behavior*, you must identify an academic task or task sequence that student/s must learn or improve. If you choose to target *a social behavior*, you will observe and record *one appropriate behavior* which needs to be increased *"or" one inappropriate behavior* which needs to be decreased.

In either case, you will be required to observe and record the behavior as it is occurring in *baseline condition* and during your *treatment condition*. You will need 3–5 pinpoints of data for the baseline condition, and 7–10 pinpoints of data for the treatment condition. (Approximately 15 contact sessions with student/s.) You will be required to graph the data collected and to submit it with a written report concerning the total project following the format below.

Directions: Respond to All of the Questions Below. Be as *Specific* as You Can

1. General description of the behavior problem and purpose of the behavioral intervention plan.
2. *Subject*: General description; use first name only.
3. *Setting*: Where will the plan be carried out?
4. *Target behavior*: Explain the behavior you have chosen and why. Provide the label you have given the behavior, and define it within the context of your project.
5. *Objective of behavior intervention plan*: State a measurable behavioral objective (BO) for the plan to include the following components and written in one long sentence format: conditions (setting/circumstances), behavior (action verb), criteria (degree of mastery), evaluation (method used to evaluate), and time expectation (when behavior is to occur).
6. *Baseline phase*: Explain the baseline condition. Describe your observations and the development of your record keeping. How was the baseline target behavior recorded? What measurement/graphing techniques were employed? If any special equipment and/or forms are used, please attach and explain. *Be detailed.*
7. *Intervention phase*: What will you do to meet your stated objective? Explain a selected treatment procedure and how it was carried out. Be sure to refer to textbooks, professional journals, etc. as you develop your intervention procedures. *Be specific.* Explain *in detail* how the intervention was done to improve the behavior. Then, *select* two (2) *additional treatments* which you "*might*" use if your first treatment failed. Explain how you will carry out these interventions in detail.
8. *Raw results*: Report the Mean of Baseline and Treatment data collected. Graph on a line graph both baseline and intervention phases.
9. *Maintenance and generalization*: Explain in writing what features you might design into your program to increase the probability that desired behavior change *will be maintained* after treatment.
10. *Rationale/defense/additional comments*: Explain the usefulness, practicality, generalizability, and possible long range effects of your proposed plan. In short, defend it! How do you know this will benefit the child? What made you think your first intervention would effectively change the behavior? You will build a stronger defense if you refer to textbooks, professional journals, etc. and cite references.

Apraxia

Apraxia is a disorder of motor planning. Apraxia comes from the Greek praxis for an act, work or deed preceded by privativea meaning without. Apraxia is a disorder caused by damage to specific areas of the brain leading to the loss of ability to execute or carry out learned, purposeful movements despite having the desire and physical ability to perform the movements. It can be acquired or related to atypical development. Apraxia is different from abulia in which individuals do not have the interest or desire to carry out an action and allochiria in which individuals confuse one side of the body with the other.

Archival Research

Maria Assunta Cuffaro
State University of NY: Potsdam, Potsdam, NY, USA

Definition

This methodology is primarily concerned with the examination of historical documents. Secondarily, it is concerned with any recorded data. All data are examined ex-post-factor by the researcher [1].

Description

Unobtrusive methods are archival records where one is given the opportunity to assess the impact of natural events and examine other issues. They are strong on external validity because of the subjects unawareness of the research or its aims. When using archival records, we must control for the possibility of internal invalidity or spurious relationships. Archival research may require the collection of additional data and temperature records. A significant issue in archival research is construct validity and reliability of the data for research purposes. Archives are subject to gaps and incompleteness that make it difficult to determine whether the data, which was available, represented the population, which was of interest. The use of archives is economical, the researcher is spared the time and costs in data collection and recording. The advantage to archival data is availability of extensive data drawn from high-quality samples over time, which would be beyond the ability of the researcher to collect themselves or herself. Low cost is involved when using archival data [2].

Arcuate Fasciculus

Chad A. Noggle
SIU School of University, Springfield, IL, USA

Synonyms

Arcuate fasciculus

Definition

Arcuate fasciculus: The arcuate fasciculus is a bundle of fibers that serves as the neural pathway connecting the expressive (i.e., Broca's area) and receptive (i.e., Wernicke's area) language areas to one another and plays a vital role in repetition [3].

Description

The arcuate fasciculus is a neural pathway compiled of fiber bundles that extend anteriorly from the posterior portion of the temporal lobe to the posterior region of the inferior prefrontal lobe, thereby linking the expressive (i.e., Broca's area) and receptive (i.e., Wernicke's area) language centers of the cortex [2, 3]. In terms of neurocognitive functioning, the arcuate fasciculus is said to play a vital role in repetition [1]. Specifically, as auditory information comes into the neural system that is to be repeated, it is first processed by the receptive center of the brain (i.e., Wernicke's). Upon recognizing the nature of the information to be repeated, the neuronal transmission must be sent anteriorly to the expressive center by way of the arcuate fasciculus in order for the word or phrase to be said [3]. As such, lesions of the arcuate fasciculus have been attributed to manifestations of conduction aphasia in which speech remains and largely preserved, as does comprehension, yet repetition is impaired due to a disruption of this posterior to anterior transmission [1]. While repetition may be the most recognized function the arcuate fasciculus plays a vital role in modulating, it may also be important in reading aloud [3].

Receptive language skills involve reading, in addition to auditory comprehension [3]. While silent reading appears preserved in lesions of the arcuate fasciculus, reading aloud may be impaired [3]. Specifically, the prior (i.e., silent reading) appears to not require anterior transmission thus the function is not dependent upon the integrity of the arcuate fasciculus pathway and rather ends transmission at Wernicke's area. However, reading aloud involves reception as well as an anterior transmission to Broca's area in order to say the material aloud [2]. In this way, reading aloud may be dependent upon the integrity of the arcuate fasciculus and thus demonstrate dysfunction in those cases where this structure is impaired in some way.

Arithmetic

Molly Millians
Marcus Autism Center, Atlanta, Georgia, USA

Synonyms

Basic number facts; Operations

Definition

Arithmetic is the understanding and use of the mathematic operations of addition, subtraction, multiplication, and division.

Description

Arithmetic is a multi-component process that includes the abilities to complete addition, subtraction, multiplication, and division operations, to recall basic number facts, and to understand and apply the principles and the relationships of the operations to solve problems.

The acquisition of arithmetic skills is based upon the understanding of the number system. This includes the concepts of counting, cardinality, and adjusting sets to change number value. Children learn to combine sets to develop the understanding of addition. Reversing the process leads to the understanding of subtraction and the relationship between the operations. Also, children use counting strategies when learning to compute addition and subtraction problems. As children gain experience with adding and subtracting, the basic number facts become more automatic and are registered in long-term memory for access.

Children learn to group numbers into equal sets. Combining the equal groups, or repeated addition, leads to the understanding of multiplication. At a young age, children learn to share an item or an amount among their friends thus learning the underpinning of division. More commonly, children learn division as the reverse operation to multiplication. The basic operations of addition, subtraction, multiplication, and division are the foundations for calculating the results of quantitative situations.

Procedural knowledge and the understanding of arithmetic principles are included in the construct of arithmetic. Procedural knowledge is the understanding of the steps needed to perform the operation. The principles or the properties of arithmetic include the commutative, the associate, and the distributive properties. Understanding and applying the properties of arithmetic are necessary to solve complex mathematical statements.

Arithmetic is a component of mathematic proficiency.

Army Alpha Examination

►Army Alpha Intelligence Test

Army Alpha Intelligence Test

David Brandwein
Kean University, Union, NJ, USA

Synonyms

Army Alpha Examination; U.S. Army Alpha Intelligence Test

Definition

The Army Alpha [5] was developed shortly after the United States entered World War I by an American Psychological Association (APA) Committee on the Psychological Examination of Recruits, led by ►Robert Yerkes. It was one of three intelligence tests that were designed to identify Army recruits with low intelligence and allow for the recognition of those who were candidates for special assignments and officer-training schools. The Army Alpha emphasized verbal skills, and was given to all recruits.

Description

Development of the Army Alpha

Once the United States decided to enter World War I, Robert Yerkes, the President of the APA at the time, was anxious to show the value of the field of psychology and the unique contribution it could make to the war effort. He first approached the United States Navy but was turned down; however, the United States Army was agreeable to have APA assist the war effort. They

responded by setting up twelve committees, one of which, the Committee on the Psychological Examination of Recruits, was chaired by Yerkes. This committee was tasked with developing a quick-to-administer intelligence test to be used when deciding what sort of advanced training a recruit would receive. Yerkes, Lewis Terman, David Wechsler and other committee members collaborated to develop three such tests, the Army Alpha, the Army Beta (for non-English speakers and illiterate recruits), and an Individual Examination (a spoken test for those who failed the Beta).

The Army Alpha emphasized verbal abilities and was based on the previous work of Arthur Otis, Henry Herbert Goddard and Leon Lewis Thurstone, pioneers in the young field of intelligence testing and the quantification of cognitive skills. For those developing the test, "...the critical points were abilities to understand language to perform reasoning with semantic and quantitative relationships, to make 'practical judgments,' to infer rules and regularities from data, and to recall general information" ([1], p. 36). The test took 25 min to administer (via group administration), was made up of eight subtests, and produced a ▶mental age score.

A trial was conducted with the test on 80,000 men. The army was happy with the trial and agreed to test all new recruits beginning in 1918. The tests were administered at a rate of 200,000 per month, and over 1,750,000 had been administered by the end of the war in November of 1918 [2].

Data and Findings

After the war, the data from the Army Alpha and Beta were analyzed, with surprising results. It appeared that the average recruit had a mental age of around 13 – a mild level of retardation. Also, data showed it was possible to grade European immigrants by their country of origin, and the average score of Black men was 10.4, which was considerably below the White average. The reason for this had to do mainly with the level of education of the recruits rather than low native intelligence, but Yerkes and others concluded incorrectly that the intelligence deficit was real, sounding alarm bells about the "menace of the feeble-minded" and the idea that the average scores from the different national groups reflected innate racial differences [3].

At least partly based on Yerkes' findings, the United States Congress passed the Immigration Restriction Act (1924), which set immigration quotas based on the US population in 1890 (immigration from Southern and Eastern Europe had been relatively low before this date).

Criticisms and Confounds

Gould [4] presented criticisms and confounds associated with the use of the Army Alpha and Army Beta, in particular the cultural bias in the tests. There were also a number of problems in the administration of the tests. In particular, many who were unable to read English were still given the Alpha test and obtained a score of zero or close to zero, and those who failed the Alpha test were often not given an opportunity to take the Beta test, on which they may have performed at a higher level. Test conditions were also an issue. For example, the time allowed was insufficient and anxiety surrounded the whole procedure. Gould writes that with such confounds, the data should be looked at with considerable doubt.

Lasting Influence

Despite the confounds involved in the administration of and resulting data from the group of tests developed by Yerkes and his colleagues for use during World War I, their use marked two important shifts in intelligence testing that helped shape the field. It expanded the idea of intelligence testing to include group, rather than only individual, administration. Also, scores were now being used for positive as well as negative selection. Instead of scores indicating what an individual could not accomplish, scores were being used to predict what one might accomplish.

Army Beta Examination

▶Army Beta Intelligence Test

Army Beta Intelligence Test

David Brandwein
Kean University, Union, NJ, USA

Synonyms

Army beta examination; U.S. army beta intelligence test

Definition

The Army Beta [4] was a non-verbal intelligence test developed shortly after the United States entered World War I by an ►American Psychological Association (APA) Committee on the Psychological Examination of Recruits , led by Robert Yerkes. It was given to non-English speaking and/or illiterate Army recruits in order to assess for low intelligence and allow for the recognition of those who were candidates for special assignments and officer-training schools.

Description

Development of the Army Beta

Once the United States decided to enter World War I, Robert Yerkes, the President of the APA at the time, was anxious to show the value of the field of psychology and the unique contribution it could make to the war effort. He first approached the United States Navy but was turned down; however, the United States Army was agreeable to have APA assist the war effort. They responded by setting up twelve committees, one of which, the Committee on the Psychological Examination of Recruits, was chaired by Yerkes. This committee was tasked with developing a quick-to-administer intelligence test to be used when deciding what sort of advanced training a recruit would receive. Yerkes, Lewis Terman, David Wechsler and other committee members collaborated to develop three such tests, one of which was the Army Beta.

The Army Beta emphasized non-verbal abilities, and required recruits to complete mazes, complete pictures with missing elements, recognize patterns in a series, and solve puzzles. The Army Beta was group administered, strictly timed. and was given to those who either performed badly on the verbally-oriented ►Army Alpha Intelligence Test or those who were non-English speaking or illiterate. Also, in determining who should take the Beta test, decisions were made frequently in terms of the number of years of education reported. Generally, those with fewer than 4, 5, or 6 years of education were sent to Beta testing [2].

Like the Army Alpha, test development was based on the previous work of Arthur Otis, Henry Herbert Goddard and Leon Lewis Thurstone, pioneers in the young field of intelligence testing and the quantification of cognitive skills. The test took 25 min to administer (via group administration), was made up of seven subtests, and produced a mental age score. Due to the fact that examinees were thought to be non-English speaking, instructions were given in pantomime by the examiner and his aides.

A trial was conducted with the test on 80,000 men. The army was happy with the trial and agreed to test all new recruits beginning in 1918. The tests were administered at a rate of 200,000 per month, and over 1,750,000 had been administered by the end of the war in November of 1918 [1].

Data and Findings

After the war, the data from the Army Beta (as well as the Army Alpha) were analyzed, with surprising results. It appeared that the average recruit had a mental age of around 13 – a mild level of retardation. Also, data showed it was possible to grade European immigrants by their country of origin, and the average score of Black men was 10.4, which was considerably below the White average. The reason for this had to do mainly with the level of education of the recruits rather than low native intelligence, but Yerkes and others concluded incorrectly that the intelligence deficit was real, sounding alarm bells about the "menace of the feeble-minded" and the idea that the average scores from the different national groups reflected innate racial differences.

At least partly based on Yerkes' findings, the United States Congress passed the Immigration Restriction Act (1924), which set immigration quotas based on the US population in 1890 (immigration from Southern and Eastern Europe had been relatively low before this date).

Criticisms and Confounds

Gould [3] presented criticisms and confounds associated with the use of the Army Beta (and the Army Alpha), in particular the cultural bias in the tests. Gould noticed that even though the Beta was non-verbal, there still were items that were heavily culturally loaded. Also, administration issues were present that could have biased the results cited by Yerkes and his colleagues. For example, recruits who performed poorly on the Army Alpha were often not given the Army Beta, preventing a true measure of their cognitive skills. Finally, Gould writes that test conditions, such as too little time to take the test and test-related anxiety that accumulated amongst recruits, likely had a negative effect on performance. Due to the presence of issues with bias, administration, and testing conditions, Gould points

out that the findings generated from Army testing during World War I should be viewed with extreme skepticism.

Lasting Influence

Despite the confounds involved in the administration of and resulting data from the group of tests (including the Army Beta) developed by Yerkes and his colleagues for use during World War I, their use marked two important shifts in intelligence testing that helped shape the field. It expanded the idea of intelligence testing to include group, rather than only individual, administration. Also, scores were now being used for positive as well as negative selection. Instead of scores indicating what an individual could not accomplish, scores were being used to predict what one might accomplish.

Art as Therapy

►Art Therapy

Art Psychotherapy

►Art Therapy

Art Therapy

Kathy DeOrnellas[1], Anne Fierro Vanderlaan[2]
[1]Texas Woman's University, Denton, TX, USA
[2]Saybrooke University, Meridian, ID, USA

Synonyms

Art as therapy; Art psychotherapy; Clinical art therapy; Expressive therapy; Inner landscapes; Play-group therapy; Psychoaesthetics

Definition

Art therapy is a mental health intervention that uses art and the creative process as a central modality. The goal of art therapy, as with any form of therapeutic intervention, is to improve the lives of individuals. Art therapy can be a creative endeavor for expression of feelings, healing painful experiences and a form of retreat.

Description

The therapeutic benefit of making art has been recognized for hundreds of years; however, it has only been in the past century that art therapy has developed into a profession capable of helping individuals to develop insight, solve problems, and resolve conflicts [8]. In art therapy, the focus is on the individual's inner experience, that is, their feelings and perceptions. The art that is created is based on these feelings rather than on something the individual sees. There are many therapeutic orientations in the field of art therapy but most can be categorized in one of two ways [6]. In the first category, the emphasis of the art therapy is on the healing to be found in the process of creating art. This is sometimes referred to as "art as therapy" [6]. The act of making art is viewed as an opportunity for self-expression that can lead to a healthier, happier life. The process of making art is fulfilling and transforming. In the second category, the product that is created within the art therapy session is viewed as a means of communicating symbolically. The drawing, painting, or other artwork is used to communicate the individual's emotions or conflicts. This approach to art therapy is frequently called "art psychotherapy." Psychotherapy is especially important in this approach and the artwork is used to open a verbal exchange between the art therapist and the client. In their discussions of the art, clients develop insights and are able to work through their problems with a better understanding of their own feelings and behaviors [6].

Art therapy integrates a number of fields, including the study of human development, training in the visual arts (i.e., drawing, painting, etc.), and training in counseling and psychotherapy. Art therapists are trained to the level of Master's degree in art therapy or a related field such as counseling. Courses in ethical standards of practice; assessment and evaluation; individual, group, and family counseling techniques; multicultural issues; and research methods are required for practice as an art therapist [1]. Before they begin practice, art therapists spend hundreds of hours completing practicum or internship experiences in clinical, community, or other settings.

Art therapy is used with children, adolescents, and families for a number of mental health or developmental

issues, including depression, anxiety, autism, sexual abuse, posttraumatic stress disorder, substance abuse, and domestic violence [2, 7–9]. Art therapists work in schools, hospitals, community clinics, public and community agencies, and in private practice. They are frequently among the first responders in natural disasters such as the tsunami that hit Sri Lanka and Hurricane Katrina, and to manmade disasters such as the terroristic attack on New York City on September 11, 2001 [3, 5]. In a review of research on art therapy with children, Eaton et al. [4] found art therapy to be very effective in the treatment of children who had experienced trauma. Art therapy provides children a safe outlet for expressing their thoughts, emotions, grief, and/or pain.

Relevance to Childhood Development

Children learn by doing and art therapy helps with fine motor coordination. When children draw or paint it helps in their developmental processes. This correlates with play therapy to understand symbols to help with speech and mirroring. Children need to continue with artistic practice to help the child how to understand how things are made. Clay can help children to see three dimensionally and to help with the development of the brain. Creativity walks hand and hand with art therapy. It is the process not the produce that enhances a child's growth and feelings of well-being. Working on group projects teaches children to be a part of society and to work with others. Children with autism can benefit from the approach and treatment of art therapy.

Articulation Disorder

Maria Assunta Cuffaro
State University of NY: Potsdam, Potsdam, NY, USA

Synonyms

Phonological disorders

Definition

Articulation disorders are difficulties with the way sounds are formed and strung together, usually characterized by substituting one sound for another (wabbit for rabbit), omitting a sound (han for hand), or distorting a sound (ship for sip).

Description

The main characteristic of the disorder is: Omissions - Sounds in words and sentences may be completely omitted. (i.e.) "I go o coo o the bu." for "I go to school on the bus." Substitutions – Children do not pronounce the sounds clearly or they replace one sound for another. (i.e.) Substitutes [w] for [l] or [r], or other similar errors Distortions – An attempt is made at the correct sound but it results in a poor production. (i.e.) a distorted/s/sound may whistle, or the tongue may be thrusting between the teeth causing a frontal lisp. Additions – Extra sounds or syllables are added to the word. (i.e.) animamal.

The most common error sounds are [s] [l] and [r]. The speech is primarily unintelligible and difficult to understand. Articulation patterns that can be attributed to cultural or ethnic background are not disabilities. Developmental delay, is the cause of most articulation disorders. This can be the direct result- of hearing problems. The child cannot hear the fine differences between sounds, so speech perception is inhibited. Articulation disorders are also associated with overall delayed language development. *Differential Diagnosis*: Some disorders have similar symptoms. The clinician, therefore, in his diagnostic attempt, has to differentiate against the following

disorders, which need to be ruled out to establish a precise diagnosis. An articulation problem sometimes sounds like baby talk because many very young children do mispronounce sounds, syllables, and words. *Cause*: In many cases, there is not a clearly identifiable, structural or physiological reason for the problem.

Articulation problems may result from brain damage or neurological dysfunction, physical handicaps, such as cerebral palsy, cleft palate or hearing loss. Or the condition may be related to lack of coordination of the movements of the mouth, even dental problems. However, most articulation problems occur in the absence of any obvious physical disability. The cause of these so-called functional articulation problems may be faulty learning of speech sounds. *Treatment*: A speech evaluation should be performed by a speech-language pathologist. If there is a problem with articulation that is not developmental in nature, speech therapy is recommended. Parent involvement is necessary for the best progress and prognosis. The length of therapy can vary from 3 months to a number of years, depending on the cause, the severity, the child's motivation, and parental support. http://www.psychneuk.com/dsm_iv/speech_articulation_disorder.htm

Asperger's Disorder

Crystal Short, Kathy DeOrnellas
Texas Woman's University, Denton, TX, USA

Synonyms

Asperger's syndrome

Definition

Asperger's Disorder is a pervasive developmental disorder characterized by impairments in social interactions; communication; play and imagination; and the development of repetitive patterns of restricted, repetitive patterns of behavior, interests, and activities [1]. It is considered one of the higher functioning Autism Spectrum Disorders.

Description

Asperger's Disorder was named after Hans Asperger, an Austrian physician, who published case descriptions of individuals displaying autistic psychopathy in 1944. The individuals described by Asperger were not as socially withdrawn as individuals with autism but their social deficits were severe with social interactions that were one-sided and lacking reciprocity [2]. Characteristics of Asperger's Disorder vary among individuals and range from severe to mild impairment. Common characteristics include impaired social interaction, behavior that is limited and repetitive, and restricted interests and activities [1]. Unlike individuals with autism, individuals with Asperger's Disorder do not have clinically significant cognitive delays or delays in language acquisition prior to the age of two.

Social Challenges

Social deficits are the most striking feature of Asperger's Disorder. Four qualitative impairments in social interactions have been reported and individuals with Asperger's Disorder may have one or more of them. First, there is impairment in the individual's use of nonverbal behaviors such as eye contact, facial expressions, body postures, and gestures to regulate social interaction. Second, there is a failure to develop peer relationships appropriate to developmental level. Many children with Asperger's Disorder seek out and feel more comfortable in the company of adults or younger peers. Third, individuals with Asperger's Disorder do not seek out opportunities to share with others. Fourth, their relationships lack reciprocity or mutual exchange [1]. Social challenges associated with Asperger's Disorder include a lack of understanding of social cues and subtleties, literal interpretation of others' words, difficulty engaging in reciprocal conversation, a tendency to speak bluntly without regard for the impact of their words on others, and focus on a single topic of interest that may not be of interest to others [7].

Although preschool-aged children with Asperger's Disorder can be difficult to diagnose because there is not the language delay associated with other autism spectrum disorders, they tend to be slower to warm up to others than their typically developing peers and they form relationships with adults but have difficulty interacting appropriately with same-age peers [3]. Social deficits continue across childhood. In elementary school, children

with Asperger's Disorder tend to be quiet and unassuming or to have behaviors that violate social boundaries in their enthusiasm. They need to be taught the social skills that other children pick up naturally from the environment and, even when these skills are taught, children with Asperger's Disorder have difficulty generalizing the skills to other social situations [3]. Middle school aged children with Asperger's Disorder are often described as silly, rude, or very inappropriate. They stand out among their peer group due to their inability to read the social cues of their peers, awkward body posture, awkward use of gestures, annoying habits (such as making noises), highly variable eye contact, and excessive talking about one topic of interest [3]. Most prefer solitary activities and spending time alone. In high school, social interactions continue to be the greatest challenge and, despite some improvement, can result in frustration, anxiety, and depression.

Restricted Patterns of Behavior, Interests, and Activities

Four types of impairments in restricted, repetitive and stereotyped patterns of behaviors, interests, and activities have been noted in children with Asperger's Disorder. The first is an all-consuming interest or focus on a particular topic. They may spend an inordinate amount of time collecting factual information about their topic of interest. Frequently noted topics include dinosaurs, video games, electronic devices, and historical events or figures. Second, individuals with Asperger's Disorder engage in specific, nonfunctional routines or rituals that can be time-consuming and frustrating to those around them. When the routine is disrupted, individuals with Asperger's Disorder can become anxious and engage in inappropriate behaviors. A third type of restricted behavior (seen more frequently in younger children) is stereotyped and repetitive motor movements such as hand or finger flapping or twisting. This appears to decrease with maturity but may be evident in adolescents when they are anxious or stressed. Finally, there may also be persistent preoccupation with parts of objects such as the wheels on a toy vehicle. Children with Asperger's Disorder may engage in each of these types of repetitive behaviors. Repetitive object use, motor movements, and rigid routines appear to be worse in the early years while circumscribed interests worsen with time [6].

Social Communication

Asperger's Disorder is not associated with a language acquisition delay; however, several communication differences have been reported, including poor prosody or speech rhythm, tangential and circumstantial speech, and verbosity [5]. Individuals with Asperger's Disorder tend to engage in long monologues about their topic of interest, not wanting to change the subject, and not noticing when others stop listening. Other communication challenges for individuals with Asperger's Disorder can include difficulty understanding social nuances such as sarcasm or metaphor, echolalia (repeating last words heard without regard for meaning), abnormal inflection and eye contact, inappropriate facial expressions or gestures, and difficulty interpreting others' nonverbal communication cues [7].

Cognitive Development

Asperger's Disorder is not associated with a significant delay in cognitive or adaptive skills [1]. Children with Asperger's Disorder generally have average or above average intelligence and their vocabularies and word identification skills typically exceed their age and grade level. Despite intact cognitive skills, many individuals with Asperger's Disorder have learning difficulties [4]. Some of the difficulties reported include a lack of awareness of time, deficits in expressive and receptive language skills, and difficulty understanding irony and humor in speech. Individuals with Asperger's Disorder tend to be visual learners rather than auditory learners. They have difficulty with abstract thinking and associated problems with comprehension in reading. In addition, students with Asperger's Disorder are not aware of their effect on others during cooperative learning times [4]. Wagner [7] also reported poor problem-solving and organizational skills, concrete literal thinking, difficulty differentiating relevant and irrelevant information, obsessive and narrowly defined interests, and difficulty generalizing and applying learned knowledge and skills across different situations, settings, and people.

Motor Difficulties and Sensory Issues

Although not a diagnostic criteria, sensory issues and motor difficulties are frequently found among some individuals with Asperger's Disorder. Issues include hypersensitivity or hyposensitivity to certain noises, smells, or textures; high threshold for physical pain; difficulties with visual tracking; difficulty with fine motor skills, such as handwriting; and awkward gait and other gross motor movements [3–5].

►Asperger's Disorder

Asphyxia

Michelle A. Prosje
Georgia School of Professional Psychology, Argosy University, Atlanta, GA, USA

Synonyms

Strangulation; Suffocation

Definition

In Greek, asphyxia means without ("a") pulse/heartbeat ("sphygmos"). Asphyxia is a condition of impaired blood gas exchange [2]. When severe, asphyxia can progress to hypoxia (decreased oxygen supply), hypoxemia (deficiency in oxygen concentration in the arterial blood), and hypercapnia (excess carbon dioxide in blood).

Description

Asphyxia can occur from suffocation, strangulation, or ingestion/inhalation of chemicals (e.g., carbon monoxide) [10]. Various types of asphyxia have been delineated: birth asphyxia/perinatal asphyxia, mechanical asphyxia, traumatic asphyxia, compression asphyxia, positional asphyxia, and restraint asphyxia [10]. Traumatic or compression asphyxia is a form of mechanical asphyxia. Birth asphyxia/perinatal asphyxia has garnered the most attention in the pediatric literature, due to its prevalence and the long-lasting sequelae that persist through the school years.

Birth Asphyxia/Perinatal Asphyxia (PA)

Birth asphyxia is a medical condition in which a neonate takes in an inadequate amount of oxygen before, during, or just after birth [2]. Also referred to as perinatal asphyxia (PA), birth asphyxia results from oxygen deprivation (hypoxia), hypoxemia, hypercapnia, and excess acid in the blood (acidosis). Prevalence rates indicate PA occurs in approximately 1–6 per 1,000 live full-term births [7, 14, 17]. Various clinical features of newborns with PA have been observed: fits, atypical movements, and muscle tone alterations, which sometimes result in consistently low Apgar scores in the minutes following birth and oftentimes progress to a diagnosis of neonatal encephalopathy [6]. Specific indicators associated with PA include: labor complications (e.g., ruptured uterus), fetal distress (decelerations in heart rate), signs of disrupted energy metabolism (e.g., acidosis or atypical lactate and phosphorous metabolite levels), and abnormal brain activity monitored by electroencephalogram (EEG) [6]. Additional markers have been outlined: (a) pre-delivery: abnormal fetal heart rate and low pH level in blood sample from the fetal scalp; and (b) at birth: bradycardia/bradyarrhythmia, poor skin color, weak muscle tone and reflexes, feeble cry, gasping or labored breathing, and meconium-stained amniotic fluid. According to guidelines established by the American Academy of Pediatrics (AAP) and the American College of Obstetricians, a diagnosis of PA is made when the following criteria are met: (a) severe acid levels (pH less than 7) in the umbilical cord's arterial blood; (b) continual Apgar score of 0–3 for longer than 5 min; (c) neurological complications as evidenced by seizures, coma, poor muscle tone, and (d) problems with the circulatory, blood, digestive, respiratory, or kidney systems [4]. Specific features pre-, during, and post-delivery have been associated with severe PA: umbilical cord compression, placenta rupture, abnormal uterine contractions, or failure to commence breathing.

PA and the associated lowered oxygen, ischemia, and/or acidosis directly impact body organs. The central nervous system, cardiovascular, gastrointestinal, pulmonary, and renal structures are particularly susceptible. In fact, there appears to be a critical threshold for asphyxia, beyond which brain damage is inevitable. If specific neurological signs associated with hypoxia appear within 7 days following birth, the condition of neonatal

encephalopathy is diagnosed. Neonatal encephalopathy is one of the most severe sequelae of PA.

Results of PA tend to take the form of global brain injury; however, some brain regions appear more susceptible than others [6]. The duration and severity of the asphyxia in addition to the brain's maturity at time of PA determine the pattern of brain damage. Research based on neuroimaging findings reveal that post-PA damage has been found in the basal ganglia, thalamus, and brain stem [6, 12]. Some studies have found specific parasagittal injury infiltrating the grey and white matter. In addition to potentially widespread white matter damage, the hippocampus has garnered attention as a focal lesion following PA.

Due to the complexity of asphyxia, investigators acknowledge the unpredictability and unavoidable nature of PA and urge clinicians to treat promptly in an effort to minimize the deleterious effects of decreased oxygen supply [4]. To treat PA prior to delivery, the mother can be given extra amounts of oxygen. In some cases, emergency delivery via cesarean section and provision of supplemental oxygen for the neonate immediately following delivery is essential. The assistance of a mechanical breathing machine and accompanying medication may also prove beneficial.

Unfortunately, statistics indicate that approximately 15–20% of infants with PA die in the neonatal period [15, 18]. Surviving infants generally fall into two distinct categories: those experiencing significant impairment and those who are essentially impairment-free. Study results indicate that about 25% of infants show major neurological impairments, whereas the remaining 75% are fortunate and experience no significantly harmful sequelae [18].

Mechanical Asphyxia

Mechanical asphyxia occurs when external pressure is applied to the chest, preventing respiration [3, 16, 19]. Traumatic asphyxia, compression asphyxia, and restraint asphyxia are forms of mechanical asphyxia and are reportedly unusual and uncommon in children [8]. When cases of traumatic asphyxia are diagnosed, they have been closely linked with smothering, overlaying (restraining), adult-child bed sharing, and motor vehicle crashes [8, 13]. Other cases of traumatic asphyxia have emerged from compression by heavy machines, furniture, and in rare occurrences, asthma, epilepsy, and deep sea diving [11]. The weight and duration of compression directly affect outcome [13]. Mechanical asphyxia that does not result in death usually leads to congestion of the head and neck and petechiae, or pinpoint hemorrhages, which surface around the eye and on the face. Investigators have postulated that petechia form because of a sudden increase in pressure in small capillaries and venules. The same mechanism is thought to be responsible for visual disturbances which oftentimes follow [1]. Although cases of accidental death have been recorded, the mortality rate from traumatic asphyxia is generally low in children [13]. When other severe injuries including thoracic and head injuries are present, the prognosis is generally guarded. However, in general the prognosis for traumatic asphyxia is good and no long-term disability, with the exception of visual difficulties, persists [1, 13]. Ophthalmological examination is key in children who have experienced traumatic asphyxia.

Positional Asphyxia

Positional Asphyxia is a condition arising due to the adoption of a particular body position that mechanically interferes with pulmonary ventilation. It is usually an accidental occurrence, and when death results, the body is usually found in a position that interferes with normal breathing [9]. Positional asphyxia occurs when the body's position restricts adequate breathing [10]. Most types of mechanical, compression, restraint, or traumatic asphyxia are related to positional asphyxia which obstructs the airway and leads to inadequate oxygen intake.

Relevance to Childhood Development

Literature has focused primarily on perinatal asphyxia and the long-term sequelae. With regard to mechanical asphyxia (traumatic, compression, and restraint asphyxia) and positional asphyxia, the experienced hypoxia and petechia frequently contribute to long-standing vision impairments and potential neuropsychological deficits similar to those resulting from PA. Hence, this section focuses on the relevance of PA to childhood development.

Perinatal asphyxia (PA) has been linked to both immediate (as noted above in terms of clinical features) and delayed onset symptoms. Correlations between PA and subsequent cognitive, motor, and behavioral impairments have been delineated. Neuropsychological deficits following PA have been found in attention, perceptual-motor skills, executive functioning, and memory [12]. Nevertheless, debate ensues regarding the nature and range of outcome severity. General consensus in the field states that poorer outcomes emerge for infants who experienced more severe asphyxia than those with milder forms. Severe PA has been found to cause poor cognitive and motor development and to precipitate neurological impairment such as ▶cerebral palsy, epilepsy or intellectual delay. Of note, many early studies document a direct connection between PA and cerebral palsy (CP); however, more recent

rigorous research has found that fewer than 10% of CP cases are due to PA. Hence, clinicians are cautioned about making direct correlations between CP and PA.

Long-term longitudinal evaluation of children with PA has shown that a significant percentage of survivors without specifically diagnosed neurologic sequelae are likely to exhibit school-related dysfunction [15]. This is true mostly because, at an early age, minor cognitive difficulties may remain undetected; however, when school subject matter increases in difficulty and greater cognitive demands are imposed on the child, he/she struggles and cognitive deficits emerge. Overall, research indicates that children with mild encephalopathy go unnoticed at school; whereas, greater than 40% of children without identified neurologic impairment but with a previous diagnosis of moderate to severe neonatal encephalopathy are identified as at-risk or already experiencing school difficulties.

Two different outcomes of PA have garnered substantial attention: memory impairment and schizophrenia [5, 6, 12]. Associated with bilateral hippocampal abnormalities, memory impairments can arise and present significant difficulty for the pre-school and school-age child. A study of adolescents indicated that those who had experienced moderate to severe PA exhibited significantly worse performance on tests of delayed recall for both verbal and visual information, perceptual-motor speed, and attention and executive functioning [5, 6, 12]. The associated hippocampal injury sheds further light on the memory deficits emerging in children with a history of moderate to severe PA. A mild form of developmental amnesia also has been found to occur as a consequence emerging a long time after the initial moderate to severe PA.

With regard to schizophrenia, some research has linked early onset schizophrenia (between 7 and 13 years of age) with obstetric complications including maternal infection, pre-eclampsia, and hypoxia at birth [5, 6, 12]. It appears that the hippocampus may actually act as a mediator in schizophrenia in that PA can lead to hippocampal abnormalities, and patients with schizophrenia show reduced hippocampal volume. Another hypothesis has surfaced noting the interaction of PA with schizophrenia susceptibility genes in the emergence of schizophrenia. Of note, although there appears to be a significant association between PA and an increased risk for schizophrenia, more than 90% of individuals who experienced PA do not develop schizophrenia.

Memory impairment and schizophrenia are being studied more closely as potentially common outcomes following PA. It is important to note that such sequelae will generally not emerge until later in childhood, usually during the school years. Further study is required to identify factors contributing to the emergence of such impairments and to elucidate the potential precursors of such problems optimally to prevent further exacerbation, specifically in terms of school-related problems.

Assessment

Elizabeth Levin
Laurentian University, Sudbury, ON, Canada

Synonyms

Evaluation; Testing

Definition

A psychological assessment is a formal clinical evaluation of an individual that typically involves the administration of standardized psychological tests.

Description

Assessment refers to the process and outcome of the process that yields information about an individual, based on the individual's history, current performance and expected future performance [2]. While an assessment may involve the use of specific tests, assessment is more than psychological testing. The use of specific standardized tests is just one component of a psychological assessment, which is a multi method approach to synthesizing information about or evaluating a child. A psychological assessment is a formal process of clinically evaluating a child.

Psychological assessments are typically conducted when there is a question about a child's behavior or performance, and information is needed in order to determine the nature of the problem, diagnostic information and/or treatment and program recommendations [2]. So, an assessment may be carried out to screen a group of children for a possible characteristic such as academic giftedness, to diagnose a particular child with a possible disorder such as conduct disorder or to evaluate the progress of treatment.

A typical assessment includes four parts [1]. First, the problem must be identified. Defining the problem is part of the referral process and usually takes place in the context of an interview. Next information must be gathered about the problem. Psychological tests are most commonly administered in this phase. Third, the information must be synthesized. This means that all the gathered information is interpreted in a meaningful way that takes into account the individual and the context surrounding the individual. Finally, recommendations for dealing with the problem such as treatment or coping strategies must be proposed.

A typical school based referral for a psychological assessment includes the administration of a number of standardized tests. Standardized tests allow the child to be compared to broad based normative populations to evaluate the child in comparison to a group of peers [3]. These tests likely include measures of intellectual ability and academic achievement. Further testing will depend on the nature of the suspected difficulty so a child referred for a possible learning disability will also receive tests of memory, attention, phonological processing and reading, etc., while a child referred for a possible developmental delay will also receive tests of adaptive behavior. In both cases there may also be additional testing of social skills, personality and behavior. The results of the testing are evaluated by the psychologist, along with previous test results, past history, school report cards, parent and teacher checklists and/or interviews and direct observation yielding the final assessment which may come in the form of a diagnosis of a disorder and suggestions for treatment and program planning.

A school based assessment may be known as a psychoeducational assessment [1, 2]. A neuropsychological assessment typically involves the administration of tests designed to elucidate brain functioning [1, 2]. A forensic assessment involves legal issues [1, 2].

Assessments may be carried out by various qualified personnel, for example, a psychologist may assess a child for a learning disability or a physician may assess a child for medication for an attention disorder. Assessments may take place in diverse settings such as clinics, hospitals, psychologist offices, or schools and for purposes other than psychological ones.

In educational settings, assessments are sometimes categorized as summative or formative [1]. Summative assessments are conducted at the conclusion of a course and may be used to evaluate the instructor or the student's learning. Formative assessment takes place during the course and can be used by the instructor to improve teaching and to determine next steps to be taught.

School based, educational assessments may also be categorized as authentic, performance or dynamic [1].

Authentic assessment typically occurs in a real-life setting. So, for example, a child may be asked to read from a book assigned in class. Performance assessment is used to measure how well a student performs in class; it uses performance rather than tests, so an essay or presentation might be evaluated. This is the typical assessment performed by a school teacher. One kind of performance assessment is known as portfolio assessment. A "portfolio" of assignments in reading or writing or mathematics is used to evaluate student progress over time. Dynamic assessment attempts to measure a student's learning potential. Pre and post measures are taken of performance on a task to evaluate how readily the student acquired the taught skill.

Assimilation

Jackie Kibler
University of Montana, Missoula, MT, USA

Synonyms

Acculturation

Jean Piaget discusses assimilation as the method by which information is included in existing schemas [1]. If you learned how to drive a car in the United States, you have a schema for driving on the right side of the street. If you live in the U.S., most of your experiences driving will fit into this schema (unless you encounter construction), thus you will assimilate the information. However, if you drive in Australia or Great Britain, you will have to adjust your schema to accommodate new information; namely driving on the opposite side of the street. For some people, accommodating this information takes a great deal of effort. Piaget explains that assimilating information takes much less mental energy, which explains why young children, and a lot of adults, prefer routine. Young children have not developed the repertoire of schemas that most adults have. Thus, they prefer to encounter things in their environment that fit into their existing schemas. If you have been around young children, you will notice that they prefer to have the same stories read to them, again and again. They do better when there is routine in their environment and they know what to expect.

Another example of assimilation involves the terrorist attacks of September 11. The initial reaction of many people watching the coverage of the September 11 attacks on the World Trade Center believed they were watching a movie. The schema that people had for that type of visual (i.e., planes crashing into a building) was "movie" because that is where they had seen that type of event before. Some individuals had to watch the news coverage numerous times before their brains were able to change their schemas to accommodate the new information of a terrorist attack. Now, in the United States, when there is an incident, such as a plane hitting a building, many people assimilate the information; initially categorizing the event as an act of terrorism (since that is the schema they now have).

Association for Retarded Citizens (ARC)

Lynna Lan Tien Nguyen Do
Walden University, Fremont, CA, USA

Description

The Arc is the world's largest community based organization of and for people with intellectual and developmental disabilities. It provides an array of services and support for families and individuals and includes over 140,000 members affiliated through more than 850 state and local chapters across the nation. The Arc is devoted to promoting and improving supports and services for all people with intellectual and developmental disabilities.

The Arc's vision is that every individual and family affected by intellectual disability in the United States has access to the information, advocacy, and skills they need to participate as active citizens of our democracy and active members of their community. We work to ensure that people with intellectual and developmental disabilities and their families have the supports they need to live an ordinary, decent American life:

- People with intellectual and developmental disabilities and their families are valued, respected and included in all communities.
- People with intellectual and developmental disabilities direct their own lives. People choose their services and supports from many available sources.
- People are empowered through nonprofit advocacy. State and federal governments administer programs and set budgets that meet everyone's needs.

Mission Statement

The Arc of the United States advocates for the rights and full participation of all children and adults with intellectual and developmental disabilities. Together with our network of members and affiliated chapters, we improve systems of supports and services; connect families; inspire communities and influence public policy.

Asthma

Angelica R. Eddington
Oklahoma State University, Stillwater, OK, USA

Synonyms

Bronchial asthma

Definition

Asthma is a chronic inflammatory disorder of the airways, in which individuals experience recurrent episodes of wheezing, breathlessness, chest tightness, and cough.

Description

Asthma is a long term disease that cannot be cured. Symptoms of asthma include coughing, wheezing, chest tightness, and shortness of breath. Coughing is often worse at night or early in the morning, making it harder to sleep. Wheezing is a whistling or squeaky sound that occurs while breathing. Chest tightness has been reported to feel like something is squeezing or sitting on the chest. Lastly, it is often conveyed that asthma makes individuals feel out of breath or feel like it is harder to catch their breath. Not all people with asthma will have all of these symptoms. The physiological reasons for asthma symptoms include the inflammation of airways. Airways are tubes that carry air in and out of lungs. During an inflammation, the tubes swell, the muscles constrict, the lungs become very sensitive, and mucus production increases. The combination of these reactions can make breathing difficult. Sometimes asthma is classified into categories based on severity of symptoms, usually referred to mild, moderate, or severe. Even though the exact causes of asthma are not known, researchers have linked certain factors that can contribute to its development. These factors include an inherited tendency to develop allergies, parents who have asthma, certain respiratory infections during childhood, and contact with some airborne allergens or exposure to some

viral infections in infancy and early childhood when the immune system is developing [3].

Asthma symptoms can be controlled with appropriate treatment. Action plans are strategic lists that include critical guidelines for asthma management and have been associated with improved asthma outcomes [2] and viewed positively by patients with asthma [3]. Doctors recommend controlling the disease by using action plans to reduce troublesome symptoms. Action plans suggest that individuals with asthma take their medicine; either long-term control medication or quick-relief medication. The first type of medication helps to reduced airway inflammation and prevents asthma symptoms; the latter relieves symptoms that may flare up. Due to the different outcomes of the medications, they should not be used in place of each other. Action plans also suggest that individuals avoid environmental contexts that may worsen their asthma. Taxing factors that affect asthma can vary by individual. The most common factors include exposure to pollen or air pollution, animal fur, and health conditions like runny nose or sinus infections. Lastly, the treatment for asthma varies by population. For instance, it is challenging to diagnose children under the age of 5 with asthma, therefore the benefits for long-term control medications are not known for this population. Also, pregnant women with asthma may be at risk for having low birth weight babies [3]. Overall, action plans are used in many nations to control asthma episodes and attacks. To date, action plans for the self management of asthma are the standard for treatment [1].

Relevance to Childhood Development

As mentioned previously, contact with airborne allergens or exposure to viral infections early in infancy or childhood when the immune system is developing can result in asthma. Referred to as the "hygiene hypothesis" some have proposed that many young children no longer experience the same types of environmental exposures and infections as children did in the past. Consequently, the immune system developed by children today is different and may be more prone to develop asthma.

Most children who have asthma develop their first symptoms before 5 years of age. However, asthma in young children (aged 0–5 years) can be hard to diagnose. Sometimes it can be difficult to tell whether a child has asthma or another childhood condition because the symptoms of both conditions can be similar.

Also, many young children who have wheezing episodes when they get colds or respiratory infections do not go on to have asthma. These symptoms may be due to the fact that infants have smaller airways that can narrow even further when they get a cold or respiratory infection. The airways grow as a child grows older, so wheezing no longer occurs when the child gets a cold [3].

At Risk

Beverly West King[1], Norma S. Guerra[2]
[1]Communities in Schools, San Antonio, TX, USA
[2]University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Exposed; In danger: in jeopardy, threatened, susceptible

Definition

The term at risk is used by educators, social service personnel, and others when referring to students who have a high probability of experiencing failure in school.

Description

Has been used to address potential failure, by definition may include students who perform poorly in school subjects. In general terms, there is a suggested notion that the child or adolescent is at risk of failing and will eventually drop out of school. It is also used to point out a set of factors in a family environment and in the individual's attitudes and activities that are associated with (school or other risk environment) failure.

Risk Factors

Research shows that students' economic status is associated with the likelihood of success in school. Whether

measured directly by parents' income or by characteristics such as parents' occupations or the number of wage earners, students from low-income families are less likely to obtain high grades and test scores, less likely to graduate with their entering class, and more likely to experience behavior problems than are students from higher-income families [1].

Behavioral risk factors are behaviors and attitudes closely related to learning. Some examples of behavioral risk are poor attendance, lack of attentiveness in class, failure to complete coursework, poor relationships with teachers, feelings of alienation at school, and developing the outlook that schooling is not important to future successes.

Academic risk factors are deficient outcomes during a school career that can interfere with the chances of success in later grades of schooling. These might include accruing a history of poor grades, low test scores, standardized test scores, and/or failure of one or more grade levels.

Multiple or cumulative risk factors can greatly increase the likelihood for a child to drop out of school.

Effective Strategies for At Risk Students

Students who are at risk of school failure tend to see their teachers as having low interest in them as people. It is imperative that a student with other attendant risk factors for failure has at least one teacher or counselor who they feel cares about them as a person. Although some critics of the at risk label cite isolation as a problem, a successful program has been shown to utilize low student-teacher ratios and separation of the at risk students from the rest of the student body. Programs that focus on basic academic and survival skills, such as attending to tasks, following directions, raising one's hand to speak, and writing legibly are also known to be successful. At risk students need to be maximally engaged in an educational program that is carefully structured to meet their individual needs, and they must be taught by people who firmly believe that these children can and will succeed [2, 3].

Attachment Theory

Cynthia Field
William Alanson White Institute, New York, NY, USA

Synonyms

Ainsworth's procedure; Infant–mother attachment studies, of ainsworth

Definition

Attachment is defined as the strong affectional tie that connects people; for infants, the first attachment is usually to the mother, and the mother-child tie often remains one of the strongest attachments.

Description

The most familiar form of attachment is between an infant and his mother. John Bowlby and Mary Ainsworth developed theoretical and empirical approaches to advance the understanding of attachment and the myriad lifelong influences of this earliest bond. In infancy, attachment is manifested by the tendency for a toddler to seek *proximity* to their attachment figure or caregiver when they experience distress. When the infant feels safe, he moves away from caregivers to explore the environment, with the confidence that he may return to the *secure base* of his mother's comfort and protection if he becomes frightened, tired or is in distress.

A*ttachment* denotes the emotional bond to a caregiver. Usually an infant's mother is the primary attachment figure, but anyone who has been consistently responsive to the infant may fulfill this need. Over time, multiple attachments may develop. However, the infant usually shows a hierarchy of preferences, with one highly preferred attachment figure. If the preferred attachment figure is not available, the infant will rely on the next person in the hierarchy as a secure base, and may even turn to a kind stranger in moments of distress.

Attachment behaviors refer to the gestures that the infant engages in to gain contact with the mother or other preferred attachment figure. In keeping with his ethological influences, Bowlby posited that humans, like animals, possess species-specific behaviors that help to keep a parent nearby. This proximity satisfies the human species' innate predilection towards forming interpersonal attachments, and offers protection from cold, hunger, and other distressing experiences. Thus, from birth, infants possess a repertoire of behaviors such as crying, orienting, crawling, cuddling, grasping and clinging that draw the attention of the mother and promote proximity. As the infant matures, the repertoire of attachment behaviors increases, and the nature of the attachment bond becomes more nuanced. (See *Bowlby's Stages of Attachment* herein.)

An infant engages in attachment behaviors when a stimulus or condition *activates* the behavior system. Activators may stem from external or internal stimuli, or a combination of both conditions. For example, when a stranger enters the room (an external activator), an infant may look over to see how his mother appears (the attachment behavior.) If his mother is present and appears calm, the child may resume his play (and thus terminate his attachment behavior). If the mother appears apprehensive, the infant responds to that cue with fussing (another attachment behavior) to draw the mother's attention and gain her protection. Alternatively, a toddler may experience stomach cramps (an internal activator) and cry (the attachment behavior). He may not terminate his attachment behavior until his mother picks him up and offers comfort. In general, the degree of contact that the infant needs to terminate the attachment behavior depends on the intensity of the stimulus that activates

the attachment behaviors, the quality of the attachment bond, and the developmental level of the child.

As the infant matures, the threshold of discomfort required to activate the attachment system is higher. With each exposure to distress and the mother's accompanying response to the infant's bid for contact, the infant internalizes a feeling that he associates with proximity. The next time that a similar distressing situation arises, the infant evokes his internal sense of the comfort and safety that he associates with proximity. If the distress is tolerable, the self-generated feelings will suffice and the attachment behavior system will terminate.

With accrued experiences, an infant develops an *internal working model* of his primary attachment relationship. Thru sucking, clinging, following, smiling, crying, and when older, by going to the caregiver when in physical or emotional distress, the child explores his relationships and builds a model or mental image of how they work. This model is a mental representation of the infant's self, his attachment figure, and the nature of their relationship, and is comprised of feelings, cognitions, expectations, behavioral strategies and constructs for processing and organizing memories. This internal working model reflects the child's relationship history, codifies behaviors that belong in intimate relationships and defines how the child will feel when in similar encounters with other people.

Ainsworth observed dozens of mother-infant dyads during her work in Uganda and later in the United States. Through these observations, she became aware of individual differences in infants' responses to distress, especially the pain engendered by separation from their mothers. She devised the *Strange Situation* (see entry herein) to study the ways in which infants use their mothers to cope with the distress. Ainsworth identified a secure baby as one who protested when his mother left the room, greeted her pleasantly upon her return, and was able to resume play. When situated in the room with the mother close by, the infant would use her as a secure base from which he would explore the toys and other objects in the room. In contrast, an infant with an avoidant attachment rarely cried when the mother departed from the laboratory room, and remained aloof on her return. He generally did not show his need for connection, although physiological studies show that he has a physically measurable stress reaction. Finally, an ambivalent (or resistant) infant is anxious before the mother leaves the room, and may become highly upset when she departs. When the mother returns, the infant engages with her in an ambivalent fashion: he seeks contact while resisting her by squirming away or kicking his mother. He has difficulty using his mother to obtain comfort and return to exploration. Later research revealed the disorganized attachment pattern. An infant who reflects this attachment style displays inconsistent or contradictory attachment strategies. For instance, the infant may happily approach the mother but turn away or shriek when she tries to pick him up. At other times the infant may evince extreme distress yet remain frozen and not seek contact with his mother.

Relevance to Childhood Development

Attachment theory offers a way to understand the nature of a developing child's self-concept and relationship patterns. The infant's experiences in his first attachment relationship with his mother sets him on a particular developmental trajectory. From that relationship, he develops an internal working model of the nature of attachments. The actual path that the developing child pursues in his relationships may be altered by subsequent experience. However, the course is generally established based upon the quality and dynamics of his bids for proximity and his mother's responsiveness and accessibility.

Attention

Elizabeth Levin, Jennifer Bernier
Laurentian University, Sudbury, ON, Canada

Synonyms

Concentration

Definition

Attention is the cognitive process of selectively focusing on one thing, sensation or idea while ignoring others.

Description

Attention has been defined as a state of awareness wherein the senses are selectively focused on components of the environment [14]. Attention is a process that varies on

a number of dimensions and is therefore considered multidimensional. Attention can be under conscious awareness or it can be unconscious, although traditionally when someone is admonished to pay attention what really is being said is focus consciously. On the other hand, a person who is not paying attention to what is being said but who is still able to repeat the message conveyed is said to be engaging in unconscious attention. For example, in an experiment by Gray and Wedderburn [7] named "Dear Aunt Jane" people were given a set of headphones in which different messages were played in each ear, 9-Aunt-6 in the right ear and Dear-7-Jane in the left ear and were told to listen to the message in the left ear only. The researchers found that although the participants were not listening to the message in the right ear they claimed to have heard "Dear Aunt Jane," showing that although they were not consciously attending to one message they were still able to process the information.

Further, attention can be directed specifically to one task or divided among multiple tasks. Attention is also dependent on the type of task. It is easier to remain focused on more stimulating tasks compared to tasks that are not as interesting. Attention can be classified into different types, including selective attention, sustained attention and executive attention. Although attention can be divided into types of attention, they follow similar patterns of development with shifts around age 6 and 11. Attention develops over the first years of life, reaching its peak around the age of sixteen. Improvements in attention are related to maturation of the frontal lobes of the brain. Attention requires arousal which regulates one's state of alertness, vigilance or the ability to select the appropriate stimuli from a set, persistence or the ability to sustain mental effort, and monitoring which is the ability to oversee or supervise one's efforts.

Selective attention is described as the ability to concentrate on certain environmental stimuli while ignoring others. Selective attention is what permits one to carry on a conversation with someone in a noisy environment, often known as the cocktail party effect. Older children perform much better on tasks of selective attention than younger children do; younger children are as likely to pay as much attention to distractor items as to relevant information.

Different models have been proposed to explain selective attention. Broadbent and Triesman both developed models to explain what occurs during selective attention and their models differ on when the information is selected. According to Broadbent's filter model [5], information is selected before it is analyzed for content. This view is also called a pre-categorical view. This model proposed that both the attended stimulus and the ignored stimulus are taken in by the senses, and then proceed through a filter. The filter only allows the attended message to pass through unchanged and the ignored stimulus is lost. The filter's selection is based on physical characteristics. Ultimately, the attended stimulus is processed further to determine higher-level characteristics, such as meaning, by the detector. The reason this model is called a pre-categorical model is because it filters out information before it is analyzed for meaning.

Treisman's [12, 13] Attenuator Model is an example of the post-categorical view. Unlike the model proposed by Broadbent, in Treisman's model the ignored stimulus is not filtered out but it is simply attenuated. Therefore, both stimuli pass through an attenuator after being taken in by the senses, which allows the attended stimulus through unchanged and attenuates the ignored stimulus. After both stimuli go through the attenuator, which happens in parallel, they are analyzed in terms of physical characteristics, language, and meaning. This model is considered a post-categorical model because the selection of stimuli for the final processing does not occur until after the information has been analyzed for meaning [6, 10].

For many years researchers debated over which of these models best explained selective attention. More recently, a third theory has been proposed. The Load Theory provides two mechanisms for selective attention [8]. The first mechanism is perceptual selection which allows for excluding irrelevant stimuli in situations with a high perceptual load. This mechanism is considered to be passive because stimuli may be ignored because they are not perceived. The second mechanism is an active mechanism that involves rejecting irrelevant information that is perceived. This second mechanism is influenced by higher order cognitive functions including working memory. This model shows that increasing perceptual load decreases distractions, but increasing cognitive load increases the effect of distractors. This theory proposes that both of these mechanisms are needed in selective attention.

Sustained attention is the ability to maintain attention over a period of time [9]. Sustained attention develops throughout childhood and reaches its peak by the age of sixteen although this ability is usually well developed by middle childhood [4]. Throughout development the factors that influence sustained attention differ. In children, sustained attention is best when many stimuli are presented during a set time frame, but when the number of target stimuli, or stimuli the child must remember is low. On the other hand, adults are best able to attend to information when fewer stimuli are presented but more of

the target stimuli are presented. This can be explained in terms of level of arousal. When fewer stimuli are presented this may be underarousing for children and the demand placed on their ability to sustain attention is higher making it more difficult to maintain attention on the task [11].

►Attention deficit/hyperactivity disorder (ADHD) is characterized by patterns of inattention and hyperactivity and difficulties with inhibition [2]. This disorder can be very problematic in academic settings as well as other settings. It affects not only academic success but also social functioning. This disorder presents with patterns of deficits in certain types of attention, but not all types. Research has shown that children with ADHD display deficits in sustained attention compared to normal children, but they do not present with deficits in selective attention. Barkley [3] developed a unified theory to explain ADHD in which he states that the primary deficits in the disorder are associated with behavioral inhibition which in turn affects the individual's ability to maintain attention on a specific task.

Executive attention more commonly known as executive functions refers to attention to one's own behavior so as to regulate it [1]. Executive attention is related to choosing what features of the environment to pay attention to and how to respond based on incoming input but also cognitive functioning based on past experiences and future goals. Executive attention involves the ability to maintain or recover information that is not in conscious awareness. Executive attention is often used synonymously with working memory. This ability begins to develop around the age of three, but children do not become proficient with this ability until the ages of 7–11 years. Executive attention is also associated with other executive functions including planning and self-regulation.

Relevance to Childhood Development

In summary, the various components of attention develop over the childhood years leading to improvements in the way children attend. Improvements in selective, sustained and executive attention are related to maturation of the frontal lobes of the brain. The ability to attend is critical to many components of social and academic success.

Attention Deficit Disorder

Jeremy R. Sullivan
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Attention deficit hyperactivity disorder, ADHD; Hyperkinetic syndrome; Minimal brain dysfunction

Definition

Attention Deficit Disorder (ADD) is an earlier term for the disorder now known as Attention Deficit Hyperactivity Disorder (ADHD; see entry for Attention Deficit Hyperactivity Disorder for a more thorough treatment of this topic).

Description

The term ADD was introduced into the diagnostic classification system with the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* [1], although the disorder was previously recognized as Minimal Brain Dysfunction, Hyperkinetic Syndrome, Hyperkinetic Reaction of Childhood, and various other names. ADD was characterized by developmentally inappropriate inattention and impulsive behaviors, and the disorder was classified into three subtypes: ADD with Hyperactivity (severe levels of inattention, impulsivity, and hyperactivity), ADD without Hyperactivity (severe levels of inattention and impulsivity without severe hyperactivity), and ADD Residual Type (hyperactivity disappeared in adolescence/adulthood, but difficulties with inattention and impulsivity continued). Thus, the DSM-III attempted to differentiate children with attention problems only from children with attention problems in addition to hyperactivity [3].

In the DSM-III, prevalence of ADD was estimated at 3% during childhood, with the disorder much more likely to occur in boys than in girls. The core features of ADD are similar to those of ADHD, although the system of classifying symptoms into subtypes has changed in order to reflect more recent empirical research findings. Whereas ADD was classified into ADD with Hyperactivity, ADD without Hyperactivity, and ADD Residual Type, the current system classifies ADHD into Predominantly Inattentive Type, Predominantly Hyperactive-Impulsive Type, and Combined Type [2]. Given this revised nomenclature, ADD is now seen as an archaic term, and contemporary diagnosis requires use of the current classification system. Research on ADHD over the last decade has greatly enhanced our understanding of the core symptoms, associated features, patterns of comorbidity, etiology, genetic contributions, assessment process, and intervention approaches [4], although debate over the definition and classification of the disorder will likely continue in response to the results of research efforts.

Attention Deficit Hyperactivity Disorder (ADHD)

►Attention Deficit Disorder

Attention Span

Elizabeth Levin, Jennifer Bernier
Laurentian University, Sudbury, ON, Canada

Synonyms

Sustained attention; Vigilance

Definition

Attention span refers to an individual's ability to attend to a stimulus or object over a period of time. This ability is also known as sustained attention or vigilance.

Description

Attention includes a number of components, one of which, attention span, is the ability to maintain focus and alertness over a period of time. Sustained attention requires persistence and motivation [2]. Thus, individuals with short attention spans may appear to give up or not put sufficient effort into tasks. Attention span increases with age, and is related to, and plays a role in other aspects of functioning including learning, memory, academic performance, and the understanding and processing of large quantities of information [1, 3].

Research has shown that a child's sustained attention develops in a linear fashion until the age of four, but then undergoes a dramatic increase between the ages of 4 and 6 years [1]. Between the ages of 7 and 8 years there is stability in sustained attention relative to slightly older and younger children. This is also the time period when attention problems, such as ►Attention-Deficit/Hyperactivity Disorder (ADHD) are frequently detected, as one of the diagnostic criteria is that some symptoms must be present before the age of seven. By the ages of 9–11 years, children undergo consistent improvements in sustained attention, but their performance is less efficient when compared to adults. Furthermore, children who are nearly 11 years of age demonstrate marked improvement in performance. Therefore, these findings suggest that sustained attention or attention span develops rapidly

between the age of 4 and 6 years. then stabilizes between ages 7 and 8, improving gradually until the age of 16, when adult like levels are achieved, although increases are smaller in magnitude after the age of 11. These periods of improvement have been linked to development of the frontal lobes of the brain.

There are a number of different factors that affect an individual's sustained attention [4]. The conditions that increase sustained attention or attention span in children are opposite to those that increase sustained attention in adults. Research shows that sustained attention in children decreases when the event rate is low. Event rate is measured by the number of stimulus presentations per minute. Adults, on the other hand, perform better when the event rate is low. This means that a child is likely better able to sustain attention when stimuli are presented frequently or quickly, while adult performance improves when fewer stimuli are presented in the same time interval. One hypothesis developed to help explain these results is that, for children, the presentation of a single stimulus (low event rate) may be under arousing and therefore places a higher demand on the child's sustained attention, which taxes attention span, compared to high event rate situations in which they perform better. Another factor that impacts attention span is the probability of an event occurring. The probability of events is the chance of a specific stimulus being presented in a set period of time. Studies have shown that children do better in tasks with low event probability, whereas adults perform better in high event probability situations. Therefore, children display better attention spans when many stimuli are presented per minute and when the target stimulus is presented infrequently. Adults have better sustained attention when fewer stimuli are presented in a minute but more of the target stimuli are presented [4].

Deficits in attention span are commonly associated with Attention-Deficit/Hyperactivity Disorder [5]. This childhood disorder which can be life-long, affects between 4% and 12% of children [6]. ADHD is characterized by patterns of inattention, hyperactivity, and problems with inhibition that cause impairments in several areas of a child's functioning including academic and social problems [7]. The deficits in attention span mean that the child likely encounters difficulty in many school related tasks, such as when faced with reading long, uninteresting material, listening to lengthy, boring lectures, completing homework assignments or projects, and at home, such as when performing household chores; in short anything that requires effort and which may be perceived as boring [1]. Neuropsychological studies which have examined frontal lobe functioning, believed to be associated with sustained attention, have also found that children with ADHD perform more poorly on measures of sustained attention than do children without attention problems. Other studies have found that children with diagnosed attention disorders perform comparably to their peers on measures of other components of attention, such as selective attention, but that their sustained attention is affected [5]. The literature also suggests that children who rate highly on scales used in the diagnosis of ADHD perform similarly to children who have a formal diagnosis. The literature seems to suggest that children with attention problems may be capable of sustaining attention under conditions of high interest but when presented with less engaging material, may shift attention to other events even when these are considered less important. For example, a child may be able to sustain attention when playing a captivating video game but in the classroom, the child will focus on distractions rather than the lesson being taught [1].

Sustained attention is often measured using the Conners' Continuous Performance Test (CPT) a computerized task that requires participants to push the space bar or click the mouse except when an "X" appears on the screen [1, 4, 5]. Research has shown that performance on the CPT is associated with the attention problems seen in children with ADHD.

Relevance to Childhood Development

In conclusion, attention span is the ability to attend to a stimulus over a period of time and is important in accomplishing other tasks. This ability is dependent on different factors including event rate and probability of events but the influence of these factors is dependent on age. Finally, deficits in attention span have been associated with attention disorders.

Attentional Strategies

Iris Montoya-Rodriguez, Betty Dooley Awbrey
University of Texas at San Antonio, College of Education and Human Development, San Antonio, TX, USA

Synonyms
Attention control; Effortful control

Definition
Attentional strategies are plans or actions devised for information processing with the goal of triggering sensory registers, voluntarily or involuntarily, in order to select the desired input and move it on to short-term memory.

Description
Attentional strategies are used to attend selectively to a limited set of cues. In processing information, attentional strategies refer to the actions needed to move new information from short-term memory (working memory) to a longer-term memory, where it is be analyzed and added to new information. Without attentional strategies, the information will be ignored.

Research has shown that a single sensory register can only fully be attended to at any one time. For example as a shift in attention occurs, the management of that information will be to attend to a single stimulus at any moment. It is up to the individuals' central processing unit (CPU) to select the stimulus that will get their attention and potentially lead to new information processing [6].

Relevance to Childhood Development
Children usually begin to learn attention strategies at infancy. An infant responds to certain cues above all others. Auditory and visual stimuli lead to eye and head movements that indicate that sensory registers have been triggered above all other stimuli. It is at this moment that continued stimulation of the registers leads to attention.

As children mature, they refine their attentional strategies to become more selective to relevant information and more adaptable to specific situations [1]. Study of information processing in young children reveals that refinement of attentional strategies evolves through four phases. Production deficiency is the initial phase. During this phase preschoolers make little use of attentional strategies, and their attempts to do so fail. Control deficiency is characterized by inconsistent and ineffective use of strategies by early elementary school children. Consistent use of strategies, but without significant improvement in performance, indicates a child has entered the utilization deficiency phase. Finally, effective strategy use, in which children use attentional strategies consistently and with improved performance, is implemented by mid-elementary years [4].

The more advanced and skilled child uses attentional strategies to attain goal acquisition and to sustain their own thoughts to details to be incorporated into long-term memory and for further analysis.

Elementary Years
Attentional strategies and skills are purposefully used and taught in schools by educators. It is necessary to rehearse and exercise attention skill in order to maintain concentration to information. Strategies are needed since attention capacity is limited. Children learn to attend to specific environmental inputs for further processing in learning. Auditory senses are triggered as a teacher says, "Let's begin," in an authoritative voice indicating a lesson is about to begin. The visual sense cues a child that a classroom has been entered by the characteristics of color and setting. These registers trigger long-term memory indicating that this is a school and prepares a child for the eventual daily lessons.

Elementary educators use proximity, voice modulation, time limits and colorful displays, for example, to gather and sustain the attention of children. Attention will shift to other stimuli in the classroom or from within the child making it necessary to reconnect with the child. Attentional strategies are used to sustain and reconnect to the informational input that is of interest by the teacher and, hopefully, later by the child.

Young students learn by using more visual cues to attend to information. As children get older, they incorporate other sensory registers, and visual cues are not as prominent. In addition, children learn to attend to other cues like printed words. Educators provide cues and educate students on obtaining their own strategies.

Secondary School Years
As a child grows and becomes more self-aware, she/he learns by processing information with more affective dynamics. Informational processing has only recently acknowledged the importance of connecting cognition and affect. In the earlier developmental years, children

are more apt to learn in order to please parents and teachers, but as they get older they want to please themselves [3].

As children enter the secondary school years, new strategies must be incorporated to encourage the input and processing of information. It is vital that teachers equip students with procedures and skills to attend to math and reading independently. Attentional strategies include note-taking skills, class participation, group learning, reading, test-taking skills. As children mature, these usually become automatic and sustained.

Strategies are progressing from teacher-centered strategies to student-centered. To learn, educators must use strategies to stimulate these affective and sensory registers. These attentional strategies take into mind visual, auditory and affective stimuli [3].

Many environmental stimuli act on the body at any one moment in time. In addition, internal factors vie for a child's attention. Most stimuli are ignored, or will be ignored over time. It is necessary to stimulate the sensory registers in order to attend to that which will trigger short-term memory so that the learning process begins. These acts refer to the skills needed by the teacher to trigger attention on the part of the students. Eventually, a child will learn to concentrate on the cues available for learning to begin. Students need skills to plan and manage their sensory registers in order to attend to lessons [2].

Use of Attentional Strategies to Address Attention Deficit Hyperactivity Disorder

Attention deficit hyperactivity disorder (ADHD) is a chronic condition affecting 3–5% of all children. It is a developmental disability caused by delayed brain development and characterized by short attention spans and the inability to focus and pay attention. Children with ADHD are easily frustrated and academic failure is high. Attentional strategies are vital in all environments to the success of children diagnosed with ADHD. Distractors abound in the classroom, as in any environment. It is important to provide a setting with a minimal number of competing sensory signals.

A classroom environment that incorporates physical exercise within the everyday routine is effective and beneficial for students with problems attending and concentrating. Exercise increases neurological activities that relate to memory, spatial perception, language and emotion. It also increases motivation and helps students to manage stress [5].

Behavior intervention strategies are frequently used in classrooms to help reduce inappropriate behaviors of students with attention deficits. Staying on task, remaining seated and interacting with others in a socially appropriate manner are reinforced with the use of reward systems. Many students are able to modify their own behaviors when teachers use low-involvement strategies to get their attention. Such strategies include making eye contact, proximity control and placing a hand on students' shoulders to gain their attention. Children with attention deficits have received much attention. Educational strategies are essential to their learning [5].

Attention-Deficit Disorder

►Attention-Deficit/Hyperactivity Disorder

Attention-Deficit/Hyperactivity Disorder

Melissa K. Stern
University of Florida, Gainesville, FL, USA

Synonyms

Attention-deficit disorder; Hyperkinetic disorder

Definition

Attention-deficit/hyperactivity disorder (ADHD) is a neurodevelopmental disorder which first appears in childhood but is a lifelong, chronic disorder. ADHD is characterized by developmentally inappropriate levels of hyperactivity, impulsivity, and inattention which result in impairment in the academic, social, or occupational

domains. It is one of the most commonly occurring disorders of childhood with estimates suggesting that it affects 3–7% of the school-age population [2].

Description

Brief History of the Disorder

Characteristics of ADHD have been present in medical literature since the beginning of the twentieth century and the disorder itself has carried a variety of diagnostic labels over the course of the past 100 years [3]. In 1902, George Still produced the first official case study of children with attention difficulties, describing 43 children he had seen in his clinical practice. He described these children as having a major deficit in moral control with aggressive and defiant behavior, and lacking inhibitory volition with a need for immediate gratification. However, significant interest in children with attention problems did not come about until the encephalitis epidemic of 1917. At that time, physicians were presented with large numbers of children who survived the epidemic but had lasting behavioral and cognitive problems. These problems are reminiscent of the way we currently conceptualize ADHD in that they experienced difficulties with attention, impulsivity, and hyperactivity. In the 1930s, brain ablation studies became popular as a way of investigating the effects of lesions on aspects of cognitive functioning such as attention and hyperactivity. Researchers discovered that lesions in the frontal lobes of monkeys resulted in problems with restlessness, hyperactivity, and inattention. In the 1940s, Strauss termed the diagnosis of minimal brain dysfunction, resulting largely from what had been learned in brain ablation studies. Also during this time, clinicians and researchers began to look for pharmacological treatments for the collection of hyperactive, impulsive, and inattentive symptoms. It was at this time medicine discovered that stimulants, notably amphetamines, were effective in reducing the symptoms of minimal brain dysfunction. In the 1950s and 1960s, researchers began to postulate that the underlying causes of the symptoms of inattention and hyperactivity were a result of a CNS deficit or brain damage and was renamed "Hyperkinetic Reaction of Childhood Disorder." In the 1960s the idea of organic brain damage as a cause of the disorder was challenged as to its accuracy and validity. In the 1970s and 1980s as old theories were falling out of favor, and with the rise of diagnostic criteria and the DSM-III, the disorder was characterized as one of primarily an attention deficit; thus, it became referred to as attention deficit disorder (ADD). The 1980s and beyond gave rise to an exponential amount of research on the diagnostic criteria for the disorder as well as treatment research. During this time a plethora of new assessment methods and new treatment methods shifted the focus of etiology onto biological factors. With the rise of neuroimaging in the 1990s and a re-evaluation of the DSM, ADD morphed into a neurodevelopmental disorder with objective specific criteria listed in the DSM and was re-termed attention-deficit/hyperactivity disorder.

Diagnosis and Prevalence

According to the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV TR: [2]), a child must have experienced six symptoms of inattention and/or six symptoms of hyperactivity/impulsivity for a period of at least 6 months to be diagnosed with the disorder. These symptoms must have first appeared before the age of 7, the symptoms must be disproportionate to the developmental level of the child, and the symptoms must cause impairment in multiple areas of functioning such as in social, academic, or occupational settings. Children who meet diagnostic criteria for ADHD are further classified into subtypes: Predominantly inattentive type, predominantly hyperactive/impulsive type, and combined type. Diagnosis may be made by a health care professional, such as a pediatrician or primary care physician, or by a mental health specialist such as a psychiatrist or psychologist. However, the majority of children are diagnosed and treated by their pediatrician. Research has suggested that males are more likely to be diagnosed with the disorder than females. Estimates have indicated that males are anywhere from two to ten times more likely to be diagnosed with the disorder than females.

While ADHD is considered a disorder first diagnosed in childhood, evidence exists to demonstrate that the disorder continues into adulthood. Indeed, approximately 75% of children diagnosed with ADHD continue to meet diagnostic criteria for the disorder in adolescence. Of those who maintain a diagnosis in adolescence, 40–50% will continue to experience impairment into adulthood. Presentation of the disorder changes as children age; they often no longer demonstrate gross motor hyperactivity as they did as children. Instead, adolescents and adults with ADHD will show motor signs such as fidgeting, restlessness, and shifting in seat. They continue to experience problems with inattention and impulsivity.

Neuropsychological and Neurological Findings

As ADHD is a neurodevelopmental disorder, it is not surprising a large amount of research has been geared towards understanding the neuropsychological and

neurological aspects of the disorder. Approximately 95% of children with ADHD do not show evidence of documented neurological impairment; however, that does not mean neurological factors are not involved. Results of neuropsychological testing have demonstrated that children and adults with ADHD have trouble with some cognitive abilities such as inhibiting behavioral responses, problems with working memory, planning, organization, perseveration, and other aspects of frontal lobe functioning. Several of these areas in which persons with ADHD show deficits are considered aspects of executive functioning. Indeed, in recent years ADHD has been characterized as a disorder of executive functioning [3]. While executive dysfunction is not yet listed in the DSM as a core symptom, problems with planning, organization and other aspects of executive functioning are frequently a dominant problem for those with ADHD. Additionally, some have argued that underlying difficulties with executive functioning are the main cause for impairment in ADHD, rather than the core symptoms as listed in the DSM-IV.

Results of neuroimaging studies have suggested numerous abnormalities in the brain [10]. Some findings include differences in cerebral blood flow, showing that those with ADHD have decreased blood flow to the prefrontal regions following to the subcortical structures, most notably the caudate nucleus. These studies have also suggested diminished metabolism in the frontal lobes. Other studies have found that children with ADHD have a smaller brain volume overall, a smaller corpus callosum, and smaller caudate nucleus compared to children without ADHD. However, while some structural abnormalities have been found in research, there is little consistency in the research literature about the presence of these structural differences. In adolescence and adulthood, there is some evidence that these differences are no longer apparent.

One of the most common guiding theories in ADHD is that symptoms of inattention, hyperactivity, and impulsivity are the result of a neurotransmitter deficit, specifically deficits in dopamine and norepinephrine. This theory originates from the fact that stimulant medication appears to be an effective treatment for ADHD (see treatment section). The neurotransmitter theory suggests that persons with ADHD either produce too little dopamine or their uptake of the transmitter within the brain is deficient.

Associated Impairments

A core feature of the ADHD presentation is impairment [3]. Children with ADHD show impairment in multiple domains, the most notable of which is the academic environment when the disorder is first diagnosed. Children with ADHD often have difficulty in environments they find to be boring, not stimulating, and which last for extended periods of time. Thus, when children enter the school environment the effects of ADHD symptoms may cause children to fall behind other children in their grade. For instance, children with ADHD have difficulty staying in their seats, may run around the classroom at inappropriate times, and are easily distracted by other children and noises. Hence, if a child with ADHD is supposed to be listening to the teacher explaining the alphabet but is instead continually distracted by a peer who frequently makes loud erasure noises, the child with ADHD may not learn the alphabet as quickly as he or she would if they had not been easily distracted. Such intrusions of inattention, hyperactivity, and impulsivity often result in slowed academic progress or prevention of reaching potential in the academic environment. However, several treatments are available to counteract the impairing effect of ADHD symptoms in the school setting (see treatment section). Such problems in the academic environment are also commonly found in the work environment. As ADHD is a chronic disorder, the symptoms can continue to impair people through college and into the workforce. Similar problems can arise, such as difficulty attending to information, restlessness, and trouble completing tasks due to erroneous distractions.

Another area of impairment experienced by many children, adolescents, and adults with ADHD is social impairment. Research has demonstrated that children with ADHD are often rejected by peers and thus have fewer friends. Reasons for such rejection include a perception that those with ADHD are more aggressive, intrusive, and noisy. Rejection by peers can often leads to problems such as lowered self-esteem and aggressive behavior. Children with ADHD also tend to socialize with deviant peers due to social rejection, which may increase aggressive behaviors. These problems have been documented in adulthood. Adults with ADHD report also having fewer friends and difficulty in mixed gender interactions.

As children age into adolescents and adults, more situations in which they can experience symptom impairments arise. For instance, in adolescence teenagers are given the opportunity to operate motor vehicles and begin driving. Research has demonstrated that adolescents and adults exhibit significantly greater frequency of unsafe driving behaviors such as speeding, driving without a license, or running stop signs [4]. Adolescents and adults with ADHD are more likely to have their license suspended, receive speeding citations, and receive greater

numbers of moving citations overall compared to adolescents and adults without ADHD. It is clear that ADHD is associated with impairment across a variety of domains and has a large impact on the lives of those who live with the disorder.

Comorbidities

The term "comorbidity" or "comorbid condition" refers in the psychological literature to the co-occurrence of disorders together. Children and adults with ADHD often suffer from multiple comorbid conditions [7]. Some of the most common comorbid psychological disorders with ADHD are the disruptive behavior disorders, oppositional defiant disorder (ODD) and conduct disorder (CD). Numbers estimate that upwards of 40% of children diagnosed with ADHD also meet DSM-IV diagnostic criteria for ODD. Similarly, estimates of upwards of 45–50% of children with ADHD also meet diagnostic criteria for conduct disorder. Several other disorders are also commonly diagnosed in children who have ADHD. Specific learning disabilities such as reading disorder, mathematics disorder, etc., are also often present.

Several other groups of disorders are also found to commonly co-occur in children with ADHD. For instance, estimates suggest that up to 30% of children with ADHD may also have an anxiety disorder, and 10–30% may have a depressive disorder. Other mood disorders such as bipolar disorder are also highly comorbid with ADHD, with rates of up to 20%. One last disorder that is often discussed in conjunction with ADHD is Tourette's disorder, a tic disorder. While estimates suggest only 7% of children with ADHD have a tic disorder, upwards of 50% of those children diagnosed with Tourette's disorder have ADHD.

Assessment

Assessment for the presence of ADHD may be done by a pediatrician, psychiatrist, or psychologist. The American Academy of Pediatrics [1] offer specific practice guidelines for the diagnosis of ADHD. The guidelines, designed for pediatricians and primary care physicians, suggest healthcare providers observe the child, conduct an interview with the parent(s) and child to gather necessary background data for diagnosis, and administer specific parent-report rating scales, such as the Conners' Parent Rating Scale. The AAP also recommend that children should be assessed for common comorbidities, but this is not required for diagnosis of ADHD. Of note, use of cognitive tests is not mandatory or recommended for use in diagnosis of ADHD. However, such tests may provide descriptive/qualitative information on the specific cognitive and executive functioning deficits experienced by a particular child.

Knowledge of prevalence rates for comorbid conditions also has implications for assessment. While assessing for comorbid conditions appears simple at first notion, there is significant complexity in the assessment of comorbid conditions. This complexity stems from the concept of symptom mimicry with disorders which are found to co-occur with ADHD [7]. For instance, there is considerable overlap in symptom presentation between ADHD and pediatric bipolar disorder. Bipolar disorder in children often presents with significant motor agitation similar to that of ADHD. Thus, teasing apart the two disorders can be an intricate endeavor. Similarly, decreased attention capacity is a symptom common to many disorders including anxiety disorders, depressive disorders, and posttraumatic stress disorder. Thus, if a child or parent reports significant symptoms of inattention, this should trigger a knowledgeable evaluator to not only assess criteria for ADHD, but also for the various disorder types mentioned in order to ensure that the cause of attention difficulties is not a function of another disorder.

In addition to mimicry with psychological disorders, persons evaluating children for the presence of ADHD also need to consider several general medical conditions (GMCs) which may result in a presentation similar to that of a child with ADHD. For instance, children with sensory impairments such as hearing difficulties are often described as inattentive or easily distracted. Thus physicians often check for hearing impairments before moving on to further assess for ADHD. Similarly, seizure disorders such as absence seizures may first be described as a child looking as if they are not paying attention. Again, this is often a GMC ruled out during an ADHD evaluation. There are several medications which may result in a significant increase in hyperactivity or difficulty concentrating. These include some medications for seizure disorders such as Phenobarbital as well as certain asthma medications. During assessment, a background information interview can help rule out such medications as causes of any reported symptoms.

Treatment

Treatment for ADHD may take many forms including psychopharmacological, parent behavioral training, or classroom management strategies. The most commonly recommended form of treatment for ADHD across the lifespan is the use of stimulant medications [5]. It has been found to be the most effective treatment option for the core symptoms of ADHD for both children and adults [5, 8]. Commonly prescribed medications include

Ritalin, Adderall, Concerta, and Vyvanse, as well as their derivatives and other available stimulants. Stimulants are available in many forms including immediate and delayed-release, and are available in various mediums such as pills, liquids, or transdermal patches. Stimulants predominantly work by affecting the levels of the neurotransmitter dopamine in the brain, either by increasing the amount of dopamine or the rate of uptake. Stimulant medications are recommended by the AAP as the number one method of treatment for ADHD. As the various stimulants have slightly differing mechanisms of action and dosing schedules, if one type of stimulant is not found to be effective, another type of stimulant is often prescribed by physicians and may have beneficial effects for the child. However, there is evidence that approximately 30% of those with the disorder do not respond to stimulate medication or have significant side effects. Thus several other medications are offered as second-line treatments for ADHD.

Side effects of stimulant medication can include loss of appetite, weight loss, sleeping problems, irritability, headache, stomachache, and a sudden deterioration of behavior. Symptoms of depression, sadness, crying, and withdrawn behavior can also occur. Some studies have also shown that stimulant medication will increase the frequency of tics for those who suffer from Tourette's disorder or another tic disorder. While side effects are certainly possible, they are often the result of inaccurate dosing or are transient in nature. Similarly, while one stimulant many produce side effects in one person, another stimulant medication may not result in any side effects for that same person.

Other medications that have been prescribed for the treatment of ADHD that are not classified in the stimulant domain include atomoxetine, which affects norepinephrine levels in the brain, tricyclic antidepressants, and bupropion. These medications have, in clinical trials, been found to be more effective than a placebo medication. Of these medications, tricyclic antidepressants have the most research support behind them as being an efficacious treatment for ADHD. Atomoxetine is a treatment often requested by patients and parents as it is not a stimulant medication and has less of a chance of producing side effects. While research studies on atomoxetine are more limited than for those of stimulants as it is a newer medication, it has demonstrated to be an effective treatment compared to placebo.

In addition to psychopharmacological treatments, parent management training or behavioral, treatments have also been found to be effective, particularly in conjunction with medication and for children who also have comorbidities [6, 8, 9]. Behavioral parent management training is considered to be a "well-established" treatment by the American Psychological Association Task-Force on Empirically Supported Treatments. This type of treatment helps parents to increase the frequency of positive behaviors as well as modify ineffective discipline techniques and parenting practices. The general concept behind the parent management training programs is one of differential attention. Here, after identifying specific problematic behaviors, parents are instructed to reward positive and prosocial behavior using praise and positive attention as well as rewards. Concurrently, parents reduce the frequency of negative behaviors using techniques of ignoring, time-out and other discipline strategies such as the removal of privileges [6]. Spanking or physical punishment is discouraged and parents are taught how to maintain an effective balance between reward and punishment.

Several treatments exist for aiding a child with ADHD in the school environment. Treatments as mentioned above, such as medication or parent management training, will often have effects which extend to the school environment. Indeed, research has demonstrated that medication is an effective treatment for reducing severity of inattention, impulsivity, and hyperactivity in the school setting. However, in addition to treatments which are provided outside the school, public schools provide children with accommodations to help reduce impairment which may be keeping them from succeeding at the level of which they are capable if they were not impaired by the disorder [3]. For instance, common accommodations given to children with ADHD are extended time on tests, taking tests in separate rooms without distracting stimuli, and preferential seating at the front of the classroom near the teacher and away from doors or noisy air conditioners. These accommodations are designed to "even the playing field" for the child with ADHD so they may perform their best regardless of their disorder. In addition, use of a daily report card has also proven to be effective in the school environment [3]. Here, children's behavior is monitored by the teacher throughout the day and then rewarded at the end of the day by a caregiver based on how well they did. This method uses positive attention and reward to help increase frequency of positive and prosocial behaviors in the school environment.

As mentioned previously, common comorbid conditions for children who suffer from ADHD are learning disorders and states are also mandated to provide services to children with specific learning disorders in the "least restrictive environment" possible. This may include additional accommodations such as being assigned a note

taker in classes, being able to have a "reader" for tests and then answer questions orally, or other such exceptions which would be most helpful given the particular type of learning disorder. States have varying statutes and guidelines on how they decide services are needed and who can make diagnoses that are accepted by the school as accurate. Some schools may demand that their own assessors perform evaluations while other districts will only accept diagnoses of ADHD from a licensed medical doctor, as opposed to a psychologist. Regardless of these guidelines, all states must provide the appropriate services to children with ADHD.

While ADHD is a disorder that affects many aspects of functioning, it is clear the there are treatments in several domains where are effective in reducing symptom severity and impairment in these domains. Medications and behavioral treatments have proven to be valid and reliable interventions for persons of any age

Attribution

Pei-Hsuan Hsieh
University of Texas at San Antonio, San Antonio, TX, USA

Definition

Attributions refer to the explanations individuals give for their success or failure in a particular performance, explanations that were described by Weiner along three dimensions, *locus*, *stability*, and *control*.

Description

Attribution theory is a cognitive motivation theory based on the assumption that individuals are rational decision makers. Children are motivated to understand the environment and themselves. By seeking explanations and understanding for the underlying causes of their success, they can predict and control the events that affect them and continue working, with the hope of succeeding again and again. Also, the process of ascribing a reason for failure can guide a child so as to avoid failing again. The process, however, is dependent upon one's beliefs. For instance, if a child believes that his or her success is due to the amount of effort he or she has put into the task, the child will expect to do well the next time he or she approaches similar tasks assuming that effort can determine the outcome. Or, if the child fails and believes that failure is due to his or her low ability, the child may avoid similar tasks in the future so as to avoid failing again. This reasoning process is known as making attributions, and it is a concept introduced in the literature to understand child's motivation and achievement in the classroom.

Attributions can be categorized along three dimensions, locus, stability, and control. It is these three causal dimensions that influence individuals to choose to

continue or to disengage doing a task. Locus is concerned with whether the individual perceives the cause of an event as internal or external. For example, a child with an internal locus of control may attribute success to ability, something that may consequently affect his or her pride and will then influence his or her expectancy for future success, while a child with an external locus of control may attribute success to luck, giving little basis for what future outcomes may be like. The stability dimension refers to whether the cause of an event is stable or unstable across time and events. Ability in this case would be characterized as being stable while effort would be unstable depending on an individual's choice in each new situation. Luck is also unstable because no one is able to predict when good or bad luck will strike. The last dimension, controllability, refers to how much control an individual has over a cause. Effort and strategy would be classified as controllable because the child can control how much effort to allocate to a task and can decide on the strategy to use. Ability, along with luck and task difficulty, on the other hand, are all categorized as uncontrollable because ability is often perceived as something that is genetically determined.

Attribution is more likely to occur if an individual comes upon a situation that is unexpected. Failure is more likely than success to lead individuals to search for reasons for the failure. Children are also more likely to find causes for an event that is important to them. Weiner claimed that children's attributions come from situational cues such as their past experiences, feedback from teachers, observation of the performance of peers, and how much help was received. Weiner also maintained that attributions come from child's self-perception.

Relevance to Childhood Development

Researchers have suggested that young children (five and under) do not have a clear understanding of the possible causes of their successes and failures. They especially have trouble distinguishing between effort and skill. By age six, they begin to realize that effort is an important factor for success. By age nine, children often equate "working hard" with "lack of ability." As children get older, they become more aware of the consequences that follow each attribution. Adults tend to be more sympathetic when children fail due to uncontrollable causes such as illness but get irritated when children fail because they don't try hard enough. Over the years, children develop a predictable pattern of attributions. This pattern may develop as a result of past similar experiences or due to teacher feedback. They develop a general sense of their capabilities and make attributions accordingly.

Atypical Neuroleptics

Nina Foster
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Atypical antipsychotics; Second generation antipsychotics

Definition

A specific group of medications used to treat psychiatric conditions.

Description

Atypical neuroleptics are used to treat schizophrenia and similar conditions. They are more widely used than typical antipsychotics. They provide a higher effectiveness rate in treating the negative symptoms of schizophrenia

and a lowered risk of developing movement problems, tardive dyskinesia, and agranulocytosis, a loss of white blood cells [1].

Abilify (Aripiprazole) is used for the treatment of schizophrenia in adults and adolescents aged 13–17, manic or mixed episodes associated with Bipolar I Disorder, adjunctive treatment to antidepressants for Major Depressive Disorder, and treatment of irritability associated with autistic disorder in patients aged 6–17 [2]. Clozaril (Clozapine) is used for the management of schizophrenia when standard treatment has failed, and for the reduction of recurrent suicidal behavior associated with schizophrenia or schizoaffective disorder [2]. Zyprexa (Olanzapine) is used for the treatment of schizophrenia and acute treatment of manic or mixed episodes associated with bipolar I disorder or as an adjunct to valproate or lithium [2]. Symbyax (Olanzapine/Fluoxetine) is indicated for the acute treatment of depressive episodes associated with bipolar disorder and treatment resistant depression in adults. It can be used adjunct to lithium or valproate for maintenance treatment of bipolar I disorder [2]. Seroquel (Quetiapine) is used for the treatment to schizophrenia and bipolar disorder maintenance for both manic and depressive episodes [2]. Risperdal (Risperidone) is used for acute and maintenance treatment of schizophrenia, bipolar I disorder, and irritability associated with autistic disorder [2]. Geodon (Ziprasidone) is used for treating Schizophrenia and Bipolar Disorder [2]. Invega (Paliperidone) is used for treatment of schizophrenia and schizoaffective disorder as monotherapy or as an adjunct to mood stabilizers and/or antidepressants [2]. The atypical neuroleptics may produce extrapyramidal side effects, but they tend to produce fewer extrapyramidal side effects than the typical antipsychotic medications.

Auditory Cortex

Chad A. Noggle
SIU School of Medicine, Springfield, IL, USA

Synonyms

Auditory cortex; Primary auditory cortex

Definition

Auditory Cortex: The auditory cortex is a region of the superior temporal lobe that is involved in the processing of auditory information.

Description

The auditory cortex, a.k.a. primary auditory cortex, of each hemisphere lies within the temporal lobe, and is localized to Heschl's Gyrus, within the lateral fissure. While that which is specifically referred to as the primary auditory cortex is localized to Heschl's Gyrus, it works in combination with the Planum Temporale which lies posterior to Heschl's Gyrus [5]. While these structures are linked neurologically, they are often separated functionally. These functional differences may be tied to differential symmetry of these structures in relationship to brain lateralization. Specifically, Heschl's Gyrus is generally larger in the right hemisphere in comparison to the left, and consequently, Heschl's Gyrus may play a more prominent role in non-speech aspects of language and musical processing [5]. In contrast, the Planum Temporal is generally larger in the left in comparison to the right and is thus believed to play a greater role in actual speech comprehension [5]. While differences may be seen between Heschl's Gyrus and the Planum Temporal, as a whole, the primary auditory cortex processes all aspects of sound, with the neurons demonstrating specialization to respond to certain frequencies [2]. The columns of neurons that lie in more anterior regions of the primary auditory cortex respond most to higher frequencies while those in more posterior regions respond more to lower frequencies [2]. While the cortex largely presents in a contralateral fashion, such that the right hemisphere corresponds with motor output and sensory input of the left and vice versa, the projections of the auditory system provides both ipsilateral and contralateral inputs to the cortex; so there is bilateral representation of each nucleus in both hemispheres [4]. This is due to the fact that projections of the auditory pathways move up from the auditory nerve which contains both crossed and uncrossed pathways, resulting in stimulation of the auditory cortex in both hemispheres. Thus auditory sensation received in one ear is conveyed to the auditory cortex to both temporal lobes [1]. After stimulation of the eighth cranial nerve, the information then passes on to the cochlear nucleus and then to the inferior colliculus, followed by the medial geniculate and then onto the primary auditory cortex [4]. Additional transmission to secondary and tertiary auditory zones follows. The shared reliance on both hemispheres may be seen as a protective factor. In fact, for one to experience cortical deafness (i.e., inability to process

sound due to neurological insult) extensive bilateral lesion involvement of Heschl's gyrus and/or the underlying white matter of this region is required [3].

Auditory Memory

Maria Assunta Cuffaro
State University of NY: Potsdam, Potsdam, NY, USA

Definition

Specific sequences of sounds predict crucial events whether they are aversive or pleasant. The processing of these sequences of these sounds including the processing of speech by humans requires exceptional quality of memory processing (e.g., see maintenance or storage of auditory events for a period beyond their perception). The memory processing of a sequence of tones constitutes a coherent melody.

Description

Auditory events must be processed sequentially and the saliency of that event is established in relation to the previous, Auditory (phonetic) representations in memory occurs when verbal materials are presented visually. Short-term retention of verbal items is better when presented acoustically than if presented visually. The greater the rehearsal time available for auditory than for visual material; spoken items are somehow greater in amplitude than written items. Regency effect in serial recall of verbal items is greater with auditory than with visual presentation of the items and is susceptible to interference from phonologically similar items. Following, the presentation of a nearly supraspan verbal unit usually 7–8 constantans or words, retention of the last component is reduced when an auditory suffix is interpolated between presentation and recall [1].

Memory is the retention of information over time. There are several types of memory. Auditory memory involves being able to take in information that is presented orally, to process such information, store it in one's mind and then recall what one has heard. Basically, it involves the skills of attending, listening, processing, storing, and recalling. There are two kinds of auditory memory: Short-term auditory memory is the ability to recall something heard very recently, while long-term auditory memory is the ability to remember something heard some time ago.

In her book *Learning Disabilities*: There is a Cure, educational therapist Addie Cusimano states that a weakness in auditory memory can have serious consequences in the realm of learning for students. Because students with auditory memory weaknesses pick up only bits and pieces of what is being said during a classroom lecture, they make sense of only little of what is said by the teacher. Afterwards, they are able to recall only a small amount or none of what was said.

"Students with auditory memory deficiencies will often experience difficulty developing a good understanding of words, remembering terms and information that has been presented orally, for example, in history and science classes," says Cusimano. "These students will also experience difficulty processing and recalling information that they have read to themselves. When we read we must listen and process information we say to ourselves, even when we read silently. If we do not attend and listen to our silent input of words, we cannot process the information or recall what we have read. Therefore, even silent reading involves a form of listening."

Research also suggests that students with spelling problems have deficits in auditory memory skills. http://www.audiblox2000.com/learning_disabilities/dica01.htm

Auditory Processing

►Central Auditory Processing Disorder

(Central) Auditory Processing Disorder

Taylor Pelchar
University of Tennessee, Knoxville, TN, USA

Synonyms

Central Auditory processing disorder [8, 9]

Definition

"(Central) Auditory Processing Disorder (C)APD is a deficit in neural processing of auditory stimuli that is not due to higher order language, cognitive, or related factors" ([1], p. 2).

Description

- [A person who has (C)APD may exhibit the following behavioral characteristics] difficulty understanding spoken language in competing messages, noisy backgrounds, or in reverberant environments; misunderstanding messages; inconsistent or inappropriate responding; frequent requests for repetitions, saying "what" and "huh" frequently; taking longer to respond in oral communication situations; difficulty paying attention; being easily distracted; difficulty following complex auditory directions or commands; difficulty localizing sound; difficulty learning songs or nursery rhymes; poor musical and singing skills; and associated reading, spelling, and learning problems ([1], p. 8).

Not all individuals diagnosed with (C)APD display the same symptoms. Different functional symptoms may be connected with different auditory deficit combinations. Furthermore, people who have the same auditory deficit might be impacted in different ways [1]. Conditions that are co-morbid with (C)APD might include learning disabilities, speech and language disorders, attention deficit disorder/attention deficit hyperactivity disorder, peripheral hearing loss, emotional disorders, and psychological disorders [2].

The occurrence rate of (C)APD in children is unknown [7]. However, estimates of the prevalence of (C)APD in children vary between 2 and 5% [6, 7]. Boys are more likely to have this disorder than girls [9].

The underlying cause of (C)APD is usually unknown [6, 10, 11]. The development of (C)APD is most likely influenced by both inherited and environmental factors [10]. The majority of people with (C)APD do not display frank Central Auditory Nervous System (CANS) lesions; however, there is significant evidence from autopsies that they display neuromorphological abnormalities within the Central Nervous System auditory areas [1]. Conductive hearing loss might contribute to (C)APD [10]. Possible risk factors of (C)APD include chronic otitis media, low birthweight, and prematurity [7].

According to the consensus conference of ASHA, the following indicators are used to diagnose (C)APD: case history, systematic observations of auditory behavior, audiological tests, and speech–language pathology measures [9]. Types of tests that are used to diagnose (C)APD include auditory temporal processing and patterning tests, binaural interaction tests, dichotic speech tests, monaural low-redundancy speech tests, auditory discrimination tests, electroacustic measures, and electrophysiological measures [1]. The majority of these tests should not be administered to children younger than the age of 7 [4, 9]. Test batteries designed to assess (C)APD include the SCAN-C: Test for Auditory Processing Disorders in Children-Revised and the SCAN-A: Test of Auditory Processing Disorders in Adolescents and Adults [9]. Assessment can be influenced by other disorders that impact the functioning of audition such as language impairment, ADHD, reading disability, learning disability, Autism, and reduced intellectual functioning [4, 9]. Although the cooperation of a multidisciplinary team is necessary during the assessment process, an audiologist is responsible for making the actual diagnosis of (C)APD [1, 3, 4].

A child might display the following specific deficits: Binaural Separation and Binaural Integration Deficits, Monaural Separation/Auditory Closure Deficits, Auditory Patterning/Temporal Ordering Deficits, Auditory Discrimination Deficits, Binaural Interaction Deficits, and Temporal Processing Deficits [3]. According to the Bellis/Ferre model, (C)APD can be categorized into the subtypes of Auditory Decoding Deficit, Prosodic Deficit, and Integration Deficit based on patterns that correspond to different locations of brain dysfunction. Each of these subtypes is characterized by different result patterns on the auditory assessment [3].

Some professionals doubt that CAPD exists as a separate entity [8]. However, ASHA [1] believes that there is "sufficient evidence to support the neurobiological and behavioral existence of CAPD as a diagnostic entity" (p. 15). Another source of disagreement is whether or not (C)APD is modality specific [1]. American Speech-Language-Association [1] disagrees with definitions of (C)APD that state the condition is completely modality-specific.

Relevance to Childhood Development

Children who have (C)APD often display co-morbid cognitive, learning, and language deficits [6]. Children's learning difficulties, as well as communication deficits, might have an adverse impact on their self-esteem development and self-worth. Also, academic difficulties are typically associated with (C)APD. Children with (C)APD might be more likely to experience behavioral, social, and emotional difficulties. Early intervention is important because treatment may lessen the likelihood of the occurrence of these secondary problems [1]. Treatment usually consists of three procedures: compensatory strategies, direct skills remediation, and environmental modifications that are delivered simultaneously [1, 4].

Compensatory strategies typically help children strengthen their central resources so that they can use these particular resources to help overcome their auditory disorder. Many compensatory strategy approaches instruct children to take responsibility for their personal listening failure or success. In addition, such approaches teach children to actively participate in daily listening activities through various problem-solving and active listening techniques [1, 4]. Examples of activities that can reinforce good listening skills with children, preschool-aged and older, are: listening to stories, following directions, inferencing, engaging in activities that reinforce executive strategies, and participating in activities that help with the development of metalingustic skills [5].

Environmental modifications improve access to information presented auditorily [4]. Examples of such modifications that can be used in the classroom include reducing reverberation by covering reflective surfaces, utilizing acoustic dividers, utilizing other absorption materials all through empty or open spaces, altering the location of study places, and removing external sources of noise from the learning area [1]. Possible environmental accommodations that can be utilized to improve the listening environment are

- preferential seating for the child with (C)APD to improve access to the acoustic (and the visual), use of visual aids, reduction of competing signals and reverberation time, use of assistive listening systems, and advising speakers to speak more slowly, pause more often, and emphasize key words ([1], p. 12).

There are a number of direct treatment attempts to remediate (C)APD. Various treatment activities address particular auditory deficits. Some treatments might be computer-assisted whereas others might incorporate individual training with a therapist. Examples of computer-based auditory training (CBAT) software programs are Brain Train, Fast ForWord, Earobics, Laurete Learning Systems, Foundations in Speech Perception, Listening and Communication Enhancement (LACE), Learning Fundamentals, Sound and Beyond, and Otto's World of Sounds [12]. Treatment might be delivered at school-based, clinical-based, or home-based therapy sessions. There is not a universal treatment approach that is appropriate for every child that has (C)APD. All aspects of therapy, such as the type, duration, and intensity, needs to be very individualized and programmed for the child's specific auditory disorder. The amount of a child's auditory deficits that will improve as a result of therapy cannot be predetermined. Some children are entirely ameliorated of their auditory difficulties whereas others might display some small degree of deficit their entire life [4].

Augmentative and Alternative Communication (AAC)

►Augmentative Communication

Augmentative Communication

Judah B. Axe
Simmons College, Boston, MA, USA

Synonyms

Augmentative and alternative communication (AAC)

Definition

The use of communication systems other than speech.

Description

Individuals with significant speech impairments (i.e., those with disabilities such as autism, mental retardation, cerebral palsy, deafness, blindness, and quadriplegia) cannot use expressive communication to indicate their needs and share social interactions. Augmentative communication is the term used to represent a set of communication systems used as replacements for speech for these individuals [1]. There are many forms of augmentative communication such as sign language, picture selection, and speech output devices.

Augmentative communication can be divided into "low-tech" and "high tech" categories. Sign language and picture-based communication are two forms of low-tech communication. Sign language is the production of hand movements representing letters and words. Deaf people use sign language as a replacement for speech, though sign language is also used by individuals with developmental disabilities. There are a variety of signing systems such as American Sign Language and signed English. In addition to sign, pictures can be used as an augmentative system. Individuals can be equipped with a set of pictures that can be handed to others to indicate requests or other points of conversation. Sentences can be formed by placing pictures in a row. The Picture Exchange Communication System is a system commonly used with children with autism. High-tech augmentative communication devices vary from a single button that emits a word or phrase to a computer that contains hundreds of icons and speech-output capabilities. Single buttons and laptop computers can be placed on a child's wheelchair for the child to use to communicate.

For individuals with severe motor impairments such as quadriplegia, augmentative communication systems involve moving only the head or parts of the head (e.g., mouth, eyes) to move devices that select messages. People can be equipped with a device that goes in the mouth and subtle mouth movements move a cursor that selects words. Laser devices can be connected to one's eyes so that words or pictures can be selected simply by looking at them. A button that generates spoken messages can be placed next to a child's head so that only a simple head movement activates the message.

Steven Hawking, the British theoretical physicist who has significantly limited muscle control due to amyotrophic lateral sclerosis, uses an augmentative communication device. Dr. Hawking has a computer attached to his wheelchair with words displayed on the screen. A cursor moves along the words and by touching a button with his finger, but without moving his entire hand, Dr. Hawking selects a word to express. Once a string of words is selected, he selects an icon that expresses the words using a speech output device. This type of augmentative communication system can be used with young children as well [2].

Authoritarian Parenting Style

Paul Borden Ingram
Western Carolina University, Sylva, NC, USA

Definition

Authoritarian parenting is an approach to child–parent interactions wherein the parent maintains large degrees of control over the child's life and wherein parental interactions are based on a strict hierarchy of power.

Description

The authoritarian parenting style (authoritative parenting style) is one of the four distinctive approaches described in depth by Dr. Diana Baumrind. Of these four approaches, the authoritarian style is most distinctly characterized by an expectation of conformity and strict adherence to the rules determined by the parent figure. This style has been described as a conservative approach to parenting. It is also described as being both high in demands of the child by the parent as well as high in parent responsiveness to the actions of the child [5].

Authoritarian responsiveness to the child's behaviors is commonly characterized by a conditional expression of warmer, more emotional support for the child when compared to other parenting styles. These expressions of emotional warmth are often tied to the child's achievements and successes at matching parental desires [3]. This parental modality of parent-child interaction is related to the conceptualization that the parent can and should act as the sole interpreter and director of the child's life [1].

Within the authoritarian parenting style, the justification of parental expectations is often based upon the parent's role as an authority figure over the child. Having the ability to exercise control over the child is of paramount importance to the authoritarian parent. As such, one of the key, established features of an authoritarian parenting style is the high degree of rule enforcement and the low degree of encouragement for the child's expressions of individuality and independence. [3]

Differentiation of Parenting Styles

In an authoritarian family, the child is often expected, without direction, to figure out the rules governing parental interactions and expectations. As a result of this characteristic of the parent–child interactions, the child is either less likely to develop initiative and curiosity or prone to rebel against parental norms [4]. The authoritarian parent relies on a non-negotiable method of strict direction for the child. This style comes in stark contrast to the direct, explanatory methods of communication employed by the authoritative parent. The use of power by the authoritarian parent in maintaining control over the child has been found to be less effective in adolescence than in childhood, suggesting that the authoritative reasoning style should be adopted at some point [2].

Authoritarian parents do not demonstrate a lack of concern with the actions of their children, as is evident in the neglectful parenting style. Authoritarian parents also do not have a lowered level of behavioral expectations for their children, as is often characteristic of ►permissive parenting. Another point of demarcation between the authoritarian and the permissive parent is the high degree of willingness of the authoritarian parent to blame the child for the results of his actions and punish him accordingly. This demarcation comes in stark contrast to the externalization of blame seen in permissive parenting interactions.

Authoritative Parenting

►Inductive Parenting

Autism

Eva R. Markham
University of Louisville School of Medicine, Louisville, KY, USA

Synonyms

Acquired autism; Autism spectrum disorders; Autistic disorder; Classical autism

Definition

Autism is one of the pervasive developmental disorders, as described in the *DSMIV-TR* [1]. It is considered to be a developmental disability, characterized by qualitative impairment in reciprocal social interaction qualitative impairment in communication skills, and by restricted, repetitive and stereotyped patterns of behavior.

Description

History

Although autism has certainly been in the headlines over the last 10 years, the disorder is undoubtedly much older. Autism is thought to have occurred throughout history. It is also known to be present in virtually all human societies known to science. Throughout the years stories have been written about unusual individuals with special abilities,

odd behaviors, or other attributes that set them apart. In the medical literature of the nineteenth century, a boy named Victor was described as a "wild boy." He appears in literature as The Wild Boy of Aveyron, or Victor of Aveyron [15]. Victor was "discovered" and variously institutionalized and "studied" by interested parties in the Toulouse area of France. A young medical student, Jean Marc Gaspard Itard eventually decided to take the case on himself. He worked to teach Victor to speak and to react in the way that persons of that era were expected to behave. Close reading of Itard's report about Victor brings to mind some of the characteristics which Dr. Leo Kanner noted in the late 1930s and 1940s as he wrote in his definitive paper, published in 1943, "Autistic disturbances of affective contact" [7]. In this seminal paper, Dr. Kanner described a group of young patients who had severe social communication deficits, problem behavior, and a seeming pattern of self-absorption.

Prior to Dr. Kanner's work, the word "autism" appeared in the literature of psychiatry in the work of Eugen Bleuler, a Swiss psychiatrist who is thought to have been the first to use the term, writing within the first 2 decades of the twentieth century. His usage referred to the symptoms of aloofness, or poor interpersonal relatedness observed in persons having schizophrenia. Indeed, from the time Kanner's work came into the public arena, until perhaps in the 1960s to 1970s, autism was felt to be a type of schizophrenia. Presumably the disorder was caused by cold, rejecting parents and treatment often involved hospitalization in a psychiatric facility.

In the 1960s investigators began to pay attention to the symptoms they saw in individuals having autism. Further, the emerging field of neuroscience created a mindset that began to consider the possible neuromaturational processes that seemed to be compromised in the persons who had autism. There were differences in relatedness, in verbal and nonverbal communication skills, and in behavior which were evident by a very early age without any evidence of neurological trauma or degenerative disease. Further, many persons having the autism diagnosis had parents who were warm and very appropriately socially related. A consensus gradually emerged rejecting the notion of faulty parenting as the etiological factor in autism. Science began to direct its attention to a variety of causal pathways. Work continues in this vein to the present.

It was not until 1990 that autism was added to the list of disabilities which qualified pupils for special education and related services under the Individuals with Disabilities Education Act [16]. With the publication of the *DSM III* in 1980 autism was added to the lexicon of psychiatry. The criteria which currently are used for diagnosis in the United States have been refined through the subsequent iterations of *The DSM* and will likely improve yet again with the unveiling of the next version of *The DSM*.

Epidemiology

Many investigators have attempted to look at the incidence of autism in the last 5–10 years. In a number of their studies, cases are included for autism, Asperger's disorder and pervasive developmental disorder not otherwise specified (PDDNOS). In such studies, the average rate in the USA is reported to be around 1 in 150. In a Canadian study which looked at incidence for each of the three diagnostic groups, autism was found to occur at a rate of about 2.2 per 1,000 individuals. In the American Academy of Pediatrics' review article on autism published in 2007, it was reported that the best estimate of the occurrence of the autism spectrum disorder in the North America and Europe is about 6 per 1,000 [6].

Criteria

The deficits and behavioral differences of autism are described in terms of three categories of symptoms. For the diagnosis to be given, the affected person must display a total of 6 symptoms from the 3 categories, with at least 2 of the symptoms reflecting differences in reciprocal social interaction [1]. Part of the difficulty in understanding autism lies in the fact that the deficits under consideration are said to represent "qualitative" impairments, rather than concrete deficits which might be characterized in terms of some metric.

With regard to the impairments of social interaction, the *DSM* suggests four types of symptoms. First, there are possible differences in use of nonverbal behaviors to regulate interaction. This might be manifest in poor eye contact, unusual body postures, lack of or inappropriate facial expression, and poor use of gestures to communicate. Next, the *DSM* further posits possible differences in development of peer relationships. It is not uncommon to find individuals with autism who relate with some success to adults but for whom relating with same age peers is markedly different than the norm. The third area where differences in reciprocal social interaction appear is in the area of wanting to share one's enjoyment of an item or activity, for example, as when a youngster proudly displays some project he or she has done for adult admiration. Persons diagnosed with autism spectrum disorders may not have this same drive to share their interests or

achievements. A final area of difference is in the area of social reciprocity. Persons having autism may not display the expected amount of social reciprocity, and may seem insensitive, uncaring, etc.

The *DSM* diagnostic criteria list several potential areas which may reflect the qualitative differences in communication skills. The most obvious symptom which may be seen is significant delay in the acquisition of language, which in some cases may be a total lack of spoken language development. What is most telling about such cases is that there is also a failure to attempt to use nonverbal means to compensate for the spoken language delay. In persons who develop spoken language, a second symptom category may be seen. This symptom is difficulty starting or maintaining conversational interchange. The "small talk" which most persons take for granted is incredibly difficult for many individuals with autism. In the third symptom relating to a lack communication skills one looks for repetitive language patterns or idiosyncratic language. Reciting bits or even whole chunks of movie scripts, immediate and delayed echolalia or odd, indirect ways of naming things are examples of this sort of deficit. The fourth difference in communication skills spelled out in the *DSM* points to a lack of varied, spontaneous make-believe play as well as possible deficits in social imitative play relative to the developmental level of the child. Many children diagnosed with autism have little to no make-believe play and rarely engage with other youngsters in childhood games such as "London Bridge" or the like.

The third category of symptoms listed in *the DSM* is the most apparent at times, at least for the untrained observer. Conversely, these symptoms may be the least salient in actually establishing the diagnosis. According to the *DSM* there must be at least one of these symptoms said to represent restricted, repetitive, and stereotyped patterns of behaviors, interests and activities. It is within this category that some of the unusual behaviors are noted. For example, the first possible symptom listed is preoccupations with interests that are either unusual with regard to intensity or simply with regard to content. A child who is exclusively interested in trash cans to the exclusion of other toys, persons, etc. would be manifesting this difference. Likewise, the young girl who gets interested in dinosaurs and plays with and talks about nothing else would meet this criterion. Second, the DSM describes a fondness for non-functional rituals and routines. Many individuals with autism know precisely how their world is supposed to be and become extremely distressed when there is a deviation from the expected course of action. A little boy in preschool may have a "meltdown" on the day when there is a school-wide assembly and his class fails to follow the usual from school course of events. Likewise a child with autism may become hysterical when a parent drives home from school by a "different" route because of the need to run an errand. The third symptom of this category is repetitive motor mannerisms such as hand-flapping, finger-flicking, rocking, spinning, etc. The final symptom named is preoccupation with parts of objects. Some children with autism line toys up rather than using them as they are intended to be used. Others may enjoy spinning the wheels on their toy cars or opening and closing the doors on the cars rather than racing them about or crashing them into one another.

To conclude the *DSM* criteria is the specification that the differences in functioning must be reported to have existed before 3 years old in at least one of the following areas: social interaction, social language or symbolic or imaginative play. There is also a qualifier which states that the symptoms being noted are not accounted for by Rett's disorder, or childhood disintegrative disorder, two of the five pervasive developmental disorders along with autism, Asperger's disorder, and pervasive developmental disorder not otherwise specified (PDDNOS).

Diagnosis

Although experts are unanimous in considering autism a neurobiological disorder, the diagnosis remains one for which there is no medical test or study. Diagnosis of autism is based upon clinical judgment, which may be built upon several kinds of information. Several practice parameters have been issued by professional groups to attempt to create an irreducible minimum standard for diagnosis. Experts emphasize the need to maintain a developmental perspective in assessment and to realize that symptoms will be present, though changed, across the lifespan of persons having this diagnosis. These considerations form the basis from which the diagnostic process must move. Autism is increasingly being diagnosed in young children with 18 months of age not being an unusually early age in specialized assessment clinics [6].

At the basis of any diagnosis, there must be a careful review of the symptoms as described in the DSM and a consideration of how, or if, the patient's developmental history reflects the deficits that would be said to characterize a person having autism. From the early 1990s until the present, there has been a gradual development of standardized instruments which aim to bring some degree of consistency to the diagnostic process. There are a variety of rating scales, observational tools, and interviews which may be used to look at symptoms of autism. Expert consensus usually holds the Autism Diagnostic Interview [13] and the Autism Diagnostic Observation

Schedule [8] be the "gold standard" in diagnosis [11]. Yet even with that level of endorsement, both instruments' users' manuals state clearly that no instrument is adequate on its own to establish the diagnosis of autism. Clinical skill is of paramount importance. Generally clinicians need the opportunity to develop diagnostic skills under the supervision of a clinician who has wide experience in working with persons having autism.

When the diagnosis of autism is suspected, establishing the hearing acuity of the patient is fundamental. An overall consideration of the patient's health status should also be undertaken. Several sets of expert guidelines prescribe specific patterns of screening and inquiry, and should be of particular value to primary care medical providers. In about 25–30% of cases of children having autism, there is a documented history of regression in language skills. These youngsters have begun to use words but then stop and do not regain their language acquisition appropriately [6]. The inquiry in these cases must include careful examination of neurological pathology.

Causes

Since professionals began to attribute autism to neurobiological causes, many theories have arisen about the possible origins of the disorder. Although a large proportion of funding for research into autism has been directed toward clearly delineating the cause, it is probably safe to say at this point in time that the cause of autism in unknown. Many would agree that the "cause" is probably multi-factorial involving genetic and pre-natal influences. Others would argue that post-natal events are also a part of the picture but this assertion has little evidence to back it.

Among the most widely disseminated theories of causality has been the belief that vaccines, or some components of the vaccines, are somehow related to the onset of autism. Brain research [2,3] has found evidence of differences in brain tissue related to developmental events which occur before the end of the first trimester of pregnancy. If that is indeed the case then the disease would been present long before any vaccines were administered. Research in the USA and abroad has reported over and again that there is no link between vaccines and autism. Indeed, some studies report higher rates of autism in unvaccinated populations probably due to the long known link between certain diseases in early pregnancy and post-natal problems, including autism. The best known of such diseases would be rubella which had been virtually eradicated in the USA through vaccination programs until recently. Rubella in the first trimester of pregnancy is known to have been associated with developmental abnormalities including mental retardation and a pattern of symptoms we would recognize as autism.

Many other potential causes have been postulated and subjected to varying degrees of scientific investigation. Some have written about gut abnormalities and an "endogenous opioid" theory of causality. Others have suggested that there is excessive yeast within the system of the person with autism. Some believe that oxidative stress [5] is important. Others have investigated various neurotransmitters and contended that variability herein lies behind the symptoms of autism. Hypotheses have also been put forward about vitamin or mineral deficiencies. As yet, none of these theories has sufficient support to be regarded as fact.

Genetics

With advances in the ability to look at individual genetic materials, professionals are increasingly aware that differences on certain genes appear to be linked with what clinicians call autism. Knowing that autism is a disorder with a highly variable phenotype, it is not surprising that the disorder has an equally variable genotype, with as many as 7–8 genes implicated as relating to the symptoms which collectively we label autism [6]. It is also significant to note that the risk of reoccurrence is 5–6% in families which have a child with autism. Some hold that the risk is higher if the child with autism is female.

Some medical literature differentiates between what is called idiopathic autism versus autism which is associated with another genetic/medical disorder. In clinical practice and in the educational or social service venues such distinctions are rarely made. It is important to be aware that autism occurs at a higher rate than could be attributed to chance in association with certain disorders. In the arena of genetic disorders, we find autism associated with several disorders, most notably Fragile X, tuberous sclerosis, and Down syndrome, to name but a few. Autism is also associated with metabolic disorders such as PKU, adenIosuccinate lyase deficiency, dihyrdopyrimidine dehydrogenase deficiency and others [5]. In spite of all these links, it is reported that about 90% of all cases of autism are not associated with a known medical disorder [5].

Complications

Even accounting for the variable phenotype seen with autism there are other factors which may need to be recognized and addressed to optimize outcomes for children with this diagnosis. As previously mentioned, intellectual limitations affect a significant number of persons with this diagnosis. Among those having fairly intact basic cognitive skills, there is a relatively high incidence of

inefficient learning. This can in some cases be attributed to organizational challenges, and in other cases may represent a specific learning disability. Hand-writing difficulties also complicate the picture.

Anxiety plays a major role in creating discomfort and sometimes fueling behavioral challenges in this group of patients. Mood disorders may also be seen. Psychotic disorders are not common but sometimes do occur. Persons with autism may also display disruptive behaviors, including problems with impulse control, attention, and activity level, as well as conduct problem. There is an emerging body of literature about alcoholism in persons with autism and likely there are other forms of substance abuse.

In the medical realm, seizures are known to affect between 11 and 39% of the population having autism [9]. Onset seems to be either during the early childhood years or in adolescence to young adulthood. It is difficult to predict which individuals may develop seizures, but some authors suggest that seizures are more common among persons having autism and severe cognitive challenges, or motor deficits or an associated etiologic medical disorder [9]. Some literature also reports a sub-set of persons with autism who have gastrointestinal issues. Feeding problems and childhood eating problems are also extremely common and may pose health hazards if diets are excessively restricted [9]. Disordered sleep is another common problem in children with autism. This may exacerbate challenging behavior and is an important area for intervention.

Relevance to Childhood Development

Individuals who live or work with persons having autism would report that these persons often have differences and challenges with regard to learning, sustaining attention, and dealing with various sensory experiences. Although these differences may have the greatest impact in childhood, their impact remains evident in many cases right into the mature life of the individual.

Given that autism is a very heterogeneous disorder with symptoms affecting persons with incredibly variable abilities and symptoms it is important to consider the ranges of ability and behavior that may be seen within the population diagnosed with this disorder. The variability that is found having children having the autism diagnosis has led to characterizing autism as a "spectrum" disorder. Intellect is perhaps the best single predictor of prognosis. Persons with autism may have abilities covering the full range of abilities. Among persons meeting criteria for the autism diagnosis, epidemiologic data has traditionally suggested a rate of mental retardation approaching 60–80%. Language ability is closely related to intellect and is an area that also predicts outcomes well. Most person having autism eventually develop some spoken language but there are a number of individuals who remain nonverbal and require the use of some sort of augmentative communication system to achieve any degree of independence. Persons with this diagnosis also differ with regard to their social interest. Some persons will have social interest and attempt interaction but lack appropriate social communication skills for success. Other individuals will be highly avoidant and do their best to avoid the need to be in the company of others. Variability is also found in the area of motor skills. Although many person diagnosed with autism develop their gross motor skills in a typical fashion, some display marked delays and may benefit from therapies. Others show delays in the acquisition of fine motor abilities required for self-care activities and basic academic tasks and may benefit from treatment in this area. A fifth area of variability is in sensory responsiveness. Some individuals are hyper-responsive to stimuli in the environment and may avoid loud sound, touch or other specific types of stimulation. Another group of persons is hypo-responsive and may want to move, touch, sniff or taste constantly. Activity level would be the final broad area where variability is seen some persons with autism display extreme levels of hyperactivity, while others are profoundly passive. Most are somewhere in between.

In the literature about autism, psychological theories have been put forward attempting to explain the underlying social communication deficit(s) exhibited by children having autism. Two of the better known theories are Theory of Mind and Central Coherence Theory [4]. Theory of Mind, according to Happe is the ability to attribute thoughts and mental states to others and to oneself in order to explain behavior. Central Coherence refers to the ability to draw upon many pieces of information in order to make sense of things in a given context. Some have said that deficits in central coherence lead to an individual being unable to see the forest for the trees. In all likelihood neither of these theories completely explains the difficulties children with autism have in making sense of the complex world of social communication.

Treatment

At present, there is no treatment that "cures" autism, although such claims are sometimes made. The natural course of the disorder is for some degree of improvement. Skillfully designed and executed educational and behavioral programming can lead to real gains in functional skills and lead to major decreases in problem behaviors and notable improvement in areas of deficit. Interventions

based upon the principles of applied behavior analysis are best supported of all such programs researched [12]. Such programming is high-intensity, expensive, and requires a high commitment from family, caregivers and educators to be successful. Less intensive programs using behavioral principles may be beneficial but are not likely to have the potential impact of a traditional behavioral program. Specially designed educational methodologies, most notably the TEACCH program have also been shown to have value. Such structured educational strategies use simple visual systems including schedules and work space set-up, along with work-reward systems, and building functional communication skills. Many other approaches to autism have been developed and marketed. Many have no scientific backing. Although various purveyors of services often tout their approach as the "best," the evidence at present suggests that young children with autism show benefit from several kinds of daily interventions [12]. The challenge for parents is wading through the competing claims of persons who offer products and services purporting value for children having autism.

Depending upon the age, language level and behavioral presentation of a child with autism, social skills may or may not seem like a high priority for intervention. When children are young, parents and caregivers often are much focused upon acquiring academic skills. If there are behavioral challenges, these too often predominate when interventions are planned. In the long run, social skills are critical for success in independent functioning and successful integration into the community. Social skill interventions need to be designed with levels of service. For example, a child might attend a "social skills group" and learn about specific topics of interest, along with other girls and boys having the autism diagnosis. To insure that the lessons from group are "carried over" family/caregivers must be aware of the focus of group sessions, and attention given to providing various opportunities in natural environments such as school, church, and other social settings to assure generalization of newly presented skills. The need for social skills intervention cannot be emphasized enough and is a key to life success for children with autism [9].

Medically, there is support for the use of several psychopharmacological agents to treat specific symptoms which cause difficulty for some people having autism. Anxiety, aggression, depression, hyperactivity, and attentional/impulse control issues may all respond to medical intervention, at least in a portion of all cases. Other types of medications sometimes prescribed include medicines which help with sleep and medications which address specific gastrointestinal issues [9].

The National Academy of Science assembled a diverse group of autism practitioners to review existing research and make recommendations with regard to the best types of programming for children having autism. In their findings the Academy group [10] notes that there is no data that shows a clear, direct relationship between any particular intervention and children's progress. The group also concluded that treatments must include regular measurement of treatment effects. This presumes that all treatments have measurable, observable goals which would lend themselves to data-collection and analysis. The Council suggested that children begin to receive services as early as possible, and that they be actively and intensively engaged in programming which lasts all day, five days a week, every week of the year. A particularly important finding, in terms of treatment planning is that improving attention to people and improving imitation skills are critical areas to target in early intervention programs.

Future Directions

Attention to the causal factors associated with autism continues to be an important direction for investigation. Equally important however is the development of sophisticated population level research on intervention efficacy in order to determine which interventions work best for specific types of persons having autism. Such knowledge would enable service providers better to tailor services to the needs of the client and guarantee the best utilization of the funds available for services. Consensus building among the autism community is also needed to diminish the conflict which undermines the ability of the community to seek the best services for all members without the rancorous strife which diminishes the voice and resources of the community. Systems of care are needed which support families having children or adult loved ones living with autism. Resources must be directed toward optimizing family functioning as there is a well-documented association between family well-being and positive outcomes for persons having ▶developmental disabilities. In spite of all the gains that have been made in assessment and treatment for autism, there remains a need for realistic aspirations and a practical understanding of outcomes for persons given this diagnosis. A 1996 article by Ruble and Dalrymple [14] wisely stated that there are many factors influencing outcomes beyond those traditionally mentioned (e.g., language and cognition) and urged a reconceptualization of outcomes generally looking at a broad array of factors which may predict outcomes, including those mentioned before, as well as social skills, vocational

development, broad life experience and a host of sometimes neglected factors, all of which may in some way work together to determine "outcome" for persons having autism ultimately.

Another very important area for future emphasis is public and professional awareness efforts. Given the well-documented benefits of early intervention for children having autism, it is imperative that professionals in medicine, early childhood education, and many other fields, along with the general public be aware of possible warning signs that early social communication development may be on an aberrant course. The 2007 AAP article suggests many possible warning signs among them being poor use of gaze, disregard for other's speech and delayed onset of babbling, deficits in prespeech gestures such as pointing and waving, and failure to respond to parents' voices [6].

Autism Behavior Checklist

Teresa L. Davenport
Ball State University, Muncie, IN, USA

Synonyms

ABC

Definition

The Autism Behavior Checklist (ABC) was designed to offer a method to more objectively identify autism in children. The scale utilizes an observer's rating of the child's behavior to quantify behaviors typically associated with Autism.

Description

The ABC was developed as a clinical measure to screen for autism in individuals 3–35-years-of-age. The scale was developed in 1980 and has not undergone revision since then. The ABC consists of 57 item and 5 scales (1) Sensory, (2) Relating, (3) Body and Object use, (4) Language and (5) Social and Self-help [11].

The items included in the ABC were grouped on the five subscales primarily based on face validity. The items themselves were chosen from many sources, including Kanner's [6] article which first outlined autism and Lovaas et al. [8] work on autism.. After items were written and finalized, internationally recognized experts in the field of autism were asked to provide feedback for the scale. The last stage of scale construction involved sending the scale to 3,000 special education professionals. After feedback from these professionals, weights were then assigned to the individual items [7].

The ABC total score is used to determine the likelihood of autism. Higher scores indicate the presence of more behaviors consistent with autism. The authors of the ABC assigned individual items a weight of 1–4 according to that behavior's relevance to autism. A total raw score of 68 or higher is used as a cut-off for indicating a high probability of autism, whereas a score between 53 and 67 indicates questionable autism, and scores of 53 or lower are considered unlikely to indicate autism. This score corresponds with one-half a standard deviation below the mean of children with autism who were included in the standardization sample [7].

Several researchers have conducted factor analyzes of the ABC to check for the content validity of the scales with mixed results [9]. In these studies, the Sensory scale typically appears to have the lowest validity. This fits with other conceptualizations of Autism; for example, even the *Diagnostic and Statistical Manual of Mental Disorders* (4th ed.) does not specifically include sensory deficits as diagnostic criteria for autism [1]. This provides further evidence for the use of the ABC as a screening tool rather than a strict diagnostic measure. Clinicians should exercise caution when using individual scales of the ABC to screen for autism and instead should utilize the entire checklist and its total raw score [5]. In addition, the ABC has not been shown to distinguish autism from other cases of developmental disorders as well as some other autism screening measures, such as the Childhood Autism Rating Scales (CARS) [10]. Overall, the ABC has a concurrent validity coefficient of 0.67 with the CARS [4]. The ABC shows a concurrent validity coefficient of 0.80 with the Pervasive Developmental Disorders Rating Scale (PDDRS) [2, 3].

The ABC total raw score has shown adequate reliability for screening purposes, though the scales individually have shown less reliability. Test–retest reliability reported by the authors is 0.87, but few other studies have examined test–retest reliability with the ABC. Measures of interrater reliability have also shown mixed results. It should be noted that many of the studies which show low interrater reliability tend to compare parent and teacher ratings. In these studies, parents tend to have higher total scores than teachers. It is possible, however, that the different environments seen between the home and school could account for some this variability. Clinicians should carefully consider the lack of strong interrater reliability evidence when comparing scores obtained by parents and teachers on the ABC.

Autism Spectrum Disorders

Eva R. Markham
University of Louisville School of Medicine, Louisville, KY, USA

Synonyms

Acquired autism; Autism; Childhood disintegrative disorder

Definitions

A group of developmental disorders that include ►Autistic disorder, ►Pervasive developmental disorder not otherwise specified, ►Asperger's disorder, ►Rett's disorder, and ►Childhood disintegrative disorder. Some experts exclude Rett's and Childhood Disintegrative disorder from the group called "Autism Spectrum Disorders."

Characteristics

Autistic disorder: A pervasive developmental disorder that is diagnosed behaviorally, based upon observation and review of developmental information. Symptoms must include at least two incidents of qualitative in reciprocal social interaction (i.e., failure to use non-verbal behavior to regulate social interaction, failure to develop peer relationships, lack of shared enjoyment, and a lack of socio-emotional reciprocity). There must be at least one deficit in communication skill (i.e., lack or delay in spoken language without use of gesture to compensate, lack of varied spontaneous make-believe or social imitative play, relative failure to initiate or sustain conversational interchange, or stereotyped, repetitive or idiosyncratic speech). There also must be at least one restricted, repetitive and stereotyped pattern of behavior (i.e., encompassing preoccupations or circumscribed interests; apparently compulsive adherence to nonfunctional routines or rituals, or preoccupations with parts of objects or non-functional elements of material). Symptoms must have been present before the age of 3 years, although the diagnosis may not be made until after that age (APA, 2000).

Pervasive developmental disorder not otherwise specified: This pervasive developmental disorder is also labeled "Atypical autism" and generally is construed to be a case where the youngster does not meet the full criteria for the diagnosis of Autistic disorder but nonetheless has significant impairment in reciprocal social interaction. *DSM* criteria do not require communication differences nor are the unusual interests and behaviors necessarily present. Another way this diagnosis is different is in the fact that there is no requirement for symptoms to have been noticed before the age of 3 (APA, 2000).

Asperger's disorder: This diagnosis is a Pervasive Developmental disorder which has the same criteria as Autistic disorder with two notable differences. First, Asperger's disorder presumes a history of no significant delays in language development. To be specific, *DSM* criteria state that there must have been single word s used meaningfully by 24 months of age, and then multi-word utterances used by 36 months of age. The second criterion which sets Asperger's apart from Autistic disorder is the requirement that the individual so diagnosed have relatively intact development in the cognitive and adaptive spheres. Unfortunately, the *DSM* does not specify precisely what is meant by this, and there is no uniform level of ability followed in diagnostic clinics. For the most part clinicians tend to not use this diagnosis for individuals who have full-scale IQ's of less than 70, but variability does exist. To receive the diagnosis of Asperger's disorder the individual must still demonstrate at least two of the symptoms of Qualitative Impairment in Reciprocal Social Interaction (i.e., failure to use non-verbal behavior to regulate social interaction, failure to develop peer relationships, lack of shared enjoyment, and a lack of socio-emotional reciprocity). Symptoms must also include at least one restricted, repetitive and stereotyped pattern of behavior (i.e., encompassing preoccupations or circumscribed interests; apparently compulsive adherence to nonfunctional routines or rituals, or preoccupations with parts of objects or non-functional elements of material) (APA, 2000).

Rett's disorder is listed as one of the Pervasive Developmental disorders within the *DSM* although it is a known genetic disorder. Genetic testing can be done to obtain a definitive diagnostic confirmation. Rett's disorder has its onset early in life and leads to a loss of early developing motor skills between 5 and 30 months of age and a deceleration of head growth which occurs between 5 and 48 months of age. Most individuals who receive this diagnosis are female. Only recently have a very small number of males been identified. Individuals given this diagnosis typically have severe or profound mental retardation. Five symptoms are specified for diagnosis: (1) head growth decelerates between 5 and 48 months (2) loss of previously acquired hand skills in the age range of 5–30 months and development of stereotyped hand movements, sometimes described as resembling hand-wringing (3) loss of social engagement early on, although such skills may later develop to some extent (4) poorly coordinated gait or trunk movements

(5) severe impairment of receptive and repressive language and severely impaired psychomotor skills. This is thought to be a fairly uncommon disorder, and has a poorer prognosis than all of the other Pervasive Developmental disorders except childhood disintegrative disorder (APA, 2000).

Childhood Disintegrative Disorder is considered to be a Pervasive Developmental Disorder. Children with this diagnosis must have documented apparently normal development for at least the first 2 years of life. This diagnosis is given when a marked loss of skills in multiple domains of functioning occurs sometime between ages 2 and 10. Skills losses must be seen in at least 2 of 5 areas, specifically, expressive or receptive language, social or adaptive behavior, bowel or bladder control, play, motor skills. The *DSM* also specifies that there must be abnormality in 2 of 3 areas which are essentially the same symptoms clusters considered for the autism diagnosis. There may be qualitative impairments in reciprocal social interaction. Communication skills may demonstrate qualitative impairment. Finally, there may be restricted, repetitive and stereotyped patterns of behavior, interests, and activities, including motor stereotypies and mannerisms. This is a very rare disorder. The prognosis is generally not good in terms of the recovery of skills lost, although over time some individuals do make limited progress. In most cases skill loss levels off, sometimes at very low levels of ability. It is critical to know that there is no associated medical condition which leads to the loss of skills. Most individuals given this diagnosis have no medical condition which might lead to the observed decline in functioning. If a medical condition did exist, for example, a head trauma, then this would appropriately be thought of as a dementia (APA, 2000).

Behavior associated with delays in language and social skills as well as restrictive, repetitive, and self-injurious behavior.

Description

A diagnosis of autism is based on three defining features: a delay in the development of language, a deficit in the amount and quality of social interactions with others, and the expression of repetitive behaviors or restricted interests. Autistic behaviors can be grouped in these three areas. In the area of language delay, autistic behaviors include abnormal speech patterns, using the manipulations of the body parts of others to communicate (e.g., leading someone to a desired item), and not responding to the speech of others. A language pattern seen in some individuals with autism is echolalia, which also falls into the category of repetitive behavior. Echolalia is the repetition of another person's speech. Immediate echolalia is the immediate repetition of another person's speech. For example, if a teacher says, "What's your name?" the child with autism says, "What's your name?" Delayed echolalia is the repetition of speech heard at an earlier point in time. Some children with autism repeatedly say, or "script," parts of movies they heard earlier in the day or earlier in the week or month. Another example of delayed echolalia is answering questions with the same phrase each time, such as "I'm a good boy."

Social behaviors characteristic of individuals with autism are gazing away from others during communication, withdrawing from social situations, and playing or spending time by oneself. Social withdrawal is the basis for describing children with autism as "being locked in their own world." Individuals with high functioning autism or Asperger syndrome often have typical language skills but are delayed in the area of pragmatics, the social domain of language. Common behaviors associated with delays in pragmatics include talking only to meet one's needs and not engaging in "social niceties" or small talk. Conversation is often one-sided and individuals with high functioning autism do not show interest in the activities or thoughts of others.

The third defining characteristic of autism is repetitive behaviors and restricted interests [2]. Children with autism, especially in the severe range of autism, engage in repetitive movements such as body rocking, arm flapping, finger manipulations, and repetitive head movements. Attempts to stop these behaviors are often unsuccessful and some describe the movements as compensation for internal, vestibular, sensory deficits. Some

people with autism describe making these movements as "calming." Repetitive movements can also occur with objects such as string and spinning tops. Children with autism can manipulate string, beads on string, or spinning tops for hours at a time. Repetitiveness in individuals with high functioning autism is manifested by their restricted interests. These individuals feel comfortable talking about only one or two areas of interest, such as computers or World War II history. An individual with Asperger Syndrome might talk only about WWF wrestling and if a communicative partner attempted to change the topic of the conversation, the individual might quickly return it to his favorite topic.

A group of autistic behaviors not associated with a diagnosis but common in children with autism are challenging behaviors such as aggression and self-injurious behavior [1]. Self-injurious behavior occurs in many forms, such as hitting one's head, banging one's head again hard surfaces, hand biting, and trichotillomania (i.e., pulling hair out of the head). The damage caused by self-injurious behavior ranges from minor abrasions to severe damage requiring hospitalization and occasionally resulting in death. These behaviors are managed with behavioral intervention and medications.

Autobiographical Memory

Lauren Gregory
Oklahoma State University, Stillwater, OK, USA

Synonyms

Episodic memory; Long-term memory; Personal recollection

Definition

It is memory for specific, genuine events that are personally experienced and when compiled, they form a long-lasting personal narrative. It is high in self-reference and is subject to personal interpretation [1].

Description

Autobiographical memories tend to be more long-lasting than episodic memories because of their self-referent nature. Information and events that are related to the self are better recalled because we process them more extensively. This results in a more elaborate and deeply encoded memory trace, which generates better recall [2].

There are three different levels of autobiographical knowledge: lifetime periods, general events, and event-specific knowledge [2]. Lifetime periods, such as going to college, are contained at the highest level. The middle level holds general events, which are composite episodes that are experienced over days, weeks, or months. For example, these general events might be a snow skiing vacation or attending college basketball games one semester. Event-specific knowledge involves memories of individual episodes, which are measured in seconds, minutes, or hours [3]. For instance, remembering your first day out on the ski slopes when you fell down in front of a crowd. Each of these levels are woven together to form our personal narratives. Lifetime periods are the skeletal structure of autobiographical memories, so locating a period in one's life (e.g., freshman year of college) makes it easier to find general-event (e.g., attending college basketball games) or event-specific memories [4].

Memory distortions are common in autobiographical memories. However, recollections of extended time periods in the past are generally accurate. Errors are more frequent when reconstructing the particulars of a personal event. When remembering the past, source confusions can occur. This is when we fail to connect the time, object, or action of an event, resulting in misremembering the time and place something occurred

[5]. Our biases get in the way of constructing an accurate picture of ourselves or events. Hindsight biases lead to filtering memories of past events so that they more closely match current knowledge. We also hold consistency biases, which cause us to reconstruct the past as overly similar to the present [5].

Relevance to Childhood Development

Our earliest memories are of events that occurred between 3 and 5 years of age, and the majority of events occurring prior to 5 years of age are irretrievable due to *childhood amnesia* [1]. In contrast, personal memories from the period between ten years of age and the early twenties are particularly accessible. This phenomenon is known as the *reminiscence bump*. It is believed to occur because the events of the teens and twenties constitute a critical period in the lifespan, one in which the individual develops a stable and enduring self-concept [4].

Autonomy

Temi Bidjerano
Furman University, Greenville, SC, USA

Synonyms

Individuation; Independent decision making; Self-choice; Self-determination; Self-regulation; Self-reliance

Definition

Opportunities to freely choose, self-endorse, and self-direct one's own behavior following inner interests, while maintaining connectedness.

Description

In earlier theories, autonomy has been viewed as independence, self-reliance, and resistance to external control [3]. Erikson (1963) [2], one of the first theorists to conceptualize autonomy, regarded autonomy as an earlier phase of psychosocial development and identity formation. In his theory, between the ages of 18 months and 3 years, the child is confronted with mastering developmental tasks such as potty training, self-feeding and physical mobility, the successful completion of which eventuates in achieving an adaptive sense of autonomy. A failure at these developmental tasks, on the other hand, results in feelings of shame and doubt. In this sense, autonomy has been equated with achieving authority and capabilities to exercise behavioral control over bodily functions as well as to experiment upon the physical and social environment.

The psychoanalytic tradition, on the other hand, describes autonomy as a process of individuation and disengagement from parents, which initially emerges in the toddlerhood years, and reappears in adolescence [5].

Current theories, however, do not construe autonomy as a unitary, one-dimensional concept akin to behavioral independence and disengagement from parents. Rather, autonomy is conceived as consisting of overlapping, yet distinctive components such as behavioral autonomy (i.e., self-regulation of behavior and independent decision making), cognitive autonomy (i.e., beliefs about control over behavior) and emotional autonomy (i.e., individuation from parents), which develop concurrently. In addition, autonomy is regarded as a universal human need, characteristic of individuals of all cultural backgrounds [4]. The role of agency, self-initiation and self-regulation is emphasized. The satisfaction of the need for autonomy results in enhanced psychological well-being. The reverse of autonomous functioning is perceptions and beliefs of being controlled, coerced to engage in a particular action, which do not stem from the self [1]. Autonomy is not only freedom to choose one's own course of action and determine one's course of behavior, but it also indicates the degree to which the individual has internalized societal values and makes effective choices consistent with them [3].

Relevance to Childhood Development

Achieving autonomous functioning is a key task in childhood and children's ability and motivation to be autonomous incrementally increases through adolescence. Providing children with warm, supportive, yet structured environments is considered a key element to the development of autonomous behavioral, cognitive and emotional functioning, regardless of the developmental stage of the child. It has been suggested that overly restrictive and unsupportive environments limit opportunities for individuals to act in accordance with their own inner interests and desires for self-direction and independent decision making, and therefore, interfere with autonomy development. Authoritarian, permissive and neglectful parenting styles have been found to have a particularly negative impact on autonomy development. In addition, specific parental behaviors linked to negative consequences for autonomy development include: power assertion, love withdrawal, manipulation, intrusion, abusive language, personal attacks, negative evaluative feedback, pressuring children to accepts parental unilateral positions, limiting opportunities for choice, self-expression, and action, lack of discourse, and not engaging in joint decision making [5].

Autonomy gradually evolves over the life span, and at different age periods has unique manifestations. In infancy, parents regulate their children's behavior, closely monitor, set limits and impose discipline. This parental regulation of child's behavior creates not only a context for autonomy development, but it also promotes internalization of standards for appropriate behavior and courses of action [3].

In toddlerhood, there are rapid changes in access to contexts as a product of increased mobility, and incremental changes in language, cognition and social skills. Children become increasingly motivated to exercise these emerging competencies. During this developmental stage, the degree to which a child can make an effective choice depends on his developing physical, cognitive and language capabilities, but also on the appropriate limits and constraints set forth by the caregiver. Parental support, control, and demands play a crucial role for internalizing the standards; they also facilitate future effective choice making in unison with the internalized standards. The emerging sense of autonomy in children is demonstrated by their desire and ability to assert themselves in communicating and interaction with parents and other adults. Early signals of autonomy include resistance to compliance, indexed by the use of phrases such as "No" and "I can do it myself." Children develop self-awareness (i.e., who they are and what they can do), which allow them to regulate and control their behavior, thinking and feelings. Engaging in limited negotiations is another sign of autonomous functioning [7].

In the elementary and middle childhood years, not only do cognitive and physical skills develop rapidly, but children's social interactions increasingly expand to new social contexts. Within this developmental stage, children's striving for autonomy is exhibited in their greater desire to control their own thinking, feelings and behavior. Children become progressively more independent from the family. They begin to express their autonomy by the inclination to perform independently actions such as engaging in activities of their own choosing (e.g., doing homework), making decisions on how to spend their time (e.g., hanging out with friends, watching TV, playing videogames), making choices regarding clothing, and expressing their own independent thinking. This developmental stage is marked by child-parent co-regulation of behavior, as individuation from parents is typically not present.

In adolescence, autonomy development is linked to other developmental processes such as physical maturation, cognitive changes, identity formation, and expanding of social relationships, rights and responsibilities. As a result, adolescents become increasingly self-reliant, self-regulating, more capable of engaging in independent decision making while maintaining healthy social connections with family and peers [5]. Parental support for autonomy has been found to predict adolescents'

enhanced emotional and academic functioning. Autonomy-supportive parenting in adolescence has been associated with a range of positive developmental outcomes, which include increased sense of self-esteem, enhanced academic competence, fewer signs of depression and less antisocial behavior. In contrast, parental psychological control during this developmental stage has been linked to psychological and somatic symptoms, depression, and decreased motivation.

Autonomy Versus Shame and Doubt

Jennifer L. Stapel-Wax
Argosy University/Atlanta, Atlanta, GA, USA

Definition

Autonomy versus Shame and Doubt is the second stage in Erik Erikson's psychodynamic theory of psychosocial development.

Description

Erikson postulates a theory of psychosocial development that spans the lifespan and emphasizes an interaction between biological needs and the environment. According to Erikson, there are stages in development in which a child's unfolding biological needs and abilities engage the child with significant adults, resulting in interactions that help or hinder the child in meeting healthy psychosocial milestones. The patterns that emerge can be described as involving (1) key areas of the physical body, (2) the types of activity that the child is engaged in mastering at that level of development, and (3) the types of social interactions that result as the growing child relates to others with their new abilities [1]. Additionally, the resulting experiences from each stage lay the foundation for transition through the subsequent developmental stages.

Autonomy versus shame and doubt is conceptualized to coincide with the toddler age group defined as between 18 and 36 months of age. This stage represents the second nuclear conflict described in Erikson's theory and is associated with the anal-urethral-muscular stage. Physically, children at this age are maturationally prepared to experiment with retention and elimination. These two conflicting modes of action are crucial in describing the child's new capacities and the interactions that they have with the environment related to the biological need for elimination [3, 4].

The stage of autonomy versus shame and doubt is characterized by the child getting practice with "holding on and letting go" [3]. While this experience is initially associated with biological needs, the child learns about themselves through interactions with the environment and significant others. During toddlerhood, the child is optimally buffered from experiences of shame and doubt by a firm and comforting sense of trust established in infancy in the first Eriksonian stage of development. Therefore, the child can safely exercise choices over their bodily functions on the path to establishing autonomy and control. Simultaneously, they must also be protected from the danger of harsh exposure to others leading to feelings of shame and fears of being punished that lead to doubt. At the successful conclusion of this stage, the child emerges with a "sense of self control without loss of self esteem" [3] leading to pride in one's abilities. Accordingly, if this stage is marked by a loss of self control or the over control of another, then the child may develop a lasting sense of shame and doubt about their abilities [3].

Relevance to Childhood Development

The Eriksonian stage of autonomy versus shame and doubt is significant to child development as it coincides with and lays the foundation for similar theories of development in the young child. Additionally, Erikson's ideas about the mechanism of exercising autonomy over one's physical abilities and protection from the toxic reactions of others to the toddler's exertion of control converges with theories detailing the origins of maladaptive behaviors and psychopathology [1, 2].

Aversive Stimulus

Josh Pritchard[1], Ivy Chong[2]
[1]University of Nevada, Reno, NV, USA
[2]Florida Institute of Technology, Melbourne, FL, USA

Synonyms

Negative reinforcer; Punisher; Unpleasant event

Definition

An aversive stimulus is an unpleasant event that is intended to decrease the probability of a behavior when it is presented as a consequence (i.e., punishment). However, an aversive stimulus may also increase the probability of a behavior when it is removed as a consequence, and in this way it will function as negative reinforcement.

Description

Aversive stimuli have been described in learning texts to include stimuli, when used as a consequence will punish a response [1]. They are contrasted with appetitive stimuli that can be used to reinforce responses. While many people consider aversive stimuli as fear and pain-causing events, it is important to realize that an aversive stimulus for one person could be an appetitive stimulus for somebody else. In fact, for the same person in different contexts and at different times, an event could serve as either aversive or appetitive. Examples of aversive stimuli can include (but are not limited to): proximity of others, loud noises, bright light, extreme cold or warmth, and social interaction.

The ethics and morality surrounding the use of aversive stimuli in the modification of behavior has been questioned, and eventually lead "the aversive controversy" in the 1970s, since then, there is a strong anti-aversive movement, including position statements of advocacy groups, legislative efforts, and development of "positive-only" treatment packages [2].

Avoidance

►Identity Diffusion

Avoidance Learning

Brady J. Phelps
South Dakota State University, Brookings, SD, USA

Synonyms

Avoidance responding

Definition

In the operant conditioning of B.F. Skinner, a behavior-strengthening contingency can involve either of two operations. If an operant response is strengthened (the rate of responding increases) by the presentation of an event after the response, this operation constitutes positive reinforcement. If an operant response is strengthened by the contingent removal or prevention of an event, this operation is negative reinforcement. When an operant increases via the removal or termination of an ongoing stimulus or event, the contingency is termed escape. When an operant increases by preventing a stimulus or event from occurring, this contingent relation between response and environmental change is termed avoidance. A stimulus or event whose offset reinforces operant behavior via these contingencies of negative reinforcement would be termed an aversive stimulus [7]. The acquisition of the response controlled by the latter contingency would be termed avoidance learning or avoidance responding [3, 9].

The study of avoidance learning has seen proposed explanations rise and fall and be replaced by proposed alternatives for decades. Organisms typically acquire escape learning more readily than avoidance learning and a history of escape from an aversive stimulus may be a prerequisite for avoidance learning [7, 9]. One account of avoidance learning in effect redefines avoidance as actually always being escape learning [7, 8]. Most of the debate has involved the question of how the prevention or nonoccurrence of an event can function as a reinforcer for avoidance learning [5]. This question has been referred to as the "avoidance paradox," [7].

The differing accounts of avoidance learning are referred to as Two-Factor Theory [8], One-Factor Theory [6], and a Cognitive Theory of Avoidance [10]. Two-factor theory is so titled because it is based on the assumption that two conditioning processes, classical conditioning and operant conditioning, are necessary for avoidance learning [7]. To illustrate the roles for the two processes, a description of Solomon and Wynne [14] is often cited. Solomon and Wynne used dogs as research subjects in a shuttle box, a rectangular enclosure divided down the middle by a barrier the subjects could leap over to cross from one side of the shuttle box to the other. Each side of the shuttle box had an overhead light as well as a metal grid floor through which shock could be delivered. Every few minutes, the overhead light in the compartment where the dog was located would be turned off while the light in the other compartment remained on. Ten seconds after the overhead light was extinguished, an electric shock was presented to the floor of the darkened compartment; the subjects could escape the shock by jumping over the barrier and for the first few occurrences of shock delivery, the subjects engaged in escape responding. After several repetitions, the subjects learned to jump over the barrier within a few seconds after the offset of the light to avoid the scheduled shock via an avoidance response and once this pattern of responding was acquired, most of the subjects never again experienced any shocks [7, 14].

To explain these findings in terms of the two factors, an unconditioned response to electric shock is fear, and through the pairing of classical conditioning, this elicited fear is transferred from the unconditioned stimulus of the shock to the darkness as a conditioned stimulus. Establishing a fear-eliciting conditioned stimulus via classical conditioning, in the case of Solomon and Wynne, darkness, is the first process of this theory. The second factor, operant conditioning, comes into play when the subjects engage in escape in the presence of the fear-producing CS and two-factor theory sees avoidance learning as actually being escape learning [7].

Several questions arise for proponents of two-factor theory. (1) Subjects can acquire avoidance learning in the absence of any discernible CS. While avoidance learning as conducted by Solomon and Wynne included an event that preceded the aversive stimulus, avoidance learning is acquired in the absence of any such "warning signal" or CS. This avoidance learning is referred to as non-discriminated avoidance, Sidman avoidance, or free-operant avoidance [9, 11]. (2) Subjects engage in avoidance learning in the absence of any observable signs of fear. (3) Any trial in which the shock US is not experienced is an extinction trial for the fear-eliciting CS; as a result, the CS will eventually no longer elicit fear and avoidance responding should become less frequent or cease. Two-factor theorists argue that subjects will have to experience shocks again for the CS to be re-established as a fear-eliciting event such that avoidance learning would be acquired, weaken and be re-acquired in a cyclical fashion. Unfortunately for the advocates of two-factor theory, such a cyclical pattern of behavior is rarely if ever observed and avoidance learning fails to undergo the extinction predicted as expected by two-factor theory [7]. The proponents of two-factor theory retort that the necessary fear is still present but is strictly an internal response and that the passage of time alone between scheduled shocks can serve as a fear-eliciting CS [3].

The questions raised concerning two-factor theory, particularly the lack or the slowness of extinction of the learned-avoidance response opened the door for alternative explanations of avoidance learning such as one-factor theory. One-factor theory has the appeal of being a simpler account and it is based solely on operant conditioning [7]. Initially Sidman [11] showed that rats could acquire avoidance learning in the absence of any obvious CS; in his experiment, if rats did not respond via a lever press, shocks were delivered every 30 s, but if an animal made a lever press, shocks were delayed by 30 s. Responding occasionally but regularly, once every 15–25 s or thereabouts would let a rat avoid all shock. While no rat did avoid all of the shocks completely, Sidman's rats did acquire avoidance learning responses that allowed them to avoid the majority of the scheduled shocks [7, 11]. One obvious question for the results of Sidman [11] is that the shocks were a regularly occurring aversive stimulus and that the passage of time since the last shock could be serving as a CS to elicit fear; as a result, results of studies like Sidman [11] were not a conclusive end to two-factor theory [7].

To more definitively challenge two-factor theory, Herrnstein and Hineline [6] performed a study in which electric shocks occurred but which were not a regularly

programmed and predictable consequence. In this study, rats were shocked according to a probability contingency in that at the end of every 2 s, a shock would be delivered according to different probabilities. If a rat did not emit a lever press, the probability of a shock had a p. of 0.3 in the next 2 s. If a rat did emit an operant response of lever pressing, the p. of a shock in the next 2 s was reduced to 0.1. Here, there were no predictable or consistent shock-free periods; the occurrences of shock inevitably followed some responses. Nevertheless, approximately 90% of the rats in this study acquired avoidance learning. Herrnstein & Hineline [6] concluded (1) animals could learn an avoidance response with neither a discernible, external CS nor the passage of time as a reliable predictor of shock, and (2) a reduction in the overall frequency of shock was sufficient for the acquisition of avoidance learning [6, 7].

How does one-factor theory account for the hindered extinction of the avoidance response? The progress of extinction of any operant is slower following intermittent reinforcement relative to behavior that had been maintained by continuous reinforcement or fixed schedules of reinforcement [9]. This partial-reinforcement effect is argued to be due to the difficulty the organism has in discriminating the change from variable reinforcement to extinction relative to the change in conditions from fixed reinforcement to extinction [7, 9]. In the Herrnstein & Hineline study, the responding of the subjects was on a highly variable schedule of negative reinforcement. Predictably, such a schedule would produce a slowed extinction of the operant [7].

It needs to be emphasized that the nature of the operant response has bearing on the likelihood that avoidance learning will be acquired. If an operant reinforced with a escape or avoidance contingency is compatible with an organism's innate responses to a threatening, aversive stimulus, the acquisition of avoidance learning will progress much more rapidly than if the response is incompatible with the organism's innate defensive responses [2]. Bolles argued that animals are born equipped with innate behaviors that serve to protect and defend the organism from predation; these innate responses were termed species-specific defensive responses (SSDRs) by Bolles and such SSDRs were elicited by a pain producing US such as electric shock [2]. As a result, an organism's SSDRs have to be considered as a variable in avoidance learning [2, 3].

The arguments of Bolles [2] seemed to raise questions that a purely operant account of avoidance learning was overlooking variables that had to be considered to explain avoidance learning [3]. This led to the proposal of a cognitive theory of avoidance learning by Seligman and Johnston [10]; this theory introduced the concept of "expectations" or "expectancies" as mental events occurring inside animals that were proposed as being variables needed to account for avoidance [3, 4, 10].

To account for avoidance learning, Seligman and Johnston argued that two important expectancies form in a situation calling for avoidance. (1) An expectancy is formed regarding the consequences of a response, and (2) another expectancy is formed concerning the consequences of no response occurring. During the course of acquiring avoidance learning, the animal gradually forms the expectancy that (1) no shock will occur if a response takes place, and (2) a shock will occur in the absence of a response. Since the second outcome is preferable to the first, the organism engages in avoidance [7, 10]). Once these expectancies are in place, these researchers argue that the animal's behavior will remain constant until the expectancies are breached; extinction is slow because responding avoids shock and the expectancies are upheld. The expectancies lead the animal to continue to engage in avoidance [3].

Seligman and Johnston [10] were only the first in a series of cognitive theories of avoidance learning [3] and the concepts of such theories are agreeable to cognitive theorists. Critics and skeptics raise questions about the reality of unobservable concepts such as expectancies and expectations. Concepts such as these are necessarily circular [15]. The presence of unobservable entities such as expectancies is inferred from behavior, yet the same concepts are then used to explain the behavior in question. If behavior changes, it is inferred that the expectancies changed and the change in expectancies produced the behavior change. The expectancies, however, can never be observed independent of behavior, are uneconomical and circular, and inspire skepticism regarding their reality [1, 12, 13, 15].

Has avoidance learning been unequivocally explained? Probably not, since one-factor theory is still the accepted account by operant theorists but considered inadequate by cognitive theorists [3, 7]. Most of the two-factor theory proponents are now largely cognitive [4]. The concepts of cognitive theorists are critiqued by operant theorists [9] and delegated to the status of "explanatory fictions" [12, 13, 15]. This type of debate is the current state of much of psychology.

Avoidance Responding

►Avoidance Learning

Avoidant Attachment

Jill Driest
Nova Southeastern University, Davie, FL, USA

Synonyms

Insecure attachment

Definition

Avoidant attachment is a form of insecure attachment between young children and their caregiver.

Description

To assess the quality of attachment between mothers and infants, Mary Ainsworth developed a standardized process called the Strange Situation Procedure. In this procedure, both the infants and their mothers were brought into a room filled with toys where infants were given the opportunity to explore. In a series of eight situations, the infants were separated from their mother twice, reunited with their mother twice, and also encountered a stranger. Based on the infants' behavior during these eight situations, the infants were classified as either secure, avoidant, resistant, or disorganized [1, 5].

Those infants that were classified as avoidant demonstrated little anxiety upon separation from their mother. Instead, these infants actively avoided, ignored, and resisted interaction with their mother. Upon reunion with their mother, these infants appeared indifferent [1, 5].

Avoidant attachment can develop from two different types of care giving. In the first pattern of care giving, mothers tend to be unresponsive and rejecting towards their infants during times of distress. In the other case, mothers are overzealous. These mothers tend to overwhelm the infant with too much stimulation, which the infant may find discomforting. As a result, they may withdraw from their caregiver's affection [1, 5].

Relevance to Childhood Development

The bond between the infant and their primary caregiver provides the foundation for social development and the manner in which they establish relationships. Infants with insecure attachments are more likely to have social problems than those with secure attachments. They are more likely to be mistrustful and may avoid close relationships with others. Avoidant attachment has been associated with schizoid, narcissism, and obsessional problems later in life [2–4].

Axon

Tracey McLellan
University of Canterbury, Christchurch, New Zealand

Synonyms

Nerve fibre; White matter

Definition

An axon is the part of a neuron that carries messages destined for other cells.

Description

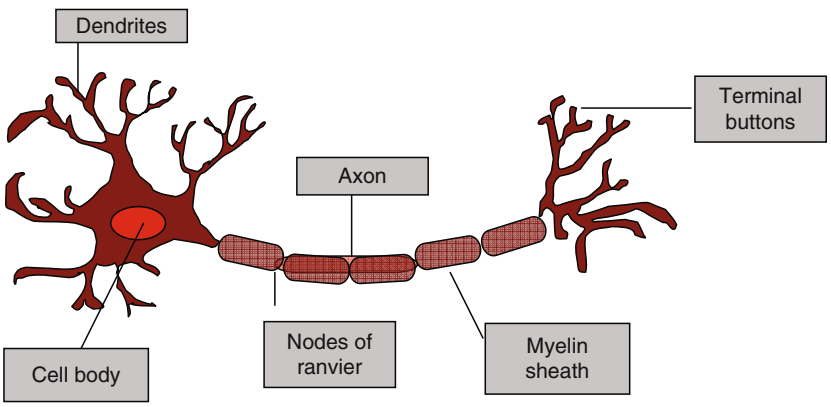
An axon is a long tube like extension coming from the cell body or soma that conducts electrical pulses from the neuron to other cells. The axon is longer than the rest of the neuron. Most axons are just several millimeters long but some axons can extend a meter in length. Most axons are also insulated with a protective coating known as the myelin sheath. The myelin sheath is made up of specialized glial cells that wrap themselves around the axon. Schwann cells sheath the neurons of the peripheral nervous system and oligodendrocytes insulate the neurons of the central nervous system [4]. The majority of myelination is complete by 5 years of age but the process continues into the forth decade of life [2]. A myelinated axon has evenly spaced gaps known as nodes of Ranvier which enable rapid propagation of electrical impulses. Axons involved in the transmission of the most important electrical messages have the greatest concentration of myelin. For example, the information signaling pain is passed through axons with large quantities of myelin. Neurotransmitters are the chemicals stored in the terminal buttons at the end of the axon. The electrical impulse results in the release of the axon's neurotransmitters which can travel across the synapse to a receptor site on another neuron's dendrite. Figure 1 shows an axon in relation to the other main components of the neuron.

The white matter of the brain consists of the myelinated axons that are grouped into bundles (nerve fibers). The grey matter is made up of the neuron's cell body and dendrites. Figure 2 demonstrates that the bundles of axons (nerve fibers) make up a large proportion of the human brain.

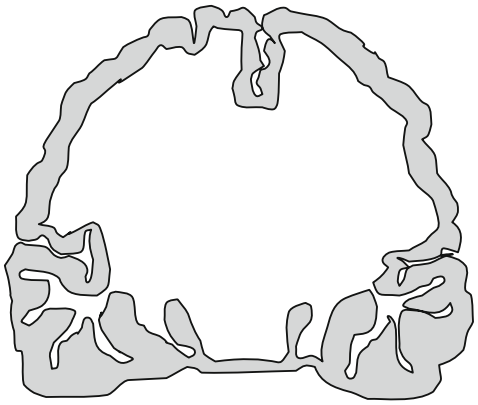
A number of diseases and disorders preferentially effect the white matter in the brain. Multiple Sclerosis (MS) is one of the most common [4]. In MS the myelin insulation around the axon has been destroyed. The amyloid plaques which are characteristic in Alzheimer's disease are known to effect white matter and atherosclerosis is likely to first occur in the tiny blood vessels that irrigate white matter.

Relevance to Childhood Development

The brain continues to develop throughout childhood and the volume of white matter increases linearly into adulthood [2]. The central nervous system is the most vulnerable human system to developmental injury. Children can suffer from a variety of diseases and disorders that effect the axon and specifically the myelin insulation of the



Axon. Fig. 1 The components of a neuron featuring the axon.



Axon. Fig. 2 A schematic picture of a coronal view of the brain depicting grey and white matter.

axon. These diseases are designated the leukodystrophies and include hereditary hypomyelinating diseases such as Pelizacus-Merzbacher disease and metabolic disorders such as Krabbe's disease and Caravan's disease [3]. Considerable research effort is being made to develop cell-based therapeutic strategies that can aid in the restoration of myelin. In addition, several environmental factors are known to interfere with the deposition of myelin. The most influential is malnutrition during the critical period between birth and 24 months of age. MS is increasingly recognised as a disease that effects children with some research suggesting that children may represent up to 10% of all MS cases [1]. As with adult-onset MS, children present with visual and sensory problems and often weakness and ataxia. Children, however, typically have fewer lesions (injuries) than adults, but are more likely to have monosymptomatic illnesses and this poses a difficulty with regard to accurate diagnosis.

B

Babbling

Meredith L. McKee
Washburn University, Topeka, KS, USA

Synonyms
Gibberish; Twaddling

Definition
Babbling is a stage of infants' *prelinguistic* speech development that consists of repetitive consonant–vowel utterances.

Description
The verbal behavior of infants during the first year of life is termed the *prelinguistic period* because it does not contain actual words [3]. Common noises during early infancy include crying, cooing, and variations in patterns of intonation. Babbling typically follows the *cooing* stage of prelinguistic speech and usually emerges between three and six months of age [2]. Consisting of the production of consonant–vowel combinations, such as "ba" or "da," babbling serves as infants' primary means of noncrying vocal communication with caregivers during playtime and other neutral interactions. At approximately 7–9 months infants begin to repeat and draw out well-practiced sounds (e.g., "babababa," or "goo-goo," "gagagaga"), a phenomenon referred to as *canonical* or *reduplicated* babbling [1].

Relevance to Childhood Development
During the latter half of the first year of child development, babbling begins to vary not only in the combinations of sounds the infant utters but also in their patterns of intonations, and thus begins to vary in both pitch and intensity [3]. Furthermore, babbling is considered a universal pattern of development in humans as it is not restricted to the language of the culture in which a child is born [3]. Cross-culturally children begin babbling at about the same age. Children who are hearing impaired also babble, and produce sounds similar to those of hearing infants until around 5 or 6 months of age [2]. Infants exposed to American Sign Language begin to produce repetitive hand movements that resembles babbling [2]. It is estimated that every child babbles every sound in every language at least some time during the first year. Toward the end of the first year, babbling shortens to single or double repetitions such as "mama" and "dada" [1]. At this point, the sounds take on more characteristics of the language in which the infant lives.

Babinski (or Babinsky) Phenomenon or Sign

▶Babinsky Response

Babinski Reflex

Jordana E. Mortimer[1], Denise E. Maricle[1], Devorah Neuhaus[2], Elisheva Konstam[2]
[1]Texas Woman's University, Denton, TX, USA
[2]Pace University, New York, NY, USA

Synonyms
Babinski's sign; Extensor Plantar reflex (pathological) toe phenomenon; Plantar reflex (non-pathological)

Definition
An infantile reflex where stroking the sole of the foot from the heel upward across the ball of the foot elicits the

Sam Goldstein & Jack A. Naglieri (eds.), *Encyclopedia of Child Behavior and Development*, DOI 10.1007/978-0-387-79061-9,

fanning and hyperextension of the toes. The Babinski reflex occurs when the large toe flexes toward the top portion of the foot while the remaining toes fan out. This reaction is normal among infants, but is considered a sign of brain or spinal cord damage if it occurs after the age of 2.

Description

The Babinski reflex is characterized by the hyperextension of the big toe and the fanning out of the other toes when the foot is stroked upward from the heel. The Babinski reflex is one of the infantile reflexes that disappear as the child's nervous system develops. In infants the Babinski reflex is considered normal [3, 7]. As the nervous system develops, the body should respond with a normal reflex movement termed the plantar reflex. In older children and adults, the Babinski reflex is the pathological response that indicates damage to the central nervous system [8]. More specifically this damage originates from the pyramidal system; the portion of the corticospinal tract on the ventral border of the medulla which is a collection of axons that travel between the motor cortex and the spinal cord [2]. Currently, there is no consensus on the specific age where the elicited response becomes pathological. Mandleco [6] states that this response should disappear at 1 year, Berk [1] gives a time span of 8 – 12 months, and Harrop, Hanna, Silva, and Sharan [4] state that the extensor response should give way to the flexor response between 12 – 18 months of age. After taking into consideration each child's individual maturation, the medical community generally views the response abnormal after the age of two [5].

In 1896, Joseph Francois Felix Babinski (1857–1932), a French neurologist, presented his observations of the toe phenomenon to the Biological Society of Paris where he delineated his observations of this reflex in a healthy and pathological response. In healthy adults, stroking the sole of the foot will result in a flexor response, where the toes curve inward. Individuals who have damage to the central nervous system will elicit an extensor response where the toes fan outward [10]. The Babinski reflex is frequently used in infant assessment and because of its reliability remains an important sign in clinical neurology [3] for adults. Because of its use in determining central nervous system damage, the Babinski reflex is indicative of a diverse range of disease processes. Damage to the spinal cord, a brain tumor along the corticospinal tract, meningitis, multiple sclerosis, stroke, rabies, amyotrophic lateral sclerosis, hepatic encephalopathy, and cerebral palsy are a portion of the diseases that may elicit a Babinski reflex [5, 6]. Individuals who exhibit a Babinski reflex will usually also show signs of weakness, incoordination, and difficulty with their muscle control [5]. Several methods need to be used to determine a specific diagnosis as stimulating the sole of the foot along its outside edge from heel to toe can evoke different reflex responses. There are now alternative stimuli that can be used to evoke the Babinski response such as flicking the fourth toe, squeezing the calf or Achilles tendon, and a downward scraping of the shin [9]. A physical examination by an individual's physician is necessary to determine an appropriate diagnosis. An MRI scan of the head and spine may be used for diagnostic testing along with angiography of the head, lumbar puncture and analysis of the cerebrospinal fluid, and somatosensory evoked potentials [5].

Relevance to Childhood Development

The Babinski reflex is a normal infantile reaction to the rubbing of the side of the foot. This reflex begins to fade when a child reaches 12–18 months. If it occurs past the age of two, it is considered a sign of neurological damage.

Babinski's Sign

►Babinski Reflex

Babinsky Response

Amie Senland
Fordham University, Bronx, NY, USA

Synonyms

Babinski (or Babinsky) phenomenon or sign; Babinski reflex; Extensor plantar response or extensor response; Toe or big-toe phenomenon or sign

Definition

The Babinsky response is a reflex where the hallux (or big toe) moves upward and the muscle extending the hallux contracts as the sole of the foot is stroked from the heel to the base of the toes [3]. While normal in infancy, the Babinsky response indicates a neurological disturbance if present in older children or adults [2].

Description

Joseph Felix Francis Babinski (1857–1932) is credited with discovering the Babinsky response [1, 4]. He first presented his findings to the Biological Society of Paris in 1896 and further described his findings in 1898 [1, 4]. The Babinsky response is a reflex occurring when the sole of the foot is stroked, causing the hallux to extend upward and the muscle extending the hallux (the extensor hallucis longus) to contract [3]. Fanning of the other toes may or may not occur and is not a criterion for the Babinsky response. When performing an examination to determine whether the Babinsky response is present, a physician first ensures that the patient is lying down with the face up and all of the leg muscles visible [3, 5]. Then, he or she uses an instrument (e.g., a thin wooden stick) to stimulate the sole of the foot from the heel to the base of the toes. Sometimes it can be difficult to determine whether an upward movement of the toe is a legitimate Babinsky response; therefore, one also examines whether the muscle extending the hallux is contracting, whether additional flexor muscles are contracting, and whether the upward movement of the toe is reproducible [3, 5].

The Babinsky response is considered normal in the first year of life because during this time the pyramidal system within the central nervous system is still developing [3]. Older children and adults generally show a flexor plantar response upon stimulation of the sole of the foot, where the hallux moves downward [5]. Absence of the flexor plantar response is not a concern unless the absence is asymmetrical [5]. If present in older children and adults, a Babinsky response can indicate neurological disturbance, specifically in the pyramidal system [1, 2]. A unilateral Babinsky response can indicate a disturbance in one side of the central nervous system. Hence, the Babinsky response is a clinically useful sign for indicating neurological disturbances in older children and adults and its presence almost always signifies abnormalities of the central nervous system [2].

Relevance to Childhood Development

The Babinsky response is considered one of the primitive reflexes in infancy and generally fades between 6 and 12-months as infants' central nervous systems develop [4]. Fanning of the other toes may or may not occur. While considered normal, the types of responses elicited in newborns in research studies have varied from extensor, to flexor, to equivocal, depending on the methodology or technique used [2]. Children and adolescents typically show a flexor plantar response, where the hallux goes downward upon stimulation of the sole of the foot [5]. If the Babinsky response persists beyond age two or reappears in childhood or adolescence, it may suggest neurological damage or dysfunction [2].

Baby

►Infancy

Baby Talk

Synonyms
Child-directed speech

Definition
Talking in a high pitch using words, sounds, or songs to an infant, animal or lover.

Description
Having a communicative interaction with a child, or infant that is soft, loving, high-pitched sounds or words.

Relevance to Childhood Development
These cooing, babbling, help the infant to imitating the voices in which they are exposed. Baby talk is important for children to learn the different sounds to help the infant to begin to use language. When babies are about 6–8 weeks they begin to make sounds. Copying those sounds back to the baby helps with the infant's social responsiveness. The cooing sounds are also the foundation for communication. These kinds of sounds help with the infant's acquisition of language.

Infants whose caretakers do not use this type of communication, the child may have delayed speech. This may happen because the infant responds more to the person who talks baby talk because of the high pitch and the softness of the sounds.

Baer, Donald M.

Derek D. Reed[1], James K. Luiselli[2]
[1]University of Kansas, Lawrence, KS, USA
[2]The May Institute, Inc., Randolph, MA, USA

Life Dates
1931–2002

Educational Information
Dr. Baer was a renowned researcher and professor in basic, applied, and developmental approaches to behavioral psychology, who contributed significantly to the areas of early childhood education intervention research, interventions for individuals with developmental and intellectual disabilities, language development, imitation, and bridging the gap between behavioral and developmental psychology.

Dr. Baer began his educational career in the public school systems of Massachusetts and Pennsylvania, which he credited for opening his eyes to the merits of science [2]. Dr. Baer completed his baccalaureate studies at the University of Chicago, where he earned his A.B. with honors in 1950. Dr. Baer earned his doctorate in 1957 in the area of experimental psychology under the direction of Jacob L. Gewirtz at Florida International University. Utilizing his expertise in experimentation, Dr. Baer – along with his colleagues Drs. Sidney W. Bijou, Todd R. Risley, and Montrose M. Wolf – would go on to translate Skinner's experimental analysis of behavior to socially valid problems in applied settings. This work was paramount in the conceptualization and formulation of the field of applied behavior analysis.

Accomplishments
Dr. Baer received many awards during his lifetime, with the most notable awards being the Don Hake Award from Division 25 (Behavior Analysis) of the American Psychological Association (APA) in 1987, the Edgar A. Doll Award from Division 33 (Intellectual and Developmental Disabilities) of the APA in 1996, and the Society for the Advancement of Behavior Analysis's 1997 award for Distinguished Service to Behavior Analysis [1]. Dr. Baer was

recognized by the University of Kansas by being named a Roy A. Roberts Distinguished Professor of Human Development and Family Life and of Psychology.

Contributions

Throughout his career, Dr. Baer mentored over 150 graduate students – many of whom have gone on to become leaders in child behavior, education and special education, and behavior analysis [3]. In addition to Dr. Baer's legacy as an esteemed mentor, he contributed to the fields of psychology and education through the publication of more than 200 professional works, ranging from peer-reviewed articles to books and book chapters [3]. Dr. Baer's service to the field also included tenure as the president of the Society for the Experimental Analysis of Behavior from 1983 to 1984, president of the Association of Behavior Analysis from 1980 to 1981, and editor of *Journal of Applied Behavior Analysis* from 1970 to 1971.

Baldwin, James Mark

Jacy L. Young
York University, Toronto, Canada

Life Dates

1861–1934

Introduction

James Mark Baldwin was a prominent American psychologist in the late-nineteenth and early twentieth centuries. In 1903, 6 years after he served as president of the American Psychological Association, a survey of American psychologists ranked Baldwin as the fifth most influential psychologist of the time [4–6].

Educational Information

Baldwin received his undergraduate and graduate degrees at what would eventually become Princeton University. There he studied with the school's president James McCosh, a Scottish realist philosopher, Presbyterian minister, and early supporter of evolution. Baldwin's educational experiences also included a year abroad during which he spent time in Wilhelm Wundt's Leipzig lab [8, 9, 12].

Accomplishments

Baldwin was one of the first psychologists to systematically study child development. His observations of children began after the birth of his first child and convinced him that thought and reason were capacities of the human mind that develop over an individual's lifetime [12]. This led Baldwin to draw a parallel between the mental development of child and that of the species [1].

The theory of child development proposed by Baldwin encompasses both social and cognitive domains and emphasizes the child's active role in the development of the self [11]. Baldwin's stage-wise theory of mental development is composed of three stages: projective, subjective, and ejective. In the projective stage the child recognizes differences in others. In the subjective stage the child develops agency and a sense self. Finally, in the ejective stage the child begins to think of others as subjects similar to the self [1, 3, 7]. Important to Baldwin's developmental theory is the concept of imitation through which the child progresses through these stages of development. It is also imitation that allows for the development of intelligence. In Baldwin's view imitation is the deviation from instinct that results in novel experiences and subsequent intellectual growth [7]. Baldwin would also go on to propose a four stage theory of the development of knowledge comprising pre-logical, logical, quasi-logical, and hyper-logical stages [2, 5, 7].

Contributions

Although largely forgotten by psychology today, James Mark Baldwin played an important role in the formation of the discipline of psychology. Baldwin founded psychological laboratories at the University of Toronto and Princeton University, and also reestablished the laboratory at Johns Hopkins University [4, 6]. Additionally, Baldwin co-founded the *Psychological Review* and the *Psychological Bulletin* [4, 10]. Baldwin's important developmental books include, *Mental Development in the Child and the Race* (1895) and its companion, *Social and Ethical Interpretation in Mental Development* (1897). In addition to his work on child development, Baldwin conducted work in the nascent fields of social psychology, evolutionary psychology, and evolutionary epistemology.

Baldwin also established the field of genetic epistemology, or the developmental theory of knowledge, which the developmentalist Jean Piaget would take up later in the

twentieth century. Through Baldwin's contact with French psychologist Pierre Janet both Jean Piaget and Lev Vygotsky would come to know of Baldwin's work [6, 11, 12]. Baldwin's terminology, including circular reaction, plasticity, imitation, accommodation, and assimilation, would figure prominently in Piaget's work [7].

Bandura, Albert

Frank Pajares
Division of Educational Studies, Atlanta, GA, USA

Life Dates

1925–Present

Introduction

Albert Bandura is an internationally renowned psychologist whose social cognitive theory has revolutionized the study of psychology and has had a profound impact in areas such as education, medicine, business, sports and athletics, economics, political science, media, and mass communication. His introduction of the psychological construct of *self-efficacy* is widely acknowledged as one of the most important developments in the history of psychology. As regards child behavior and development, it is not possible to explain phenomena such as motivation, learning, self-regulation, and academic achievement without discussing the role played by self-efficacy beliefs.

Educational Information

Albert Bandura was born in Mundare, Alberta, Canada. His elementary and high school years were spent at the only school in town, which was woefully short both on resources and teachers. The school contained eight classrooms for grades 1–12, and two teachers handled the entire high school curriculum. Bandura obtained his undergraduate degree in psychology at the University of British Columbia in 1949, where he graduated with the Bolocan Award. He obtained a doctoral degree in clinical psychology from the University of Iowa in 1952 under the direction of adviser Art Benton and went on to a postdoctoral internship at the Wichita Guidance Center.

Accomplishments

Bandura has authored seven books and edited two others, and he has published over 230 articles and book chapters. His books have been translated in numerous languages, including Spanish, Italian, Portuguese, French, Polish, German, Russian, Chinese, Japanese, and Korean.

His contributions to psychology have been recognized in the many honors and awards he has received. These include the *William James Award* of the American Psychological Society for outstanding achievements in psychological science, the *Thorndike Award for Distinguished Contributions of Psychology to Education* from the APA, the *Outstanding Lifetime Contribution to Psychology Award* from the American Psychological Association, the *Distinguished Lifetime Achievement Award for Advancement of Health Promotion through Health Promotion Research* from the American Academy of Health Behavior, the *Distinguished Contribution Award* from the International Society for Research in Aggression, the *Distinguished Scientist Award* of the Society of Behavioral Medicine, and the *Gold Medal Award for Distinguished Lifetime Contribution to Psychological Science* from the American Psychological Foundation. In 2007 he received the *Everett M. Rogers*

Award in Entertainment-Education, an award that honors exceptional creativity in the practice of entertainment-education and excellence in research on the use of entertainment to deliver pro-social messages aimed at improving the quality of life of audiences in the United States and abroad. In 2008, he was awarded the prestigious *Grawemeyer Award* for his contributions to psychology.

Bandura was elected to the presidencies of the APA in 1974 and of the Western Psychological Association in 1981, and he was appointed Honorary President of the Canadian Psychological Association. He has been elected to the American Academy of Arts and Sciences and to the Institute of Medicine of the National Academy of Sciences.

Contribution

Bandura joined the faculty of the Department of Psychology at Stanford University in 1953. When he arrived on campus, the renowned psychologist Robert Sears was chair of the department. Influenced by Sears' work on familial antecedents of social behavior and identificatory learning, Bandura's initial research centered on the role of social modeling in human motivation, thought, and action. In collaboration with Richard Walters, his first doctoral student, Bandura began to engage in field studies of social learning and aggression. Their joint efforts illustrated the critical role of modeling in human behavior and led to a program of research into the determinants and mechanisms of observational learning (part of which is known in the history of psychology as the "Bobo Doll studies."). The program also led to Bandura's first book, *Adolescent Aggression*, and to a subsequent book, *Aggression: A Social Learning Analysis.*

Having gained a better sense of how people learn by observation, Bandura extended this work to abstract modeling of rule-governed behavior and to disinhibition through vicarious experience. Again with Richard Walters, in 1963 Bandura published his second book, *Social Learning and Personality Development.* In 1974, he became David Starr Jordan Professor of Social Science in Psychology. In 1977, Bandura published the ambitious *Social Learning Theory*, a book that dramatically altered the direction psychology was to take in the 1980s. The growth of interest in social learning and psychological modeling that took place during the last decade of the twentieth century owes much to Bandura's theoretical analyses of this phenomenon.

During his time at Stanford, Bandura collaborated in and developed joint projects with internationally renowned scholars such as Jack Barchas and Barr Taylor in psychiatry, Robert DeBusk in cardiology, and Halsted Holman in internal medicine. One of these projects studied how people's perceptions of their own ability to control what they viewed as threats to themselves influence the release of neurotransmitters and stress-related hormones into the bloodstream. A major finding that resulted from these studies was that people can regulate their level of physiological activation through their belief in their own capabilities to do so, or their *self-efficacy* beliefs.

In the course of investigating the processes by which modeling alleviates phobic disorders in snake phobics, Bandura again found that changes in behavior and fear arousal were mediated largely through the self-beliefs that the phobic individuals had in their own capabilities to alleviate their phobia. Bandura then launched a major program of research examining the influential role of self-referent thought in psychological functioning. Although he continued to explore and write on theoretical problems relating to myriad topicsC including observational learning, self-regulation, aggression, psychotherapeutic change, and moral disengagementC from the late 1970s a major share of his attention was devoted to exploring the role that self-efficacy beliefs play in human functioning.

By the mid-1980s Bandura had developed a *social cognitive theory* of human functioning that accords a central role to cognitive, vicarious, self-regulatory and self-reflective processes in human adaptation and change. This theory is rooted in an agentic perspective that views people as self-organizing, proactive, self-reflecting and self-regulating, not just as reactive organisms shaped by environmental forces or driven by inner impulses. In Bandura's social cognitive theory, human functioning is seen as the product of a dynamic interplay among personal, behavioral, and environmental influences. In this model of triadic reciprocal causation, people are producers as well as products of their environment. His 1986 book, *Social Foundations of Thought and Action: A Social Cognitive Theory*, provided the conceptual framework and analyzed the large body of knowledge bearing on this theory.

Emphasizing that human lives are not lived in isolationCthat people work together on shared beliefs about their capabilities and common aspirations to better their livesCBandura expanded the conception of human agency to include collective agency. This conceptual extension makes the theory applicable to human adaptation and change in collectivistically oriented societies as well as individualistically-oriented ones. In his 1997 book, *Self-Efficacy: The Exercise of Control*, Bandura set forth the tenets of his theory of self-efficacy and its applications to

fields as diverse as life-course development, education, health, psychopathology, athletics, business, and international affairs.

With social cognitive theory, Bandura has created one of the few "grand theories" that continues to thrive at the beginning of the twenty-first century. He has defied the general trend in psychology and education toward mini-models by focusing on processes that are influential in diverse areas of human functioning, be they education, sports, health, organizational settings, medicine, mental health, and social political spheres. The broad scope of Bandura's theory stems from his diverse scientific interests, and his theory's ready applicability. Social modeling, self-enabling beliefs, and self-regulation are pervasive across contexts and domains of human functioning.

As the new century dawned, Bandura broadened the scope of his thinking to expound a social cognitive theory capable of encompassing the critical issues and problems of the new millennium. He has spoken and written on topics as diverse as escaping homelessness, how environmental sustainability can be aided by sociocognitive deceleration of population growth, and how self-efficacy can be cultivated for personal and organizational effectiveness. He has proposed a social cognitive view of mass communication, explained the self-regulatory mechanisms governing transgressive behavior, and shown how perceived social inefficacy help lead to childhood depression and substance abuse. Exploring the moral disengagement in the perpetration of inhumanities, Bandura outlined the psychosocial tactics by which individuals and societies selectively disengage moral self-sanctions from inhumane conduct and called for "a civilized life" in which humane standards are buttressed "by safeguards built into social systems that uphold compassionate behavior and renounce cruelty."

Current Involvements

Bandura continues to research and teach at Stanford University, and he still travels a world eager to convey on him numerous measures of recognition and respect for his accomplishments. In addition to social cognitive theory and self-efficacy, his current writing focuses on moral disengagement, terrorism, media effects and mass communication, the psychology of environmental harm, and ecological sustainability.

Barkley Home Situations Questionnaire

Synonyms

Home Situations Questionnaire; HSQ

Definition

Developed by Dr. Russell Barkley, the Home Situations Questionnaires is designed specifically to gather information from parents about behaviors and symptoms directly associated with Attention Deficit Hyperactivity Disorder.

Parents complete the Home Situations Questionnaire by evaluating various symptoms of ADHD and how they disrupt the children in normal home situations such as meal time or completing chores. Parents determine if there were problems in 16 different areas and then rate those problems on a scale of 1-9. This rating scale, along with others, is used to help determine the correct diagnosis for a child. The scale was developed by Russell Barkley, Ph.D. in the early 1990's and is widely used in the assessment and diagnosis of children with symptoms associated with ADHD. There have been numerous psychometric studies conducted on the HSQ and its utility in the assessment of attention-deficit hyperactivity disorder and related behavior disorders in which attention problems are an important focus of evaluation (DuPaul, 1992). Copies of the HSQ can be found in Attention Deficit Hyperactivity Disorder Third Edition A Clinical Workbook (Barkley, 1998).

Barkley School Situations Questionnaire

Synonyms

School Situations Questionnaire; SSQ

Definition

Developed by Dr. Russell Barkley, the School Situations Questionnaire (SSQ) is designed specifically to gather information from teachers about behaviors and symptoms directly associated with Attention Deficit Hyperactivity Disorder that may displayed in a classroom setting. This instrument, in combination with the Home Situations Questionnaire was developed to assess the severity and cross-situational pervasiveness of attention problems, particularly in the classroom.

Teachers complete the School Situations Questionnaire by evaluating various symptoms of ADHD and disruptive behaviors and how they disrupt the children in classroom situations such as individual seat work or lecture activities. Teachers determine if there were problems in a number of different areas and then rate those problems on a scale of 1-9. This rating scale, along with others, is used to help determine the correct diagnosis for a child. The scale was developed by Russell Barkley, Ph.D. in the early 1990's and is widely used in the assessment and diagnosis of children with symptoms associated with ADHD. There have been numerous psychometric studies conducted on the SSQ and its utility in the assessment of attention-deficit hyperactivity disorder and related behavior disorders in which attention problems are an important focus of evaluation (DuPaul, 1992). Copies of the HSQ can be found in Attention Deficit Hyperactivity Disorder Third Edition: a Clinical Workbook (Barkley, 1998)

Nova Southeastern University, Ft. Lauderdale, FL, USA

Life Dates

1949–Present

Educational Information

Dr. Russell A. Barkley, Ph.D., is an internationally recognized clinical psychologist and one of the most recognized researchers in the area of Attention Deficit Hyperactivity Disorder (ADHD). Over the past 30 years, Dr. Barkley has dedicated his research to the assessment and treatment of ADHD in children and adults [1].

Barkley obtained his Bachelor's Degree from the University of North Carolina at Chapel Hill in 1973 [1]. He earned his Masters Degree in 1975 and his Ph.D. in 1977 in Clinical Psychology from Bowling Green State University in Ohio [1, 2]. Barkley completed pre-doctoral internship training at the Oregon Health Sciences University with an emphasis upon developmental, learning, and behavioral disorders in children [2]. In 1977, Barkley joined the Department of Neurology at the Medical College of Wisconsin and Milwaukee Children's Hospital where he founded the Neuropsychology Service and served as Chief Professor and Associate Professor of Neurology until 1985 [1, 2]. From 1985 to 2002, Barkley served as the Director of Psychology and as a Professor of Psychiatry and Neurology at the University of Massachusetts Medical School [1, 2]. There, he established the research clinics for both child and adult Attention Deficit Hyperactivity Disorder [1, 2]. In 2003, he moved to Medical University of South Carolina, where he served as a Professor in the Department of Psychiatry [1]. In 2005, he joined the faculty of the Department of Psychiatry at the SUNY Upstate Medical University in Syracuse, NY, where he is currently employed [1].

Accomplishments

Barkley holds a Diplomate in three specialties: Clinical Psychology (ABPP), Clinical Child and Adolescent

Psychology (ABCN), and Clinical Neuropsychology (ABPP) [1, 2].

Barkley has presented more than 600 invited workshops, public addresses, and scientific presentations worldwide [1]. He has appeared on numerous national television and radio programs throughout North America and internationally [1].

Some of Barkley's numerous awards include: the Distinguished Contribution Award (1994) from the American Association of Applied and Preventive Psychology, the C. Anderson Aldrich Award (1996) from the American Academy of Pediatrics, the Award for Distinguished Contribution to Research (1998) from the Section on Clinical Child Psychology of the American Psychological Association. Barkley received the Dissemination Award from the Society for a Science of Clinical Psychology (2002) of the American Psychological Association for his career- long efforts to educate the public and other professionals about ADHD. Barkley received an award for distinguished service to the profession of psychology from the American Board of Professional Psychology (2005) [1].

Contribution

Parent training in behavior management used with defiant children, training in problem-solving and communication skills in family therapy, classroom behavior modification, social skills training, self-control training, and special education services for ADHD in the schools are some of the many treatments refined by Dr. Barkley. He has also studied the efficacy of stimulant (methylphenidate and amphetamine and nonstimulant (atomoxetine) medications for the treatment of ADHD in children [1].

Dr. Barkley has authored, co-authored, or co-edited 15 books and clinical manuals now numbering 23 separate editions. Some of his most recent books include *ADHD in Adults: What the Science Says* (2008); *ADHD in Adults: Diagnosis and Management* (2007); *Your Defiant Teen (2008); Attention Deficit Hyperactivity Disorder: A Handbook for Diagnosis and Treatment* (3rd ed., 2006), *Taking Charge of ADHD: The Complete Authoritative Guide for Parents* (2005, 3rd ed.), and *Assessment of Childhood Disorders* (2007) [1].

Dr. Barkley has published more than 230 scientific articles and book chapters in the area of ADHD and related disorders. In 1993, Dr. Barkley founded *The ADHD Report* (Guilford), a bimonthly newsletter for clinical professionals [1, 2]. Three out of seven of his professional videotapes on ADHD and defiant children have won the 1992 and 1994 Golden Apple Award from the National Education Association [1]. Dr. Barkley has served on the editorial boards of 11 scientific journals and as a reviewer for numerous others [1]. He was the President of the Section of Clinical Child Psychology - Division 12, American Psychological Association (1988), and was President of the International Society for Research in Child and Adolescent Psychopathology (1991) [1].

Current Involvement

Currently, Dr. Barkley is a Research Professor at the Department of Psychiatry at the SUNY Upstate Medical University in Syracuse, New York and a clinical professor of psychiatry at the Medical University of South Carolina [1].

Barr-Shaver-Carr Syndrome

►XXXY Syndrome

Basal Ganglia

Audrey McKinlay
University of Canterbury, Christchurch, Canterbury, New Zealand

Definition

A group of interconnected subcortical structures that are responsible for movement.

Description

The basal ganglia are a group of interconnected subcortical structures in the forebrain. Although the structures that are considered to be part of the basal ganglia vary, there is general agreement that they include the caudate nucleus, putamen (these two structures are often referred to as the striatum), globus pallidus (globus pallidus and putamen are sometimes referred to as the lenticular nucleus) and the nucleus accumbens [1]. Many authorities also include the substantia nigra, subthalamic nucleus and the amygdala as structures of the basal ganglia [1–4]. The ventral striatum, comprising the ventromedial caudate, ventral putamen, nucleus accumbens and olfactory

tubercle, is a term more recently used to describe parts of basal ganglia that are closer to limbic structures [4]. Traditionally, the basal ganglia have been considered to be involved primarily in movement, but it is now recognised that they also play a vital role in cognitive, behavioural, and psychiatric functions [1].

Deficits Associated with Basal Ganglia Dysfunction

Dysfunctions within the basal ganglia are implicated in a range of movement, psychiatric, and cognitive problems, often resembling deficits usually associated with lesions of the prefrontal cortex [5–12]. Recent reviews suggest different regions of the basal ganglia are associated with diverse range of functions. For example, the ventral regions of the basal ganglia are key in reward and reinforcement, the central regions with cognitive functions that include procedural learning, and working memory, while dorsolateral portions of the striatum control movement [4].

This general topography has been supported to some extent by clinical cases. Bhatia and Marsden [5] reviewed available literature and reported outcomes for 240 patients who had experienced focal lesions to different basal ganglia structures. Of the 240 patients, 111 had behavioural problems, including abulia (defined by the authors as apathy with loss of initiative and spontaneous thought and emotional responses), disinhibition, obsessive compulsive disorder, speech disorder and depression. Abulia was the most common behaviour disturbance, and 13% of the 240 patients had symptoms consistent with this disorder. The most frequent motor disorders included dyskinesia, Parkinsonism, changes in muscle tone (muscular rigidity) and resting tremor. Deficits varied depending on the position of the lesions experienced by the patients.

From clinical cases such as those described, it is possible to make some general assumptions about lesions in the basal ganglia. For example, the authors reported that lesions confined to the caudate rarely caused motor problems and were more likely to cause problems with behaviour, whereas lesions in the lenticular nuclei rarely caused behavioural problems, but were highly likely to cause motor problems.

Contemporary Model of the Basal Ganglia

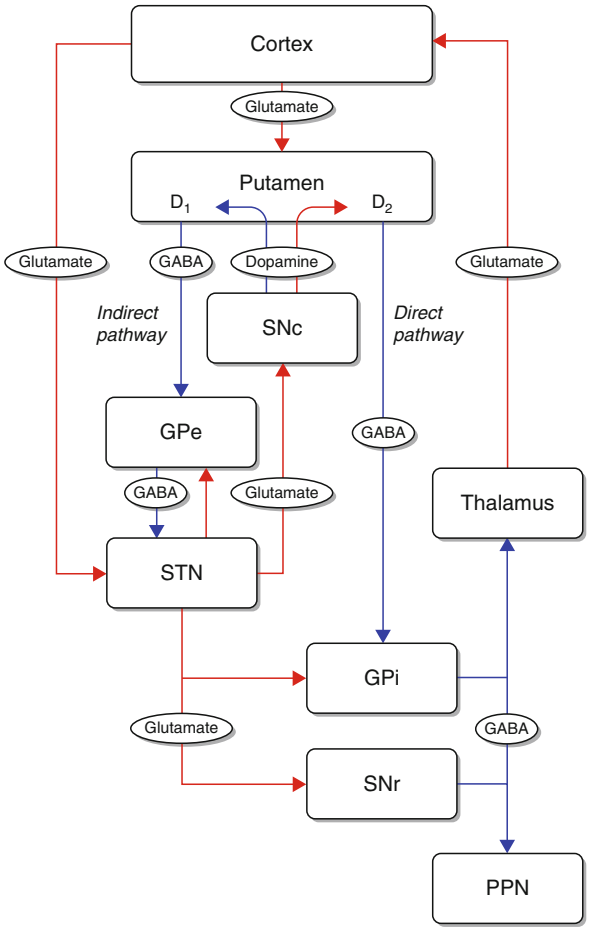
Because early theorists emphasised the role of the basal ganglia in motor functioning, its function was originally conceptualised as receiving information from diverse areas of the sensory and association cortices, and funnelling this information to the motor cortex. However, this view has been substantially revised over the past 20 years. One of the most influential models has been that suggested by Alexander and colleagues (1986; 1990). These authors propose that the basal ganglia are involved in at least 5 parallel loops with the cerebral cortex. Two of these loops are associated with the control of movement, and involve areas of the cerebral cortex associated with motor and oculomotor functioning. The remaining three loops are involved in cognition and behaviour, and include dorsolateral prefrontal, lateral orbitofrontal and the anterior cingulate regions of the cerebral cortex [13, 14]. Each basal ganglia-thalamocortical loop receives input from multiple functionally-related cortical areas and have been described as being closed, in that each receives input from and projects output to a specific cortical area [13, 15]. However, while each of the loops was conceptualised as segregated, they also receive inputs from, and output to, other structures [4, 13, 15]. Since its original inception, the model has been developed to include both direct and indirect pathways [16].

The motor circuit is most commonly used to facilitate an understanding of how the basal ganglia function (see Fig. 1). The direct pathway, which comprises mainly D1-type receptors, projects to the main output nuclei of the basal ganglia, the globus pallidus interna (GPi) and the substantia nigra pars reticulata (SNr). The GPi/SNr inhibits targets in thalamus and brain stem, with an excitatory effect on thalamo-cortical projection [2]. The indirect pathway, which comprises mainly D2- type receptors, projects primarily to the external segment of the globus pallidus (GPe), which outputs to the subthalamic nucleus (STN). Output from the STN to the GPi/SNr is excitatory, with an inhibitory effect on the thalamo-cortical projection [2, 17]. When functioning effectively, the two pathways work in unison to create a balanced system. More recently, a number of deviations to the classic basal ganglia model have been suggested, including projections to the pendunculo-pontine nucleus and the spinal cord [18].

The direct pathway, represented by the blue lines, projects to the globus pallidus interna (GPi) and the substantia nigra pars reticulata (SNr). The GPi/SNr inhibits targets in thalamus and brain stem with an excitatory effect on thalamo-cortical projection. The indirect pathway represented by the red lines, projects primarily to the external segment of the globus pallidus (GPe) which outputs to the subthalamic nucleus (STN). Output from the STN to the GPi/SNr is excitatory, with an inhibitory effect on the thalamo-cortical projection [Adapted from 17, 19].

Limitations of the Model

While this model has provided a useful framework from which to conceptualise the basal ganglia and associated



Basal Ganglia. Fig. 1 A schematic representation of the basal ganglia using the motor circuit.

disorders, it is important to be aware of some of the model's limitations (see Hauber, 1998 and Saint-Cyr, 2003 for comprehensive reviews). For example, it is clear that a degree of information integration occurs within the basal ganglia, given that the multiple related cortical areas project to a given sub-region of the striatum, and input structures (striatum) comprise of approximately 30 times more neurons than the output structures (SNr, and the GPi, Hauber, [20]). However, the current model lacks explanatory value in terms of how this information is integrated [21].

Further, a number of more recent findings are not easily explained by the model. For example, D1 and D2 neurons have been found to "co-localize" on striatal neurons and all striatal neurons that project to the GPi also project to the GPe. Therefore, the conceptualisation of the D1 /D2 neurons in the basal ganglia as being either excitatory or inhibitory is considered to be an over-simplification [22].

Other aspects of the original model remain a matter of debate, including the extent to which the loops are segregated, whether there is functional overlap, and whether there are additional basal ganglia-thalamocortical loops [21, 23–25]. Major regions of the cortex project to overlapping areas of the striatum, suggesting that the circuits are not totally segregated on the basis of cortical input [21]. Also, there are projections back to the cortex from the GPe and projections from the basal ganglia to the brain stem. However, the role of these open circuits is not adequately explained by the model [18, 26]. Despite the limitations covered above, anatomical observations and clinical studies have provided wide support for the model suggested by Alexander and colleagues, and it has been used to inform both research and surgical interventions [15, 27].

Relevance to Childhood Development

As outlined above the basal ganglia include a number of subcortical structures that are involved in the control of movement. Broadly speaking a disorder of the basal ganglia can either lead to an excess or retardation of movement and a number of these disorders may manifest in childhood. Some of the more common disorders include, Cerebral palsy, Tourette's syndrome, Obsessive Compulsive Disorder (OCD), Attention Deficit Disorder (ADD), Huntington's disease and Wilson's disease[28]. Each of these disorders is briefly described below in terms of the motor symptoms that may accompany them.

Cerebral palsy is a term used to describe a group of disorders affecting multiple aspects of movement. The disorder may result in muscular rigidity (stiffness), chorea (unwanted jerking movements), athetosis (slow, writhing movements), or dystonia (fixed, twisted postures)[28]. Overactive of the caudate has been implicated in disorders such as OCD[29], defined as recurrent obsessions or compulsions by the DSM-IV, while an under activation of the caudate may be involved in Attention Deficit Disorder ADD[28]. Under activation of the putamen, has been implicated in Tourette's syndrome. Tourette's syndrome involves involuntary muscle movements known as tics these may manifest motorically or vocally. Although less common in children, Huntington's disease is another disorder of the basal ganglia that may make its first appearance in early childhood. Huntington's, a hereditary disease involves cell death in the caudate nucleus, and is associated with deficits in cognition and movement (most notably chorea). Wilson's disease is a rare inherited disorder which causes the body to take in and keep too much copper, which causes damage to tissue in the body and brain structures. Many individuals with Wilson's disease will

demonstrate clumsiness, and in time symptoms consistent with parkinsonism (increased rigidity, slowness of movement). Disorders such as Cerebral palsy, Huntington's disease and Wilson's disease are often accompanied by other neuropsychiatric and cognitive disorders and in extreme cases are associated with intellectual disability [28, 29].

Base Rate

Teresa L. Davenport
Ball State University, Muncie, IN, USA

Synonyms

Norm rate

Definition

A base rate is a frequency or likelihood of an event occurring without intervention.

Description

Base rates are a statistic used to describe the percentage of a population that demonstrates some characteristic. Base

rates indicate probability based on the absence of other information. Base rates developed out of Bayes' Theorem.

An example of a base rate would be a professor who teaches a 7:30 a.m. statistics class. On a typical class day, approximately 25% of the class is not in attendance. The base rate for students who do not attend class is therefore 25%, and the base rate for students who do attend class is 75%. Thus the chance that any given student name listed on the roster will represent a student will be in attendance is 75%. It is important to remember that this statistic is made without any other given information other than the history of attendance.

In contrast, if you know that a particular student is a statistics major with a 4.0 grade point average, you are likely to conclude the chances of this particular student being in attendance is greater than 75%. These types of conclusions are of particular interest to psychologists. These decisions are known as "base rate neglect" or the "base rate fallacy [1, 2, 3]." In these cases, people tend to ignore base rate evidence in favor of other decision making modes [2]. Psychologists will often consider the base rates of disorders along with case-specific information when making diagnostic decisions, but also will engage in base rate neglect. Interestingly, base rate neglect has also been found to be accentuated in groups, and may be affected by the presentation of a problem [4]. Some researchers have presented models for why base rate neglect occurs; however, the origin of base rate neglect is still highly debated in the literature [2, 5].

Battelle Developmental Inventory: 2nd Edition

Angela Hilton-Mounger
University of Tennessee, Knoxville, TN, USA

Synonyms

BDI-2

Definition

The Battelle Developmental Inventory, 2nd Edition (BDI-2) is an individually administered, standardized assessment battery designed for use with children aged birth to 7 years, 11 months. The BDI-2 measures key developmental skills in the following areas: Adaptive, personal-social, communication, motor, and cognitive [1].

Description

The BDI-2 was developed based upon the theory that children achieve specific developmental milestones in sequence and that reaching milestones generally depends on mastering preceding milestones. The test is a revision of the Battelle Developmental Inventory developed in 1984 by Jean Newborg in response to the need for assessments that measure the developmental progress of young children. The BDI-2 provides information to professionals at the preschool, kindergarten, and primary school levels on the developmental and functional skills of young children. Examples of professionals who may administer the BDI-2 include: Teachers at the preschool, kindergarten, and primary levels; special education teachers; infant interventionists; psychologists; speech and language pathologists; adaptive physical education specialists; clinical diagnosticians; health professionals; and other related service providers.

The purpose of the BDI-2 is to assess key developmental skills in children from birth to 7 years, 11 months. The complete BDI-2 consists of 450 items grouped into five domains: Adaptive, personal-social, communication, motor, and cognitive.

The Adaptive domain measures the ability to use information and skills acquired in the other domains of personal social, communication, motor, and cognitive.

Containing 60 items, the Adaptive domain is divided into two sections: Self -Care and Personal Responsibility. The Self-care subdomain consists of 35 items measuring skills in the areas of eating, dressing, toileting, grooming, and preparing for sleep. Administration of this subdomain is appropriate for children aged birth to 6 years. The Personal Responsibility subdomain is appropriate for children aged 2–8 years. This subdomain measures the child's ability to interact safely and in a useful manner with the environment.

The Personal-Social domain assesses a child's ability to form meaningful social interactions with peers and adults as well as the ability to develop a self-concept and social role. This domain consists of 100 items and is divided into three subdomains including: Adult Interaction (AI), Peer Interaction (PI), and Self-Concept and Social Role (SR). Adult Interaction is assessed in children ages birth to l year, Peer Interaction is measured in children aged 2–6 years, and Self-Concept and Social Role are assessed over the range of items in the BDI-2.

The Communication domain contains 85 items and is administered to children aged birth to 8 years. The communication domain consists of two subdomains: Receptive and Expressive. The Receptive subdomain assesses a child's ability to understand spoken language along with information received through nonverbal means such as gestures. The Expressive subdomain measures how well a child is able to communicate information to others through sounds, words, and gestures.

The Motor domain consists of 100 items that assesses the child's ability to use both large and small muscles in three domains: Gross Motor, Fine Motor, and Perceptual Motor. The Gross motor subdomain consists of 45 items that assess that assess the use of large muscles used for walking, running, jumping, and coordinated movements such as throwing. The Fine motor domain uses 30 items to assess the control and coordination of small muscles in the arms and hands. Both the Gross and Fine motor subdomains are used to assess children ages birth to 6 years. The Perceptual motor subdomain contains 25 items related to the child's ability to integrate fine motor and perceptual skills for activities such as stacking blocks and copying circles. This subdomain is appropriate for children ages 2–8 years.

The Cognitive domain consists of 105 items designed to assess intellectual ability without regard to language. Areas such as attending to, perceiving, and processing information, remembering, thinking, and knowing are assessed in this domain. The Cognitive domain is divided into three subdomains: Attention and Memory, Reasoning and Academic Skills, and Perception and Concepts. Attention and Memory consists of 30 items that measures the child's ability to attend to stimuli both visually and auditorily for varying lengths of time and then retrieve information in the short and long term. Children ages 2 through 6 are appropriate for assessment in the Attention and Memory subdomain. The 35 items on the Reasoning and Academic subdomain assess critical thinking skills needs in order to: (1) perceive, identify, and solve problems; (2) analyze and appraise the elements of a situation; (3) identify missing components, contradictions, and inconsistencies; and (4) judge and evaluate new ideas. Skills necessary for reading, writing, spelling, enumeration, and mathematics are also assessed. This subdomain may be administered to children ages birth to 7 years, 11 months. The Perception and Concepts subdomain possesses 40 items that examine an infant's sensorimotor interactions with the environment as well as the older child's ability to conceptualize and discriminate features. This subdomain is appropriate for assessing children ages birth to 7 years, 11 months.

The administration time for the BDI-2 is 1 h for children younger than 2 and older than 5, and approximately 90 min for children between the ages of 2 and 5. A screening test is also offered as part of the BDI-2 which contains 100 of the 450 items. Results obtained from the screener help with determining in full administration of the BDI-2 is necessary for specific domains. The time needed to administer the screener varies from 10 to 30 min depending on the age of the child. Individual domains are assessed in separate Item Test Books to facilitate ease of administration. Information gathered from the administration of the BDI-2 is useful in assisting professionals with identifying developmental areas of concern at a young age.

Domains and subdomains are individually administered using structured, observation, or interview administrations. Additionally, the domains may be given in any order. The structured procedure involves the examiner eliciting responses from the child using manipulatives or other stimuli. The observation administration procedure involves the examiner observing the child and how the child responds during typical home, school, and other natural settings. Ideally with the observation administration procedure the examiner will be able to observe the child over a period of time to obtain the best representation of the child's abilities. The interview administration procedure is implemented when information about specific conditions or frequencies regarding the child's behaviors need to be obtained from a parent, caregiver, or teacher. The interview administration is most frequently used for early age items when the child is not able to

answer the question and must rely on a parent, teacher, or caregiver to provide the information.

The BDI-2 produces a total score that is a composite of all five domains and provides a general level of where the child is developmentally. Each domain is assigned a developmental quotient (DQ) that is based on a mean of 100 and standard deviation of 15. According to the test authors the Total BDI-2 DQ score is the most reliable score for the test because it considers all of the domain areas. Scoring Pro software is available to assist with scoring for the BDI-2.

Prior to beginning standardization, the BDI-2 was subjected to a tryout phase. During this phase, a 466 item tryout edition with new items, reconfigured subdomains, and new toys and manipulatives were prepared. 850 cases were collected during this period from a wide range of geographical locations across the United States. Following the collection of these cases, a data analysis took place and items that were identified as problematic were either adjusted or replaced.

Following the tryout phase, standardization was conducted using a sample of 2,500 children ages birth to 7 years, 11 months. Four United States census regions were used: Northeast, Midwest, South, and West and data was collected over a 14-month period. As part of the standardization process, 310 examiners from the various census regions were selected to administer the BDI-2. Stratified random sampling based on age, sex, race/ethnicity, geographic region, and socioeconomic level was conducted to select child participants although the number of children from each of the various regions was not provided. According to the test authors the sample was nationally representative and matched to percentages provided by the US Census Bureau (2001).

The BDI-2 has reliability coefficients in all subdomains at or above .85 and ranging from .85 to .95 indicating moderately high to excellent reliability. The reliability coefficient for the Total BDI-2 DQ score was .99 indicating excellent reliability for internal consistency.

The BDI-2 test kit contains numerous toys and manipulatives that are visually interesting for children in the targeted age range. Additionally, skills targeted within each subdomain are distributed in an age appropriate sequence for the development of milestones. Sensitivity to the child's ability to perform tasks and provide information is displayed through the use of structured administrations, observations, and interviews depending on the type of information to be obtained and the age of the child.

Concurrent validity studies were completed by individually administering the BDI-2 and the Bayley Scales of Infant Development, Second Edition (BSID-II). A moderate correlation of .61 was found to exist between the BDI-2 Cognitive DQ scores and the Mental Index Score on the BSID-II. Additionally, a moderately high correlation of .75 was found between the BDI-2 Communication DQ and the BSID-II Mental Index Score along with a moderate correlation of .64 between the BDI-2 Motor DQ and the BSID-II Motor Index score. Lower correlations were found in the following areas: .34 for the BDI-2 Cognitive domain and the BSID-II Motor Index, .43 for the BDI-2 Communication DQ and the BSID-II Motor Index score, and .48 between the BDI-2 Motor DQ score and the BSID-II Mental Index. The lower scores support divergent validity.

Additionally, extensive studies on the BDI-2 with special population groups were conducted. These groups consisted of children with autism, cognitive delays, developmental delays, motor delays, prematurity, and speech/language delays. Specificity values indicating whether a child will be correctly identified using the BDI-2 scores were at .91 for autism, .86 for cognitive delays, .83 for developmental delay, .80 for motor delay, .75 for speech and language delay.

Relevance to Childhood Development

The BDI-2 is a useful tool in assessing developmental milestones in children ages birth to 7 years, 11 months. Adaptive, Communication, Cognitive, Motor, and Personal-Social milestones are assessed for this age group using child-friendly language and manipulatives. Results of this assessment are helpful in providing professionals with information regarding how a child is progressing developmentally and identifying children who may require early intervention in conjunction with other assessment measures.

Battered Child Syndrome

Stephanie Dvorak, Tasha R. Howe
Humboldt State University, Arcata, CA, USA

Synonyms

Abused children; Child maltreatment; Effects of physical abuse; Physical abuse; Shaken baby syndrome

Definition

The multitudes of physical and emotional issues that manifest in children as a result of long term and repeated abuse or neglect.

Description

Battered child syndrome is the name for the combination of physical and psychological problems that are found in children after a history of repeated abuse. Battered Child Syndrome as a concept was developed in 1962 by Kempe and colleagues [4]. They developed the term as a way of explaining a clinical condition found in children who had suffered from repeated abuse [3].

Abuse can occur in many different ways including bruises, burns, broken bones, internal injuries, sexual assault, choking, and verbal abuse [1]. Child maltreatment accounts for approximately 1,400 deaths of children each year and about 14,000 children are seriously injured as a result of abuse or neglect [1]. Indicators of child physical abuse include broken bones that cannot be explained or are unusual, bruise marks that have patterns such as fingers, hands, or belts, bruises that are not in typical areas where normal childhood activity causes bruising (i.e., knees), burns of various types including burns to the hand or foot (called "sock" and "glove" patterns), cigarette burns, radiator or burns from other hot objects, bite marks, black eyes, choke marks, circular marks often found on the wrists or ankles that indicate twisting or tying up, and unexplained abdominal injuries [1]. Some of the physical, emotional, and behavioral issues that may arise in Battered Child Syndrome include problems at school, suicide, acting out sexually, feelings of rejection, attachment issues, brain damage, blindness, disfigurement, and death [1, 2]. In some cases the symptoms appear right away and other times they have a gradual onset. Battered Child Syndrome can be difficult to prove in the legal system and it faces the scrutiny of professionals disagreeing about whether or not is an actual syndrome. Physical proof of repeated abuse can be found in x-rays where bones exhibit fractures at different levels of healing. Physicians are now able to assess from x-rays the type of break the child experienced. For example, if the fracture has a spiral pattern, it is indicative of a bone being twisted, in comparison to a clean break seen as a result of a fall [1, 3]. Other types of physical evidence may be bruises that are at different stages of healing, burns or scars from past burns, fractured ribs or skulls, or bleeding in the brain, behind the eye or other internal organs [1]. In summary, Battered Child Syndrome is the combination of injuries resulting from repeated abuse and the physical and emotional ways repeated abuse can affect the child [1–3].

Baumrind's Parenting Styles

Elizabeth Levin
Laurentian University, Sudbury, ON, Canada

Synonyms

Child-rearing; Discipline; Family structure; Parenting styles

Definition

Parenting styles refer to the typical ways parents think, feel and behave in terms of child-rearing.

Description

The most widely known categories of parenting styles are based on the work of Diana Baumrind [1, 2]. Most of her research has focused on two dimensions of parenting style: authority and affection [1, 2]. Authority or demandingness refers to the degree to which parents try to control their children's behavior by setting rational standards for behavior. Affection or responsiveness refers to the amount and way love is expressed to the child and acceptance of the child's points of view. Based on these dimensions, Baumrind identified three categories of parenting styles [1].

The ▶Authoritative parent shows high levels of control, coupled with high levels of warmth. Authoritative parents exercise significant authority over their children's behavior but at the same time they do this with warmth and affection. Authoritative parents make reasonable demands, are consistent and sensitive, and they provide reasons for their expectations. In this family structure, children's opinions are listened to and valued, though not necessarily followed. The child is encouraged to communicate and when parent and child disagree, joint

decision making is preferred. The child is gradually taught how to make decisions, leading to co-regulation of behavior, which prepares the child to assume eventual self-regulation of behavior [4].

The Authoritative parenting style is seen as the most effective approach to child-rearing. This style of parenting leads to socially responsible, competent children. In addition, children reared in this way become achievement oriented and cooperative with both adults and peers. Children are given autonomy appropriate to their age and ability but ultimately it is the parents who are in charge. This is the optimal approach to ensure good decision making ability in the children. This approach leads to greater compliance by the child, when compliance is critical. Children are not only more likely to comply with authoritative parenting; they are most likely to want to be like their parents.

The Authoritarian parent displays high levels of control and little warmth. This parent has lots of rules, strictly enforces them, and is unwilling to discuss or modify the rules. This produces passive, dependent children who are unhappy, moody and lack self-confidence. The child has to have some opportunity to understand the reasons behind the rules to appreciate them. The Authoritarian parent values obedience as a virtue and believes the child should accept her word for what is right. "Do what I say because I say so" is the motto of the Authoritarian parent. The child may obey but later flounders when faced with tough decisions because she has not learned to think and take responsibility for her actions.

The Permissive parent shows little control, makes few demands but displays lots of warmth. While permissive parents are nurturing, they do not take responsibility for guiding their children. This leads to children who lack social responsibility and self-control. These children are selfish; they have never learned to put others' needs ahead of their own and this affects friendships and relationships. Children are not done any favors by never having limits put on them. Society demands limits and one needs to learn this while young. When children are young many parents are reluctant to enforce limits or say "no" but when children are older and they have not learned to listen to authority, watch out. One day your teen may be bigger than you are.

Power does serve to legitimate authority to the child, thus if one had to choose, authoritarian approaches are preferable to permissive approaches up to about age 6. Power is not only far less successful when dealing with older children and adolescents it can actually undermine authority. Adolescents can reason formally and can see alternatives to parental directives. Setting limits when children are young teaches children to acquire self-discipline which permits children greater self-direction in later life.

Using the two dimensions of control and affection suggests a fourth category of parenting style: parents who are low in both authority and warmth. Baumrind did not find sufficient numbers of these parents to study them, but others [6] have described these parents as uninvolved or neglectful.

Relevance to Childhood Development

According to Baumrind's work, the optimal parent is both demanding and affectionate. In addition, parents differ in their beliefs that their children can act maturely and in their levels of communication with their children [3]. The parent has expectations for behavior based on the child's level of development and these expectations change with age of the child. With increasing age, the relationship between parenting practices and child behavior becomes increasingly bi-directional, that is, parents influence their children and children in turn influence parenting practices [5]. According to Baumrind however, parental effects are the most influential in this regard. Although it is easy to be an authoritative parent with a child who is very cooperative, parents who emulate the authoritative style can do so with less compliant children because authoritative parents are patient, consistent and prepared for children who are uncooperative. This approach will eventually lead to a more cooperative, compliant child. The research then generally favors the authoritative parenting style but the evidence comes primarily from North American Caucasian families [4]. The ideal style may be different in other cultures although support for this model has been found in Asian families [6]. And while parents are important, child temperament and marital quality have important roles to play in child outcomes.

Bayley Scales of Infant Development: Third Edition

David Michalec
Nationwide Children's Hospital/The Ohio State University, Westerville, OH, USA

Definition

The Bayley Scales of Infant and Toddler Development, Third Edition (Bayley-III) is an individually administered instrument to assess the developmental functioning of infants and young children. It is normed for children 1 month to 42 months of age and was recently updated in 2006. Like its predecessor the Bayley-II, the Bayley-III is intended to identify children with developmental delay. The measure is also designed to present information that will be used in treatment planning.

Description

Information is gathered from both the child and caregiver. The child is administered three separate scales: cognitive, language, and motor. The cognitive scale assesses play skills, information processing, memory and habituation skills, and reasoning abilities. The language scale is divided into two separate abilities: receptive and expressive. Receptive skills assessed by the Bayley-III include comprehending and responding to requests and discriminating between sounds in the environment. The evaluation of expressive language skills includes the ability to name objects and actions, communicate wants, respond to questions, and use multiword sentences. The Motor scales of the Bayley-III evaluate both fine and gross motor skills. Reaching objects, visual tracking, and use of a "pincer" grasp are some of the fine motor skills assessed. Gross motor skills evaluated include locomotion, balance, and jumping.

Information about the child's social-emotional functioning and adaptive behavioral skills are obtained from the child's caregiver. Adapted from the work of Greenspan (2004), the social-emotional scale assesses the child's mastery of functional emotional skills including self-regulation, socialization, and the ability to use emotional gestures to communicate. The adaptive behavior scale, also completed by a primary caregiver, evaluates functional skills in the areas of conceptual, social, and practical abilities. Scaled scores are derived from all scales on the Bayley-III.

The Bayley-III offers several updates from the earlier version including new normative data (gathered in 2004), more accurate norms listed in 10-day increments, expansion of the floor and ceiling and the addition of new items. Additionally, the authors made changes to improve the ease of administration. Empirical support for both reliability and validity has been achieved during the 2006 update.

Relevance to Childhood Development

The Bayley-III is widely used in a multitude of settings and programs. Medical clinics, child care agencies, community agencies that assist individuals with developmental disabilities, and private practitioners utilize this tool to document current functioning and determine appropriateness for services.

Beck Anxiety Inventory

Michael M. Grant
Coastal Center for Cognitive Therapy, PA. Myrtle Beach, SC

Definition

The Beck Anxiety Inventory is a well accepted self-report measure of anxiety in adults and adolescents for use in both clinical and research settings.

Description

Background

The Beck Anxiety Inventory (BAI), created by Aaron T. Beck, MD, and colleagues, is a 21-item multiple-choice self-report inventory that measures the severity of an anxiety in adults and adolescents. Because the items in the BAI describe the emotional, physiological, and cognitive symptoms of anxiety but not depression, it can discriminate anxiety from depression. Although the age range for the measure is from 17 to 80, it has been used in peer-reviewed studies with younger adolescents aged 12 and older. Each of the items on the BAI is a simple description of a symptom of anxiety in one of its four expressed aspects: (1) subjective (e.g., "unable to relax"), (2) neurophysiologic (e.g., "numbness or tingling"), (3) autonomic (e.g., "feeling hot") or (4) panic-related (e.g., "fear of losing control"). The BAI requires only a basic reading level, can be used with individuals who have intellectual disabilities, and can be completed in 5–10 min using the pre-printed paper form and a pencil. Because of the relative simplicity of the inventory, it can also be administered orally for sight-impaired individuals. The BAI may be administered and scored by paraprofessionals, but it should be used and interpreted only by professionals with appropriate clinical training and experience.

Administration, Scoring, and Interpretation

Respondents are asked to report the extent to which they have been bothered by each of the 21 symptoms in the week preceding (including the day of) their completion of the BAI. Each symptom item has four possible answer choices: *Not at All*; *Mildly* (It did not bother me much); *Moderately* (It was very unpleasant, but I could stand it), and; *Severely* (I could barely stand it). The clinician assigns the following values to each response: *Not at All* = 0; *Mildly* = 1; *Moderately* = 2, and; *Severely* = 3. The values for each item are summed yielding an overall or total score for all 21 symptoms that can range between 0 and 63 points. A total score of 0–7 is interpreted as a "Minimal" level of anxiety; 8–15 as "Mild"; 16–25 as "Moderate", and; 26–63 as "Severe". Clinicians examine specific item responses to determine whether the symptoms appear mostly subjective, neurophysiologic, autonomic, or panic-related. The clinical can then further assess using DSM criteria to arrive at a specific diagnostic category and plan interventions targeting the underlying cause of the respondent's anxious symptomatology and/or diagnosis.

Psychometric Properties

The BAI is psychometrically sound. Internal consistency (Cronbach's alpha) ranges from .92 to .94 for adults and test-retest (one week interval) reliability is .75. Concurrent validity with the *Hamilton Anxiety Rating Scale, Revised* is .51; .58 for the *State* and .47 for the *Trait* subscales of the *State-Trait Anxiety Inventory, Form Y*, and; .54 for the mean 7 day anxiety rating of the *Weekly Record of Anxiety and Depression*. The BAI has also been shown to possess acceptable reliability and convergent and discriminant validity for both 14–18 year and inpatients and outpatients.

Clinical and Research Uses

The BAI can be used to assess and establish a baseline anxiety level, as a diagnostic aid, to detect the effectiveness of treatment as it progresses, and as a post-treatment outcome measure. Other advantages of the BAI include its fast and easy administration, repeatability, discrimination between symptoms of anxiety and depression, ability to highlight the connection between mind and body for those seeking help to reduce their anxiety, and proven validity across languages, cultures, and age ranges. Some researchers have suggested that the BAI may be less sensitive to symptoms secondary to medical or other trauma, more sensitive to panic disorder than it is to the symptoms of other anxiety disorders, and may need separate norms for males, females, and more ethnically/socioeconomically diverse samples.

The BAI is copyrighted by and currently available from Pearson Education, Inc. (http://www.pearsonassess.com). Since the development of the BAI and its documented use with adolescents, it has been adapted specifically for youth as the BAI-Y (one of five Beck Inventories adapted for younger patients and collectively called "The Beck Youth Inventories"). The BAI-Y consists of twenty self report items rated on a three point scale that assess a child's fears, worrying, and physiological symptoms associated with anxiety. Like the other Beck Youth Inventories, it can be used with patients aged 7–18 and is also copyrighted and available from Pearson. Because it was specifically developed and normed on children aged 7–14, it is a more appropriate measure of anxiety in patients in that age range and slightly higher. If appropriate, the clinician can use the adult form of BAI for the ending adolescent years and with young adult patients.

Relevance to Childhood Development

Anxiety is the state of heightened unpleasant physical and emotional arousal caused, usually, by awareness of and attention to some feared consequence, condition, or perceived threat. It can be experienced, subjectively, as

feelings of dread, discomfort, feeling ill-at-ease, and unprepared to address the anticipated or current situation effectively. Neurophysiologically, anxiety can be experienced as paresthesia (numbness or tingling), increased startle response (hypervigilance), and difficulty concentrating. Autonomic experiences of anxiety include feeling "hot," increased sweating (diaphoresis), increased heart rate (tachycardia), flushed face, etc. Anxiety is a normal emotion that prepares the mind and body to respond to a threat. As such, it is adaptive for survival. However, when anxious arousal persists over long periods it can cause a number of negative medical and psychological outcomes including the development of anxiety disorders.

Children with anxiety disorders frequently present with other problems that may be produced, in part, by their anxiety and that often serve to further increase their anxiety. These co-morbid problems include ADHD, depression, school refusal, poor behavioral control, poor peer relations, social skills deficits, bed wetting (enuresis), poor academic performance, eating disorders, etc. Unaddressed childhood anxiety will likely cause problems later in adolescence and adulthood since early experience has such a profound impact on the development of negative beliefs about self, world, and future. Negative beliefs, in turn, create a fertile environment for the construction of distorted assumptions, rules, and thoughts that only serve to heighten anxiety. Identifying anxiety through the use of simple measures like the BAI may alert us to the need to intervene in a child's life to remove real threats to physical and psychological safety. Such interventions would also, ideally, include helping the child learn to identify and dispute distorted perceptions of "threats" that are not real. In this way, the child can learn that feelings and emotions, including anxiety, can be controlled and/or managed.

Beck Depression Inventory

Preston Visser[1], R. Trent Codd III[2]
[1]East Tennessee State University, Johnson, TN, USA
[2]Cognitive-Behavioral Therapy Center of Western North Carolina, P.A., Asheville, NC, USA

Synonyms

Similar Scales include: Hamilton Rating Scale for Depression (HRSD) [1]; Center for Epidemiologic Studies Depression scale (CES-D) [2]; Children's Depression Inventory (CDI) [3]

Definition

The Beck Depression Inventory is a 21-item self-report questionnaire that provides a measure of the severity of depressive symptoms [4].

Description

The Beck Depression Inventory (BDI) provides healthcare workers and researchers the ability to briefly (approximately 5–10 min) assess the severity of various cognitive and somatic symptoms of depression. It can either be

self-administered or read to clients by an interviewer. The BDI was originally designed for use with psychiatric patients, but it is frequently used with non-depressed individuals. Since it was first developed in 1961, it has been used extensively in clinical and research settings and with various populations [5].

Theoretical Background

The BDI is based on the cognitive theory of depression introduced by Aaron Beck in the 1950s and 1960s [6]. In working with several depressed patients, Beck noticed that they tended to display very similar negative thought patterns and dysfunctional beliefs (e.g., "Unless everyone loves me, I am worthless"). He hypothesized that these maladaptive cognitions existed prior to and caused the current depressive episode rather than resulted from the depression.

The Items

The BDI is composed of 21 items representing cognitive and somatic symptoms that are commonly displayed by clinically depressed individuals. Participants are asked to respond to each item based on how they have felt in the preceding week. They endorse each item based on a four-point scale (0–3), with 0 representing almost no presence of the symptom and 3 representing severe symptom presence. The following symptoms are assessed: mood, pessimism, sense of failure, self-dissatisfaction, guilt, punishment, self-dislike, self-accusation, suicidal ideas, crying, irritability, social withdrawal, indecisiveness, body image, work difficulties, insomnia, fatigue, appetite, weight loss, bodily preoccupation, and loss of libido.

Psychometric Properties

The internal consistency of the BDI has been supported in both depressed and non-depressed samples, with most studies reporting high alpha coefficients (.82–.88 on average) [5]. The test-retest reliability may not be an appropriate measure for use with the BDI in psychiatric samples given the high probability of therapeutic change, but studies reporting test-retest reliability coefficients in non-depressed samples typically suggest good stability of BDI scores. The content validity is supported by the BDI's development from direct clinical observation of depressed patients and its congruence with DSM-III criteria for depression [7]. Convergent validity is supported by strong correlations between the BDI and other psychometrically sound measures of depression. Researchers have some concern with the high correlation between BDI scores and measures of anxiety; however, it is not clear if such effects are due to measurement error or high comorbidity between depression and anxiety. Nonetheless, studies have shown that the BDI can effectively discriminate between depressed and non-depressed individuals [8]. Although the BDI items can be generally categorized as either assessing cognitive or physical symptoms of depression, factor analytic studies show that the BDI is best conceptualized as being composed of a general factor, unlike the second edition of the BDI (BDI-II), which suggests either two or three latent factors of depression [8].

Interpretation

Summing the BDI items will result in a total score of 0–63, with higher scores indicating more severe depressive symptomology. Normative studies have determined cutoffs to be: 0–9 = minimal depressive symptoms, 10–16 = mild depression, 17–29 = moderate depression, 30–63 = severe depression.

Use with Children

Researchers have indicated doubt of the BDI's appropriateness for use with children (under 13 years of age) and even adolescents (13–17 years of age) [9]. Modeling it after the original BDI, Maria Kovacs developed the 27-item Children's Depression Inventory for use with ages 7–17 years [3, 9]. Since that time, the Beck Institute has developed a 20 item inventory for children and youth (the BDI-Y) to assess depressive symptoms that more closely adhere to the DSM-IV criteria for depression [10].

Beck Therapy

Elaine A. Thomas
Argosy University, Atlanta, GA, USA

Synonyms

Cognitive therapy

Definition

Beck Therapy is a form of therapy developed by Aran T. Beck. Considered the father of cognitive therapy he has made unparalleled contributions to theory, psychotherapy and empirical research [12]. A core tenet of the therapy and the theory from which it derives is the notion that at the core of many common psychiatric disorders is dysfunctional or distorted thinking. Changing dysfunctional or distorted thinking is therefore a cornerstone of the therapy approach. Originally developed for use with depressive disorders, Beck Therapy has been used for anxiety disorders, substance use disorders, schizophrenia, personality disorders and medically related conditions. Beck Therapy has been incorporated into many cognitive behavior therapy approaches however the two are not synonymous.

Description

Theory

Building on the cognitive model that states that thoughts influence mood and behavior and that distorted or dysfunctional thinking is common to all psychiatric disturbances, Beck proposes that specific psychiatric disorders or diagnoses are associated with specific disturbances in thinking. Known as the content specificity hypothesis [1], disorder specific cognitive profiles have been generated for different disorders [2, 3, 4, 5]. In depressive disorders for example, themes of hopelessness and irreversible loss are present. In anxiety, themes of threat and vulnerability to harm are present. Key to the approach is specifying and understanding a number of cognitive phenomena that affect thought and behavior [6]. At the surface level, are automatic thoughts that are generated in specific situations and are actual words or images that go quickly through one's mind without reasoning. Some automatic thoughts are dysfunctional in that they distort reality and are associated with emotional distress and inability to achieve goals. Moreover Beck describes common errors in thinking detected in psychiatric disorders. Two of twelve such distortions identified include catastrophizing (assuming the worst will happen in the future) and all-or-nothing thinking (viewing a situation in two extreme categories rather than on a continuum) [6]. Automatic thoughts are derived from two deeper thought structures that operate outside of awareness unless specifically articulated: intermediate beliefs and core beliefs. Intermediate beliefs refer to rules, attitudes and assumptions. Core beliefs are absolutistic, rigid, central and global ideas about one and others. Intermediate beliefs are more accessible and modifiable than core beliefs. Core beliefs (or schema) develop in childhood about self, others and the world. They are largely negative in psychiatric populations and when activated, individuals find it difficult to process information that is not consistent with the core belief.

Therapy

Beck Therapy is considered a structured, goal-oriented, problem-focused and time-sensitive therapy. The therapist works from a continually evolving individualized cognitive conceptualization of the patient's difficulties. The cognitive conceptualization includes identification of current thinking that maintains problematic behaviors and emotions, identification of precipitating factors and, identification of developmental events and patient's enduring patterns of relating to these events that may be related to the presenting difficulties [6]. Therapists adopt an active, directive and collaborative style. Collaborative empiricism captures the practice of including the patient as an active participant in the therapy and that the therapist and patient form an equal working partnership [4, 6]. It also reflects the practice of ongoing evaluation of interventions and outcome by using both subjective and objective measures. Other important techniques include: (1) Socratic questioning – asking a client questions to elicit cognitive phenomena and to evaluate their validity, and (2) Guided discovery – a process through which patients are led to uncover underlying intermediate and core beliefs, followed by questioning whose goal is to evaluate the validity and functionality of beliefs [6].

Assessment Instruments

Ongoing assessment is an essential feature of Beck Therapy. For children, the Beck Youth Inventories of Social Impairment tap depression, anxiety, anger, disruptive behavior and self-concept [7].

Child Applications

Beck (cognitive) therapy has been adapted for use with children and its principles have been incorporated into a plethora of treatment models for treating disorders such as depression, anxiety, social phobia, and anger. Many

cognitive behavioral treatments incorporate the principles of cognitive therapy into their models. Therapy with children follows the foundational principles of the cognitive model, content-specificity hypothesis and the hierarchical structural organizational model of cognitive phenomena. Collaborative empiricism and guided discovery are also included. Therapy is also structured, goal-oriented, problem-focused, and time-sensitive. Not followed are developmentally incongruent tasks such as completion of thought records, reliance on talk only, rational analysis and disputation, and the completion of written homework. Treatment is likely to incorporate experiential methods such as games, drawings, stories, exercises, puppet and doll play, and the use of metaphors in rational analysis [9].

Relevance to Child Development

Child applications require attunement and adjustment to the cognitive developmental level of the child. The Beck model of treatment requires skills such as self-reflection, metacognition, consequential thinking, perspective-taking, understanding causality, reasoning and consideration of future possibilities [10, 11]. Children are still developing these skills so a role of the therapist can be to facilitate the development of these skills. Indeed, a model of child psychopathology consistent with cognitive deficit rather than distortion (the view from Beck's conceptualization) is more consistent with the current evidence [10]. Many practitioners offer modifications of cognitive therapy to be used in child therapy [9, 13]. DiGiuseppe [8], for example, notes that it is not until the Piagetian formal operational stage is achieved that one can expect a child to be capable of extensive rational analysis because it is at this stage that the child becomes capable of hypotheticodeductive reasoning. Between the ages of 7 and 11, or prior to the achievement of formal operations, the therapy must aim to restructure cognition through analyses of specific situations and use concrete examples. For children under seven, there is a need to rely less on verbally mediated instruction and means of conveying ideas, and more on concrete examples and representation materials such as use of pictures, diagrams, books and play. Although the literature shows that cognitive behavioral therapies that use adaptation of cognitive techniques with other methods are quite effective in treating a number of child problems, there is strong evidence to suggest that age and presumably cognitive developmental level plays a mediating role in the effectiveness of CBT [10]. Thus, older children are more likely to benefit from CBT however there is little support for the notion that it is more advanced cognitive skills that is the mechanism for behavior change [10]. Many studies do not examine or measure cognitive developmental level, many do not measure cognitive change and, many use age as a proxy for cognitive-developmental level [10, 11]. Moreover most treatments also use behavioral interventions as well. Much research remains to done, therefore, to understand the efficacy of use of cognitive interventions with children.

Bedwetting

Synonyms

Enuresis; Urinary incontinence

Definition

The loss of control of urine during sleep making the bed wet. Enuresis is the Greek explanation of to make water.

Description

Some children have no control of their bladder during the night and wet the bed. This can be stressful for the child and the parents. This has been an ongoing worry for parents because they expect the child to stay dry during the night. The aged adult sometimes experience enuresis during the night as well as teens.

Relevance to Childhood Development

Parents worry about their kid's bedwetting and need to be supportive and patient. There are various items on the market that help to wake a child when the child begins to wet. Another alternative is to take the child to the bathroom during the middle of the night. The child should be taught to take care of their bedding the next morning if they have wet the bed. This helps the child to be responsible and releases the child from any feelings of shame associated from bedwetting. Anger and intimidation can make the problem worse. Children at a young age can learn to use the washing machine. Punishment does not solve the problem for the child who has little control of their bladder at night. Some children who have developmental problems also have problems staying dry at night. Children who have had trauma or major change in their lives may also wet at night. Most children will outgrow the problem by age ten. This is has been an ongoing problem though out history in all cultures and in both genders. How many children, teens or adults have this problem is unclear because cause of the embarrassment it can brings so it may often not openly discussed.

Behavior

Steuart T. Watson, Dale Brown
Miami University (OH), Oxford, OH, USA

Synonyms

Action; Movement, Response

Definition

Behavior may be most broadly defined as any activity engaged in by living organisms. A useful test is the dead man's test, which states that if a dead man can "do" it, then it is not behavior. Conversely, if a dead man can't do it, it is probably behavior [1].

Description

Behavior is a living organism's act of "doing," which includes, but is not limited to, moving, speaking, thinking, imagining, and feeling. However, it is only an action that is produced by an individual organism. For instance, behavior does not include a movement if the movement was produced by a force external to the organism such as wind or a body of water. Definitions of behavior tend to focus on its external aspects, or those behaviors which have an effect on the external environment of the organism. The only way behavior can be measured, and therefore accurately observed is to measure the environmental changes that the behavior produced [2]. Even the simple act of moving a hand displaces air and changes how light reflects off of the hand as it moves, thus indicating to observers that the hand did in fact move. Internal behaviors such as thinking, feeling, perceiving, etc. are still considered behaviors, but because they do not have an observable and measurable effect on the environment, they tend to be de-emphasized in scientific definitions of behavior [3]. Observable dimensions of behavior include topography, or form, temporal locus (time of occurrence), temporal extent (duration of occurrence), repeatability (frequency of occurrence), and intensity (e.g., a punch vs. a light tap on the shoulder).

Behavior Assessment

Ivy Chong
Florida Institute of Technology, Melbourne, FL, USA

Synonyms

Behavioral assessment; Functional analysis; Functional assessment

Definition

Multimethod approach to gathering information about the occurrence and frequency of behaviors across multiple settings. May also include the process of determining the cause (or "function") of behavior before developing an intervention [1].

Description

Behavior assessment deals with both overt (clearly observable) and covert (internal events such as thoughts, feelings) behaviors and may include tests that measure general or specific behavior within educational, vocation, community, or home settings [1, 2]. Indirect methods such as checklists, rating scales, and surveys may be used to measure behavior of a target individual in relation to their adaptive skills, social skills, functional skills, and appropriateness or dysfunction within different settings and situations. Additionally, direct methods such as systematic observation of the individual in the setting may also be used to collect useful data on the cause of the behavior. A second direct method may be used, in which different environmental events are manipulated to see how behavior changes. Indirect methods and systematic observation are generally referred to as functional assessment, whereas the manipulation of environmental variables is generally referred to as a functional analysis. Various interviews and rating scales exist to attempt to get at the cause of behavior. However, reliability is usually poor and these should be used only as a starting point for systematic and direct observation of the person's behavior [2].

Behavior Assessment System for Children: Second Edition (BASC-2)

Jessica R. Gurley
Argosy University, Arlington, VA, USA

Synonyms

Parent report measures; Personality testing; Self-report measures; Teacher report measures

Definition

The Behavior Assessment System for Children: Second Edition is a series of instruments designed to help aid in the diagnosis and treatment of children, adolescents, and young adults between the ages of 2 and 25.

Description

The Behavior Assessment System for Children: Second Edition (BASC-2) is a series of instruments for children, adolescents, and young adults between the ages of 2 and 25. The BASC-2 system has Parent Rating Scales (PRS), Teacher Rating Scales (TRS), Self-Report of Personality (SRP and SPR-I), a Structured Developmental History (SDH), and a Student Observation System (SOS). The TRS, PRS, and SRP have multiple forms for different age groups. In addition to these forms, the BASC-2 has a Parenting Relationship Questionnaire (PRQ) that assesses the relationships between the child and his/her caregiver(s). The forms are available in English and in Spanish [1, 2].

The BASC-2 TRS and PRS were written to be at the sixth grade reading level and can be completed by the raters in under 20 minutes. The SRP was written at the second grade reading level and can be completed in approximately 30 minutes. On the BASC-2 TRS and PRS, teachers and parents rate how often the examinee's behavior and symptoms occur on a four point rating scale ranging from Never (N) to Always (A). On the BASC-2 SRP, examinees rate their behavior on the same four point rating scale, as true/false, or as yes/no, depending on the age group [1, 4].

Scales

The items on each form of the BASC-2 can be used to calculate a variety of scales designed to assess for adaptive functioning and for symptoms of psychopathology [3]. Additionally, each form contains validity indices that assess how the rater approached the test.

The items on the TRS and PRS can be used to calculate five composite scales: Adaptive Skills, a Behavioral Symptoms Index, Externalizing Problems, Internalizing Problems, and School Problems. The items can also be used to calculate 16 Clinical and Adaptive Scales and seven Content Scales. The Content Scales can only be calculated by using the scoring software and cannot be calculated by hand [1].

The items on the SRP can also be used to calculate five composite scales: The Emotional Symptoms Index, Inattention/Hyperactivity, Internalizing Problems, Personal Adjustment, and School Problems. In addition to these composite scales, the items on the SRP can be used to calculate 18 Clinical and Adaptive Scales and seven content scales [1].

Scoring

The BASC-2 can be scored either by hand in approximately 30 min or by using the ASSIST Plus software profile. The raw scores are transformed into T scores and percentiles [1, 2].

Psychometric Properties

The BASC-2 was standardized on samples from the United States between 2002 and 2004. The standardization samples for each of the instruments (TRS, PRS, and SRP) were large, ranging from 3,400 (SRP) to 4,800 (PRS). The sample used was representative of the population of the United States at the time of standardization for race, sex, geographic region, and parent's socioeconomic status. The internal consistency of the BASC-2 instruments is adequate ranges from 0.67 to 0.97. Similarly, the test-retest reliability is good, ranging from 0.56 to 0.99 [1].

Relevance to Childhood Development

The BASC-2 can be used to evaluate children for the presence of psychopathology.

Behavior Disorders

Alandra Weller-Clarke
Benedictine University, Lisle, IL, USA

Synonyms

Emotional and Behavioral Disorders (EBD); Emotional disturbance; Emotional Disturbances or Behavioral Disorders (ED/BD); Parent management training; Serious Emotional Disturbance (SED)

Definition

A disability characterized by behavioral or emotional responses that are not accepted by the norm and referent group and have adverse effects on educational performance.

Defining Behavior Disorders

For more than 50 years, emotional disturbance has been an umbrella term for a variety of behavior disorders, including schizophrenia, autism, phobias, withdrawal, antisocial behavior, psychosomatic disorders, depression, anxiety, elective mutism, and a host of other pathologies. The term behavior disorders is one used to classify abnormal, atypical, or deviant behavior. Other terms sometimes used interchangeably include impairment, handicapped, psychopathology, mental illness, or mental disorder. This

terminology variation reflects theoretical positions or can be in reference to particular professions, oftentimes in disagreement regarding assessment and treatment. In addition to the definitional problem of behavior disorders is a general reluctance to label individuals as behavior disordered, due to the high cost of treatment and/ or negative connotation in our society. Although both fields of education and psychology have made great strides in this area with awareness, public acceptance and treatment options, there still remains lack of consensus on definition and terminology [5].

The Federal Definition

The federal definition, used in IDEA '04 (Individual with Disability Education Act) uses the term *emotional disturbance* to describe students with emotional or behavior disorders, which is the special education category under which students whose behavioral or emotional responses are not typical are provided funding and special services. That term is described as a condition that "exhibits one or more of the following characteristics over a long period of time and to a marked degree that adversely affects a child's educational performance:

1. An inability to learn that cannot be explained by intellectual, sensory, or health factors
2. An inability to build or maintain satisfactory interpersonal relationships with peers and teachers
3. Inappropriate types of behavior or feelings under normal circumstances
4. A general pervasive mood of unhappiness or depression
5. A tendency to develop physical symptoms related to fears associated with personal or school problems

Emotional disturbance includes schizophrenia. The term does not apply to children who are socially maladjusted, unless it is determined that they have an emotional disturbance.

It is important to note that if a child fails to meet the above criteria, special education services will not be funded or provided in public schools" [1].

The National Mental Health and Special Education Coalition Definition

As the IDEA '04 term and definition were criticized by many professionals, 17 organizations came together and drafted another definition and continues to lobby federal and state governments to adopt it. The definition for *Emotional or Behavior Disorders* is as follows: "The term emotional or behavioral disorder means a disability characterized by behavioral or emotional responses in school so different from appropriate age, culture, or ethnic norms that they adversely affect educational performance. Educational performance includes academic, social, vocational, and personal skills. Such a disability:

1. Is more than temporary, expected response to stressful events in the environment
2. Is consistently exhibited in two different settings, at least on of which is school-related
3. Is unresponsive to direct intervention in general education, or the child's condition is such that general educational interventions would be insufficient

Emotional or behavioral disorders can coexist with other disabilities. This category may include children or youth with schizophrenic disorders, affective disorders, anxiety disorder, or other sustained disorders or adjustment when they adversely affect educational performance."

The term behavior disordered is often seen as less stigmatizing, less severe, more socially acceptable, and more practical than other terms. Still, emotionally disturbed and behaviorally disordered are used interchangeably in keeping with popular usage, but emotional behavior disorders (EBD) is the term of choice in the field of education [2].

Description

Common Characteristics of Students with Behavior Disorders

Children and adolescents with behavior disorders can be divided into three groups:

1. Externalizing behaviors
2. Internalizing behaviors
3. Low incidence behaviors

Externalizing behaviors constitute an acting-out style that could be described as aggressive, impulsive, and noncompliant. Some examples of this include hyperactivity, aggression, and delinquency. Internalizing behaviors are more typical of a style that appears withdrawn, lonely, depressed and anxious. Some examples of this include anorexia or bulimia, depression or anxiety. Low incidence disorders are those that occur infrequently but are serious when they do occur. Schizophrenia, for example, can include bizarre delusions and dissociation from reality and incoherence [7].

Demographics

The typical population that has been diagnosed as having a behavior disorder is predominately male, likely to be African American, and between the ages of 8 and 17 years old. These students are often over 13 year old when they

are identified and come from families that report an annual income of less than $12,000. About 44% come from single parent homes. Student with behavior disorders are more likely to be educated in restrictive settings including self-contained classrooms, separate schools, residential facilitates, and hospital environments [3].

Social Skills

Students with behavior disorders are typically less socially skilled than their peers. Their impulsivity, poor interpersonal skills with both peers and adults are typical reasons for their referral to special education. These children's behavior patterns are oftentimes self-defeating and are likely to include tantrums, aggression, coercion, noncompliance, and poor academic achievement. Early intervention is the key to instruction for social skills, and should be embedded in the general education curriculum.

Academic Performance

Regardless of intellectual potential, children with behavior disorders typically do not perform as well as their peers academically. They are often referred to as underachievers and unmotivated. They are more likely to drop out of school than their general education classmates and more likely to become delinquent. Once in the criminal justice system, they are less likely to receive necessary support and services, thus enabling their frustration to manifest more behavior problems [4].

Causes

The reasons why problems arise in children are usually difficult to identify, and the disability is likely to be the result of several and overlapping variables. Five popular models that contribute to the explanation of how behavior disorders occur include the biophysical model, psychodynamic model, cognitive model, the behavioral model, and the ecological/systems model [8].

Prevention and Treatment

Prevention and treatment of behavior disorders can be accomplished in many ways. From a school's perspective, the most effective approach is to create a school culture where positive behavior support, social skills instruction, and consistency serve as direct intervention. Programs that apply functional behavior assessments to determine the cause of the behavior and help identify actions that will effectively remediate patterns are the most successful. Behavior intervention plans can be most helpful when educators are designing individualized instruction for students. In addition, programs that focus on children's strengths, rather than their deficits and teach from a wellness perspective have much higher results in achieving success for this particular population.

Relevance to Childhood Development

Exactly what constitutes behavior disorders reflects societal standards for behavior and expectations about the development of children. Many behaviors that our society labels as disordered in a particular child might be acceptable if that child were a different age, lived in another society, came from a different culture, or behaved under different circumstances. Early screening and evidenced-based interventions with children with behavior disorders is critical to avoid the negative outcomes awaiting these children in the absence of effective instruction and support [6].

Behavior Modeling

Judith Husband, Ivy Chong
Florida Institute of Technology, Melbourne, FL, USA

Synonyms

Copying; Demonstrating; Imitation training; Observational learning

Definition

Teaching by demonstrating a response and a consequence.

Description

Social learning theory, specifically the work of Albert Bandura provides the foundation for behavior modeling. In behavior modeling, an individual can learn new behaviors by observing. The correct behavior is demonstrated for the learner, the learner observes the model, and then imitates the behavior of the model [1]. For modeling to be most effective the learner must demonstrate attending and imitative skills in their repertoire; that is, the learner must be able to pay attention and perform the behavior that the model just demonstrated. Modeling is an easy, practical, and successful way of teaching.

Behavior modeling can be effective for both simple and complex behaviors. The behavior should be modeled in many ways, in a variety of situations, and as many times necessary for the learner to imitate the behavior correctly. Finally, if the model is of high status, resembles the observer/ learner and there are successful outcomes for the model (i.e., reinforcement delivered for the behavior), the learner is more likely to imitate the behavior [2, 3].

Behavior Modification

Jason Levi
Psychologist, Winston Salem, NC, USA

Synonyms

Behavior analysis; Behavior change; Behavior therapy

Definition

Behavior modification is the use of empirical techniques to assess, evaluate, and change behaviors.

Description

During the Behaviorist movement, behaviors were thought to be a result of learned responses to environmental stimuli. Research on humans and animals was conducted to examine how behavior develops and changes over time with the use of modification techniques [2]. Behavioral modification techniques have since become an effective means to evaluate and modify behaviors. These techniques are not only used by psychologists in private practice but also in everyday life settings, such as hospitals, schools, businesses, and private practice [2, 4].

Early attempts at behavior modification were done with animals and primarily involved pairing environmental stimuli (i.e., sounds, smells) with physiological reflexes. The earliest and most noted example of classical conditioning is of Pavlov's dog. Ivan Pavlov was able to elicit a salivary response from dogs by pairing the presence of food with a loud noise, therefore creating a learned response from the dog when exposed to particular stimuli [6].

Research conducted by E.L. Thorndike and later by B.F. Skinner demonstrated that behavior could be shaped not only by pairing stimuli with physiological reflexes, but also with consequences to behavior [6]. This process is termed Operate Conditioning, implying that behaviors can be function of environmental stimuli. There are several consequences associated with Operate Conditioning: Reinforcement, Punishment, and Extinction. Reinforcement techniques can be either positive or negative. A positive reinforcement occurs when something is awarded as a consequence of a particular behavior, thus increasing the chance that the behavior will occur again. A negative reinforcement occurs when something is taken away as a consequence, also increasing a particular behavior. Punishment is different from reinforcement because it is concerned with decreasing rather than increasing behaviors [2, 4]. Extinction is different from reinforcement because it does not involve the use of consequences. When a behavior is neither followed by a positive or negative consequence, the frequency of that behavior will decrease, such as ignoring particular behaviors [4].

Albert Bandura found that behavior could also be modified through observational learning or by simply watching others. Children in his study watched physical and verbal aggression and were, in turn, more likely to engage in similar aggressive acts. Boys in his study were more aggression to dolls than girls [1]. Therefore, children in his study learned aggressive behavior simply by watching others.

The most effective way of modifying behaviors involves functionally analyzing behaviors. A functional analysis refers to identifying and defining, assessing, measuring, and evaluating behaviors. One must identify target behaviors, specifically defining those behaviors in a way that can be easily measured, then assessing for such characteristics as frequency, duration and consistency [5].

Assessment also involves determining what factors might be influencing the behaviors [4]. Empirical techniques, such as reinforcements, punishments, modeling, and shaping, may be used to modify existing behaviors or increase desired behaviors. The target behaviors are then measured to determine if the empirical techniques had an influence on the behaviors [2, 4]. An evaluation answers the question: Did the techniques used have an impact on the target behaviors?

When studying behaviors, it is important to consider reinforcement contingencies: Antecendents, Behaviors, and Consequences, often referred to as the ABCs of behavior modification. They are often used with programs to help change or modify behaviors. These contingencies can be used to better understand target behaviors (e.g., what happens before a behavior and after the occurrence of a behavior). Specifically, it is important to understand a particular behavior in terms of what may be increasing or decreasing the likelihood of that behavior. Antecedents refer to the setting or what is going on prior to a behavior that may be creating a situation to reinforce the behavior, such as prompting behaviors by giving instructions or requests. Consequences refer to the responses from the behavior that may also be reinforcing [2].

There are several assessment procedures that can be used to help measure behaviors: Indirect, direct, and experimental procedures. Indirect procedures consist of less empirical assessment and rely more on others' perceptions [4]. Information about particular behaviors can be obtained from interviews, informal observations, and questionnaires. Direct procedures are a more formal means of obtaining information from others. Information can be gathered through the use of formal observations. Specific behaviors are defined and require observers to monitor target behaviors. Formal observations can involve the use of documenting such characteristics of the behaviors as frequency and duration [4]. Experimental procedures are a means to determine whether particular antecedents or consequences of the target behaviors influence them. After these techniques, an evaluation is conducted to determine if the empirical techniques made an impact on the target behaviors [4].

Once an assessment has been conducted, it is important to determine whether the empirical technique(s) had an impact on the target behavior(s). This is usually done by comparing baseline data with intervention data, that is comparing characteristics about the behavior (frequency, duration) with the data collected after implementation of behavior modification techniques [4]. If the difference between the data is greater than expected by chance, one can say that the empirical techniques made the difference. In other words, the behavior changed is likely due to the techniques used.

Relevance to Childhood Development

Before entering school, children are taught at home by parents. Parents, therefore, have the initial responsibility to shape their child's behavior and to how interact with others in the world [4]. Behavioral modification skills have been taught to parents to more effectively teach their children developmental milestones, such as language use, fine and gross motor use and socializing with others.

Beginning in the 1960s, schools have increasingly applied behavior modification techniques for classroom management. Schools have adopted a system called Positive Behavior Support to help understand the context of student behaviors. For example, this system has been used to help teachers with classroom management and to better develop school work habits with students. These applications have particularly been successful with students with learning problems or inappropriate school behaviors [4]. Typically, observations are conducted in the environment in which the student is having some trouble, then application of empirical techniques, such as schedules of reinforcement, punishment, or extinction, are used to modify identified problem behaviors.

Behavior modification has also been used to help management and teach students with more severe developmental problems, such as Autism and those identified with significantly lower intellectual ability [4]. Programs have been used to teach everyday functional skills (e.g., dressing, brushing teeth) and with pro-social skills (e.g., eye contact, playing with others). Further, behavior modification techniques have been used to teach vocational and more academic related skills as well [4]. Behavioral therapy for a wide array of developmental disabilities and disorders has been found to be an effective means of treatment.

Behavior Rating Scale

Robert Walrath
Rivier College, Nashua, NH, USA

Definition

An assessment instrument designed to obtain the perceptions or judgments of a subject's behavior in a standardized format. Rater's may be the subject (self-rating) or others with the opportunity to observe and describe aspects of the subject's behavior (i.e., parents, teachers, etc.) [2].

Description

Behavior rating scales are often used as screening devices to obtain information on and help to identify individuals who may benefit from a more detailed assessment or who may be at risk for developing more serious problem and who may benefit from early interventions. Behavior Rating Scales are also used to monitor progress in treatment programs [1]. Behavior Rating Scales should never be utilized as the sole source of information for the purposes of diagnosis or classification of a specific educational or psychological problem.

Behavior Rating Scales are described as "narrow band" if designed to measure a specific behavior or attribute and "broad band" if designed to measure multiple behavioral and emotional attributes simultaneously [4]. Many rating scales have different forms for self, parent, caregiver or teacher ratings.

Behavior Rating Scales are cost effective tools to obtain information from various informants in a cost effective way, and are widely accepted. Reliability and validity vary across the many rating scales available, but are typically acceptable. Limitations of rating scales include the potential for rater bias [2], as well as the concept that ratings scales are a "slice of time" measurement and therefore subject to some variability based on external factors of both the rater and the subject.

Behavior Therapy

Steuart T. Watson, Tonya S. Watson
Miami University (OH), Oxford, OH, USA

Synonyms

Behavior modification

Definition

Behavior therapy refers to both a therapeutic process and a set of techniques that are based on operant and respondent conditioning.

Description

Behavior therapy began in the early 1950s as an alternative to the mentalistic (psychodynamic) approaches that dominated psychology. Based on research from both operant and respondent conditioning, it is more about a theoretical approach to understanding human behavior and a commitment to scientific methodology than a mere set of therapy techniques. The term "behavior therapy" is credited to three researchers: Ogden Lindsley in 1953, Arnold Lazarus in 1958, and Hans Eysenck in 1959 [1]. It is distinguished from other forms of therapy by five primary characteristics: (1) focus on the current, as opposed to historical, influences on behavior, (2) emphasis on using overt behavior change as the ultimate determinant of treatment progress/success, (3) clear specification of treatment procedures to foster replication, (4) reliance on empirical research for selecting treatment procedures, and (5) clear specification in defining, measuring, and treating target populations [1]. Behavior therapy is used for individuals, couples, groups, and families experiencing a wide range of problems (e.g., childhood noncompliance, phobias/fears, enuresis, marital relationship difficulties, sexual dysfunctions, aggression, headaches/ stomachaches, social skills, and impulsivity).

The focus in behavior therapy is on eliminating maladaptive behaviors and replacing them with more adaptive

and socially appropriate responses. This is accomplished by identifying the conditions under which the behavior occurs and the consequences that reinforce the maladaptive behavior. A number of empirically validated treatments are used within a behavior therapy model including systematic desensitization, modeling, rehearsal, behavioral skills training, anxiety management training, and biofeedback, to name a few [3].

Relevance to Childhood Development

Most models of counseling/therapy focus on talk as the mechanism of change. For children and adolescents, the research consistently indicates that the counseling/therapy approach must be much more concrete, active, and with less focus on talk and working through "issues" or past history. Behavior therapy takes a more active approach by focusing on selecting specific target behaviors, identifying replacement behaviors, teaching new behaviors, and helping the child use their skills/behavior in the environment where those behaviors are needed. The ultimate criterion of success in behavior therapy is whether or not the child is mastering and using their new skills at the right time in the right place [2].

Behavioral Assessment

►Behavior Assessment

Behavioral Consultation

Danielle R. Palmer, Andy V. Pham, John S. Carlson
Michigan State University, East Lansing, MI, USA

Synonyms

Eco-behavioral consultation; Problem-solving consultation; Solution-oriented consultation

Definition

Behavioral consultation is described as a multi-step problem solving process that provides indirect service delivery to a client. This triadic relationship is facilitated through a consultant-consultee relationship in which the consultant works to change the client's behavior by empowering the consultee with skills for future problem solving.

Description

Behavioral consultation emerged in the 1970s and is now considered an integral part of school-based practice. Within the school system, the consultant is typically the school psychologist while the client is the student. The consultee is typically a teacher or parent who works directly with the student (i.e., client). The earlier models of behavioral consultation drew on the operant learning theory as its theoretical basis. This theoretical foundation remained at the core for years with an underlying assumption that the consultant led the consultation process by using specific interviewing techniques and reinforcing the consultee for their desired responses and/or behaviors [2]. Currently, behavioral consultation can be carried out in many forms [1].

Behavioral consultation is structured around a series of five stages that focus on problem-solving. These five stages include: (1) developing a relationship between the consultant and consultee, (2) problem identification, (3) problem analysis, (4) plan implementation, and (5) plan evaluation. These five steps are integral parts of the behavior consultation model that produces the client's change in behavior. Although the five steps are outlined in a specific order, they tend to overlap with one another and do not always occur in the exact order [4]. In order for the steps to be carried out successfully, a strong working relationship between the consultant and the consultee must be established.

Building a Strong Relationship

One of the most important steps of a successful consultation is a good working relationship between the consultant and consultee. Positive working relationships help decrease resistance to the consultation process and intervention implementation, increase the probability that consultees with follow through with the intervention, and in turn increase the effectiveness of the process for the client. When the consultant and the consultee meet for the first time each participant works to become more familiar with one another through conversation. The goal of this is to create a safe and judgment free relationship in which both parties have a mutual respect for one another and feel their opinion and expertise is valued [5].

During this stage it is also recommended that the consultant and consultee create a "working contract" that defines the roles and responsibilities of all parties throughout the consultation as well as the various activities that will take place during the consultation.

Problem Identification

This stage is dedicated to describing the problem in clear, concise, complete, and measurable terms. The consultant uses various interviewing techniques such as questioning, paraphrasing, and clarifying questions to allow the consultee to operationally define the child's behavior. Often, consultees provide vague descriptions of the presenting behavior and need the consultant to help them think about the problem in a concrete manner. Providing a description of a specific and observable behavior allows for ease in data collection during the next step of the problem identification phase: baseline data collection. The consultee collects baseline data on the presenting behavior to determine if a discrepancy exists between the child's current level of behavior and the expected level of behavior. Once a discrepancy is noted through reliable data collection, the consultant and consultee work together to identify underlying factors that may be contributing the occurrence of the observed behavior.

Problem Analysis

During this stage, baseline data collected from the Problem Identification stage is reviewed. This analysis provides an in depth look at factors that may be contributing to the child's behavior. The collected data will provide information about when and how frequently the behavior occurs. Also, it provides information about behavioral patterns that help identify antecedents and/or consequences that are possibly maintaining the behavior. These factors are then manipulated through intervention to improve the target behavior. In the classroom, environmental as well as instructional variables should be identified for analysis. This process helps to refine, and in some instances, alter the definition of the target behavior. The information gathered in this stage of the behavioral consultation helps to determine the intervention that will be implemented to address these underlying functions of behavior.

Plan Implementation

This is the stage in which the most appropriate intervention is selected and implemented by the consultee. It is important to design an intervention that is feasible to carry out and to consider the roles, resources, and training needed to implement the intervention. The selection and design of an intervention are often based on empirically supported theories and methods [3]. Data are routinely collected throughout the intervention phase as a means to evaluate the effectiveness of the intervention and whether the intervention is implemented as planned. Intervention implementation can take several weeks. During this time the consultee remains in frequent contact with the consultant for questions and concerns throughout this stage. Consultees may have questions about the implementation plan or encounter unforeseen challenges and/or effects of the intervention that may need immediate attention.

Plan Evaluation

This final stage of the behavioral consultation model is aimed at determining the success of the intervention plan as well as determining the level of satisfaction of the consultee. A successful behavioral consultation is indicated when there is a reduction in the discrepancy between the child's current level of functioning and the desired level of functioning. This would indicate that behavioral or social competency skills of the child were gained and/or skills and behaviors of the teacher were changed. This change in behavior should be maintained over time and generalize across multiple settings. Evidence of the above mentioned criteria may lead to the termination of a consultative relationship. At this time, a maintenance plan is put into place to ensure that the behavior is maintained once the behavioral consultation has ended.

Relevance to Childhood Development

Behavioral consultation is a practice that is becoming increasingly popular in today's school systems. This indirect service delivery approach provides teachers with the skills and self-efficacy to work with the most challenging students. The classroom is becoming progressively more diverse requiring teachers to work with students of various social-economic and cultural backgrounds, as well as disabilities. These factors coupled with typical childhood development could create a wide array of behavioral and academic challenges within the school setting. Behavioral consultants work closely with teachers to help them operationally define behavior and develop better data-based decision-making skills. Teachers gain knowledge and skills which allow them to work more effectively with the entire student population.

Behavioral Observation

Jennifer L. Stapel-Wax
Argosy University/Atlanta, Atlanta, GA, USA

Synonyms

Assessment observations; Observations; Test observations

Definition

Behavioral observation is a broad term referring to a wide range of formal and informal techniques used by clinicians and researchers to document the behaviors of their clients and subjects. Often the term is used to describe behaviors that are observed during the course of an assessment. It also refers to observations made in other settings such as at home, work or school. Overall, the purpose of behavioral observations is to facilitate an accurate description and understanding of the client [2].

Description

Behavioral observations are building blocks that contribute to the foundation of clinical assessments. Observations are routinely collected as a part of a formal and structured psychological assessment process or as a component of a clinical assessment of behavior. Observations can be collected in numerous ways and in several settings [1, 3, 5].

In the most widely used definition of the term, behavioral observation refers to behaviors collected during a testing session that are crucial in the hypothesis testing that may help explain the performance of a child. Detailed observation often makes interpretation of quantitative test scores easier and can provide rich clinical data. Additionally, detailing the trends of observable behaviors allows the clinician to generalize across situations and times [4, 5].

Assessment behavioral observations often examine a broad range of variables that are observable to the examiner including a description of the examinee, their mental status, and the attitude of the examinee toward the examiner and the test situation. Readily observable behaviors that address sensory and motor abilities are also documented by attending to vision and hearing abilities and gross and fine motor skills. Behaviors that impact the testing may also include the examinee's activity level, attention/concentration, motivation and effort, persistence and tolerance for frustration. Communication and speech-language abilities as well as social emotional behaviors such as eye contact, affect, reaction to praise and encouragement and self confidence are all noteworthy. In some evaluations, more detailed observations about the problem solving strategies of the examinee are collected and used in generating a hypothesis about their functioning [4].

When a formal psychological assessment is being done, the clinician can often observe the child in several settings and situations to collect data on which to base their hypotheses. The waiting room behavior of the parent/caregiver and child as well as the behavior of both with a sibling can often provide meaningful information about variables such as family relationships, parenting strategies and parent-child

or child-sibling conflict. Similar behaviors may also be observed during breaks from testing. The clinician will also routinely observe the child during the assessment in structured and unstructured situations for behaviors that provide insight into the child's functioning [4].

In psychological, neuropsychological and psychoeducational reports, behavioral observations are a significant section of the report. The purpose of this section is to describe and interpret the behavior of the client with a focus on the presence of behaviors and what the specific behaviors may suggest about the child, the task, or the setting [4].

In documenting behavioral observations, examiners can use structured behavioral observation procedures as well as informal or formal assessment tools. For observing children in a natural setting, there are numerous formal and informal observation procedures to be utilized. Observational methods can provide for a systematic observation of behavior. In this case, the clinician will observe a child's behavior in a natural or specifically designed setting, and record or classify each behavior objectively. This data is analyzed for reliability and validity and converted into quantitative information. This is often done through operationally defining target behaviors to provide more accurate observations. Variables to consider are whether observations will be conducted in a sequence, what the period of observation will be, how to account for special, possibly low incidence occurrences, and preparation for unexpected situations [1, 3].

Observations can be an easily applied and effective assessment method. The planned incident procedure allows the clinician to conduct observations in a controlled situation while an ecological assessment focuses on the physical and psychological aspects of the situation. Home observations may allow the clinician to observe both the physical home environment as well as the functioning of the family within the home.

Recoding of data can occur in several distinct ways and can be selected based on the setting, the frequency and intensity of the behavior and the time frame chosen for observations. Narrative or anecdotal recording refers to the clinician keeping a running record of the child's behavior without the requirement of a time frame or category of behavior. An interval recording allows the clinician to do time and/or interval sampling. In this form of behavioral observation, the clinician samples the presence, frequency and intensity of behavior in specific observation segments. There are various techniques that can be utilized using time and/or interval sampling.

Event recording is a behavioral observation technique in which each instance of the behavior in an observation period is noted. Finally, ratings recording dictate that the clinician rates the behavior on a scale or checklist that documents the degree to which the attribute was observed [1, 3, 5].

Relevance to Childhood Development

Behavioral observations provide valuable qualitative and in some case quantitative details about how a child reacts to specific stimuli, settings and situations. This information often provides evidence of typical or atypical development of the child. Often the behaviors manifested by the child provide the clinician with valuable insight into the etiology of problems and/or provide specifically strong skills that are useful for the remediation of more challenging areas.

Behaviorism

Synonyms

Learning

Behaviorism is a philosophy of psychology built upon the proposition that everything an organism does including

acting, thinking and feeling should be thought of as behavior. This school of psychology maintains that all behaviors can be described scientifically without relying on internal physiological events or hypothetical constructs such as the mind. Behaviorism posits that there are no philosophical differences between publicly observable phenomena such as actions and privately observable processes such as thinking or feeling.

The behavioral school of psychology began in the early 19th century with the work of Ivan Pavlov investigating classical conditioning, Edward Thorndike, and John B. Watson. These researchers rejected introspective methods and sought to restrict psychology only to experimental and observable methods. Behaviorism is best associated with the writings and work of B. F. Skinner. His primary work involved operant conditioning.

In the second half of the 20th century behaviorism lost favor to the cognitive school. These two schools of psychological thought however have complimented each other well particularly in clinical areas. The most popular psychological treatment today is referred to as cognitive behavioral therapy (CBT). CBT involves the application of behavioral theory along with efforts to change thoughts and feelings as a means of motivating behavioral change.

Bender Visual Motor Gestalt Test

Robert Walrath
Rivier College, Nashua, NH, USA

Synonyms

Bender Gestalt Test (BGT); Bender Gestalt II

Definition

A standardized, brief, nonverbal perceptual-motor, neuropsychological assessment technique consisting of nine figures presented to a subject one at a time, with the directions to copy the figures on a blank piece of paper. The Bender Gestalt II (2003) adds seven new stimulus cards, scoring procedures to obtain standard scores (see below), and a Motor Test and a Performance Test.

Description

Developed by Lauretta Bender in 1938 to study the role of perception in psychopathology [1], the Bender Gestalt Test is one of the more widely used tests in psychology. Variously described as a test of visual-motor integration, visuospatial skills, and perceptual-motor test, the Bender has been used in numerous clinical setting across all ages. Uses have including, screening for brain impairment, as a projective personality assessment technique, and as part of an in-depth neuropsychological examination.

Numerous scoring systems for the Bender Gestalt Test have been developed, most notable by Koppitz [4], Pascal and Suttell [6], and Hutt and Briskin [3]. Brannigan and Decker [2] in the latest revision to the Bender Gestalt Test (Bender Gestalt II) have developed a Global Scoring System yielding *T*-scores, percentile ranks, confidence intervals, reproductive quality and recall of designs.

While research has shown the BGT to correlate well with other neuropsychology measures and in differentiating patients with psychiatric problems from those with neuropsychiatric problems [5], criticism have centered on validity issues related with research hampered by use of competing scoring systems, small sample sizes, and varying populations.

Bereavement

Morgan Brooks
Niagara University Academic Complex, Niagara, NY, USA

Synonyms

Affliction; Deprivation; Distress; Misfortune; Mourning; Sorrow; Tribulation

Definition

State of sorrow over the death or loss of a loved one.

Description

Bereavement has typically been associated with the loss of a loved one through death. While many researchers have studied bereavement through multiple lenses, the stages associated with bereavement proposed by Kubler-Ross [2] have remained the seminal framework. The five stages of bereavement are: (a) denial, (b) anger, (c) bargaining, (d) depression, and (e) acceptance What has changed regarding the stages of bereavement is the notion that the stages occur in a explicit order and that people remain in each stage through completion as originally asserted by Kubler-Ross . It is unknown why people go through stages of bereavement or grief in unique orders or why they often come back to stages they have already visited. It is also now thought that a true acceptance may never be fully achieved for many. A common misconception regarding bereavement is that there is a normative length of in which an individual should resolve a given stage or finally reach acceptance. Rather, bereavement is a process that is unique for individuals and is confounded by other variables such as the effects of suffering multiple losses and individual's ability to cope with certain types of losses. Though everyone ultimately experiences bereavement, it remains one of the most misunderstood aspects of life.

Relevance to Childhood Development

During early and middle childhood, children develop a conscious awareness of death [5]. The concepts to be mastered are multifaceted and include: (a) death is irreversible, (b) death is the end result for all living things, and (c) after death all bodily functions cease [6]. How children grasp death and loss can further be broken down into age groups. Before the age of 2, though they may not have the words to express how they feel, children may show bereavement through crying, looking for the person who is now gone, or becoming withdrawn. From the ages of 2–5, children's behavior may regress and they tend to ask the same questions time and again. These children seem to need clear and concrete answers to their questions. When children are between the ages of 5 and 9, they begin to understand the irreversibility of death. This may be shown through questions about mortality. When children are between the ages of 9–13, friends are especially important, and they may feel different from their friends due to their loss. These children seem to understand the long-term consequences of the loss and may show an increased level of distress. Finally, adolescents find their peer groups and trusted adults to be especially important during their period of grief and may reveal emotional distress by withdrawing or engaging in risk-taking behavior [3].

It takes time and maturity for children to fully grasp what death means on both an intellectual and emotional level [7]. Further, when the death experienced is that of a loved one, children often have heightened fears about what has taken place and what they may expect in the future [1]. This may be especially difficult for adolescents who are struggling to deal with the concept of their own mortality. Also, death can be even more difficult for children to handle when parental figures do not know how to talk to their children about what has happened [4]. One example of this is when a parental figure tells a child that the person who died has "gone away" or is "sleeping" for a very long time. The same confusion can occur when children are told that a loved one went to the hospital to die. These messages are often confusing to young children and can lead the children to believe that the same thing may happen to them if they, for example, go on a trip, go

to sleep, or have to go to the hospital themselves. When addressing bereaved children and adolescents, it is essential to provide developmentally appropriate information that assists the child in making sense of their experience. Also, it is acceptable, and may even be helpful, for parents to show grief in the presence of their children. Though some parents fear this will create negative feelings in children, it can indeed help to normalize the feelings they are already experiencing. Further, parents are often distressed by children and adolescents' behavior during a time of grief and loss. For example, it is not uncommon for children and adolescents to be upset 1 min and want to go out and play the next, yet parents may be confused and worried by this behavior [3].

In summary, practitioners need to be knowledgeable about the grief cycle and understand that individual variations are expected. Each individual will go through the stages of grief at different rates in different orders and will reach acceptance at different times. The central tenet to therapeutic support is to help people understand that their emotional reactions to loss are normal and to encourage positive coping strategies. Working directly with the families of bereaved children and adolescents can ensure that they have information on bereavement that is vital to helping them to best help their loved ones.

Bias, Race

Stacy A. S. Williams
State University of New York at Albany, Albany, NY, USA

Synonyms

Prejudice; Unfairness

Definition

Racial bias is a personal and sometimes unreasoned judgment made solely on an individual's race.

Description

Biases affect the way we think, our attitudes and how we interact with those around us. Biases are based on the sum of our socialization experiences. They operate at both the conscious and the unconscious levels and in many cases are rooted in stereotypes and prejudices. A stereotype is a distorted or faulty observation based on a prejudgment of habits, traits, abilities or expectations of a specific group or individual. While many White Americans consider themselves to be unbiased in their interactions with people of color, 90% continue to link Blacks with negative traits. It is this association that creates the foundation for racial bias [3].

The term race, though a socially defined construct, is in actuality an anthropological concept often used to classify people according to physical characteristics, such as skin color, hair texture, eye color, facial features, and shape of head. As a classification system, no value judgment is ascribed to group differences. However, as a socially defined construct, race is often used as an "unjust, invalid standard upon which to generalize and draw conclusions about any one person or group of people" ([5], p. 9). Thus, the construct of race affords dominance and allocation of resources to one group to the detriment of the other. Singleton and Linton argue that what affects our relationships with each other is how we live race in America rather than what race means [5].

American history is steeped in the historical and moral ramifications of biases in relation to race. To understand racial bias is to study the history of race relations in the United States. While the definition of race is historically bound to physical features, the intermarriage and

immigration history of newcomers tend to invalidate classification and thus the allocations of resources to individuals based solely on physical characteristics. For example, how does one classify a mullato from the Dominican Republic using America's race classification system? Regardless of the complexity, American society continues to classify and allocate resources based on the Black/White dichotomy.

The Black/White Dichotomy

The Black/White dichotomy in the United States has had a long and rocky history dating back to the arrival of Northern and Western European settlers in the 1600s. This period was marked by attempts to exterminate the native population and the enslavement of Africans. The emerging social order elevated the status of Whites and subjugated that of non-Whites. White-skinned ethnic newcomers were encouraged to acculturate and assimilate to the dominant White structure. Whiteness was afforded a position of privilege and with it came full rights of citizenship. To further cement the great divide between the groups, non-Whites, especially enslaved Blacks were considered to be subhuman and were denied basic human rights. In fact, during slavery, the Constitution originally defined Blacks as three fifths of a person and stated it was illegal to educate them [7]. In the late 1800s it became evident to non-White immigrants that the meaningful classification in the United States was White and Black. Hence, Chinese, Japanese, Arabs, and Armenians, to name a few, have strived for the label of Whiteness in seeking to enjoy political, social, and economic benefits [4].

In the twentieth century, government sponsored privilege programs for Whites further widened the gap. For example, in Brodkin's essay on how the Jews became White, she documented how government sponsored GI bills enabled Jews to educate themselves and purchase homes in the suburbs in pursuit of whiteness. In addition, government sponsored programs provided loans to Whites, enabling them to move out of the low income neighborhoods and purchase homes in the suburbs, taking much needed capital out of urban communities. Additionally, she noted that the GI benefits provided educational and occupational opportunities to White males and were not extended to African Americans or women of any race [1]. Hence, it was against the backdrop of wartime racism and postwar sexism that shaped White male privilege [1].

Biases

As suggested earlier, racial bias is rooted in stereotype and prejudice. It is the belief and the enactment of beliefs that one set of characteristics or qualities is better or superior than another. Someone who interacts differently with one from another race, whether unconsciously or intentionally but based on racial differences, is said to be racist. The systematic allocation of resources to one group over the other is called racism. Singleton and Linton quote Pine and Hilliard who define racism as "the combination of individual prejudice and individual discrimination, on the one hand, and institutional policies and practices, on the other, that result in unjustified negative treatment and subordination of members of a racial or ethnic group. By convention, the term racism has been reserved to describe the mistreatment of members of racial and ethnic groups that have experienced a history of discrimination" ([4], p. 40).

While institutional biases may be easier to identify, individual biases tend to be more covert. Due to the advent of political correctness, researchers believe that overt racism has been replaced by a more subtle and ambiguous form of expression (i.e., aversive racism) [6]. Therefore, aversive racism theory contends that bias is the result of White people's ambivalent attitudes toward Blacks. This theory stipulates that although Whites believe in equality and fair play, they continue to have negative attitudes about Blacks that lead them to discriminate under certain conditions [2]. For example, in a recent study of racial bias in emergency medical situations, the researchers noted that as the need for medical attention increased, the speed and quality of help that White participants gave to Black victims relative to White victims decreased. In addition, White individuals interpreted a situation involving a Black victim as less severe and themselves as less responsible to help Black victims compared to White victims [2].

Biases have also been noted in education as numerous studies have documented the relationship between teacher expectations and student performance. In a recent meta-analysis investigating whether teacher's expectations differed based on group membership, researchers noted that teachers had more positive expectations, made more positive referrals, provided fewer negative referrals, and provided more positive speech for European American children than for African American or Latino/a children. In addition, teachers held higher expectations for Asian American students compared to European American children. Furthermore, teachers were less likely to refer students of color to gifted programs and more likely to refer them to special education programs [8].

In summary, racial biases are steeped in stereotypes and prejudices. They facilitate our interactions at the conscious and unconscious levels and are a byproduct of

our socialization experiences. It is the differential treatment of individuals based on faulty observations. In order to combat biases, we need to begin to unpack the privileges that are associated with the Black/White dichotomy.

Bibliopsychology

▶Bibliotherapy

Bibliotherapy

Susanne Long
University of Florida, Gainesville, FL, USA

Synonyms

Bibliocounseling; Bibliopsychology; Book matching; Library therapeutics; Literatherapy

Definition

Bibliotherapy refers to the therapeutic use of books to help people cope with life changes, emotional difficulties, or mental illnesses. The purpose of bibliotherapy is to promote healing by providing guidance for solving personal problems through the use of books that are relevant to people's life situations and needs. Bibliotherapy is used to change affect and behavior, promote the development of coping skills, and enhance one's self-awareness and understanding through literature.

Description

History

The use of books as a treatment modality has a unique and long history. Some trace its origins as far back to the ancient Greek times, as seen by the inscription "The medicine chest of the soul" above the library door of Thebes. However, bibliotherapy did not start to gain recognition in the United States until the mid-1800s, when Benjamin Rush, MD, and John Minson Galt II, MD, incorporated books into their patients' treatment plans. In the 1920s, Sadie Peterson Delaney, the chief librarian of the United States Veterans Administration Hospital, used books to help with the treatment of African American war veterans who were experiencing psychological and physical difficulties. Dr. William C. Menninger, a renowned psychiatrist, also helped establish bibliotherapy as a form of treatment during the 1930s in his Kansas clinic. In 1941, bibliotherapy gained additional recognition when it was defined in the 11th edition of *Dorland's Illustrated Medical Dictionary.*

Since it was first introduced, bibliotherapy has been studied by individuals interested in mental health in an attempt to better understand its uses and effectiveness. Caroline Shrodes [8] was one of the first writers to address bibliotherapy from a philosophical perspective. Some of the earliest efforts to study bibliotherapy examined its implications for attitude change [4], reducing stress [1], reducing fears of children [10], and treating young drug abusers [2]. Although some studies suggest its ineffectiveness, bibliotherapy continues to gain popularity as a beneficial and practicable treatment technique among psychiatrists, psychologists, counselors, social workers, and other mental health professionals.

Overview

Although bibliotherapy has been used to help treat people of all ages, bibliotherapists have found it to be particularly useful when helping children. When choosing reading material, the bibliotherapist may consider the child's age,

level of maturity, and emotional and developmental needs. Selection of the material may also be based on the isoprinciple, meaning that the character of the story shares similar feelings and emotions to those of the child. The story character may also match the child in aspects of behavior and face events similar to those the child is facing.

When an appropriate book has been selected, it must be presented so that children are able to identify with the character. This is typically achieved when children recognize how they share similarities with the character. The next stage that generally follows is catharsis, which refers to the release of emotional tension children experience when they are able to relate to the character in the story. Once the child is able to internalize how the character resolved the issue, the child can reflect on the situation with more understanding and awareness, and this is referred to as insight.

Controversy still exists over which professionals are qualified to use this treatment with children. Some critics feel that this practice should only be undertaken by those who have an expertise with psychotherapy and related areas. Others feel that this practice can be safely used by people who have experience working with children, including teachers, librarians, and parents. Despite this debate, most will agree that bibliotherapy has numerous benefits including its ease of access, and its flexibility in application for people with varying problems and of different ages and backgrounds.

Bicultural Identity

Tony Wu
Walden University, Diamond Bar, CA, USA

Synonyms

Ethnic identification; Identity formation and development; Racial identity

Definition

The acceptance of both the dominant and home cultures that is within an individual's identity. The person is able to embrace values from the host and home cultures and engage in positive intercultural exchange.

Description

Berry [3] defined bicultural identity as the successful understanding and incorporation of two cultures contained by a person's self and consciousness; the individual is able to function appropriately and effectively in a multicultural context. Benet-Martinez et al. [1] suggested that the state and process of bicultural identify identification can be either harmonious or conflictual. Specifically, harmonious integration refers to consistent self and cognitive style that is in the same and parallel cultural context. In contrast, conflictual state is contradictory. In other words, the individual struggles with psychological distress between the host and home cultures; he or she has paradoxical and often inconsistent cognitive style and altered behaviors.

It is generally recognized that the course of bicultural identify is multidimensional. Research suggested that cultural identifications reveal various structures as well as magnitudes [7]. For example, when individuals immigrate from other countries, bicultural persons identify both with their primary and secondary cultures [2], however, the degree to which each individual identifies with host-home customs and values might be blended versus separated [1].

Similar conceptual framework regarding bicultural identity has been proposed from a sociological perspective. Previous research and theories suggested that people's subjective identifications often reflect their objective interpersonal processes and structures. Coleman [4] observed that an actor's relationships communicate a character both to self and others; nonetheless, Swann [6] indicated that there is a need for individuals to confirm their individual subjective identification through the negotiation of relationships with the environment and others.

Lastly, when discussing bicultural identity, it is crucial to understand the acculturation level of the person because acculturation was recognized as one of the most important variables in the studies of ethnic minority identity development. According to Helms and Cook [5], acculturation was related to the degree in which an individual accepted the values and attitude of one's culture in relation to the host or dominant culture. For example, many ethnic Americans went through the process of acculturation, however often failed to differentiate and navigate between home and host culture. Because acculturation is such a complex process, it may be quite difficult for people to meet and resolve differences in the expectations of often contradicting cultural values.

Bicycle Accidents

MaryBeth Bailar-Heath
Nova Southeastern University, Fort Lauderdale, FL, USA

Synonyms

Bicycle unintentional injuries; Wheeled sports accidents

Definition

A bicycle accident is an unintentional injury that occurs to an individual while he or she is riding on a bicycle.

Description

Numerous factors could potentially cause a bicycle accident, including the behavior of the bicyclist, a pedestrian, another bicyclist, or the driver of a motor vehicle. For example, a rider who is engaging in risky behaviors such as taking his or her hands off while riding may accidentally fall. A pedestrian or another bicyclist who does not move out of the way of a bicyclist may cause the bicyclist to go off course and lose balance. The driver of a car or other vehicle may not see a bicyclist and accidentally hit him or her. Additionally, environmental factors, such as uneven pavement or the malfunctioning of a bicycle, can be responsible for a bicycle accident.

The outcome of a bicycle accident can range from scratches and bruises to orthopedic injuries such as a broken limb, to a traumatic brain injury, spinal cord injury or even death. Typically, an accident involving a motor vehicle results in the most severe outcomes, given that the mass and force of the vehicle is overwhelming compared to the mass and force of the bicycle and cyclist.

Relevance to Childhood Development

In the United States, in 2001 alone, approximately 315,000 children ages 14 years and younger were treated in hospital emergency departments for bicycle-related injuries [1]. Approximately 250 children and adolescents between the age of 5 and 19 are killed annually as a result of bicycle-related accidents. Children between 10 and 14 years of age have the highest rate of bicycle-related fatalities, and severe head injuries are responsible for 64–86% of these deaths [2]. These statistics illustrate the risk of a child experiencing a bicycle accident at some point during childhood. Of the possible outcomes of a bicycle accident, head injury is one of the greatest risks. Nearly half of all childhood bicycle-related hospitalizations are diagnosed as traumatic brain injury [3].

Various studies and meta-analyses have investigated the effectiveness of a variety of different programs aimed at preventing childhood bicycle-related unintentional injuries. Most studies have focused on programs to increase helmet use, since the use of helmets has been identified as the single best strategy to prevent head injury while riding a bicycle [4, 5]. In fact, helmet use reduces the risk of traumatic brain injury up to 88% [6]. However, many children do not regularly wear helmets, putting them at great risk for long-lasting cognitive deficits or death as a result of a head injury. Effective programs for increasing helmet use include educational interventions coupled with legislative campaigns and economic incentives for purchasing helmets [6]. Programs incorporating parental education and awareness, as well as changing peer

pressure to make helmet-wearing "cool," also showed effectiveness [7]. Additionally, research supports the positive influence of adults modeling helmet use to children [7].

Educational programs to improve riding behavior and safety have also been suggested in order to prevent childhood injuries while bicycling. Little research has been conducted to investigate the effectiveness of this prevention strategy. Of this limited body of research, some has actually shown harmful effects of such programs, indicating they might inadvertently increase risk taking bicycling behavior [8].

Bilingualism

Corey E. Ray-Subramanian
University of Wisconsin-Madison, Madison, WI, USA

Definition

Bilingualism is the ability to use two languages.

Description

Bilingualism results from prolonged exposure to and/or formal instruction in two languages. An individual is typically referred to as bilingual if he or she can understand and speak (or produce language in another form, i.e., in the case of a sign language) two languages fluently. Simultaneous bilingualism is the development of fluency in two languages at the same time, whereas sequential/consecutive bilingualism is the development of fluency in a second language after fluency in a first language has been reached. Multilingualism generally refers to the ability to speak and understand two or more languages.

Individuals may develop bilingualism for a variety of reasons: exposure from an early age to two languages because of caregivers' diverse primary languages or residence in a multilingual society; primary exposure to one language at home throughout childhood and formal instruction in another language as a child or adult; relocation for an extended time to another country or region that uses a different language than the individual; etc. The social, cultural, economic, political, and/or individual reasons for prolonged exposure to more than one language influence the development and maintenance of bilingualism [1–3].

Relevance to Childhood Development

Research has shown that bilingual children with proficiency in both languages tend to have better developed metalinguistic skills such as analyzing their knowledge of language and exhibiting greater control of internal language processing, as compared to both monolingual children and bilingual children who are less proficient in one or both languages [4]. More common, however, is an imbalance in the proficiency of the two languages for

children who learn two languages sequentially or use a minority language at home and a majority language at school and in their community.

The term bilingual education is used differently throughout the world. In the United States, for example, bilingual education typically refers to educational programs for children whose first language is not English and such programs do not necessarily have bilingualism as a goal [1]. Transitional bilingual education in the U.S. is an educational approach in which students are instructed in their primary, minority language for a limited time until they have reached sufficient proficiency in English to receive English-only instruction. Such programs are referred to as *early-exit* programs if students receive bilingual instruction for 2 years or less and *late-exit* if students receive bilingual instruction for most or all of their elementary school years [3]. Structured English immersion is an instructional approach designed for students with limited English proficiency to develop proficiency in English and benefit from academic content instruction in English. It does not have bilingualism as its central goal. Two-way/dual immersion bilingual education in the United States has as its goal the development of balanced fluency in two languages and typically includes both children who have the majority language (i.e., English) as their primary language and children whose primary language is the other focal language of the program (e.g., Spanish) [4]. Heritage language education, or developmental maintenance education, is designed so that students whose primary language is a minority language can maintain knowledge of their home language [4]. Longitudinal research has demonstrated that bilingual education programs that provide students with more than 40% of their instruction in their primary language for an extended period (i.e., late-exit transitional bilingual education) are associated with faster growth rates in academic achievement and similar growth rates in English language proficiency as compared to programs that quickly transition students to English-only instruction (e.g., structured English immersion and early-exit transitional bilingual education) [5].

Synonyms

Bili-lights; Phototherapy

Definition

A phototherapy treatment that involves the use of bilirubin lights, which are high intensity lights in the invisible spectrum to treat neonatal jaundice.

Description

Bilirubin lights, a type of phototherapy is utilized when a neonate suffers from hyperbilirubinemia. Hyperbilirubinemia (commonly known as jaundice) displays a yellowish pigmentation to a newborn's skin, which progresses cephalad to caudad with the eyes affected last. This is caused by excess levels of bilirubin in the neonate's blood. Bilirubin is a product of red blood cells that have previously broken down [4]. Bilirubin in the blood is bound to albumin, a blood plasma protein. If the amount of bilirubin exceeds the level of albumin to which it is able to bind, the remainder is unconjugated and can pass through the blood brain barrier. The probability of passage is increased particularly with metabolic acidosis, sepsis and meningitis. If untreated, severe hyperbilirubinemia can result in Kerinicterus (bilirubin in the brain), which may result in neurotoxic effects which can include one or more of the following; cerebral palsy (particularly athetoid cerebral palsy), paralysis of upward gaze, hearing loss, intellectual impairment, seizures and death [2].

The use of bilirubin lights for the treatment of hyperbilirubinemia is common practice and highly effective within hospitals. The use of bilirubin lights as a home-based phototherapy treatment is also common. The bilirubin molecule reacts to the wavelength of the light. The absorption of the light results in three photochemical reactions; configurational isomerization, structural isomerization and photo-oxidation. The configurational isomer is excreted slowly, while the structural isomer, lumirubin, becomes water soluble and does not need the liver's assistance for excretion [3].

Bilirubin lights have come in white, blue and green colors. More recently, studies have shown that a turquoise colored light decreases bilirubin levels efficiently with fewer side effects [1]. Side effects resulting from phototherapy are hyperthermia, dehydration and irritation of skin. These side effects are preventative by close monitoring from the medical staff.

Binet, Alfred

Anna Mazur-Mosiewicz, Andrew S. Davis
Ball State University, Muncie, IN, USA

Life Dates

1857–1911

Introduction

Alfred Binet was a French child psychologist who played a dominant role in the development of experimental psychology, and who made fundamental contributions to the measurement of intelligence. As a member of the French commission investigating educational concerns, his principal goal was to identify students who needed special help in coping with school curriculums [2]. For this reason, Binet developed the first modern intelligence test, the *Binet-Simon Scale*, in 1905. His intelligence scales have since inspired and influenced the development of intelligence tests across America and Europe [3, 7].

Educational Information

Binet attended law school in Paris and received his law license in 1878. He was a self-trained psychologist from reading of the works of major thinkers of the time, especially English associationists such as John Stuart Mill, Hebert Spencer, and Alexander Bain [7]. In 1883, Binet started working in Jean-Martin Charcot's laboratory at a well-known hospital in Paris, the Salpetriere. During this time, he co-authored a paper arguing that the use of magnets could impact hypnotic states. This suggestion met considerable criticism, and Binet retracted his claim in print [2, 3].

Binet gradually resurrected his reputation by becoming an unpaid research assistant at the Laboratory of Physiological Psychology at the Sorbonne in Paris in 1981. He was named a director of the laboratory 3 years later, a position he held until his death in 1911. Binet was also a member of the Commission on the Education of Retarded Children, appointed by the French Ministry of Public Instruction in 1904 [2, 3].

Accomplishments

During his years at the Sorbonne, Binet developed a program of research that focused on individual differences in human intelligence and cognition. Working with his assistant, Victor Henri, Binet described *individual psychology* as a branch of science concerned with individual differences in cognitive processes [2, 6]. In order to measure individual differences, Binet developed various tests of mental abilities, which served as the groundwork for his intelligence scales. Along with his colleague, Theodore Simon, Binet developed multiple sets of tasks that were able to differentiate between normal and intellectually impaired children.

These tasks were published as the *Binet-Simon Intelligence Scale* in a French academic journal *L'Anneé Psychologique* in 1905 [6]. Binet and Simon revised the scales in 1908 and again in 1911. The third revision of the Binet-Simon Scale contained 58 different tests and the tasks were arranged within 11 different age groups, or *age levels*. Binet believed that intellectual abilities and skills should be described through age-based comparisons. The level at which a child scored was referred to as the *mental level* ([2]). The third revision of the *Binet-Simon Intelligence Scale* was the last French version of the test, and after Binet's death, progress in intelligence testing shifted to the United States. In fact, Binet's work soon became more popular in the United States than in France [6].

Binet's tests were translated from French and presented to American psychologists in 1908 by Henry Goddard. Goddard called this version of the test the *Binet-Simon Measuring Scale for Intelligence*. Goddard

used the test to identify and classify children with lower than average intellectual abilities. Although his version of the test became accepted and used by others, the *Binet-Simon Measuring Scale for Intelligence* was soon overshadowed by another version of the Binet-Simon test published in 1916 by Lewis M. Terman [2, 3]. Terman not only translated the third version of the Binet-Simon assessment tasks, but also revised, standardized, and normed the test using about 2,300 participants. Terman named his version of the scale the *Stanford-Binet Intelligence Scales*, after the university with which he was affiliated [5, 7]. The *Stanford-Binet Intelligence Scales* contained the concept of *intelligence quotient* (*IQ*), which represented the relationship between the mental and chronological age [2]. The Stanford-Binet tests have undergone several revisions and continue to be widely used. The latest edition of the scales was published in 2005 as the *Stanford-Binet Intelligence Scales, Fifth Edition.*

Contributions

Throughout his career, Binet authored almost 300 books, articles, and reviews that dealt with a broad variety of cognitive phenomena. Although his contributions to the field of psychology are often associated with the concepts of mental level and IQ, Binet's work also became instrumental in understanding human intelligence, child development, and memory [4]. Binet's scales embodied a number of ideas that still are still relevant today, including the notions that the best way to understand unusual performance is with regard to typical performance, intelligence is not a unitary trait but is composed of multiple processes that need to be measured and considered separately, and that a useful composite estimate of intellectual development can be created based on multiple samples of specific cognitive processes. In addition, Binet's 1905 test was the first objective measure of cognitive functioning in children and adults. Since he was highly skeptical in regard to subjective assessment methods and often noted that parents and teachers tend to be biased and inaccurate in their reports of students' intellectual abilities, Binet became an active advocate of objective and standardized assessment methods in public schools [4].

Although viewing cognitive assessment as preferable to subjective evaluations, Binet was aware that objective intellectual testing posed numerous shortcomings. For example, Binet pointed out that his tests were not an absolute measure of intelligence, but only yielded an ordinal classification in which the measure of intelligence was relative to that of other individuals of the same age [4]. At the same time, he pointed out that a multitude of factors other than intellectual ability could impact performance on cognitive assessments including the testing environment, mental fatigue, cognitive style, and physical health of children [2–4].

A substantial part of his research and work was devoted to children. His work included child mental processes and cognitive development. Although he did not believe in discrete stages of development, his methodological approach and findings resemble those reported by Piaget [4]. Binet believed that cognitive development is a constructive process, and the purpose of development is adaptation to the social and physical environment. Binet also suggested that children assimilate new knowledge into existing ways of thinking; yet, he believed that the cognitive processes of children and adults are different. For example, he noticed that children tend to be less abstract and objective in their process of analyzing and understanding their environments [4].

Binet also contributed to understanding memory and argued for the existence of different types of memory, and noticed that children are better at recalling ideas than isolated words [6]. Binet also pioneered the research on the validity of children eyewitness testimony, and found the accuracy of the recall is dependent upon the particular wording of questions. Binet reported that when children were asked what they had seen, they made fewer but more accurate observations than children who were asked specific and detailed questions. His research in this area is the first evidence for the impact of suggestibility on children's recall and memory [1].

Binge Eating Disorder

►Eating Disorders

Binge/Purge Eating

Tiffany Rush-Wilson
Walden University, Minneapolis, MN, USA

Synonyms

Bulimia; Bulimia nervosa

Definition

Binge/Purge eating is the diagnosis that describes the behaviors of ingesting large quantities of food (more than most people would believe to be acceptable) and then eliminating this food from the body using unhealthy and inappropriate means such causing one's self to vomit, exercising excessively, abusing laxatives or abusing diuretics.

Description

Eating, stress and obesity among both adults and children have been greatly studied during the past few years in North Americans. Among the eating patterns studied in great detail has been that of binge/purge behaviors. Binge/Purge Eating, or bulimia nervosa, is one diagnosis in a group of conditions identified as eating disorders. These conditions describe inappropriate management of food with a basis in the mental health, or psychology, of the afflicted person. Related conditions such as anorexia nervosa (restrictive eating patterns) [3], binge eating disorder (excessive consumption of food without inappropriate compensatory behaviors) [3], orthorexia (dangerous, unhealthy obsession with eating healthy foods) [7] and bulimarexia (fluxuation between restrictive eating patterns and the binge/ purge eating cycle) are often linked to bulimia nervosa. Despite the various identified categories of eating disorders, the American Psychiatric Association formally recognizes only anorexia nervosa, bulimia nervosa and eating disorder Not Otherwise Specified [3]. Most researched sufferers of bulimia nervosa are females in late adolescence [3]. In recent times there have been younger boys and girls who report binge-purge behaviors, children from various socioeconomic backgrounds, and multiracial presentations of eating disorders [20, 21, 24]. Children and adolescents of diverse backgrounds can be impacted [10, 15, 16].

History

The term Bulimia Nervosa comes from Latin and translates as "ox hunger due to nerves" [5]. The diagnostic criteria for the disorder include recurrent, uncontrollable eating binges followed by purging food at least two times per week for a period of at least 3 months [3]. The ways in which people purge include self-induced vomiting, excessive exercise, diuretic abuse and laxative abuse to compensate for food intake [3]. People who engage in binge/purge eating often gauge their personal worth in a way that is very heavily influenced by their body shape and weight [27]. In order to receive the diagnosis Bulimia Nervosa, the patient may not have an existing diagnosis of Anorexia Nervosa [2, 3].

Some scholars have traced documented binge/ purge behavior back to ancient Roman aristocracy. At festivities some guests consumed and eliminated large quantities of food by vomiting in structures known as "vomitoriums" [5]. This elimination would relieve them of their physical discomfort and enable them to continue eating more food. There was, however, not necessarily a psychological basis for this behavior. Today, Bulimia Nervosa occurs in 1–3% of adolescent and young adult females in the United States [3]. While most reported sufferers are female it is known that bulimia nervosa has similar prevalence rates across race and socioeconomic status (SES) [18]. People from various educational levels and sexes are also impacted with about 10% of reported sufferers being identified as male [14].

Bulimia and Anorexia Similarities

Although there are some distinctly different characteristics, Anorexia Nervosa and Bulimia Nervosa were considered separate aspects of a similar disorder until the publication of the Diagnostic and Statistical Manual of Mental Disorders III-Revised (DSM 111-R) [1], where they were reclassified as separate disorders. This change followed the published research of Dr. Gerald Russell [23] who detailed discrepancies between the two disorders and therefore coined the term "Bulimia Nervosa" [5]. They are now identified as discrete, yet related, illnesses [26]. Contemporary researchers have attempted to further extend the gap between Bulimia Nervosa and Anorexia Nervosa by identifying a characteristic profile of sufferers [8]. The profile of a person who has Bulimia Nervosa is that of low self-esteem, excessive anxiety, exhibition of self-doubt and a notable degree of helplessness [8]. They also may have strong impulse control problems, may be sexually promiscuous and demonstrate chaotic eating patterns that often mirror their perceptions of their lives [12]. It is important to keep in mind that the *perception* of stressors and personal feelings of self-worth can be a predominant factor in the psychological etiology of bulimia nervosa.

Controversy lingers regarding the APA's distinctions between Bulimia Nervosa and Anorexia Nervosa in the

DSM as separate conditions [6, 26]. One reason for the controversy is that the name "bulimia" does not capture the underlying emotions, thoughts and feelings associated with this disorder [26]. Although many of the women and girls diagnosed with Bulimia Nervosa have many of the same underlying issues, they are of average or above average weight. This distinction sets them apart from people who exhibit symptoms of binge/purge-type Anorexia Nervosa [3] and the life-threatening nature of the condition may be thru minimized. Further, they often feel out of control and may be more likely to seek support for their eating problem than those who suffer from other eating disorders, particularly Anorexia Nervosa [26]. Those who have Bulimia Nervosa tend to be more notably distressed about their binge and purge behavior and see it as a problem [3]. The concern about their purging also sets them apart from those who have Binge Eating Disorder.

Children, Health Consequences and Treatment

The binge/purge behaviors of bulimia nervosa have been linked to several serious health conditions in children and adolescents. Because children are increasingly facing disordered eating patterns and reporting eating as a coping mechanism in reaction to stressors understanding the health consequences of these behaviors are important [13]. It has been documented that one of the stress-releasing aspects for those who engage in binge/ purge behaviors is the numbing effects of binge eating [25] and the release of purging [21]. These behaviors, in children and adults are not without health consequence.

Stomach and esophageal ruptures can be caused by extreme overeating while vomiting, bowel problems and chemical (electrolyte) imbalances can result from laxative abuse. Other complications, such as cardiac problems, dental erosion, dorsal scarring on the fingers, metabolic changes, specific types of ulcers and rare forms of esophageal cancer are also associated with Bulimia nervosa [11].

Effective treatment of eating disorders is best served using a multidimensional effort [9]. In particular the multidimensional approach is useful for children with family support being an imperative component of the regiment. While a combination of individual, family and group therapy has shown to be most effective [4] the Maudsley Method has demonstrated success with younger eating disorder sufferers [19]. Further, while cognitive behavioral techniques have proven to have strong, positive outcomes with children [21], interventions such as Dialectical Behavioral Therapy (DBT) and pharmacotherapies have also shown promising results and may be considered. Clinicians and researcher have also become increasingly aware of counter-therapies, often websites promoted on the internet as "Ana-Mia" groups that may actually provide "tips" about how to maintain the illness and avoid detection [17]. Further they provide a community of support for those who want to increase the severity, and thus lethality, of their condition.

Bingeing

Maria Assunta Cuffaro
State University of NY: Potsdam, Potsdam, NY, USA

Definition

The consumption of large amounts of food while experiencing a lack of control over eating. Bingeing; is a psychiatric disorder in which a subject shows the following symptoms: Periodically, does not exercise control over consumption of food, eats an unusually large amount of food at one time-more than a normal person would eat in the same amount of time, eats much more quickly during a binge episode than during normal eating episodes, eats until physically uncomfortable, eats large amounts of food event when they are not really hungry, usually eats alone during binge eating episodes, in order to avoid discovery of the disorder, often eats alone during periods of normal eating, owing to feelings of embarrassment about food, feels disgusted, depressed and guilty after binge eating [2].

Description

Diagnostic criteria include: recurrent episodes of binge eating, which are characterized by (1) Eating a larger amount of food than normal during a short period of time (within a 2 h period), (2) Lack of control over eating during the binge episodes (i.e., feeling that one cannot stop eating). B. Binge eating episodes are associated with three or more of the following: (1) Eating until feeling uncomfortably full, (2) Eating large amounts of food when not physically hungry, (3) Eating much more rapidly than normal, (4) Eating alone because you are embarrassed by how much you're eating, (5) Feeling disgusted, depressed, or guilty after overeating, (6) Marked distress regarding binge eating is present, (7) Binge eating occurs, on average, at least 2 days a week for 6 months and the binge eating is not associated with the regular use of inappropriate compensatory behavior (i.e., purging and excessive exercise) and does not occur exclusively during the course of bulimia nervosa or anorexia nervosa [1].

Bioecological Approach to Development

Tasha R. Howe
Humboldt State University, Arcata, CA, USA

Synonyms

Bronfenbrenner's theory; Ecological theory; Multisystemic influences

Definition

Urie Bronfenbrenner's Bioecological Approach to Development emphasizes the complex interactions between multiple systems of influence on individuals' development. These influences range from biological, individual, family, peers, and media, to cultural and historical forces that impact how we change over time.

Description

Bronfenbrenner's Ecological Theory [1] is considered by many to be one of the most important organizing frameworks in the field of developmental psychology. This perspective emphasizes the individual's interactions within a series of larger systemic influences, from family, peers, neighbors and teachers, to schools, media, institutions, culture, and the relative "chronosystem," or time period of development.

In light of recent neuroscience and behavior genetics research illustrating the importance of biological influences on human interactions in families, Bronfenbrenner further refined his theory [2] to include these pivotal findings. This *bioecological* approach takes into account that we are both biological and social beings. This

perspective has changed the way most scholars in the field of human development view the complex interplays between neurons in the brain, hormones and neurotransmitters, inborn personality traits, parental socialization of children, and larger media, religious, and contextual and cultural forces. Only when one considers these overlapping and inseparable forces together, can a true understanding emerge regarding how modern families develop in such diverse ways across the globe.

In brief, the systems of influence are depicted as an individual situated in the center of consecutively larger concentric circles. The most immediate and direct system of influence on the person is the *microsystem*, which includes people like parents and peers. The next larger circle is the *mesosystem*, which consists of interactions between those in one's microsystem. For example, if a child's parent dislikes a child's peer, the parent may disparage or scold this peer, leading to the peer's hostility toward the child. This interaction in the mesosystem adds another layer of influence onto the child's development, beyond what either member of the microsystem would have alone. The third layer is the *exosystem*, a circle consisting of indirect influences. The child may not come into contact with these influences, but they impact development indirectly, usually through members of the microsystem. For example, a mother's employer may keep her late so that she is not available for the child in the evenings. This indirect influence impacts the parent-child relationship. Finally, there are the *macro* and *chrono* systems, which consist of larger cultural and time-period influences. Examples include living in a racist country, or a democracy, and living during the time of the Great Depression. For a visual depiction of this model, please see https://blogs.wharton.upenn.edu/staff/remurphy/WindowsLiveWriter/MovingTowardsaSystemicViewofLearning_AAB9/image025_2.jpg

Bioecological Systems Theory

►Bioecological Theory of Development

Bioecological Theory of Development

Purvita A. Patel
Argosy University, Atlanta, GA, USA

Synonyms

Bioecological systems theory; Ecological systems theory; Ecological theory of development; Ecological-transactional model of development

Definition

The bioecological theory of development was formulated by Urie Bronfenbrenner and posits that human development is a transactional process in which an individual's development is influenced by his or her interactions with various aspects and spheres of their environment.

Description

A systemic view of development, this theoretical perspective goes beyond consideration of developmental processes occurring within the child and his or her immediate environment to describe several interacting systems that impact child development. Within the frame of the bioecological theory, Bronfenbrenner defines development as "a lasting change in the way in which a person perceives and deals with his environment" [3, 4]. Development can further be defined as an individual's "evolving conception of the ecological environment and his relation to it, as well as the person's growing capacity to discover, sustain, or alter its properties" [4, 1].

The environment in which a child grows and develops is conceptualized as a network of ecological subsystems. The subsystem most proximal to the child (*microsystem*) includes factors such as biological or innate characteristics of the child and caregiver(s), factors associated with the home in which the child resides, and the attachment the child and caregiver share. Relationships and interactions between settings in which a child functions (such as the home, school, and/or church) are referred to as the *mesosystem*. Interactions between settings in which a child is an active participant can influence the manner in which a child functions and develops within each individual setting. The development of a child is also influenced by events that take place in settings in which the child does not actively participate (*exosystem*). Although these events may not directly impact the child, they impact the settings in which the child is developing and thereby indirectly

impact the child. Furthermore, the culture, society, and belief systems that exist within the overarching social framework the child exists in (*macrosystem*) also have effects. Finally, a child's development is impacted by the factor of time; the child and environment in which he or she grows both change over time (*chronosystem*) [5]. Relationships among the network of systems a child exists in also change over time and these changes influence the child and the manner in which he or she develops. Thus in order to understand a child's development, one must understand the underlying factors that influence how development occurs.

A number of fundamental concepts further capture and describe how development occurs. Inherent in Bronfenbrenner's bioecological theory is the concept of *experience*. The concept of experience is the notion that it is not only the events that take place in an individual's environment that impact his or her development, but also how he or she experiences these events. Therefore, development can be thought of as being influenced by objective factors (the events that take place in the environment) and subjective factors (experiences and feelings such as hopes, fears, anticipation, anxiety). Also underlying the theory is the notion that "human development takes place through processes" of interactions between the individual and events in his or her environment [4, 7]. Bronfenbrenner posits that in order for interactions between the individual and his or her environment to effectively influence development, the interactions must occur on a regular basis over an extended period of time. These interactions are the primary driving force of human development. Furthermore, factors such as the power and direction the interactions have on development, along with the direction in which the influence occurs, vary depending on the characteristics of the individual and the environment. Additionally, in order for development to occur, the child must experience and participate in activities that progressively increase in complexity. This must further occur regularly over an extended period of time and must occur with a caregiver or other individual "with whom the child develops a strong mutual emotional attachment, and who is committed to the child's well-being and development" [4, 1]. An additional and important underlying concept of this theory is that the child internalizes the affection and positive regard of the parents as a function of the strong and mutual emotional attachment he or she shares with them. It is these internalizations that serve as vehicles for the child's motivation to engage in various aspects of the environment – fueling development. Each of these underlying concepts and the interactions between them fuel child development and are important factors of consideration in understanding the process of development overall.

Bronfenbrenner's bioecological theory of development has influenced the manner in which many childhood processes are understood. For example, in the context of child maltreatment, the bioecological theory of development provides a framework through which the processes and consequences of child maltreatment may be understood. Through this framework, the effects of child maltreatment as they relate to the child's social, academic, emotional, and behavioral functioning can be understood. Additionally, and often of great importance, is that this theory provides a lens through which to consider characteristics within the child, caregiver, and environment that influence and are influenced by child maltreatment.

The bioecological theory has also provided a foundation for the development of various forms of therapy. For example, Multisystemic Therapy as a treatment approach to serious emotional and behavioral problems in youth is rooted partly in Bronfenbrenner's theory of development [6]. By understanding how these behaviors develop through events that occur in various subsystems of a child's environment, clinicians are able to develop relevant treatment approaches in an effort to treat the child's difficulties in each sphere of his or her functioning [2, 8].

Relevance to Childhood Development

The environment and social structure children are growing up in today is drastically different from what it once was. A child's upbringing was once primarily handled by the parents; however, today, children spend less time with parents and more time in the context of other adults and same-age peers. Therefore, the characteristics of these individuals have more influence on a child's development in today's society than they once did. Additionally, our society as it currently functions is experiencing a significant degree of crime, community and world violence, school failure and, disruptions in parental subsystems. It is safe to say that these components of our society greatly impact the development of a child in a multitude of ways. Therefore, in order to mitigate the negative impact these factors may have on child development it becomes important to first understand the ecological factors that impact development. This knowledge and relevant research can then be shared with policy makers and citizens of our society to improve developmental outcomes and to help children reach their full potential.

Biofeedback

Definition

A process that enables an individual to monitor and learn how to alter physiological activity to help improve health or physical performance using instruments that measure physiological activity such as heart function, breathing, brainwaves, muscle activity, and skin temperature.

Description

Biofeedback gives people tools to use their own thoughts to control their body, and is often used as a relaxation technique. It helps improve physical performance, and treats and monitors a number of health conditions including, anxiety/stress, headaches, asthma, chemotherapy side effects, heart problems, high blood pressure, constipation, incontinence, pain, irritable bowel syndrome, and Raynaud's disease. Further, studies have shown that it may be effective in treating attention deficit/hyperactivity disorder (ADHD), autistic spectrum disorders (ASD), posttraumatic stress disorder, seizures, depression, and brain injury.

The most common sensor modalities of biofeedback are as follows:

- Electromyography (EMG)- detects muscle action potentials
- Feedback thermometer- measures skin temperature
- Electroencephalography (EEG)- detects electrical activation in the brain
- Photoplethysmograph (PPG)- measures relative blood flow
- Electrocardiography (ECG)- measures electrical activity of the heart
- Pneumograph- measures the relative expansion and contraction of the chest and abdomen
- Capnometer- measures breathing quality, especially carbon dioxide levels
- Hemoencephalography (HEG)- measures blood flow in the brain

Bipolar Disorder

Jeffrey S. Trotter, Andrew S. Davis
Ball State University, Muncie, IN, USA

Synonyms

Manic-depressive illness

Definition

Bipolar Disorder is a mood disorder characterized by the presence of one or more episodes of abnormally and persistently elevated, expansive, or irritable mood (mania).

Description

The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* (American Psychiatric Association; DSM-IV-TR) differentiates between four different types of Bipolar Disorder: Bipolar I, Bipolar II, Cyclothymia, and Bipolar Disorder Not Otherwise Specified (BD-NOS). Differential diagnosis is dependent upon the various combinations of mood states the individual has experienced. Bipolar I Disorder requires the presence of at least one Mixed or Manic episode during a person's lifetime. Individuals diagnosed with Bipolar I Disorder also have had one or more Major Depressive episodes. Manic and mixed states require that the change in an individual's

behavior causes marked impairment much of the day for most days over a period of 1 week, or the disturbance is extreme enough to result in psychiatric hospitalization. A diagnosis of Bipolar II requires the presence of a Major Depressive Episode and a Hypomanic episode. Although hypomania typically is more subtle than mania, the primary distinction is that the hypomanic disturbance persists throughout at least 4 days and is not severe enough to require psychiatric hospitalization. Cyclothymia Disorder is identified by a chronic, fluctuating mood disturbance with many of the symptoms of hypomania and depression; however, the symptoms are insufficient in number, severity, or duration to meet the criteria for a Major Depressive or Hypomanic episode. The Bipolar Disorder NOS category describes clinical presentations with bipolar features that do not meet full criteria for one of the other conditions.

Relevance to Childhood Behavior/ Development

Identifying children with Pediatric Bipolar Disorder (PBD) has increased in prevalence over the past 10 years and a growing body of literature has emerged focusing on the identification of the characteristics of PBD to assist clinicians in making a differential diagnosis [2, 3]. Although these studies have increased understanding of PBD, there remains considerable debate regarding the diagnostic features of children with PBD. Therefore, there remains need for research that would enhance diagnostic accuracy as well as help in better understanding the overlap of symptoms with other disorders. It is likely many mental health professionals experience difficulty in accurately differentiating PBD and may be at risk of either misdiagnosing or underdiagnosing the disorder.

Within the past 10 years, there has been a growing body of published research focused on identifying the characteristics of PBD to assist clinicians in making a differential diagnosis. Although the onset of BD in mid- to late-adolescence is considered to be similar to that of adult BD, the diagnostic characteristics of BD during the prepubertal and early adolescence phases of development is a matter of debate [2]. Like the adult expression of the disorder, PBD involves episodes of mania and depression. However, whereas mood changes in adults with Bipolar Disorder often are expressed as a euphoric or sad mood, manic and depressive moods in children often are expressed differently. In children, a manic episode may be defined as either a distinct period of excessively elevated (i.e., inappropriately happy) or irritable (i.e., excessive temper tantrums, rages out of proportion to events) mood, or both [3]. The National Association of School Psychologists (NASP) criteria for "altered mood" requires identifying three or more symptoms [3] including: (a) inflated self-esteem (e.g., child thinks she is smarter than everyone else despite failing grades); (b) grandiosity (e.g., a child believes and tells others he is able to run faster than a car); (c) decreased need for sleep (e.g., a child claims to be rested after a few hours of sleep); (d) rapid, loud, or uninterruptible speech; (e) racing thoughts, increased distractibility, increased goal-directed activity/psychomotor agitation (e.g., a child starts to rearrange the school library, cleans everyone's desks, and plans to build an elaborate tree house in the backyard, but never finishes any of these projects); and (f) excessive involvement in pleasurable or dangerous activities (e.g., a previously mild-mannered child writes offensive notes to other children in class or attempts to jump out of a second story window. An episode of depression is defined by NASP as a distinct period of sad or irritable mood or markedly diminished interest and/or pleasure in most activities. This period of depression includes four or more of the following symptoms: (a) significant appetite change; (b) sleep problems; (c) restlessness or slowed movement, (d) fatigue; (e) feelings of worthlessness or excessive guilt; (f) problems concentrating; and (g) recurrent thoughts of death and/or recurrent suicidal thoughts, plans or attempts.

In 2001, the National Institute of Mental Health Research Roundtable on prepubertal Bipolar Disorder promoted the idea that pediatric BD can present in "narrow" and "broad" phenotypes [4]. The narrow type is marked by recurrent periods of depression and mania or hypomania and fits the classic definition of BD as described in the DSM-IV-TR. Children also experience multiple episodes with rapid cycling and have symptomology that is influenced by the child's developmental stage. It is believed that despite having classic symptoms of hypomania or mania, most children fail to fulfill the criteria for duration of 4–7 days, respectively. In this case, the diagnosis of BD-NOS is to be applied and serves to accommodate children with severe affective instability. The broad phenotype constitutes the majority of the referrals to clinicians. Symptoms include severe irritability, mood lability, severe temper outburst, symptoms of depression, anxiety, hyperactivity, poor concentration, and impulsivity with or without clear episodicity. The idea that there is a spectrum describing PBD, including broad and narrow types, is gaining consensus. The phenotyping model is viewed as "critical" in helping researchers as well as clinicians determine variables related to psychopharmacology, neurophysiology, treatment response, and prognosis. However, consensus is not yet

universal and clinicians should be aware that researchers often use different sets of diagnostic criteria to define PBD.

Unlike adults with BD, children with mania typically do not manifest euphoria, but severe irritability [5]. Without the typical manic presentation, clinicians may erroneously attribute a child's emotional outbursts and belligerence to psychosocial factors or behavior disorders. Not only must clinicians differentiate PBD from more common childhood disorders but they also need to consider whether behaviors (e.g., playing, activity levels, rate of speech) are consistent with those displayed by normal children and adolescents [2].

In addition to the debate on core symptoms and the presence or absence of episodes, there also is the definition and role of "cycling" to be considered. In contrast to adults, who are more likely to present with discrete cycles of depression and mania, it is believed children with BD may exhibit both manic and depressive symptoms at the same time or within the same day [2]. Instead of being episodic or acute in course, as is the case with most adults, pediatric BD tends to be chronic and continuous, which makes identifying discrete episodes very difficult; however, this does not mean that on occasion children will not demonstrate similar syndromal characteristics observed in adults with BD. Geller and colleagues coined the term "complex cycling" [6] to describe the presence of short cycles embedded within a more prolonged cycle or episode. Mood shifts in children are currently characterized by mixed states (i.e., simultaneous manic and depressive symptoms), rapid cycling (i.e., four or more mood episodes per year), ultra-rapid cycling (i.e., more than four mood episodes per year), and ultradian cycling (i.e., multiple episodes per day, requiring more than 4 h of mania per day).

It is difficult to estimate prevalence of PBD due to the paucity of national (or international) epidemiological studies to determine the prevalence in the pediatric population [4]. For adults, the lifetime prevalence is estimated to be 0.8% [1]. Studies of the prevalence rates for adolescents are similar to adults and have ranged from 0.7% to 1.41%. Retrospective studies in adults with BD have reported as many as 60% experienced the onset of their BD before 20 years of age, and 10–20% reported the onset before 10 years of age. Given the reluctance of clinicians in the past to diagnose children with BD, it is likely the prevalence rate has been underestimated historically. In addition, understanding prevalence is made all the more difficult by the disorder's diagnostic complexity.

Because of overlapping symptoms with other psychiatric disorders, it often is difficult to differentiate PBD from other childhood problems. Rates of comorbidity vary according to the age of the child, sample selection, and methods used to ascertain the symptomatology. In a review of research on rates of comorbidity of PBD with other disorders, it was reported that rates ranged between 11% and 75% for ADHD, 46.4% and 75% for ODD, 5.6% and 37% for CD, 12.5% and 56% for anxiety disorders, and 0% and 40% for substance abuse disorders [4].

In particular, diagnostic confusion exists because of the similarity between PBD and ADHD. Symptoms such as impulsivity, hyperactivity, irritability and distractibility are shared by both disorders [7], whereas the presence of grandiosity, elated mood, flight of ideas, hypersexuality, and decreased need for sleep are more common to PBD. The ease of misdiagnosis is highlighted by the work of Biederman and colleagues [8] who found that 96% of children who met the criteria for BD did so for ADHD; however, only 16% of ADHD patients met the criteria of mania/hypomania. Similarly, in another study it was reported that of children presenting bipolar symptoms, approximately 90% of prepubertal and 30% of adolescent subjects were classified as ADHD. This significant comorbidity makes prognosis and treatment all the more difficult for children with BD. However, differentiation is not impossible. For example, it has been suggested that the two disorders can be distinguished by examining the history of the child to determine the persistence and earlier onset of ADHD versus the lack of euphoria or depressed mood of pediatric PBD. Children with BD also may be more irritable compared to children classified with ADHD.

The differential diagnosis between pediatric BD and conduct disorder (CD) also can be difficult due to the overlap in symptomology. Outbursts of anger, antisocial behavior, substance abuse, hypersexuality, and adolescent turmoil often are associated with PBD and misdiagnosed as CD [9], although there are instances of comorbidity too. The diagnostic history may reveal a sudden onset of severe behavioral disturbances with pediatric BD whereas with conduct disorder the duration of disturbances may have been evident over several years. A further possibility for delineation lies in determining the nature of the troubling behaviors. Mischievousness and not vindictiveness distinguishes a manic child's behavior from one who has conduct disorder, whose behavior is typically more hurtful of others. Additionally, children with conduct disorder typically do not have psychotic symptoms, push of speech or flight of ideas as do children with mania.

Children and adolescents with BD often present with significant cognitive deficits that may adversely affect school functioning. Compromised academic functioning in PBD has resulted in the increased use of special

education services [10]. It has been estimated the incidence of math and reading difficulties in PBD to be approximately 30–40% and that children with PBD have lower full scale IQ and lower Wide Range Achievement Test (WRAT) Arithmetic percentiles and WRAT/Gilmore Reading standard scores compared with children with ADHD and no disorder [11]. Little is known about the cause of these learning difficulties in children with PBD. Learning disabilities and complications in executive functioning in children with PBD may not simply be secondary symptoms of the disorder, but may provide anatomical clues related to the causes of the disorder. Either way, children with PBD are expected to have learning difficulties related to cognitive functioning and will need appropriate educational accommodations.

As with adult BD, psychopharmacological treatment is considered by many as the first line treatment for PBD; however, the efficacy of medications used to treat children with PBD has yet to be established which is primarily due to the lack of studies using children and the poor quality of the few conducted studies [12]. Nevertheless, existing research indicates that most children with BD require multiple medications to alleviate symptoms of mania, depression, and co-occurring conditions [3]. It also is important to consider that several medications (e.g., Lithium, Carbamazepine, Valporate) used to treat children and adolescents with BD have not been approved by the Food and Drug Administration, although these medications are often used as mood stabilizers with children [4]. Combination pharmacotherapy appears to be a trend that is increasing. For example, during manic episodes, it is not uncommon for both antipsychotics and mood stabilizing medications to be prescribed. Typically, mood stabilizers (Depakote, Lithium, Tegretol, Topamax) are considered the first line of pharmacological intervention and, if necessary, are followed by anti-psychotic medications (Abilify, Clozaril, Geodon, Risperdal, Seroquel) to help reduce aggressive or psychotic symptoms [3]. After a child's mood has been stabilized with a mood stabilizer, low dose anti-depressant medications may be used to reduce depressive and anxiety symptoms and psychostimulants may reduce ADHD symptoms of inattention, impulsivity, and hyperactivity; however, both anti-depressants and psychostimulants pose a risk of activating manic symptoms and therefore must be monitored carefully. Although there appears to be increasing support for the use of combination pharmacotherapy along with various combinations of newly developed medications, only a limited number of studies have been published demonstrating their capacity to produce the desires results.

There are few evidence-based psychosocial treatment methods for pediatric BD and only a few published preliminary studies [13]. Although there has been a large amount of research published supporting cognitive and behavioral interventions when treating unipolar depression with children and adolescents, few studies have been produced regarding their effectiveness with PBD. Given the lack of empirical data supporting the efficacy of psychosocial treatments for children with PBD, it may be beneficial to consider the research concerning similar treatments on adults with BD. Reviews of the literature indicate that cognitive, cognitive-behavioral, and schema-focused therapies are the most effective psychosocial interventions [13]. Furthermore, there was little research to support the use of these therapies in addressing the manic or hypomanic symptoms of adult BD. Instead, pharmacological treatments appear most beneficial in addressing these symptoms. It is suspected the same may be true when treating children and adolescents with PBD. Nearly all of the studies reviewed for treatment of PBD, implemented therapy as soon as the youngster was stabilized through the use of medication. Pavuluri and colleagues [14] developed a child and family focused cognitive behavioral therapy specifically designed for children with BD. The therapy integrated cognitive-behavioral therapy and interpersonal principles of psychotherapy, modified the conventional behavior therapy and emphasized empathic validation. In addition to addressing the needs of the child, this model also helped parents become aware of their own unhelpful cognitions and to learn new tools in order to serve as "coaches" for their affected offspring. For example, the use of psychoeducation can help parents (and teachers) better understand the biological basis of mood swings often displayed among children with PBD. By recognizing that difficulties with regulation of affect may have a biological basis, parents may recognize the unintentional aspects of PBD and be more likely to respond empathically. The psychoeducation aspect of this model also taught parents how to monitor a child's mood and address rapid cycling. In addition, the parents learned anger-management skills they could implement with their children to help in affect regulation. Preliminary results indicated a good symptomatic response and parent satisfaction.

Children and adolescents with BPD tend to experience a protracted duration of affective instability. Considering the critical developmental processes unfolding during pre- and post-pubertal stages, this chronic/recurrent course is likely to have profound and lasting impact on the individual's life. For example, adolescents with BPD have an increased rate of substance use disorders, placement in

special classes, and need for psychiatric hospitalization [2]. Other correlates include impairment in social, family, and especially school functioning. Bipolar youth also demonstrate high life time rates of comorbidity with anxiety, ADHD, disruptive behavior disorders, suicidality, and substance use. It is clear that PBD, even at the subthreshold level, has serious negative consequences for this population. Developmental influences, atypical presentation, comorbidity, symptomatic overlap with other disorders, is believed to result in the misdiagnosis and underdiagnosis of BD in children and adolescents. Further research studying the effectiveness of psychological, behavioral, and academic management strategies is warranted. Improving understanding and awareness will promote early detection and remediation of PBD and therefore should be a high concern for mental health professionals.

Birth Cohort

Audrey McKinlay,
University of Canterbury, Christchurch, Canterbury, New Zealand

Synonyms

Cohort; Generation

Definition

A birth cohort refers to a group of children born in a given year, or over a given period of time [1].

Description

A birth cohort can be used to describe a subgroup of children born over a given period of time. Birth cohorts are increasingly used in research design to provide information regarding health and development of different populations within a community [2]. Birth cohorts may also be followed over time to systematically explore different health related events that occur during the life span. For example, obesity is considered to be a major problem for individuals in the developed world. Careful follow-up of children all born at a particular time can reveal patterns of behaviour that might lead to obesity. The follow-up of multiple birth cohorts born at different points in time may reveal how any changes in eating habits influence obesity.

Birth Complications

Renee Grizzle
Ball State University, Muncie, IN, USA

Synonyms

Abnormal presentation; Atypical delivery; Birth trauma

Definition

Any atypical feature of birthing process which increases the risk, impacts the delivery, health, or vitality of the infant, and is seen as a complication.

Description

Many factors may place the fetus at risk of poor outcomes. These may arise as a result of abnormal prenatal development in addition to atypical factors that can occur during the birthing process. The major complications of the birth are:

Cesarean delivery: In a cesarean delivery (c-section) the baby is surgically removed from the uterus by making an incision in the abdomen of the mother. This type of delivery is used most often when the fetus is in distress or danger and medical professionals feel it is unwise to wait for the baby to travel through the birth canal [2–5, 7]. Caesarean deliveries are also used when the baby is in a breech position (feet or buttocks first), transverse position (crosswise), or the head of the baby is too large to travel through the birth canal [2–4, 7]. Although the mother and baby require more time for recovery than is typically needed in a vaginal birth, the number of cesarean deliveries increases internationally each year. Labor exceeding 24 h is an indication of the need for a c-section due to the stress placed upon the infant [2].

Oxygen deprivation (anoxia): Breathing problems can occur during or after the birth process. Anoxia can be caused by Rh factor incompatibility between the mother's and baby's blood types or by entanglement of the umbilical cord during labor [1]. In addition, premature separation (abruption) of the placenta can cause inadequate oxygen supply to the baby and become life threatening without immediate medical intervention. Teratogens such as tobacco and cocaine have also been associated with anoxia. Newborns can also fail to start breathing upon delivery which may result in brain injury and long-term physical and cognitive deficits [1–3].

Low-birthweight and very-low-birthweight infants: Low-birthweight infants weigh less than 5½ lb compared to the average newborn weight of approximately 7½ lb. Approximately 7% of newborns in the United States can be characterized as low-birthweight infants and this category accounts for most cases of newborn death. Low-birthweight infants can be separated into two groups: preterm and small-for-date [2–4, 6]. Very-low-birthweight infants weigh less than 2¼ lb. An infant can also be included in the very-low-birthweight category if they have been in the womb less than 30 weeks before delivery. A large number of low and very-low-birthweight infant births remain unexplained; however, risk factors for delivering a low or very-low birthweight baby include an immature reproductive system of the mother, poverty, women who become pregnant within 6 months of a previous delivery, poor nutrition, a lack of medical care, and other medical conditions that may impact the pregnancy [4]. These are risk factors of respiratory and neurological abnormalities [7].

Preterm and small-for-date infants: Preterm infants are those born several weeks or more before their due date. Although they are small, their weight may still be appropriate for the amount of time spent in the womb. Small-for-date infants are infants below their expected weight considering the length of the pregnancy. Small-for-date infants typically experience more serious problems than preterm infants. Research suggests small-for-fate infants have difficulties with illness, cognitive functioning, and attention through childhood [1–3].

Postmaturity: Babies who have not been delivered 2 weeks after the mother's due date, or 42 weeks after the last menstrual period are considered postmature. Toward the end of gestation, postmature babies receive insufficient blood supply and less oxygen than normal. Due to the labor complications that the large size of postmature babies poses as well as the heightened risk of postmature fetus brain damage or death, labor may be induced or the baby may be delivered by caesarean. Very often mothers with diabetes may have this problem [6].

Stillbirth: A stillbirth occurs when a fetus has died in the uterus, during labor, or delivery. The death of a fetus can be diagnosed during any of these periods although the causes of stillbirths are largely unknown. Electric fetal monitoring, ultrasound, and other observational methods likely have contributed to the decline in third-trimester stillbirths in the past 2 decades [6].

Infant mortality: Infant mortality, or death within the first year of life, is approximately 7 deaths for every 1,000 live births in the United States. The rate of infant survival is influenced by problems that can occur prenatally as well as difficulties that may occur during labor and delivery. Racial differences can be found in rates of infant mortality that are likely due to socioeconomic factors. Infant

mortality rates in the United States have been associated with the high incidence of low-birthweight and preterm deliveries, poverty, and a lack of national health-care insurance [4] or policies that reduces access to services providing prenatal care.

Birth Defects

Renee Grizzle
Ball State University, Muncie, IN, USA

Synonyms

Chromosomal abnormalities; Congenital morbidity

Definition

Structural, functional or developmental abnormalities present at birth that have been genetically determined or are the result of environmental interference or trauma during embryonic or fetal life.

Description

Birth defects differ in severity, localization, and are the leading cause of infant mortality in the United States and many other nations. Many parents concerned about genetic abnormalities seek genetic counseling. Genetic counselors can provide information concerning estimated risks of having a child with birth defects, health care options, prenatal diagnostic techniques, and reproductive methods [1, 2]. Birth defects occur in infants of parents from every race, geographical region, and socio-economic status. These birth defects can impair the physical, cognitive, and social-emotional functioning of the individual throughout the lifespan.

The complex processes of prenatal development make the infant susceptible to genetic and environmental influences. These place the neonate at risk of a disruption of normal development and may result in birth defects. A brief list of the primary genetic and environmental influences associated with birth defects are discussed below.

Genetic Influences

Chromosomal Abnormalities: Some chromosomal abnormalities are inherited while others result from accidents during prenatal development. Chromosomal defects may result from mutations which are permanent alterations in genes or chromosomes that may produce harmful characteristics. Mutations can occur spontaneously or can be triggered by environmental hazards. Most chromosomal defects occur from mistakes during meiosis and are a major cause of birth defects. The most common chromosomal disorder is *Down syndrome,* sometimes called *trisomy 21,* which affects 1 out of every 1,000 births. In approximately 95% of cases, this disorder results from a failure of the 21st pair of chromosomes to separate during meiosis. This lack of separation causes the individual to receive three chromosomes instead of the two that are received in normal development. In few cases, an extra 21st chromosome is attached to part of another chromosome [1–4].

Sex chromosome disorders are often identified as late as adolescence and typically result in fewer problems than chromosomal abnormalities that occur in the autosomes. *XYY syndrome* occurs in 1 in 1,000 male births and is caused by an extra Y chromosome. *Triple X syndrome* (XXX) occurs in 1 in 500 to 1,250 female births due to an extra X chromosome. *Klinefelter syndrome* (XXY) occurs in 1 in 900 male births in which the individual carries an extra X chromosome. A missing X chromosome characterizes *Turner syndrome* (XO) that occurs in 1 in 2,500 to 8,000 female births. In *Fragile X syndrome*, an abnormal repetition of a sequence of DNA bases occurs in a particular spot on the X chromosome and damages a particular gene. This syndrome is carried by approximately 1 in 250 females and 1 in 800 males.

Environmental Influences

A teratogen is an environmental agent that causes damage during the prenatal period. In many cases, prenatal exposure to teratogens results in mild to severe birth defects. Teratogens include many prescription and nonprescription drugs, alcohol, infectious diseases such as rubella or *acquired immune deficiency syndrome* (AIDS), and environmental chemicals such as lead or mercury. The amount of harm caused depends upon the quantity of dose, the period of time in which the developing organism is exposed to it, the genetic makeup of the mother as well as the organism, other negative influences such as poor nutrition or lack of medical care, and the age of the organism at time of exposure. Teratogens cause the most damage during the embryonic period but also cause harm during the fetal period. Although teratogens cause immediate physical damage, the effects are often delayed but persistent upon onset. An abundance of research has been collected concerning the outcomes of individuals who were prenatally exposed to teratogens. Examples of disorders attributed to teratogens include *Fetal alcohol syndrome* (FAS) and *Alcohol-related neurodevelopmental disorder* (ARND) [1–3].

Birth Order

Anne Fierro Vanderlaan
Saybrook University, Meridian, ID, USA

Synonyms

Child's position; Family constellation; Order of birth; Sibling order

Definition

The birth order is the order in which a child is born. The first child is normally the oldest child that is born into a family. The middle child is can be the second or third child all the way to the last born or the baby of the family. The birth order can change if there is a large difference in ages from one child to the next. A child who is the second born can change if the child has an older sibling that he/she was not raised with. The birth order then changes for the child to be a second first born child of the parent. Some families have several babies in one family that is not directly related to the order of the birth. If children are raised alone then the child could be considered either a first born or the baby. In some large families the birth order is not just the order of birth because of large spans of time between children changes the birth order. A family may have two children, then 10 years latter have another two children. So the children even though they are the forth and fifth child their birth order is thus first born and last born. The term birth order indicates the relationship, behaviors, and personality that emerge. Each child discovers their position in the family and each position has a different meaning [1].

Description

Personalities of a child are influenced by the relationships into which they are born. Each child who is born examines his place in the family. When a new child is born into the family a type the previous child who was the king or queen becomes dethroned. When comparing one child to the next child the behaviors of each child will be different. If you compare two different families first born children there will be more similarities between these two children then their siblings [4].

Relevance to Childhood Development

Understanding the birth order or the family constellation and how it evolves with each child, a parent will can investigate how each child finds his place in the world. A first born child inner environment will be adjusted to

figure out if he will compete or compensate either by giving up or get ahead of his siblings. The second child will focus on the older siblings relationship. This child will try and surpass the first born child or will also give up. Each child's temperament can be affected by the numerical position and how he/she interprets his/her role. Most first and second born children will compete between each other to try and move in one direction or in opposite directions [1]. A parent must be careful not to pit one child against the other. This is a common problem in many families. The middle child no longer is the baby and does not have the privileges of being the baby. This child may always feel that life is unfair. The middle child needs to the reassurance that he/she is cared for and cherished. The baby of the family will normally always have the position of being the privileged child. A parent needs to be aware of the baby of the family and how the position, of being the baby is maintained by the family. They may expect others to take care of their needs and may not feel the need to receive more than to give. Every child develops their own skills and figures out what methods work for him/her and they will figure out their personal identity. In each family everyone has their own personality. Parents need to make interpretations about the child's place in the family constellation and be sensitive to what the child may feel about him/herself [3].

Birth Process

Renee Grizzle
Ball State University, Muncie, IN, USA

Synonyms

Childbirth; Labor and delivery

Definition

The birth process is the time period from the start of productive contractions to birth. The process is typically divided into three stages.

Description

Parturition, the process of uterine, cervical, and other changes that brings on labor, typically begins about 2 weeks before delivery as a result of hormonal changes.

Stage 1: Dilation and Effacement of the Cervix

In the first stage of the birthing process, uterine contractions occur approximately three to four times an hour and typically last for a period of 1 m. As the first stage progresses, contractions become more frequent and intense and water eruption occurs. As a result of these contractions, the woman's cervix (the opening into the birth canal) stretches, opens, and thins [1, 2, 4]. By the end of the first stage, the cervix (or uterine opening) has been dilated to about four inches [2, 4]. This widening allows the baby to move from the uterus to the birth canal (vagina). The first stage of the birthing process is the longest of the three stages and can last between 12 and 24 h for a woman having her first child. In later births, the first stage is shorter and typically lasts between 4 and 6 h [2].

Stage 2: Delivery of the Baby

The second stage of labor begins when the baby's head starts to move through cervix and birth canal and terminates when baby completely emerges from the mother's body [2, 4]. In this stage, strong contractions of the uterus continue and the mother feels the natural urge to squeeze and push with her abdominal muscles. Once the cervix is open, the baby is ready to be born. The baby comes through the birth canal and is born covered in amniotic flood and occasionally blood. The baby is delivered with the umbilical cord still attached so after delivery the umbilical cord is cut and clamped and a quick assessment of newborn health is conducted [1, 2]. The second stage of labor is shorter than the first and can last for up to an hour and a half for a first-time birth. In later births, the second stage is approximately 20–30 min. If the delivery of the baby lasts longer than 2 h, doctors may intervene with forceps or use vacuum extraction to remove the baby [3].

Stage 3: Birth of the Placenta (Afterbirth)

The birth of the placenta is the third and shortest stage of labor. This stage occurs after the baby has been born. The mother experiences a few more contractions and will usually push a few more times to times to expel the placenta and other membranes [4]. Delivery of placenta typically takes between 5 and 30 min and concludes the labor process. Some researchers have added a fourth stage to the birth process. This stage occurs a couple of hours

after the delivery and the mother rests in bed while her recovery is monitored [2].

Birth Trauma

►Birth Complications

Birth Weight

Matthew J. Holcomb, Raymond S. Dean
Ball State University, Muncie, IN, USA

Definition

The weight of a child at birth, which is considered along with gestational age of child at birth.

Description

Birth weight has been conclusively shown to be linked to the gestational age of a child. With every gestational week of progress there is a concomitant increase in birth weight that is expected in a developing fetus. A child who has a birth weight that falls within a range for gestational age is considered to have birth weight that is appropriate for gestational age (AGA). Deviation from the normal birth weight has been attributed to genetics, health factors of the fetus, health of the mother, multiple births, and environmental factors [2, 4].

Relevance to Childhood Development

There have been numerous studies which have linked weight for gestational age to later life developments as well as morbidity and mortality. These studies have seen various degrees of success in linking later life occurrences such as propensity for cerebral palsy and other developmental disorders [1], blood pressure [3], and obesity [2]. Definitive links that can be found between birth weight and later life occurrences can help in the creation of early interventions and special programs designed to compensate for the experiences of low birth weight children.

Bisexual

Lisa Kilanowski-Press
Niagara University, Niagara, NY, USA

Synonyms

Ambisexuality; Homosexuality; People who "swing both ways"; Switch-hitter

Definition

The state or condition of being sexually attracted to members of both sexes.

Description

Bisexuality refers to the sexual attraction to members of both the same and opposite sex. The term "bisexuality" is couched in the sexual continuum of heterosexuality, as defined by attraction to members of the opposite sex, and homosexual, defined as being attracted to members of the same sex. Although predominant culture intuits that there are bipolarities of sexuality, with bisexuality as an intermediary, significant bodies of literature have challenged this viewpoint in reference to bisexuality. Researchers Alfred Kinsey and Fritz Klein are two prominent scholars who spent a great deal of time examining bisexuality. Therefore, to further understand the concept of

bisexuality, the work of these two authors will be examined in detail in addition to other authors, cultural, and societal viewpoints.

Societal views of bisexuality may have changed over time, but there is still no set of rules or behaviors used comprehensively to define bisexuality as a cultural, personal, and societal phenomenon. The term bisexuality has been in flux for centuries and, therefore, difficult to define [16]. Additionally, there is a discrepancy in regard to who creates and uses the term bisexual. Kinsey (1990) reported that a number of males and females who had sexual relations with members of the opposite sex have identified themselves as lesbian, gay, and/or bisexual. The opposite also exists, wherein individuals who have had involvement with both sexes have identified as heterosexual. The cultural influences on sexuality have also implicated that individuals who identify as bisexual are "closeted homosexuals" [11]. The assumption has been made that socialization has caused individuals "lean toward" attraction to one sex or the other [2]. The determination of whether an individual or society is able to label one as bisexual has the potential for a large shift in the number of people for whom the category of bisexuality is fitting.

Predominant culture in early to mid-twentieth century assumed that most people were heterosexual, with relatively few homosexuals, and a drastic underestimate of the proportion of the population that could be defined as bisexual. There was an inherent assumption that someone was either heterosexual or homosexual [9]. A digression from the traditional definition of bisexual created a revolutionary glimpse into the bedrooms of Americans. Kinsey reported in the late 30s and 40s that there were a large number of individuals who did not fall within the traditional realm of sexuality. Kinsey's research brought about a revelation that homosexuality was much more widespread than previously thought. By broadening the definition of bisexuality to include a number of factors not previously predominant in the fields of sexuality, Kinsey described a population whose sexuality was measured by sexual attraction, fantasies, behaviors, emotions, and self identification. These were all factored into Kinsey's determination of one's sexual designation. These practices defied what was, and in many ways still is, perceived as the norm [12].

Kinsey designed a heterosexual-homosexual seven point rating scale, wherein zero was assigned to individuals who where exclusively heterosexual with no homosexual psychological reactions nor overt experiences, and six was assigned to individuals with exclusively homosexual psychological reactions and overt experiences (Kinsey, 1940; [9]). There are no discrete, intrinsic categories of sexuality, but, rather, individuals fall on a continuum of sexual reactions and experiences. Within this framework, bisexuality is the predominant sexuality, while the outliers are those who are strictly hetero or homo sexual.

Kinsey also proposed that there is a continuum of sexuality. This continuum purports that there is not, as previously thought, explicit boxes of sexuality, but rather that there is a linear outlook in which there can be shades of sexuality ranging from strictly heterosexual to solely homosexual. Additionally, an individual's sexuality can shift on the continuum over time, allowing distinct periods of sexuality through a lifetime. Under this theory, one may be defined as a heterosexual at one point, but when circumstances arise in which one finds the same sex appealing, a transition takes place wherein the label of bisexual is applied. The same holds true for the transition from homosexual; the point in time at which a homosexual individual finds attractive qualities in the opposite sex, the classification then shifts to bisexual (Kinsey, 1940; [9]). These methods of defining sexuality have broadened the scope of interpretation, allowing the prevalence of bisexuality to garner more attention publicly than previously imagined.

In addition to the continuum, many different types of bisexuality have been discussed. There are individuals who are experimenting to discover sexual preferences; people in transition from either homosexuality to heterosexuality or from heterosexuality to homosexuality; people who participate in sexual acts with the same sex for pay; people who are responsive to sexual stimulation from any person; and people who have a definite preference for persons of the same gender [11]. Definitions of bisexuality do not necessarily distinguish between actual sexual activity versus the attraction and love of both sexes. Situational sexual activity has also been described in largely homogenous groups, wherein same sex acts occur between individuals labeling themselves as heterosexual. For instance, in groups that are sexually separated, either by designation or through cultural ideals, individuals identifying as heterosexual may engage in homosexual sex acts while maintaining a heterosexual identity. One such example is prison, where males and females are segregated.

Consideration must also be given to the attribution of "behaviorally bisexual" versus sexual orientation. It cannot be predicted with certainty the actual sexual behavior of a person whom has labeled themselves hetero, homo, or bi, as research has indicated that the sexual history of both men and women does not accurately reflect the chosen term [14]. For example, one who chooses to label themselves as a lesbian may have slept with men in the past and

shunned the label of bisexual. Some view bisexuality, not through the mere attraction of qualities, but by the relationship that has a potential to manifest. When there is an opportunity, in the mind of the individual, for a relationship to be established with someone of the same sex, then there is also a greater level of consideration given to the term bisexuality. Contradictory to Kinsey's research, Klein's theory considers that there is the ability for people to find qualities attractive in members of the same sex, without delving into the terminology bisexuality [10].

Kline, who published an instrumental book in the 1990s, drew heavily from the work of Kinsey. Klein expanded the use of the term bisexuality by incorporating various aspects, dimensions, and facets. Klein spoke about sexual orientation, where one is oriented toward heterosexuality, homosexuality, or bisexuality. This contemporary viewpoint discusses bisexuality as a lifestyle, rather than simply a label affixed to one's sexual activities. Additionally, a cultural and biological analysis is presented. Klein's work included, but was not limited to, a grid based on the work on Kinsey that looks at seven factors over three time periods to deduce sexual orientation, and the "threat" of bisexuality [10].

Klein's Sexual Orientation Grid utilized the following seven factors: sexual attraction, sexual behavior, sexual fantasies, emotional preference, social preference, lifestyle preference, and self-identification. A scale ranging from 1 to 7 was used to categorize an individual's responses, where 1 equaled other sex only to 7 equaling same sex only. Time periods examined were past, present (last 12 months of life), and ideal. Values 2 through 6 included aspects of bisexuality. Unlike Kinsey, Klein's grid examined more factors and did not affix the label of bisexual to a person from a definitive point in time. Instead, Klein reported that sexuality is an ongoing, dynamic process, where, at distinct points in time, a person may shift from bisexuality back to either homosexuality or heterosexuality, from homosexuality to heterosexuality, and so on.

The "threat" of bisexuality is also discussed. Bisexuals face not only outside discrimination by heterosexuals, but also in-group discrimination and stigmatization from lesbians and gay men. Bisexuals have faced anger in a number of different ways. Heterosexuals may discriminate against bisexuals by subjecting bisexuals to the same stigmatization as lesbians and gays. In addition, the in-group discrimination against bisexuals may include thoughts, statements, or actions meant to convey the following: Bisexuals cannot make up their minds, bisexuals are greedy and want to be able to "choose" from both sexes, and bisexuals are attempting to assimilate into heterosexual culture by choosing to date members of the opposite sex. People indentifying as bisexual are "betraying" gay culture by participating in heterogeneous rights. This echoes earlier statements about closeted homosexuals. Facing discrimination from the dominant and stigmatized cultures leaves those with a bisexual orientation at a great social disadvantage.

Relevance to Childhood Development

The sexuality of a child is an ongoing state of change, not concluding at any finite point. Much of the literature refers to any non-heterosexual youth as "minority youth" [5–7]. While there is a deficit of information on bisexuality specifically, a number of factors related to healthy sexual development have been discussed in relation to sexual minority youth, as encompassed by lesbian, gay, bisexual, transgendered, questioning, and queer youth. Gay, lesbian, bisexual, transgender and questioning (GLBTQ) youth face tremendous difficulties in a society where heterosexuality often seems the only acceptable orientation, homosexuality is regarded as deviant, and variation from cultural concepts of "normal gender" often evokes hostility or violence. Research shows that homophobia and heterosexism greatly contribute to GLBTQ youth's high rates of attempted and completed suicide, violence victimization, substance abuse, teenage pregnancy, and HIV-associated risk behaviors. Additionally, bisexuality can place youth at greater risk for harassment, homelessness, substance abuse and risky survival strategies than their heterosexual counterparts ([4, 8, 13]; Whitebeck et al., 2004).

The victimization of sexual minority youth is a present and concerning occurrence. Sexual minority youth as a whole can be said to have an environmental predisposition to a number of risk factors due the potential lack of support from family and peers [8]. A strong support system is needed in order to protect bisexual youth from the risk-factors that are present. This support is instrumental in providing a safe environment for identity development. In an atmosphere where victimization and harassment of bisexual youth are normative, supportive and non-judgmental role models are crucial. Due to the cultural demands to conform to hetero-normative, childhood development can be greatly aided by supportive adults and community members [13].

Furthermore, a greater risk has been found for gay, lesbian, and bisexual homeless and runaways than for heterosexual youth. Lesbian, Gay, Bisexual, and Transgender (LGBT) youth run away from home more frequently, and are more likely to engage in sexual survival strategies on the streets [15]. Victimization on the streets, both

physical and sexual, was more likely as well. For sexual minority youth, both leaving home and the dangers on the street appear to be amplified [4, 15].

Black Intelligence Test of Cultural Homogeneity

LaRicka R. Wingate
Oklahoma State University, Stillwater, OK, USA

Definition

The Black Intelligence Test of Cultural Homogeneity (BITCH) is a 100-question culturally specific test developed by Williams [2].

Description

Assessment tests in psychology have historically been culturally biased against members of ethnic minority groups. Psychological assessments were commonly normed on White middle-class people and consisted of questions relevant to the White middle-class lifestyle and language usage. Williams wanted to develop a test that was both culture specific and dialect specific.

The process of test development began with Williams identifying over 100 terms that were both specific to Black culture and common. He then piloted the words for clarity, objectivity, and ability to discriminate between Black and White experimental groups. The test is composed of 100 multiple choice questions that assess culturally correct definitions for the exam items. These questions consisted of words common in Black dialect, slang, and vernacular in the 1970s.

The BITCH has been tested for reliability and validity. The BITCH has good test-retest reliability, indicating that most individuals will score similarly on each subsequent administration of the test. Some researchers have attempted to test the validity of the BITCH by comparing the scores of the BITCH to scores on other intelligence tests, such as the Wechsler Adult Intelligence Scale, Wechsler Intelligence Scale for Children, and Stanford-Binet. The results generally suggest that the BITCH is not highly correlated with the other more familiar tests of intelligence. Some may argue that because the BITCH is not highly correlated with the other measures of intelligence, it cannot be a valid measure of intelligence. However, this argument is not necessarily valid given that at that in the 1970s, the other measures of intelligence were normed mostly White populations. Therefore, it would not be scientifically sound to validate one measure that was developed for and normed on a Black population by comparing it to measures that were developed for and normed on a White population.

Although some research has been conducted to develop, explore, and test the reliability and validity of the BITCH, published research is not readily available. Several studies conducted on the BITCH have been those of doctoral students as dissertation projects. Only a few articles on the BITCH have been published in scholarly journals [1]. The BITCH is currently used as a discussion tool in classrooms (at Oklahoma State University and elsewhere) to introduce the concepts of cultural bias in testing, test problems, and test validity.

Blastocyst

Jill A. Anderson
University of Texas Health Science Center - Houston, Houston, TX, USA

Synonyms

Blastodermic vesicle

Definition

The blastocyst is a thin-walled hollow structure formed in early embryonic development [2–4].

Description

The blastocyst is a hollow, thin-walled sphere of about 100–150 cells, which is divided into an outer layer and an inner layer [1–6].

Relevance to Childhood Development

The blastocyst is formed during the germinal period of prenatal development [1, 4–6]. After conception, the newly fertilized egg (the *zygote*) moves through the fallopian tube, undergoing a series of mitotic cell divisions called cleavages. This process continues until the formation of a solid sphere of sixteen undifferentiated cells called a *morula* [1, 4–6]. Once the cells start to differentiate, they segregate into an outer layer (*trophoblast*) and an inner layer (inner cell mass), forming the blastocyst [1–6]. The outer layer of the blastocyst eventually becomes the *placenta* and other supporting tissue needed for fetal development within the *uterus* [1–6]. The inner layer of the blastocyst becomes the tissues of the body. The implantation of the blastocyst into the lining of the uterus marks the end of the germinal period of prenatal development and the beginning of the embryonic period [1, 4–6]. The implanted blastocyst is called the *embryo* [1, 2, 4–6].

Blindness

Stephanie A. Grote-Garcia
University of the Incarnate Word College of Education, Texas A&M University-Corpus Christi, Corpus Christi, TX, USA

Synonyms

Blind; Visually impaired

Definition

Blindness is a condition that describes the lack of visual perception, which cannot be corrected with glasses or contact lenses.

Description

There are two levels and multiple variations of blindness. Two levels of blindness include total blindness and *legal blindness.* Total blindness refers to the complete lack of form and visual light perception. Legal blindness refers to the visual acuity of 20/200 or less in the better eye with glasses or contact lenses.

Multiple variations within blindness also exist. Some of these variations include monocular blindness, color blindness, and night blindness. The following are descriptions of these three variations in blindness:

- Monocular blindness refers to blindness in one eye.
- Color blindness, also referred to as color blindness, is a condition that describes the difficulty or the inability to identity differences between colors.
- Night blindness, also known as nyctalopia, is a condition that describes the difficulty or the inability to see in low light.

In addition, and not to be confused with night blindness, individuals described as having only light perception have no more sight than the ability to tell light from dark and the general direction of a light source.

Causes

Multiple causes of blindness have been identified such as lazy eye, optic neuritis, stroke, tay-sachs disease, retinitis pigmentosa, retinoblastoma, and optic glioma. Additional common causes of blindness are as follows:

- Disease (e.g., diabetes, cataracts, glaucoma, and retinitis pigmentosa, age-related macular degeneration)
- Malnutrition
- Abnormalities (e.g., blocked blood vessels)
- Injuries (e.g., injuries to the occipital lobe of the brain and complications of eye surgery)
- Genetic defects (e.g., albinism Leber's congenital amaurosis)
- Poisoning (e.g., lead poisoning)

Management

Many routines, *adaptive technologies*, and other forms of assistance have been created to assist individuals with vision impairments while completing their daily activities using their remaining senses. The following are examples of such routines:

- Labeling or tagging personal items allows individuals to identify items through their sense of touch.
- Placing different types of food at different positions on a dinner plate allows individuals to locate specific foods on his or her plate.

- Folding money that is in the form of paper bills allows individuals to identify specific bills.

In addition to routines, many adaptive technologies have been created to allow individuals with vision impairments to complete tasks by using their remaining senses. The following are examples of these adaptive technologies:

- Screen readers or screen magnifiers are categorized as adaptive computer and mobile phone software that allow individuals to interact with their computers and phones.
- Mobility may be assisted by a cane or guide dog.
- Tactile paving and audible traffic signals make it safer for visually impaired pedestrians to cross the streets.
- Adaptation of coins and banknotes allows individuals to determine value by touch.
- Large-print, magnifying glasses, Braille, talking books, reading machines, and scanners assist individuals with the tasks associated with the act of reading.

Bobo Doll Experiment

Lynna Lan Tien Nguyen Do
Walden University, Fremont, CA, USA

Description

The Bobo doll experiment was conducted by Albert Bandura in 1961 [1] and studied patterns of behavior associated with aggression. Additional studies of this type were conducted by Bandura in 1963 [2] and 1965. A Bobo doll is an inflatable toy that is approximately the same size as a prepubescent child.

The aim of Bandura's experiment was to demonstrate that if children were witnesses to an aggressive display by an adult they would imitate this aggressive behavior when given the opportunity.

Bandura et al. tested 36 boys and 36 girls from a Stanford nursery school – aged between 37 and 69 months (mean = 4 years and 4 months). Their role models were one male adult and one female adult.

The children were matched on the basis of their pre-existing aggressiveness. They did this by observing the children in the nursery school and judged their aggressive behavior on four 5-point rating scales. It was then possible to match the children in each group so that they had similar levels of aggression in their everyday behavior. The experiment is therefore an example of a matched pairs design.

There were three main conditions – the aggressive condition, non-aggressive condition and the control group.

Relevance to Childhood Development

This experiment is important to psychology because it was a precedent that sparked many more studies about the effects of viewing violence on children.

Definition

A multidimensional concept generally defined as the subjective mental representation of one's own body and one's own appearance.

Description

Body image is a complex phenomena which has been described using various terms and which often focuses on different aspects of body image, e.g., affective, cognitive, perceptual, sociocultural, and physiological aspects [15]. The primary focus of body image research has been on body dissatisfaction and its role in eating disorder development.

Etiology. Body image, particularly body dissatisfaction, is believed to have multiple contributing factors. Sociocultural theory has emphasized the portrayal of the thin ideal as a key factor in the development of body dissatisfaction. Western society has created a so-called beauty ideal that contributes to high levels of body dissatisfaction among boys and girls [6]. Successful and happy women are portrayed as being thin, tall and attractive while successful and happy men are portrayed as being muscular and tall.

Parents and peers have also been shown to have an impact on a child's body image [1]. The dynamic of the mother–daughter relationship has been identified as playing a large role in the development of body image in young girls [2]. Mothers convey societal messages and often model negative body image and eating dysfunction which ultimately results in the daughter demonstrating increased body dissatisfaction. Messages from peers are also conveyed early in development. Body size stigmatization has been found in preschoolers as young as 3 and 4 years old [3, 16]. When young girls compare themselves to other girls they believe are more attractive, it can lead to feelings of inadequacy and body dissatisfaction [5].

Cognitive approaches have emphasized how these sociocultural messages are integrated into body schemas which influence later information processing [17]. Thus, children who have developed a negative body schema are more likely to view media images portraying a thin ideal as being directed toward them. This internalization then increases the strength of the negative body schema, creating a vicious cycle.

Assessment. The assessment of body image has generally focused on perceptual disturbances of body size or attitudinal components of body dissatisfaction [7]. The most common methodology to assess perceptual disturbances of body size include body site estimation and whole body size estimation techniques. Attitudinal and affective components of body dissatisfaction are often assessed using the Eating Disorder Inventory 3 [8] in preteen or older populations. In younger children, figural stimuli are often used to determine the discrepancy between perceived body size and idealized body size.

Treatment/Prevention. No single course of treatment has been widely accepted for body image disturbance. Several factors have been identified as being important for the treatment process. These factors include training in media literacy and involvement of family members. Research regarding the prevention of body image disturbance (and eating disorders) has raised critical concerns about the efficacy of prevention programs and possible harm caused by the programs [13]. Professionals developing prevention programs, particularly those in a school setting, should avoid glamorizing the thin ideal, introducing participants to unhealthy eating behaviors, and normalizing eating dysfunction. In addition, professionals must not model their own negative body image or fear of fat to participants.

Relevance to Childhood Development

Body image disturbance and eating disorders exist in young children [14]. Children as young as 6 years old, have shown body dissatisfaction and concerns about their weight [4]. Research has consistently shown that body dissatisfaction at younger ages has been associated with later development of eating dysfunction, anxiety, depression and low self esteem [9–12]. Therefore, the development of a healthy body image is critical to the overall emotional, social and physical health of developing children and adolescents.

Body Mass Index (BMI)

Jeffrey S. Anderson
Oklahoma State University, USA

Definition

Body Mass Index (BMI) is a ratio of a person's weight to their height, which can be used as an indicator of potential weight problems. BMI is routinely used to assess an individual's risk for health problems due to overweight.

Description

BMI is computed by dividing an individual's weight (kg) by the square of their height (m^2). Although BMI is a reliable measure for overweight in most people, it cannot be used as a diagnostic tool; rather, it is used to screen identify individuals who may be at risk for health problems related due to overweight. For adults 20 years and over, four BMI groups are commonly identified: Underweight (BMI $<$ 18.5), Normal (BMI = 18.5 – 24.9), Overweight (BMI = 25 – 29.9), and Obese (BMI $>$ 30). The BMI ranges for these four groups differ for infants, preschoolers, children and adolescents. Healthcare providers use growth charts from the Center for Disease Control (CDC) to interpret BMIs for Infants, preschoolers, children, and adolescents. For children, the four groups are defined in terms of the percentile ranking among peers of the same sex and age. Children with BMIs at the fifth percentile or less are considered underweight. Children with BMIs between the 5th and 85th percentile are considered normal weight. Children with BMIs between the 85th and the 95th percentile are considered at-risk of overweight. Children with BMIs at or above the 95th percentile are considered overweight. Only a qualified healthcare provider can determine the specific health risk associated with an individual's BMI [1, 2].

Relevance to Childhood Development

BMI is routinely used by healthcare providers and researchers to measure overweight in children. Recent research has indicated a dramatic rise in obesity in the United States. The trend is expected to continue. In children, overweight can result in numerous physical and psychological problems. Children who are in the overweight population are more at risk for medical problems such as Type 2 diabetes, intracranial pressure, circulatory problems, as well as psychological problems such as behavioral problems, depression, and social rejection by peers. Long-term medical and psychological conditions related to childhood overweight are also a concern. Children who are overweight also have a significantly greater risk of being overweight as adults, a population that also has increased medical and psychological problems, compared to normal weight children [3].

Bonding

Douglas K. Symons
Acadia University, Wolfville, Ontario, Canada

Synonyms

Attachment; Imprinting; Male bonding; Parent-child relationships

Definition

From the 12C English *band* as in to tie together, bonding refers to the formation of a social relationship.

Description

Bonding is the formation of a close relationship between individuals that helps them survive, learn, love, and procreate. The concept arose within a few streams of comparative research [7]. For example, Konrad Lorenz conducted work with ducks and geese, and showed that goslings would imprint and learn to follow the initial object they encountered after birth. Niko Tinbergen also studied bird species and the stimulus parameters of the formation of this initial social relationship. Harry Harlow examined new born rhesus monkeys and found that they preferred a surrogate mother who provided physical security and comfort over one who provided only nutrition [6]. This work contributed to Bowlby's development of Attachment Theory [2], which was also based on his own observations of orphans from World War II in the UK. These orphans had physical but not emotional needs met within care, and consequently had difficulties in social relationships later in life. When applied to humans, the phrase bonding has largely been replaced by attachment formation in child development research, although it continues to be used by the lay public and within Family Court proceedings, e.g., is the child bonded to the parent? Bonding implies a relationship, but does not mean the relationship is necessarily positive, as in traumatic bonding [4] or deviant peer bonding when high-risk youth are brought together and reinforce negative behaviors of one another [3].

Based on its roots with imprinting, the concept of bonding as applied to mother-infant attachment formation has led to research that has investigated the potential negative impact of early separation experience on the mother-child bond that forms [5]. For example, it was hypothesized that early separation due to preterm birth and associated medical intervention/hospitalization, separation due to maternal employment, and even bottle as opposed to breast-feeding a newborn would be disruptive to the mother-child bonding experience, in other words, insecure attachment formation. But data do not support these hypotheses. Instead, the mother child (and father-child) bond is robust with respect to short and predictable separations and what is more important is the quality of interaction when parents are with the infant. Attachment research has therefore focused on maternal sensitivity and predictable care for infant needs as bases of secure attachment formation and an indication of bonding [1].

The concept of bonding has also been applied to the formation of other social groups, such as the bonding that goes on between roommates new to university, children assigned to a specific cabin at summer camp, and high school sport teams. Here there is a common goal that motivates the bond which forms, whether it is friendship, competition with other groups that are formed, or winning games. Other terms have been applied to these processes, such as peer group formation or ingroup/outgroup competition. The television show *Survivor* demonstrates these points well as contestants on this show are assigned to "tribes" in a semi-random fashion, but competition with other tribes in contests enhances within-group bond formation that often lasts even after the tribes are not living separately. Humans are inherently social creatures who tend to form social bonds whenever they are assigned to groups, and these bonds can enhance intergroup competition.

Borderline Personality Disorder

Greta Winograd
SUNY New Paltz, New Paltz, NY, USA

Definition

Borderline personality disorder (BPD) is a complex and clinically problematic psychiatric condition that interferes with the ability to regulate emotions and behaviors. Like all personality disorders, BPD is associated with serious deficits in interpersonal functioning. According to the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders, 4th Edition* (DSM-IV), individuals who meet criteria for BPD are characterized by five or more of the following criteria: an unstable sense of self, dissociative or paranoid thoughts, extreme mood swings, fears of abandonment, impulsive behaviors, a tendency to inflict self-harm, difficulty controlling anger, feelings of emptiness, and turbulent relationships with others. While youth may display symptoms of BPD, and while features may be present as early as middle-childhood, BPD tends to be clinically diagnosed first in late adolescence or early adulthood.

Description

Individuals with BPD struggle with symptoms that adversely affect their mood, self-image, thought patterns, behavior in daily life, and relationships with others. Due to the seemingly intolerable emotional distress and difficulty functioning that accompany BPD, frequent use of mental health services and a high risk of suicide are common [12]. While BPD is typically not diagnosed until the age of 18, borderline symptoms as described in the DSM-IV-TR often present earlier in adolescence and growing evidence suggests that children also exhibit developmentally relevant features of this severe mental illness (see [7]).

Five of nine criteria outlined in the DSM-IV are required to receive a diagnosis of BPD. Lieb et al. [12]

organize the criteria into four categories. *Affective criteria* include (a) a high degree of reactivity to the external environment and difficulty regulating emotions, reflected by extreme mood swings within brief periods of time, (b) a tendency towards angry outbursts, and (c) feelings of emptiness. *Cognitive criteria* include (a) dissociative or paranoid thoughts and (b) an unstable sense of self. *Behavioral criteria* include both (a) a tendency towards self-harm, including self-mutilation and suicide attempts; and (b) impulsive aggression and more general impulsive behaviors, including "substance abuse, disordered eating, spending sprees, verbal outbursts, [and] reckless driving" (p. 453). Finally, *interpersonal criteria* include (a) fears of abandonment, and (b) turbulent relationships with others. Both of these interpersonal criteria are likely rooted in rejection sensitivity and make it extremely challenging to establish long-lasting and meaningful relationships [15].

For a person to qualify for a diagnosis of BPD, the associated pattern of experience and behavior must have begun relatively early in life (by late adolescence or young adulthood), be consistent over time and across situations, deviate in a clearly noticeable way from expectations within the individual's culture, and cause distress or impairment in functioning [9]. BPD tends to be highly comorbid with Axis I disorders such as depression, anxiety, PTSD, substance abuse, and eating disorders [2]. In adolescence, BPD tends to also be comorbid with disruptive behavior disorders [5].

Prevalence

According to epidemiological studies, rates of BPD among adolescents in the community range from 0.9% to 3%, while rates of BPD among adolescents who receive outpatient treatment have been estimated at 11% and inpatient treatment at 49% (see review by [4]). In inpatient clinical settings, girls are much more likely to receive a BPD diagnosis than boys [10]. Research with representative community samples, however, has found rates of severe BPD among young males and females to be equivalent [1]. That BPD features are incongruent with cultural expectations for females may at least partially account for this discrepancy [15].

Borderline Pathology in Younger Populations

The expression of BPD features in late childhood and adolescence tends to reflect level of development and situational factors unique to these periods. Youth with affective features of BPD may react in an unusually emotional manner, especially when they perceive they are being snubbed or left out. Compared to same-age peers, youth with cognitive features of BPD may have more trouble establishing an identity, have less insight into their own thoughts and behaviors, and be highly sensitive to negative social cues. Youth with behavioral features of BPD will likely be more impulsive than is age-appropriate and may show sudden acts of aggression towards others when they are angry. Children and adolescents with interpersonal features of BPD may have overly close, exclusive, or dependent friendships that they find difficult to maintain (for a broader discussion of the expression of BPD features in youth, see [7]).

Youth who possess a maladaptive, immature, and inflexible response repertoire to people and situations – especially when their temperament is characterized by depression, anxiety, affective instability, and/or impulsivity – face significant challenges in navigating successive developmental stages [14]. High symptom levels and a clinical diagnosis of BPD in early through late adolescence have been associated with current difficulties in functioning across many domains: in school, e.g., lower levels of academic achievement and truancy; at home, e.g., more likely to have family problems for which child protective services are involved, more likely to live in a residential placement; and in social interactions with friends, romantic partners, and family members [1, 5, 16].

Risk Factors

Multiple pathways bridging biology, environment, and culture are likely responsible for the development of BPD across individuals [9]. Family aggregation of BPD is not uncommon, suggesting a role for heritable temperament [7]. Parental psychopathology in general also predicts BPD among offspring [2]. While borderline pathology of childhood is associated with deficits in executive function, such deficits may coincide with or be the result of environmental stressors [18]. Chaotic or dysfunctional family environments, poor attachments to caregivers, as well as adverse childhood events – including sexual abuse, physical abuse, neglect, and traumatic separation from caregivers – are very common among individuals who go on to develop BPD [2]. Traumatic experiences, however, are neither necessary nor sufficient for the development of BPD. Rather, temperament or genetic characteristics may make certain children more susceptible to the effects of environmental risks [14]. Cognitive strengths, social support (e.g., secure attachment to parents), and a less anxious temperament may offset the effect of individual risk factors, especially when such factors occur in isolation [6, 7].

The role of culture is also worth considering in an analysis of risk factors for BPD. Modern societies

emphasize independence and autonomy and in turn, expect adolescents to create their social networks and identities [14]. Such expectations may work against adolescents who are already impulsive and thrill-seeking: for instance, leading them to select peers and environments that increase their psychosocial risks for developing BPD (see [7]). On the other hand, traditional societies tend to provide a more predictable structure and more clear social role expectations, leaving fewer opportunities for impulsive behaviors characteristic of BPD and the problematic consequences of such behaviors [14].

Prognosis

BPD in youth has been associated with future difficulties in functioning at school, in one's relationships, and in employment settings. At school, youth BPD has been associated with subsequent failure, including grade retention and dropout [1]. In terms of relationships, high levels of BPD symptoms in adolescence have been linked to subsequent conflict, estrangement, and poor quality interactions with friends, family members, and intimate partners (e.g., [8]). In the long-term, high adolescent borderline symptom levels predict the attainment of fewer developmental milestones in middle adulthood (e.g., starting a family, establishing a career), more difficulty functioning in one's primary role (as student, homemaker, or in employment settings) and significantly lower adult levels of life satisfaction. The more severe symptoms are in late adolescence, the worse the prognosis (see [16]). Suicidal behavior is common among those meeting criteria for BPD – up to 10% will complete suicide (see [12]). When comorbid depression and substance abuse are present, this outcome is even more prevalent [17].

Course

Precursors to BPD, which may appear as temperamental characteristics rather than symptoms, are often present in childhood; problems become harder to ignore, however, with the higher levels of impulsivity that accompany and follow puberty (see [7]). BPD symptoms, particularly impulsivity and aggression, tend to decline with age through early and middle adulthood (e.g., [11]). However, difficulties in intimate relationships, role dysfunction, and other forms of impairment appear to continue even when formal criteria for BPD are no longer met (e.g., [16]).

Assessment

Assessment of borderline pathology in youth may point the way towards stabilization of symptoms and timely treatment while helping avert the serious risks associated with BPD [9]. A lack of developmentally appropriate criteria for personality disorders in the DSM-IV and the World Health Organization's (WHO) International Classification of Diseases (ICD-10), the fact that there are few reliable and valid instruments presently available for clinical use with children and adolescents, and a reluctance to recognize BPD symptoms in youth, however, make such assessment challenging.

Crick and colleagues' self-report Borderline Features Scale for Children (BPFS-C) is one measure that may be administered to children as young as 9 years old. From this age on, most children are able to provide information on their characteristics or problems. Another self-report instrument that includes a measure of BPD symptoms is Reynolds' Adolescent Psychopathology Scale, designed specifically for youth between the ages of 12 and 19. Poreh and colleagues' Borderline Personality Questionnaire (BPQ) is recommended for screening purposes among adolescents who seek help in clinical outpatient settings [4]. First and colleagues' Structured Clinical Interview for Axis II disorders (SCID-II), shows some promise for assessing adolescents for personality disorders including BPD, as does the Shedler-Westen Assessment Procedure for adolescents (SWAP IIA), which allows clinicians to communicate their observations and inferences in a quantified manner. Teacher-report, parent-report, and behavioral observations are also useful and important sources of information; at this time, however, standardized instruments specifically designed to assess BPD via such methods are not available. Common comorbid conditions should be evaluated simultaneously so they too may be treated when present.

Characteristic behaviors must show significant consistency and persistence across time and settings for BPD to be considered. However, clinicians should also take into account that underlying pathology may be expressed differently as children grow older. Prior to concluding that youth traits, symptoms and behaviors are indicative of borderline pathology, clinicians should rule out normal developmental explanations and developmental delays. Clinicians should also gather information about the youth's larger social system (peers, family, school setting, social circumstances, cultural context) to determine the extent to which individual or societal expectations may play a role in the expression of borderline features, and whether such features are in fact discordant with environmental conditions. Information about past stressful life events (e.g., history of abuse), family member's needs, and the function or value of specific behaviors to the individual may also be useful for treatment planning.

Identification of youth borderline symptomatology is a prerequisite for the provision of intensive and

appropriate care. However, clinicians may be reluctant to officially describe youth in BPD terms, given that BPD is highly stigmatized and commonly viewed as untreatable. Clinicians may also fear that such a description will lead important figures to give up on such youth [9]. Thus, when clinicians report assessment results indicative of borderline pathology, they should simultaneously correct misconceptions and provide psychoeducation about BPD to young clients and their families.

Treatment

Depending on individual needs and available resources, treatment options for youth with BPD may include one or more of the following: medication, hospitalization, individual psychotherapy, group psychotherapy, family therapy, and family psychoeducation. Among adults with severe BPD, multiple medications are often prescribed to help clients manage symptoms ranging from mood swings to impulsivity [12], despite the lack of research evidence for such combinations. Little is known about the use of medications and their effectiveness in the treatment of borderline pathology in youth.

When individuals with BPD attempt suicide, exhibit psychotic symptoms, or experience acute crisis, hospitalization is often the first line of treatment; however, aggressive out-patient treatment with strong therapeutic outreach may be considered as an alternative to hospitalization (see [12]). Once life-threatening behaviors are reduced and hopefully eliminated, treatment may focus on helping clients manage their emotional experiences.

A primary goal of individual psychotherapy is to provide a supportive relationship within which clients can be helped to manage their symptoms and accompanying problems, especially those associated with suicidal thoughts and behaviors. Psychoanalytical approaches to the treatment of BPD use the client–therapist relationship to address problems faced by the client, while cognitive approaches help clients develop more adaptive views of themselves, e.g., as acceptable and valuable human beings, and of the world as a more benevolent and safe place than previously thought. Developing problem-solving skills can also be a part of this approach. Young people who still have relatively concrete cognitive reasoning skills may benefit from behavioral strategies such as modeling and shaping. In terms of social interaction with others, therapists can help youth build a more adaptive and flexible repertoire of responses to improve their ability to relate to and cope with others in their environment or family and social system. Therapists can also teach their young clients to pay attention to internal states experienced while interacting with others and to interpret, respond to, and represent human behavior more accurately, along the lines of Fonagy and Bateman's mentalization-based treatment approach (see [7], where many of the psychotherapy treatment modalities discussed in this section are explored more fully).

Dialectical behavior therapy (DBT) is one of the most effective and widely used treatments for BPD. According to this model, clinicians work with clients, both individually and in groups, to become less impulsive, improve interpersonal communication skills, practice mindfulness, tolerate distress, regulate emotions, cope with post-traumatic stress, and develop self-respect. In DBT, clinicians also help clients to eliminate suicidal and other behaviors, such as substance abuse and unsafe sex, that pose significant risks to well-being. A modified version of DBT appears promising in reducing suicidal behavior among youth [13]. Cognitive analytical therapy (CAT), an approach that draws on cognitive psychology and psychoanalytic object relations theory, appears to help youth with BPD control their externalizing symptoms even after the conclusion of treatment [3].

Family psychoeducation, support, and skill development are often a very important supplement to treatment approaches, given the level of pathology, stress, and dysfunction often present in families of individuals diagnosed with BPD. Family therapies such as Dialectical Behavioral Therapy-Family Skills Training (DBT-FBT) help family members regulate their emotions, improve interpersonal skills, and interact in a more validating manner. Clinicians treating youth can also work with parents to develop more effective parenting strategies. Integrative Borderline Adolescent Family Therapy (I-BAFT) is recommended when substance abuse and BPD are present. Regardless of treatment approach, clinicians treating youth for symptoms of BPD should consider level of development, current contexts in which youth function (e.g., family, school, friendships, early romantic relationships), and current tasks that youth are negotiating within these contexts as they help such youth develop a more integrated sense of self.

Relevance to Childhood Development

While BPD is typically considered an adult disorder, BPD features or symptoms are not uncommon among children and adolescents. Rather, a sizable percentage of youth meet criteria for BPD in treatment settings as well as in the general community, and even more youth experience symptoms or display features of borderline pathology. Such youth tend to have associated problems at school, home, and in interpersonal relationships that interfere with their ability to smoothly transition from one developmental stage to the next. In fact, adolescent symptoms of BPD predict lower levels of functioning and attainment

all the way through middle adulthood, with higher youth symptom levels associated with more severe outcomes later in life.

A comprehensive assessment of youth borderline pathology should take into account both actual and expected levels of development and the contexts in which purported emotions, thoughts, behaviors, and interpersonal relationships characteristic of BPD occur. When symptoms and features are identified early on, interventions can be put in place that help youth, families, and school personnel better understand the nature of borderline pathology, cope with its manifestations, and hopefully reduce the likelihood of adverse outcomes. Parental psychopathology, poor attachment relationships between caregivers and offspring, trauma and abuse all pose serious risks for children's subsequent development of BPD and other forms of psychopathology. If recognized, such risk factors may be addressed early on via parental education and mental health treatment. Access to social support and opportunities to further develop cognitive strengths and interpersonal skills may also help children who are already at risk for developing BPD cultivate resilience.

Bowlby's Attachment Theory

Jerry Gold
Adelphi University, Garden City, NY, USA

Definition

John Bowlby's Attachment Theory is an integrative model that relies on concepts from psychoanalytic theory,

information processing theory, theories and research on emotion development, and ▶ethology. It describes the central role of attachment to a reliable caregiver in the healthy psychological development of the child, and the significant detrimental effects on mental health when reliable attachments are disrupted or lost. Originally described by Bowlby as a revision of psychoanalytic theory, its emphasis on interpersonal experiences and rejection of Freud's drive theory caused it to be controversial in that community and to be dismissed by many psychoanalysts. It became popular in the 1980s and 1990s among cognitive-behavior therapists who were searching for a comprehensive theory of personality upon which to base their clinical interventions. During the 1990s, as psychoanalysis began to shed its Freudian assumption and to move in a more relational direction, Attachment theory was rediscovered and was enthusiastically utilized by many in that discipline.

Description

Attachment theory originally evolved out of clinical and theoretical psychoanalysis. John Bowlby was a leading British psychoanalyst and child psychiatrist who was trained and practiced traditional Freudian psychoanalysis. In this model, a child's attachment to his or her mother was understood to be derived from, and secondary to, the gratification that derived from feeding and other sources of drive reduction. Bowlby gradually became convinced, through a variety of experiences and sources of data, that this view was incorrect. In his clinical work he had begun to experiment with expansions of the psychoanalytic frame, often working with several members of a family simultaneously. At the same time, his work as a consulting child psychiatrist in the British National Health Service allowed him access to direct observation of children and their parents. He also made an in-depth study of the newly emerging research in child development and in biology, and was impressed by finding such as those reported by Harlow, who found in a study of infant monkeys that those infants choose the comfort of a clothing mother-surrogate over a wire surrogate which offered food. Bowlby's experiences, observations and insights led him to a revolutionary revision of psychoanalytic theory that evolved into an independent theory of child development, the organization of personality, and of developmental and adult psychopathology.

Attachment as a Biological Given

Attachment theory is based on the premise that all human beings are biologically programmed to seek comfort and safety through proximity to a reliable and protective caregiver. Bowlby argued that this is a basic, if not the basic, psychological need in children, and that such needs and behavior can in fact be observed in other species (he argued ethological studies of imprinting supported this conclusion). The primacy of the human need for attachment derives from evolutionary considerations and from the extended period of helplessness and dependency that is experienced by the human child. Individual children would suffer or perish if left to their own devices during infancy and childhood, and humans as a species might face extinction were reliable caretakers unavailable to our young.

Attachment theory also postulates a biologically derived reciprocity on the part of adults, which makes adults ready and willing to serve as attachment figures and caretakers. Bowlby observed that human adult seems to have a universally positive response to babies, young children, and to the young of other species: adults tend to find these persons and creatures to be "cute," "adorable" and so on, and to experience spontaneous desire to cuddle and care for the child in close physical and psychological proximity. This is not accidental, but is part of the human genetic heritage that ensures that the safety of attachment will be available to infants and children who cannot take more of an active role in establishing those contacts.

Attachment in the earlier phases of psychological development therefore is understood to be a mutually established and mutually regulated process: it stems form the intrinsic biological and psychological needs of both parties (infant or child and giver) and is expressed in the behavior of both individuals. Child and caregiver monitor the affective, behavioral, and environmental conditions and make changes in proximity and connectedness through signaling (crying, talking, gesturing) and actions.

The need for safety and comfort in relation to attachment figures persists throughout life, but in the psychologically healthy older child, it is expressed in more subtle, more mature, and often symbolic ways. Attachment theory posits that disturbances of attachment processes in early development may lead to later consequences in intimate interpersonal relationships. These consequences will be explored in a later section of this article.

Exploration: The Attachment Figure as a Safe Haven

Attachment theory states that the need to separate and to explore the world is an equally important and parallel psychological need that also is rooted in the biology of the human species. As a child progresses from infancy

through childhood and adolescence he or she must naturally spend more time at greater distances away from primary attachment figures. The failure to do so will lead to a person whose development is stunted and who able to cope with life is limited and skewed. Exploration of the world is best done gradually, supported by attachment figures who are encouraging and yet watchful, alerting the child to danger and intervening when necessary. Healthy exploration involves repeated "checking in" with the adult and regular periods of returning to that safe haven of attachment. Attachment figures who prematurely allow the child to explore beyond the limits of his or her safety and abilities can be extremely disruptive, as can those adults who inhibit the child's freedom to explore because of the adult's own anxieties and needs for connection.

Safety and Anxiety: The Affective Response to Attachment and Separation

Empirical studies and clinical observations have demonstrated with great redundancy that infants and children experience emotional distress when separated from their caregivers, and that they evince reduction of that distress when re-united. Attachment theory suggests that the negative emotional experiences that are correlated with separation are the precursors of such emotions as sadness, anxiety, and depression.

The Response to Separation: Protest, Detachment, and Despair

Attachment theory postulates that a specific, predictable and regular progression of affective and behavioral reactions occurs when a child is separated from an attachment figure. The first component of this sequence is *Protest*, manifested by crying; angry gestures, facial expressions, and utterances, and attempts to restrain the attachment figure or to find that person. This is followed by the *Detachment* phase, during which the child becomes listless, removed, and affectively cut-off from the world. Seemingly, he or she seems to have concluded that protesting has failed. The final stage of *Despair* has been likened to adult depression. The child is openly sad, distressed and seemingly hopeless about the return of the attachment figure. These emotional and cognitive reactions are powerful and enduring, even when the periods of separation are expectable and of relatively limited duration. Children who have reached the latter two phases of this sequence do not immediately greet the returning caregiver with open arms. They often ignore or respond angrily to his or her return, and a period of repair and re-attachment frequently is necessary.

Loss: The Effects of Unresolved Grief and Mourning

Bowlby's formulation of attachment theory posed a significant challenge to the received wisdom in the fields of child psychiatry and psychoanalysis concerning children's responses to loss. Those disciplines had long held that children younger than adolescence were largely invulnerable to the more serious effects of object loss, such as depression and complicated bereavement, because of their (supposedly) limited affective ties to adults. Bowlby's clinical and theoretical work exposed and contradicted totally this fallacy. Attachment theory argues that children are greatly effected by losses of significant others, and that these losses, if not mourned properly, can and will have permanent ill effects on the child's psychological development and health. Often, it is assumed, these losses are a major component of psychopathology in adulthood.

Why had it been assumed that children did not suffer from loss? An answer can be found in the basic assumptions of attachment theory. Just as children cannot meet their basic needs for security and survival by themselves, and there must be tended to by a caretaking adult, children cannot grieve without adult assistance, example, and support. Often, the very person whose attentions are crucial in this process (perhaps, e.g., the parent who survives the death of a spouse) is limited by grief themselves and cannot be of use to the child in grieving. Also, as Bowlby's research demonstrated, many families are uncomfortable with powerful emotions and work actively to inhibit the emotional reactions of family members, including of children. What had been assumed to be a lack of response to loss was now understood to be the response of the child to environmental failures, neglect, or unavailability. When children do receive the necessary support and guidance after a loss, and they perceive the expression of emotion to be safe and desirable, they will be observed to grieve and mourn much as do adults.

Working Models: The Internalization of Attachment Experiences

The developing child's experiences of attachment and exploration become over time a permanent part of his or her psychology (internalization). Borrowing from cognitive science and information processing theory, Bowlby postulated that the individual builds up intrapsychic representations or working models (similar to the *scheme* in Piagetian theory) of his or her interpersonal world which are generalized perspectives about the availability and reliability of potential attachment figures, and the safety

and permissibility of exploration in relation to those caretakers. These working models are a kind of mathematical summation and averaging of the person's experiences that allow him or her to make predictions about the future and about new interpersonal experiences. Those children who attachment needs have been met, and whose exploration has been encouraged and supported safely by the provision of a safe haven, will naturally establish healthy and optimistic working models of attachment and exploration, and will use these models to identify new persons who are most likely to be consistent with the positive predictions of safety. However, children for whom reliable attachment experiences have been absent or inconsistent, and/or who have lacked a safe haven for exploration are very likely to develop pessimistic and gloomy representational models. In new interpersonal situations these children, and the adult who they become, will predict dire and disappointing interactions that are replicas of earlier events. These persons will therefore find new relationships to be potentially hurtful, fraught with anxiety and the possibility of loss, and therefore will develop coping or compensatory strategies for managing new attachment failures that will further compromise their adaption and psychological health.

Anxious Attachment: The Results of Early Failures of Relatedness

Bowlby reported that those individuals whose early lives, as described above, eventuated in insecure working models of attachment, had few good choices for managing the attendant anxiety that was provoked in new intimate relationships. He described several variants of pathological working models and their intrapsychic and behavioral correlated. The person with an *anxious attachment* style sees and fears rejection, abandonment, and loss at every turn. He or she often attempts to please significant others at every opportunity, displaying a clingy, dependent, and subservient attitude toward the other person. Those whose attachment style is *avoidant* attempt to remain self-sufficient and independent, and are described as aloof or distant by others. This person will become extremely anxious and uncomfortable in intimate situations. The individual who demonstrates a pattern of behavior known as *compulsive caregiving* appears to be repeating the particular failure of attachment that he or she experienced as a child, having been placed in the role of "parentified child" or caregiver to a parent who was incapacitated by psychopathology, physical illness or some other condition. All of these variants of anxious attachment are highly correlated with, and perhaps causative of, psychopathology such as depression, obsessive-compulsive disorder, and anxiety disorders, among many conditions.

Relevance to Childhood Development

Attachment theory provides the student of child development with a theoretical framework that integrates clinical observation with empirical research, and studies of depth psychology with social observations. Attachment theory can explain the ways in which early experiences are internalized and therefore continue to exert an impact on subsequent development and on adult behavior. It also serves as the link between investigations of parent-child interactions and clinical phenomena.

Bowlby's Stages of Attachment

Cynthia Field
William Alanson White Institute, New York, NY, USA

Definition

The British psychiatrist and psychoanalyst John Bowlby described four phases in the early development of human attachment. Each phase is characterized by behaviors and, as the child matures, cognitions that are used to maintain proximity to or contact, both emotional and physical, with primarily the mother as well as other figures. Bowlby believed that humans are biologically built to become attached as a survival strategy.

Description

An attachment is an affectional bond that one person has with another, which connects them to each other and usually indicates affection or love. Normally, the first attachment the child forms is to the mother (or primary mother figure), and this attachment develops over time as the child matures. Bowlby developed a theory of human attachment to explain the child's close affectional bond with the mother and based this theory of psychological development in part on and on Darwinian evolutionary principles of survival. He theorized that human

infants – similar to animals – are endowed with species-specific behaviors that promote survival by both keeping the infant in close proximity with others and eliciting their care and protection. Initially he theorized that sucking, clinging, following, crying, and smiling were the behaviors that largely mediated attachment. Later he recognized more sophisticated behavioral systems as integral to attachment and proposed a control systems model in which the initial simple attachment behaviors become part of a goal-corrected behavioral system that is more flexible, purposive, and responsive to feedback from the environment. In contrast to Freud and other psychoanalysts, Bowlby did not believe that infants become attached as an outcome of having its needs gratified by others. Instead he theorized that humans are biologically endowed to become attached and supported his theory with a vast amount of data from studies of both animal behavior and early childhood development. For Bowlby, the nature of the early attachment determined psychological development and emotional well-being and served as a template for later attachments. Bowlby identified four phases in the development of attachment; the time frame he delineated for each phase could be delayed either because of normal individual differences or because of impaired functioning of the mother-child dyad.

Phase 1. Orientation and signals with limited discrimination of figure

In this phase (from birth to 2–3 months), the child's ability to distinguish people is limited, and the child responds in similar ways to all people. A repertoire of simply structured behaviors – orientation toward people, visual and auditory tracking, grasping and reaching, babbling, smiling, and ceasing to cry at the sound of a voice or seeing a face – attract and keep people close to the child. By about 3 months, the child's friendly response is clearly present in all its spontaneity, liveliness, and delight.

Bowlby believed that it is primarily the human response to the child rather than oral gratification (such as the satisfaction of being fed) or gratification of other basic drives or needs that reinforces or modifies these attachment behaviors. How the child reacts (e.g., whether with signs of pleasure or displeasure) to sensory stimuli can greatly increase or decrease the likelihood of their reoccurrence. It is well established that the child's responses are inherently biased toward the development of social interactions. From early on, although the child responds to a broad range of stimuli, the child demonstrates a preference for the human voice and face, for moving versus static objects, and for tactile and kinesthetic stimulation. The mother's ways of handling the young child are also inherently biased toward promoting an early interaction. For example, in cradling the child to her during feeding, the mother brings the child into close proximity, which affords the child the opportunity to be oriented toward the mother, to gaze at her face, and to be in physical contact with her.

Phase 2. Orientation and signals directed toward one or more discriminated figures

During this phase, which lasts until about 6 months of age, the child demonstrates the same friendly responses as evident in the first phase, but this behavior is more marked with the mother than with other individuals. Bowlby's description of the attachment behaviors characteristic of this phase are largely drawn from the research of his colleague Mary Ainsworth. The child greets the mother differently as well as vocalizes and smiles differently with her. The child is more likely to cry at the mother's departure and to stop crying when she returns. Even when held by others, the child is likely to maintain a visual-postural orientation toward the mother. It is also recognized that during this phase the child can establish a pattern of differential behaviors with other familiar people.

Phase 3. Maintenance of proximity to a discriminated figure by means of locomotion as well as signals

In this phase, which lasts through the second year and into the third, the child's primary attachment to the mother is clearly evident. With the onset of locomotion, the child's range of attachment behaviors expands to following the mother as she departs, approaching her upon her return, and using her a home base from which to explore. Concomitantly, the child's generally friendly and nondifferentiating responses to others decreases, and the child reacts with caution and even alarm and withdrawal in the presence of strangers. In the majority of children, fear of strangers is evident by 8 months.

Cognitive development during this phase advances the child's behavior from fixed-action (the essentially instinctive attachment behaviors of the earlier phases) to goal-corrected (purposive and directed at a goal). The child begins to be able to plan and to adjust its behavior to maintain a comfortable proximity to the mother. The child's ability to plan is predicated on the development of working models that the child is beginning to construct from its growing knowledge of the world and people and expectations about them. Whereas earlier the child had no understanding of the mother as a separate individual and generally displayed a fixed pattern of attachment behaviors no matter the situation or response from the environment, the child in the third phase comes to

perceive the mother as someone existing independently in the world and begins to regulate its proximity to the mother using a built-up but still primitive cognitive schemata of its environment and expectations about her whereabouts. This phase overlaps with Piaget's sensorimotor stage and the development of object permanence when the child begins to understands that an object still exists even when it is not visible and will search for a hidden object.

Phase 4. Formation of a goal-corrected partnership

In this phase, which may start in some children by the middle of the third year, the child perceives the mother not only as a separate physical entity but also as someone whose behavior is influenced by her own set-goals. The child's growing cognitive competence, including a capacity for insight, enables it to make inferences about the mother's point of view and the feelings and motives influencing her behavior, factors that can be multivariate and possibly inconsistent and thus not always readily understood. Greater flexibility on the part of the child is required. Previously, proximity was largely decided by the mother; in this final phase, proximity is more mutually negotiated and determined.

Braille

Stephanie A. Grote-Garcia
University of the Incarnate Word College of Education, Texas A&M University-Corpus Christi, Corpus Christi, TX, USA

Definition

Braille is a reading and writing system that is used by individuals who are vision impaired (see *blindness*). Braille allows individuals who cannot use their sense of sight in reading to instead, read text with their sense of touch. Braille consists of raised dots that form characters. Individuals who are totally blind or legally blind feel these raised dots with their fingertips. This process allows them to create meaning from Braille text, much like a visual reader would from printed text.

Description

Braille characters, also called cells, are typically made up of one to six raised dots that are arranged into rectangular embossed patterns. Each of the rectangular patterns, contain two columns of three dots each. There is also an extended variation of Braille that includes a pattern of eight dots. Punctuation is represented by its own unique set of characters.

Braille characters may be produced using a slate and stylus, a Braille typewriter, or a Perkins Brailler. Similar to printed text, Braille is printed in horizontal lines that are read in a right to left motion. Also similar to printed text, the horizontal lines of Braille are separated by a space. This space assists the reader in differentiating the cells in one line from the cells in the line above and below.

History

Louis Braille, a blind Frenchman teaching at the National Institute for the Blind, devised Braille in 1821. His idea for the Braille system was based on a method of communication originally developed by Charles Barbier. Barbier's method of communication was used by soldiers in the early nineteenth century to communicate silently and without light at night. Barbier's method of communication was found too complex by the soldiers. Louis Braille created the Braille system as a less complex solution. He is credited as the creator of the Braille system which revolutionized written communication for the vision impaired.

Relevance to Childhood Development

Children who are vision impaired may experience educational disadvantages that are connected to their inability or difficulty in seeing printed text. Many children who are totally blind or legally blind experience complications in learning to read. According to the 4, 90% of children who are vision impaired are not taught to read even though Braille exist. The inability to read printed text can lead to other educational obstacles, such as reading in other subject areas. It can also lead to obstacles in completing everyday tasks such as those requiring children to read environmental print.

Brain

Sean Cunningham
University of Utah, Salt Lake City, UT, USA

Synonyms

Cerebral cortex; Cortex; Neo-cortex

Definition

The brain, from Old English *brægen*, is the tissue of the central nervous system (CNS) housed in the skull, composed of neurons and supportive cells (e.g., glial), that is responsible for the direction and coordination of mental and physical processes, learning, and processing sensory information.

Description

The brain is an organ of the CNS. The CNS, which consists of the brain and spinal cord, is connected to the body through a series of afferent and efferent nerve fibers that carry various types of information (e.g., motor, sensory) to and from the brain. The brain itself can be broadly thought of as comprised the cerebral cortex, cerebellum, and brain stem, each discussed in turn.

The cerebral cortex is tissue that makes up most of the brain (approximately 80%), which consists of white and gray matter, and has a folded appearance. Folds of the brain are referred to as gyri. The creases between the folds are referred to as sculi. The cerebral cortex is responsible for higher order cognitive functions such as language, learning, and memory. In general, the cerebral cortex can be thought of as divided into two parts, right and left, called hemispheres, which are relatively symmetrical. The right hemisphere is responsible for motor movements and processing the majority of the sensory information for the left side of the body. The left hemisphere is responsible for motor movements and processing most of the sensory information for the right side of the body. Each hemisphere of the brain is connected by the corpus callosum, which is a series of neural fibers, known as commissural fibers, connecting different areas of the brain, allowing communication back and forth. Each of the two hemispheres of the brain, the right and left, can be further divided into four different lobes: the temporal lobe, frontal lobe, parietal lobe, and the occipital lobe.

With regard to brain functioning, each hemisphere and lobe has a certain amount of specialization, although brain functioning is diffuse, and shared widely among the different areas. The right hemisphere appears more dominate in processing spatial abilities, face recognition, visual imagery, and music, whereas the left hemisphere dominates in processing abilities requiring logic, and language. The *occipital lobe*, which rests at the posterior region of the hemispheres, is involved primarily in processing visual information. The *parietal lobe* is in front of the occipital lobe, yet behind the frontal lobe, and can be though of as resting on top of the brain. The parietal lobe has two distinct roles. The anterior region processes somatic sensation, whereas the posterior region integrates sensory input. The *temporal lobe* is split on each side of the brain, located below the parietal lobe and in front of the occipital lobe. The temporal lobe has been identified in having a multitude of functions. The temporal lobe serves to process sensory input, such as object recognition, auditory information, and memory of sensory experience. Additionally, the temporal lobe plays a role in language and memory. The *frontal lobe* is located at the most anterior part of the brain, just behind the forehead. Primary among its functions concerns temporal organization. The frontal lobe selects and implements behavioral strategies to manage cues from the immediate environment, as well as internal cues, and processes emotions, as well as language. The functions of the frontal lobe are popularly referred to as executive functioning. It is important to note that although the different sections of the cortex have primary responsibilities, the interplay of neural connections between them is complex. Processing occurs throughout the brain in a relatively simultaneous manner, with the different areas of the brain performing operations in concert with each other.

The cerebellum, which is located under the cortex at the base of the skull, is a second major section of the brain. The cerebellum's primary responsibility has to do with the coordination and learning of voluntary and skilled movements. Additionally, the cerebellum plays a role in balance and equilibrium, muscle tone, and posture.

The brainstem is a third major section of the brain. The brainstem is located deep in the brain and controls several processes vital to life, such as the regulation of eating and drinking, sleeping, and body temperature. The brainstem also plays a major role in responding to environmental sensory stimuli, and in movements associated with walking, grooming, and sexual behavior.

In addition to the brain structures previously discussed, there are two additional parts of the forebrain, the limbic system and basal ganglia, which have important roles. The limbic system plays a role in a variety of behaviors including aggressive behavior, sexual behavior, memory, and even personality. The limbic system encompasses several interrelated structures, primary among these are: the hippocampus, amygdala, olfactory bulb, thalamus, and cingulated gyrus. The first of these structures, the hippocampus, is believed to play a role in memory, especially the formation of memory about experienced events, and spatial memory. The amygdala plays a role in the processing of emotional memories, such as fear conditioning. Olfactory, or smell, stimuli is processed by the olfactory bulb. The thalamus is responsible for motor control, and is a primary relay station of sensory information to the cortex. The cingulated gyrus plays a role in the formation and processing of emotion, learning, and memory.

A basic building block to the brain is the neuron. A neuron is a specialized cell in the brain and nervous system that allows for the exchange of information. Similar to all cells, the neuron has a cell body that houses the nucleus, intracellular fluid, mitochondrion, and other organelles. What makes the axon more distinctive, are branch-like structures that extend away from the cell body, dendrites and axons. Dendrites and axons have the unique responsibility of transferring information between the cells. Dendrites are neural fibers that bring information to the cell. The word dendrite comes from a Greek word meaning "tree," which is relevant to its appearance, as dendrites have a branched, treelike appearance. A neuron can have several dendrites, each of which can have a further set of branches, which can ultimately number in the thousands.

The axon is a neural fiber that takes information away from the cell body to other neurons, muscles, or glands. Each neuron has one axon. Axons can be lengthy structures (some over a meter in length) that have branches emerging from them called axon collaterals. The end of the axon can branch out into what are called teleodendria. The end of the teleodendria contains the end foot, or terminal button, that rests close to the dendrite of another neuron. The area between the end foot of one neuron and dendrite of another is called a synapse, the primary communication hub where information between neurons is shared.

The transmission of information across a synapse is part of a series of events that allow neurons to communicate. Communication between neurons is essential to the ability of the brain to perform all its functions. The series of events begins with an action potential, an electrical impulse that allows for the travel of information along an axon. When the action potential arrives at the end of the axon, a series of events occurs that results in the release of chemical messengers, or neurotransmitters, stored in the presynaptic neuron. Neurotransmitters get released across the synapse into the space between the presynaptic axon and postsynaptic dendrite. The space between the presynaptic axon and postsynaptic dendrite is referred to as the synaptic cleft. Neurotransmitters travel across the synaptic cleft and bind to receptor sites on the postsynaptic membrane (i.e., dendrite). Depending on the interplay between the specific neurotransmitters and receptors involved in the process, the postsynaptic cell responds in one of three ways. The postsynaptic cell can continue to send the message along to other neurons in the form of another action potential, stop the message, or initiate a series of chemical reaction sequences changing the message, or bringing about some other change in the cell.

The development of the brain, neurulation, begins 19 days after fertilization [2]. Each brain cell is derived from a stem cell, which is a single, undifferentiated cell in the brain of the embryo. In all, the brain contains about 100 billion cells [9]. A layer of embryonic tissue, the ectoderm, develops into the brain and nervous system. The brain goes through several processes of growth. The fundamental processes of brain development are: neural induction, proliferation of nerve cells and glia, cell migration, cell death, cell differentiation, formation of synapses, and pruning of synapses [4].

During the *neural induction* process, the neural plate develops from the ectoderm and folds into the neural tube at about the third or fourth week after conception. The front of the neural tube forms the brain, the tail forms the spinal cord. The hollow inside of the tube begins to develop into the ventricles, and the lining develops the cells of the brain. The tube closes around 25 days after conception and becomes filled with cerebrospinal fluid, cells divide, and layers then begin to from. The cell division continues in the *neural proliferation* phase until about

the 18th week. During this phase, neurons can be generated upwards of half a million a minute [2]. During *cell migration*, glial cells guide newly forming neurons, or neuroblasts, typically from lower areas of the brain (i.e., ventricular zone) where the proliferation of cells occurs, to higher, or surface areas of the brain. The particular glial cells responsible for this scaffolding effect are radial glia. Cells eventually come to rest at the area they will occupy in the mature brain. The next phase of brain development, *cell death*, occurs when the neurons have reached their destination and synapses have started to form. During the cell death process, several neurons and synapses are eliminated as competition for life sustaining forces, or trophic factors arise. Eventually, the proper number of neurons and synapses is reached [1]. During the process of *cell differentiation*, which can occur at the same time as cell death, neural cells that have reached their destination further differentiate. Two aspects of cell differentiation during this process include the branching out of dendrites, and the guidance of axons to their targets. The *formation of synapses*, or *synaptogenesis*, is a process that begins within weeks of conception, continues at a rapid rate in the first 2–4 months, and may occur throughout life [8]. After birth, during the most active time of synaptogenesis, experience plays a dominate role in determining axon and dendrite architecture. Studies have found that the rate of synaptogenesis differs depending in what area of the cortex the process is taking place [7]. The final process of brain development discussed here, *pruning of synapses*, begins at 7 months, and continues to adolescence. By 21 months, 40% of synapses can be eliminated [2]. The pruning process involves the elimination of synapses, and is considered a part of normal development. Throughout the early years of life, synaptic density reaches its peak, and then levels off to adult levels throughout childhood. As with synaptogenesis, pruning occurs at different rates, depending on what cortex the process is occurring [8].

Another important process of brain development is myelination. Myelination allows for better and faster communication between axons. Myelination is a process by which axons become covered in a fatty substance, myelin. Myelin is an insulation that surrounds axon fibers and allows information to be moved along the axon at a faster rate. Myelinated axons can carry messages 50–100 times faster than unmyelinated axons [10]. A considerable portion of myelination occurs before birth, with particular emphasis between 22 and 24 weeks, but continues into adulthood. Schwann cells, a support cell to the CNS, forms the myelin around the axon. The myelin is formed in segments around the axon, as opposed to one continuous layer of insulation. The spaces between the sections of myelin are referred to as nodes of Ranvier. The distance between the segments of myelin play a central role in how fast information can travel along that axon.

Whereas the brain can be divided into left and right hemispheres, with each side relatively specialized for a certain set of mental functions (e.g., language on the left), the brain can also be thought of as being divided into anterior and posterior regions, which also have a localization of function. The anterior region of the brain primarily handles motor functions and the posterior region primarily handles sensory functions. Alexander Luria, a famous Soviet neuropsychologist and developmental psychologist, advanced this theory in the 1960s. The two regions of the brain are separated by the central sculus, which is a deep groove, or fissure, into anterior and posterior regions. Adjacent to the central sculus, just anterior, is the motor strip, also referred to as the motor cortex, which is a narrow band running across the brain. Tissue of the motor strip, is proportional to the quantity to which motor control is required by a particular body part. The role of the motor cortex in movement is somewhat controversial. It is thought that cells of the motor cortex instruct muscle movements in a direct fashion, causing them to contract. Other lines of research hypothesize that the cells of the motor cortex specify the target of movement. In general, the motor cortex has pathways which extend outward to the spinal cord. Axons, in the form of large pyramidal cells, and long support axons, diffuse into several specific specialized tracts to assist in transferring information regarding movement.

Directly posterior to the central sculus is the sensory strip, also referred to as the sensory cortex or somatasensory cortex, which, like the motor strip, is a narrow band running across the brain. The sensory strip receives input from external as well as internal sensory stimuli. Similar to the motor strip, the amount of tissue in the sensory strip is proportional to the degree of sensory information associated with certain body locations, based on function. For example, more tissue of the sensory strip is dedicated to the hands as opposed to the arm, as the hands require a more developed sense of touch.

Both motor and sensory stimuli are processed in localized sections of the brain (e.g., sensory information in the posterior regions), however, the complete integration of this information for conscious perception involves processing in diffuse association areas, as well. Different theories have been proposed to address the

functional organization of the cortex, in order to describe how the primary processing areas and association areas of the brain work together to synthesize information. The brain synthesizes information in a way that allows the phenomenological experience to be one of a unified whole, with spatial and temporal continuity. Given the distributed nature of processing around the brain, researchers have not been able to fully explain how all areas of the brain come together to incorporate their information into an integrated whole for the subjective experience. This area researchers struggle to explain is referred to as the binding problem. Different models have been proposed to explain the functional organization of the brain, which work to address the binding problem.

Luria [11] believed that sensory stimuli were transmitted by organs to a areas of the sensory cortex to be processed, then to a secondary association cortex, where meaning was assigned to the sensory input, and finally to a tertiary association cortex, where it was integrated with other cortical functions, resulting in symbolic processes. "For example, the perception of any particular series of movements could be processed by the sensory cortex, while secondary processing areas would indicate what the movements constituted (e.g., orchestra concert, football game), and finally, the tertiary areas would synthesize information about the stimuli into what could be referred to as knowledge (e.g., the song playing by the orchestra is recognized as Debussy's Pre´lude a' l'Apre's-midi d'un faune)."

A more contemporary theory of functional organization is the distributed hierarchical model, proposed by Felleman and Van Essen [5]. The distributed hierarchical model proposes a more simple organization of sensory processing in the cortex. The central tenet of the Fellman and Van Essen model suggests there are several hierarchical links between the sensory and motor areas of the brain. Within these links there are connections to other areas of the brain (e.g., limbic system). The essential hypothesis of the distributed hierarchical model purports that depending on what property of the brain is required to interpret a situation or solve a problem (e.g., color information, size information), the brain has developed cortical association areas which can communicate with each other to simultaneously pass on the information. The cortical activity is influenced by feedback loops from other parts of cortex, as well as subcortical regions. At times, all of these cortical areas are summoned simultaneously in order for binding to occur, and symbolic processes to result.

Relevance to Childhood Development

The brain of a child goes through a pace of maturation unmatched by any other phase of life. At birth, the child's brain, in such an immature state, renders the child dependent upon others for survival. The child merely acts upon instinct to obtain nourishment and attempts to survive. As the child grows, the brain matures, and the child is eventually able to perform more sophisticated cognitive functions (e.g., language, consciousness). Brain maturation takes a considerable amount of time, many years, with later developing areas, such as the frontal cortex, not fully developing until late adolescence [6, 12]. Brain processes such as synaptogenesis, pruning, and myelenation continue to organize the brain into emerging adulthood [7].

Life experience shapes the architecture and function of the growing brain, thus, any aspect interfering with brain growth in childhood can potentially have detrimental, far reaching effects (e.g., injury, neglect). These effects can impact any aspect of the individual's functioning mediated by the brain (e.g., learning, motor coordination). Along similar lines, an environment rich and complex can work to benefit the growing child's brain development. Those environmental aspects that can harm or benefit a child's brain maturation come in many forms, including caregiver bonding, nutrition, caregiver responsiveness, exposure to language, and learning environments. Structural changes in the brain dependent upon environmental conditions can affect brain size, glial cell density, density of dendrites, and dendrite length, among others.

The developing brain of a child has more plasticity than the adult brain, making it better able to compensate for insult. Plasticity refers to the capability of the brain to change in response to an injury, allowing it to compensate for the loss of any particular function. Before age five, an injury to the brain can be almost fully compensated for by rerouting and restructuring neural networks to other parts of the brain [3]. For example, language typically develops in the left-hemisphere, but can be rerouted in young children to the right hemisphere in the face of a brain injury to the left hemisphere [13]. However, injury before the age of 1 year can have more detrimental effects on development with little or no ability for the brain to compensate.

Critical periods have been identified as a particularly sensitive periods in brain development where certain conditions or experiences in the environment need to be present in order for a child's brain to make appropriate connections. Critical periods can exist parentally, as well as

after birth. Several mental processes can be affected by lack of appropriate environmental conditions, including vision and development of language.

Brain Abnormalities

Matthew J. Holcomb, Raymond S. Dean
Ball State University, Muncie, IN, USA

Synonyms

Neurological

Definition

The term *brain abnormalities*, refers to any atypical feature in brain functioning, structure or biochemical levels. The etiologies of abnormalities differ widely, from genetic, parinatal compactions, developmental and traumatic disorders, toxins and diseases of the mother and/or child. The severity of the abnormalities differ widely, and the extent to which they are obvious in the patient is not always predictable.

Description

Brain abnormalities are wide ranging and can be both organic, developmental or a combination of both in origin. Research has linked the presence of brain abnormalities to a variety of conditions including developmental disorders such as Autism [2], Schizophrenia [3], Alcoholism [5], various types of brain tumors, and dementias.

With the remarkably complex nature of early brain development, human brain is extremely susceptible to chemical imbalances, problems with infections, and malnutrition. All these factors can interact in the developing brain to cause both functional and physical abnormalities, which can have wide ranging consequences. The developing brain is especially susceptible to chemical imbalances. For example, in a mature brain, thyroid malfunctioning can lead to lethargy. In a developing brain however thyroid malfunction can lead to permanent mental retardation. Details of brain developments are given in Table 1 the *Handbook of school neuropsychology* which details some of the more common abnormalities in brain development [4].

Relevance to Child Development

Neurological development begins at conception and is an orderly process vulnerable to interference [1]. Brain abnormalities in children can be additive, with problems in early development leading or creating other problems later in life. For this reason, it is extremely important for psychologists working with children to be aware that multiple factors may contribute to the interference of normal brain development from conception through adolescence [6]. Unfortunately, there is a high degree of latitude when it comes to developmental trajectories especially in children and so global statements of brain impairments are difficult to make with much confidence. For a more in-depth discussion of different brain abnormalities particular to children refer to the chapter entitled Abnormalities of neurological development in *The handbook of school neuropsychology* (2003)[6].

Brain Abnormalities. Table 1 Common abnormalities in brain development (from The Handbook of School Neuropsychology (2005))

Abnormality	Description	Possible causes	Other associated features
Agenesis of corpus callosum	Complete or partial absence of the corpus callosum	Genetically transmitted in some cases; metabolic disorders; other teratogens	Anterior commissure ay become hypertrophied to compensate, mental retardation, seizure disorder, language disorders
Anencephaly	Failure of neuronal tube to close at rostral end; absence of differentiated cerebral hemispheres, diencephalon, and midbrain	Maternal diabetes, radiation, neurotoxins, excess vitamin A	Possibly no development of spinal cord, distorted facial features
Cerebral asymmetry	Hemispheres are of significantly unequal size	Variable	Reading disorders
Down Syndrome (trisomy 21)	Genetic disorder involving chromosome 21	Genetically transmitted, autosomal disorder	Mental retardation, dysmorphic facial features, brachycephaly, brushfield sports, short/broad neck, broad/ stubby hands and feet, seizure disorders, other medical difficulties, dementia, alzheimer's disease, death
Dysplasia (heterotopia)	Development of abnormal cell clusters when migration is interrupted or stops prematurely; the clusters are in the wrong location for their genetically coded function	Presence of teratogens; mechanisms that interfere or disrupt process are usually unknown	Developmental disorders, learning disabilities, attention-deficit/ hyperactivity disorder; some may be asymptomatic
Fetal alcohol syndrome	Syndrome caused by maternal consumption of alcohol or ethanol; associated with malformations of neural tube development, including holoprosencephaly, myelomeningocele, and spina bifida	Maternal consumption of alcohol or ethanol	Dysmorphic facial feature, microcephaly, cortical thinning, prenatal and/or postnatal growth deficiency, learning disorders, attention-deficit/hyperactivity disorder, memory loss, perceptual problems, delayed adaptive behavior, mild mental retardation
Microencephaly	Subnormal brain size, small frontal and occipital lobes small cerebellum, reduced white matter, normal-size basal ganglia	Genetically transmitted, due to deletions or other transformations, malnutrition, metabolic disorders, inflammatory disease, radiation during first trimester, other teratogens	Small head, thickened scalp, absent forehead, disproportionate facial features, possible decreased cognitive ability and learning disabilities
Spina bifida	Failure of neural tube to close at caudal end; malformation of spinal cord, vertebral column and individual vertebrae	Maternal fevers, intrauterine viral infections, hormonal effects, vitamin deficiencies, excess of vitamin A, maternal diabetes, maternal alcohol use, other teratogens	Visible lesion on back, lipomas, decreased sensitivity to pain, paralysis, weakness of lower extremities, incontinence, hydrocephalus, meningitis, pneumonia

Brain Damage

Audrey McKinlay
University of Canterbury, Christchurch, Canterbury, New Zealand

Synonyms

Brain disorders; Brain impairment; Brain injury; Frontal lesion; Head injury

Definition

Any form of compromise to brain either pre or post birth, congenital or traumatic.

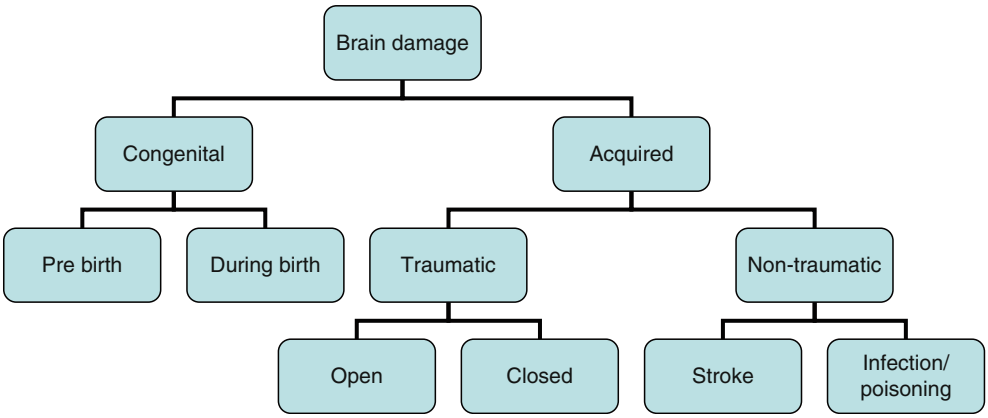
Description

The human brain is a complex organ about the size of a large grapefruit that allows us to think, move, feel see, hear, taste, and smell. Not surprisingly any injury to the brain can have a substantial impact on who we are and how we function in our environment. The brain is protected in a number of ways. The Blood brain barrier which protects the brain from disease (blood vessels of the central nervous system (CNS) lack the ability to transport large molecules across their walls) by the dura, a tough translucent membrane which covers the brain, and cerebral spinal fluid (CFS) a clear watery liquid that surrounds the brain and inside the skull [18]. However, damage can still occur and the most common ways that this can occur are outline in Fig. 1.

Congenital

Pre-Birth – Brain damage may occur prior to birth related to early damage to the embryo or fetus [1]. This may occur for a number of reasons including the ingestion of toxins by the mother i.e., fetal alcohol syndrome caused by alcohol consumption by the mother, or viral infections experienced by the mother during pregnancy. Pre-birth brain damage may also be related to environmental factors such as maternal malnutrition [1].

During Birth – Prematurity may result in brain damage as brain development may be interrupted. In addition problems during the birth process may lead to early brain damage [1]. For example, insufficient oxygen to the brain may result in anoxia or hypoxia (anoxia refers to a condition in which there is absences of oxygen supply to the organs tissue although there is adequate blood flow to the tissue [18].



Brain Damage. Fig.1 Schematic representation of the most common pathways to brain damage.

Hypoxia is a condition in which there is a decrease of oxygen to the tissue, however, these terms are often used interchangeably). When there is an insufficient supply of oxygen to the brain then brain tissue begins to be damaged [18].

Acquired

Strokes – Strokes are very common in the elderly. A stroke may involve a blockage by a blood clot or embolism being lodged in an artery (embolic stroke) or a bursting of an artery (haemorrhagic stroke) [7]. The situation may be aggravated by atherosclerosis (build up of plague on walls of artery). In both instances areas of the brain are deprived of oxygen causing a hypoxic or anoxic event [7]. Anoxia and hypoxia can create psychological and neurological abnormalities because of damage to the brain. Some problems seen after anoxia include metal confusion, personality changes and amnesia [7].

Infection – Meningitis is an inflammation of the brain tissue. It is caused by a range of different bacteria and viruses that can infect the tissues covering the brain [7]. Viral encephalitis is inflammation of the brain caused by a virus. Some viral diseases, such as measles and rubella, can also result in the inflammation of the brain [7].

Poisoning – Different poisons may also cause brain damage, for example, lead or Carbon Monoxide [18].

Traumatic Brain injury – Traumatic brain injury (TBI) is one of the most common injury events, affecting 20% children prior to 14 years of age [21]. Acutely, children who sustain TBI are at high risk for disruptive behavior [10, 20], social [9, 15, 19], attentional [2], language [24] and memory problems [5, 6]. Children who experience TBI during the preschool years appear to be particularly vulnerable to adverse outcomes [4, 6, 14]. Behavioral problems are reported as the most difficult TBI outcome to manage. The resulting unmanaged behavior commonly leads to expulsion from school, rejection by peers and difficulties with siblings [11, 12]. Moreover, secondary problems such as disruptive behavior, alcohol and substance abuse and youth offending more likely during adolescence [13, 14, 16, 22, 23].

There are two broad classifications of traumatic brain injury: open and closed.

Open head injury occurs when the skull is penetrated by a sharp instrument (such as a knife) or an explosive missile (such as a bullet or shell fragments). In penetrating head injuries, tissue damage will be found at the point of penetration and surrounding the path of the intruding object.

Closed head injury is primarily caused by a blunt impact or blow to the head without penetrating the skull. The most common form of brain damage is caused by closed head injury. Consequences of a closed head injury can be swelling, increased inter cranial pressure, and tissue compression.

Relevance to Childhood Disorders

As has been outlined here brain damage may occur via a variety of different routes. Some of these are more frequent than others. For example, while stroke would be a relatively rare event during childhood traumatic brain injury is an extremely common occurrence. Childhood is characterized by developmental change and any compromise to brain functioning may interrupt this process. Children who experience brain damage may be impaired academically and socially. Moreover, this interruption to the developmental process may extend into adulthood. Brain damage in childhood has been associated with behavioral problems such as Attention Deficit and conduct disorder, and academic problems such as difficulties learning to read or problems with arithmetic [18]. The extent of any damage will to a large extent depend on the degree to which the brain has been damage and the child's environment [8] Children who are injured early in the developmental process may be more vulnerable to ongoing problems as they have less pre-damage information which they can draw on [3, 20]. As a degree of plasticity is present during childhood early identification and intervention is essential for optimal outcomes.

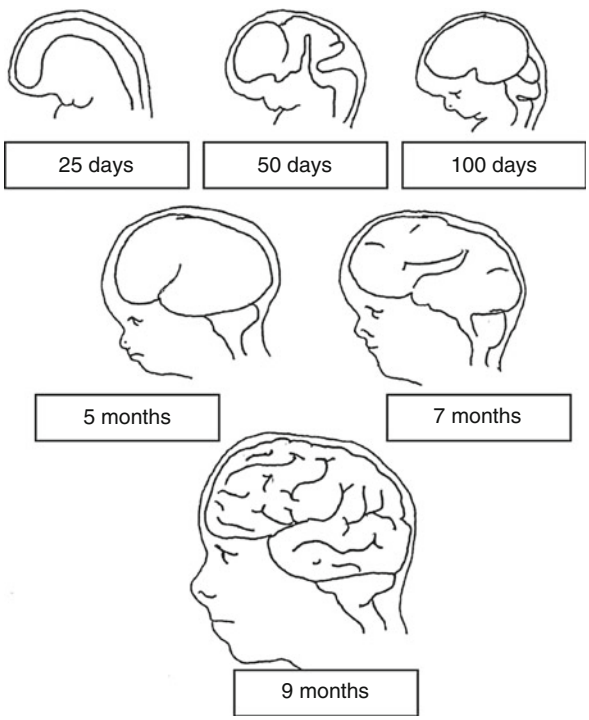
Brain Development

Tracey McLellan
University of Canterbury, Christchurch, New Zealand

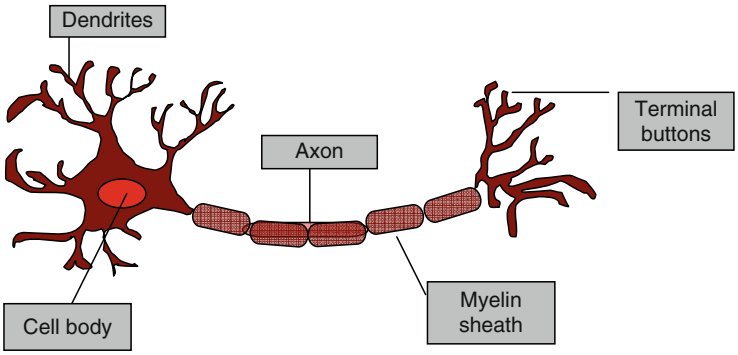
Definition

Brain development begins very early in the embryonic stage. The neural tube forms into the structure that we call the brain (see Fig. 1). The development of the brain occurs in several stages. These stages include cell proliferation, cell migration, cell differentiation, dendritic and axonal growth, cell and axonal death and gliogenesis [4].

The neural tube consists of cells (neurons and glial) that will form the central nervous system. Neurons are cells that communicate to each other through the release of chemicals and glial cells are support cells that, for example, remove unwanted debris or form the myelin insulation around the axons of many neurons. As the brain forms, neurons (see Fig. 2) migrate to specific areas to form connections and perform their respective functions. For example, some neurons will migrate to the occipital lobe at the back of the brain to become vision



Brain Development. Fig. 1 Development of the human brain.



Brain Development. Fig. 2 A neuron.

neurons. The developing brain is particularly vulnerable to toxins and maternal stress during the time of neuronal migration and connection making [1, 5].

The generation of neurons is so rapid during this early period of development that to achieve the 100 billion neurons typical of a new born human brain, approximately 250,000 neurons are generated each minute and each neuron forms approximately 15,000 connections [4]. Interestingly, the brain overproduces neurons and an important part of brain development is that the extra cells die off and the extra connections are lost. It is thought that a variety of developmental disorders may be due to the failure of the developing brain to engage in this neuronal loss [2].

Relevance to Childhood Development

By the time a child is born, they have generated almost all of the neurons that they will ever have. However, the brain is the least developed organ at birth and weighs approximately 25% of the average adult brain. By the time a child is 3 years old their brain will weigh 80% of an adult brain [4]. This growth represents the formation of trillions of connections between the cells of the brain. Although the "raw materials" (neurons) have been generated prenatally, the environment now has an enormous impact on how these neurons connect with each other.

In the child's first year of life, a number of emerging psychological developments occur that correspond to changes in the developing brain. At 2–3 months, a number of newborn reflexes disappear, for example, the palmar grasp and the Babinski reflex. This is likely due to cortical inhibition of brainstem neurons [3]. This inhibition may also be responsible for the reduction in crying during this period. Another development at 2–3 months is the ability to recruit and sustain attention to a stimulus. Researchers have suggested this is due to the hippocampal maturation that occurs at this time [3]. At 7–12 months, a child experiences an enhancement of working memory that is accompanied by a growth spurt in the prefrontal cortex. Patterns of growth in the amygdala and prefrontal cortex are also likely to be associated with the emergence of separation and stranger fear at this stage of development. The ability to adjust sensory motor structures to attain a goal also emerges between 7 and 12 months. For example, 5 month olds will use both hands to reach for an object regardless of size, whereas, 8 months olds will reach toward a small object with one hand and only a larger object with both hands [3].

The second year sees the emergence of the ability to comprehend and express speech, the ability to infer selected mental states in others and the first signs of awareness of their own feelings and intentions. The emergence of speech coincides with dendritic growth in Broca's area and the corpus callosum [3]. Likewise, the limbic system matures and this corresponds to the enhanced emotional processing.

Between ages 2 and 8 years, a child develops a set of universal skills that fall under the umbrella of (1) the ability to integrate the past with the present (conservation), (2) an expanded reliance on semantic networks, and (3) an ability to detect shared relations. The first skill was classically demonstrated by Piaget (1950, as cited in [3]). When a child is shown two identical balls of clay he/she can declare that they are the same size, but when one is rolled into a sausage shape, many 4 year olds will answer this question independently of the first and declare the sausage is bigger. Most 7 year olds will demonstrate the emergence of conservation and declare they are still the same. Utilizing semantic networks means that more developed children (i.e., 7 year olds) can group together information into semantic categories. This has obvious advantages in learning new information and improving memory function. Likewise, the ability to understand the shared relations of objects and events (i.e., that "smaller" and "bigger" are not absolute but refer to the relationship

between objects) is functionally adaptive [3]. The development of these skills requires the coordination of many brain areas and it is a new level of *connectivity* in the brain that allows for such developmental advances. Another important feature of brain development during this stage of life is that the number of synapses eliminated exceeds the number of new synapses. This counter-intuitive event reflects that the connections that have proven adaptive are strengthening while those that have not proven adaptive are simply being eliminated [3].

This elimination or synaptic pruning continues during adolescence. Pruning of synapses in the prefrontal cortex and the myelination of the axons that connect the prefrontal cortex to other parts of the brain are the hallmarks of brain development during adolescence [3, 6]. While many other parts of the brain have fully developed already, the frontal lobes are the last to do so and do not reach full maturity until after puberty. It is during adolescence that we see the emergence and enhancement of the executive functions that are subserved by the prefrontal cortex, such as planning, cognitive flexibility and logical reasoning.

Brain damage; Neurological disorders; Traumatic brain injury

Definition

A brain disorder is any disorder or disease of the brain. There are hundreds of documented disorders that can affect the brain. The most common, however, are usually classified in terms of their method of origin. These include neurogenetic diseases, neurodevelopmental disorders, degenerative diseases, metabolic diseases, traumatic brain injury, brain tumors, and psychological/mental disorders.

Description

Due to the high numbers of known brain disorders, and their increasing complexity and variability, only a cursory explanation will be provided for this entry. Each disorder will be described in terms of their root of origin. Please note that many of the disorders mentioned can be classified into more than one category.

Neurogenetic Disease

These disorders, also referred to as inborn or genetic brain disorders, are caused by a variation or mutation of the genes that result in an impairment of the development and function of the brain. Some of these disorders are due to random gene mutations or mutations due to environmental exposures, while others are inherited though the passing down of mutated genes from parent to child. Examples of genetic brain disorders include Gaucher disease, Krabbe disease, Lesch-Nyhan syndrome, Tay-Sachs disease, Down Syndrome, Fragile-X syndrome, Spina Bifida, and Wilson disease. The symptoms of these disorders are varied, ranging from mild retardation to severe disability and death.

Neurodevelopmental Disorder

A neurodevelopmental disorder, or a disorder of neural development, is an impairment of the growth and development of the brain or central nervous system. These disorders are often classified by their direct affects on emotion, learning ability, and memory. These disorders can include Autism and Autism Spectrum Disorders, learning disorders, epilepsy, speech and language disorders, and other diseases that incur neurodevelopmental consequences.

Degenerative Disease

A degenerative brain disease is often diagnosed by the progressive worsening or loss of brain function over time. These disorders can be genetic or caused by environmental influences. Though these diseases can occur at developmental periods, many of the disorders are more common in elderly patients. These disorders include Alzheimer's disease, Amyotrophic lateral sclerosis (ALS), Huntington's disease, Parkinson's disease, and Spinal

muscular atrophy. Other degenerative brain disorders can be a result of stroke, old age, brain injury, chronic alcohol and drug use, and exposure to viruses such as AIDS and Creutzfeldt-Jakob disease (Mad Cow Disease).

Metabolic Brain Disease

Metabolic brain disorders produce changes in brain metabolism and structure, resulting in changes in enzyme function, protein formation, and cellular expression. These disorders can include primary (disorders intrinsic/specific to the brain) and secondary (disorders extracranial/outside of the brain) metabolic conditions that adversely affect brain function. These disorders lead to accumulation of materials in the brain, lessened production of certain enzymes, or toxic levels of certain materials in the brain and spinal fluid. These disorders include Phenylketonurias, Maple-Syrup Urine Disease, Glutamine Deficiency, MELAS Syndrome, Reye syndrome and Encephalopathy.

Traumatic Brain Injury

Traumatic brain injury (TBI, also called intracranial injury) occurs when an outside force traumatically injures the brain. TBI is often classified based on severity, mechanism, or other features of the injury type. TBI can cause varied levels of physical, cognitive, emotional, and behavioral effects, and outcome can range from complete recovery to permanent disability or death. TBI can be a result of car accidents, sports injuries, child abuse and shaken baby syndrome, and war-related incidents (such as exposure to nearby explosions).

Brain Tumors

Brain cancer, or brain tumors, is an abnormal growth of cells within the brain or inside the skull, which can be cancerous or non-cancerous (benign). These tumors can occur within the brain tissue (in the neurons, glial cells, and blood vessels), in the cranial nerves, in the tissues surrounding the brain, in the skull bones, or within the brain glands (pituitary and pineal gland). Brain tumors can also form as a result of cancer that has spread from other organs of the body (metastatic tumors). These tumors can cause severe damage to brain, including loss of functioning such as paralysis, blindness, loss of speech and cognition disabilities, and other varied effects.

Psychological/Mental Disorders

A psychological or mental disorder, also referred to as mental illness, is a psychological or behavioral pattern that occurs in an individual and causes distress or disability. These disorders are characterized by abnormalities in cognition, emotion or mood, or the highest integrative aspects of behavior, such as social interactions or planning of future activities. Professionals have classified some of these high numbers of psychological disorders into the following categories: dissociative disorders, mood disorders, anxiety disorders, psychotic disorders, eating disorders, developmental disorders, personality disorders, ambulatory disorders. However, there are many other disorders that fall into additional categories.

Brain Imaging

Nina Foster
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Functional imaging; Neuroimaging; Structural imaging

Definition

A group of methods used in research and clinical practice that examines and provides an image of the brain anatomy.

Description

The primary purpose of brain imaging is to produce an image of the structure of the brain for examination of

function. It is used to show a relationship between brain structure and behavior, and to record brain activity during behavior and psychological tasks. In certain brain imaging methods, behaviors are elicited to study the activity in response to the stimulus which is termed evoked potentials or evoked responses. Another purpose is to study the effects of brain damage. Finally, brain imaging is also utilized to research the outcome of stimulating specific brain areas. Both invasive (i.e., inserting electrodes) and noninvasive (i.e., magnetic field or chemical injection) procedures can be used to accomplish stimulation [2].

Common brain imaging techniques include: Computerized axial tomography (CT or CAT scan), in which dye is injected into the bloodstream and the CT scanner uses X-rays to take measurements and generate an image of the brain; Electroencephalograph (EEG), in which electrical brain activity is measured noninvasively via electrodes attached to the scalp; Magnetoencephalograph (MEG), which provides a record of brain activity that is produced by magnetic fields; Positron-emission tomography (PET), which produces a high resolution representation of the brain by the release of radioactivity from chemicals injected into the bloodstream; Single Photon Emission Computerized Tomography (SPECT), which provides a computer generated three-dimensional image of the brain by the use of gamma rays produced from gamma emitting radioisotope injected into the bloodstream; Magnetic resonance imaging (MRI), which produces an image of the brain by utilizing a magnetic field, radio frequency, and measuring the electromagnetic energy created; and Functional magnetic resonance imaging (fMRI), which detects changes in the levels of oxygen in various brain activity areas [1–3].

Brain Stem

Erin Hambrick
University of Kansas, Lawrence, KS, USA

Synonyms

Hindbrain; Midbrain; Upper spinal cord

Definition

The brain stem is located directly above the spinal cord, directly within the cerebellum, and directly below the cortex of the brain. It is the most basic and primitive portion of the brain; its main contribution is to regulate homeostatic functions that are automatic and thus occur pre-consciously.

Description

Arousal, blood pressure, heart rate, respiratory rhythms, the sleep-wake cycle, sensation, motion, and the perception of pain are all controlled and synchronized by the brain stem. The brain stem is the first portion of the brain

to develop, and carries out vital visceral functions. These functions must operate even before the human brain evolves into an organ that reasons, analyzes, and comprehends, and while the brain is asleep or otherwise dissociated. Because the brain stem is the lowest portion of the brain – or toward the "bottom" of the brain, it is the first part of the brain to process incoming signals, both internal and external. Thus, it influences the type of signal the entire brain receives; for example, fear, joy, or uncertainty. Immediate, almost reflexive responses humans make that seem irrational are often representative of brain stem influenced behavior. Our initial reactions are often based on our brain stem's "perception" of a situation and occur before our rational cortex can make sense of the situation and elicit a logical, measured response.

The brain stem extends contiguously from the spinal cord, and thus its appearance is largely similar to the spinal cord; it is much smaller and more solid than the soft and wrinkled cortex. The brain stem consists of neurons ("brain cells") and glial cells (which maintain and facilitate neurons) that communicate with each other via sending and receiving diverse chemicals called neurotransmitters. Some neurons have only a local effect because their axons (neural fibers that extend from the cell body and include the sites of neurotransmitter emission) are short, and other neurons have axons that extend throughout the brain and considerable portions of the central nervous system. Moreover, some neurons in the brain stem work in a lateral manner and communicate solely within the brain stem; however, most neurons in the brain stem communicate in ascending and descending pathways that influence the cortex and corticospinal motor neurons [2].

The brain stem consists of three of the six sections of the brain that arise from the developing neural tube in a process called neuralation [4], and in its fully developed state the three major parts of the brain stem are called the pons (or hindbrain), the medulla (or medulla oblongata), and the midbrain. The pons is largely responsible for dissemination of information from the brain stem to the rest of the brain. The reticular formation, or the reticular activating system, is located inside the pons, and mediates alertness, arousal, and attention. The medulla regulates blood pressure, respiration, and digestion, and the midbrain relays audio and visual information and regulates saccadic eye movements.

The homeostatic functions of sleeping, breathing, heart rate, and body temperature are the most visceral activities the brain stem governs. The brain stem contains several excitatory and inhibitory neurotransmitters (glutamate and GABA, or gamma-aminobutyric acid, respectively) [9] that are able to attenuate incoming sensory information when the body needs sleep, arouse the central nervous system when circumstances require rapt attention, and generally inhibit and excite as necessary to maintain consistent rhythmic regulation. The brain stem supports the rest of the brain and allows humans to grow and learn uninterrupted. A malfunctioning brain stem creates chaos; for example, unpredictable, primitive actions, arousal or sleep and dissociation at the wrong moments, or the inability to attend to stimuli long enough to learn.

The brain stem's role in sensation is diverse. Cranial nerves connected to the brain stem receive input primarily from the face and neck, but also from the body's extremities. Auditory sections of the brain stem compare incoming information in order to estimate where in space a sound exists. Gustatory portions of the brain stem signal satiety levels. Visual portions communicate and integrate eye, head, and trunk positions to facilitate balance. Moreover, our first understanding of our environment is interpreted by the brain stem; only later does our cortex take over by integrating and making sense of incoming signals concerning our surroundings. For example, if you are on a diet, your brain stem will communicate that you are not full after eating a small meal. However, your cortex, which understands the purpose of your choice to eat a lighter meal, can then communicate to the brain stem that though you may not be full, you have had enough, and there is no reason to fear for a lack of food.

The brain stem is surrounded by the cerebellum, which regulates coordination, and connects the spinal cord to the brain's motor cortex. Therefore, the brain stem is vital in the body's ability to move. Two pathways are crucial to the brain stem's involvement in motion. The medial pathway controls posture, and the lateral pathway controls purposeful motor actions, such as reaching for an item [3]. Further, Parkinson's disease sufferers often have their symptoms traced to a malfunctioning neurotransmitter balance in their brain stem [1].

Norepinephrine, dopamine, and serotonin neurotransmitters reside in and are disseminated by the brain stem [4]. Thus, signals that pertain to arousal, motion, and mood and bodily homeostasis, respectively, are first mediated by the brain stem. Depending on axonal length, signals emanating from the brain stem that transmit these three neurotransmitters can directly influence the entire brain. For example, we often may not be sure why we have the sensation of fear or unrest in certain situations. The likely explanation is that our brain stem perceived an object, person, or situation as unfamiliar or alarming and set off a cascade of arousal signals. These signals

then influenced our conscious perception before our cortex was able to re-communicate with the brain stem that the particular object, person, or place was safe.

Recent research further highlights the function and importance of the brain stem. Lam and Place [5] observed a child who suffered moderate brain stem injury. Initially, the child's major homeostatic functions seemed normal, as well as her motor skills. However, only a day later the child returned with a rise in temperature, respiratory difficulty, a partially paralyzed and droopy right side of her face, and a vomit reflex that prevented her from ingesting enough food. Because at intake not all of these conditions had been evident and because a computed tomography (CT) scan did not indicate any brain stem damage, other conditions, such as pneumonia, were suspected. The real source of the child's symptoms was not evinced until later than it should have been. Thus, whenever a child suffers traumatic brain insults, neurological exams should be intense and brain stem damage should be suspected even if well-respected CT scans do not initially show damage. Because the brain stem affects so many vital functions, even small amounts of damage can result in multiple negative effects.

Additionally, the role of neuronal cell death in the brain stems of children with sudden infant death syndrome (SIDS) has recently been further explored [6]. Apoptosis (planned cell death) is evident in the medulla of children with SIDS, and was found to be exacerbated by lying prone while sleeping (on one's belly), by cigarette smoke exposure, and by being male. There is speculation that compromised respiratory systems promote apoptosis and that males are more susceptible to the apoptotic effects of a strained system.

Relevance to Childhood Development

When the brain stem is affected by traumatic brain injury (TBI), many effects are seen in the functioning of a child. A severely injured brain stem often causes death, and partially injured brain stems can produce a host of complications: difficulties with sleep cycles and REM sleep, respiratory issues, irregular heart rates, abnormally high or low blood pressure, impulsive actions that arise from issues with goal-directed motor movement, trouble with balance and posture, difficulty tasting, lack of saccadic eye movements, and poor perception of sound location. However, it is important to understand that explicitly recognizable TBI is not the only cause of brain stem dysfunction.

According to Perry [7], a dysregulated brain stem is often the result of extreme neglect, sexual abuse, or physical abuse during a child's early, critical years. The brain stem, just like the brain in its entirety, has critical and sensitive periods in which certain sensory experiences are necessary to elicit normal development. The brain stem is the first part of the brain to fully develop, so it is often most affected by early insults. One way in which trauma and neglect affect the development of the brain stem is because the reticular formation, which regulates arousal, is either under stimulated or is overused and stressed. Thus, the child's brain stem defaults to sending either extreme amounts of inhibitory signals or extreme and random amounts of excitatory signals. Inhibitory signals are manifest in children who dissociate during prolonged neglect or traumatic experiences. Excitatory signals are manifest in hypervigilance, a higher than normal resting heart rate, impulsivity, and brain stem driven, fearful, reactionary behaviors in response to seemingly innocuous stimuli.

The brain is a rhythmic organ, and these rhythms are most evident in the patterns and rhythms the brain stem creates so we can breathe, sleep and know when to eat. A neglected child has dysregulated brain stem rhythms because the sensory experiences that are a normal part of a healthy attachment relationship – rocking, comforting, and predictable feeding – were absent when they needed them most. Thus, the vital patterns that regulate homeostasis and behavioral control do not function as they do in children who had a healthy attachment relationship. Similar is true for traumatized children; they may have received attention, time, and care, but because it was unpredictable and because caregivers were often a paradox of fear and comfort, the child's brain stem did not develop in a systemized, controlled manner. The child's brain stem-based dopaminergic, serotonergic, and noradrenergic neurotransmitter pathways become unable to send signals that make sense. Their actions and reactions are often not systemized and controlled, and their levels of arousal, impulsivity, and mood control are altered and affect even the "smarter" cortex; for example, these signals keep the cortex from being successful at inhibiting unfavorable actions.

When understanding the developing child, the level of brain stem regulation must be assessed. When diagnosing and caring for a young child with psychological difficulties, all physical insults to the brain stem, all traumatic experiences, and all cases of neglect in the child's history should be noted and used to shape the understanding of the child's current level of functioning. Unfortunately for psychological providers or caregivers, the brain stem is not as plastic as other parts of the brain. The brain stem cannot be changed by well-intentioned cognitive-behavioral interventions, which only use and alter the cortex, because these interventions do not stimulate the brain stem. However, patterned,

repetitive activities and predictable schedules that simulate the rhythmic activities of the brain stem can begin reorganization and can eventually cause behavioral control and predictable homeostatic function [8]. The brain stem may become more and more important to study as child development specialists and caregivers try to delineate appropriate and efficacious therapy for children.

Breastfeeding

Laura Bruder
Nova Southeastern University, Davie, FL, USA

Synonyms

Feeding; Lactating; Nursing; Suckling

Definition

Breastfeeding is providing human breast milk to meet the nutrient needs of an infant.

Description

The Breast

Breastfeeding is the nourishment of an infant or young child directly from milk produced in a woman's breast. The breast contains mammary glands which consist of 15–25 separate branched segments. Surrounded by fat tissue, milk producing cells line the alveoli. Milk ducts lead from the alveoli to larger ducts which widen to the sinuses behind the opening of the nipple. The force of the baby's tongue and bottom lip against the sinuses combined with inner pressure ejects the milk allowing the baby to feed directly from the sinuses [4]. When the baby is breastfeeding, the "let-down reflex" is created where the hormones prolactin and oxytocin are released increasing milk flow towards the sinuses. The mere thought of ones child may initiate this reflex and create a milk-flow. In contrast, negative emotions such as worry and sadness can temporarily stall milk flow. The more the breast is stimulated, the more hormones are released, thereby producing more milk. Therefore, milk production adjusts to the baby's needs. Avoiding unnecessary restriction of the breast to the baby is vital in preventing premature reduction of milk flow [4].

Breast Milk

Breast milk production follows three distinct stages. The first milk is colostrum and is typically produced during pregnancy and lasts for 2–4 days following birth. It can

appear creamy or yellowish in color, and contains a high source of protein, fat-soluble vitamins, minerals and antibodies passed from the mother, providing passive immunity. Following colostrum, transitional milk is produced and lasts for about 2 weeks. Transition milk contains high levels of fat, lactose, water-soluble vitamins, and calories. Lastly, mature milk begins production and contains 90% water, necessary to provide infant with hydration. The remaining 10% is comprised of protein, fat, carbohydrates, and other nutrients necessary for infant's growth and development. Mature milk is divided into foremilk (found during the beginning of mature milk production) and hind-milk (containing higher levels of fat to ensure infant weight gain) [1].

While, the United Stages Surgeon General recommends that babies are fed only breast milk for the first 6 months of life, the American Academy of Pediatrics (AAP) recommends at least 1 year of breastfeeding and exclusive breastfeeding for the first 6 months of life. Mothers may choose to breastfeed their babies longer, but should introduce solid foods when the baby is 6 months of age. Standards of infant growth, health, and development are based upon breastfed infants. Therefore, breastfeeding is the model which all other feeding methods are compared [3, 6]. Most women are physically able to breastfeed but should refrain from doing so if they are HIV positive, as the virus can be transferred through breast milk. Mothers should not breastfeed if they are using illicit drugs as they can make a baby more irritable, disrupt sleeping patterns, and can even lead babies to develop physical addictions to these substances. Women with severe illnesses such as cancer, heart disease, hepatitis, active untreated tuberculosis, severe malnutrition, and active herpes lesions on the breast should also not breastfeed. Babies who are born with galactosemia, in which they cannot break down the galactose present in breast milk, should not be breastfed [2].

Relevance to Childhood Development

Breast milk provides optimal nutrition to a baby and is the preferred choice for feeding. Breastfed babies have been found more able to fight off infection and disease such as diarrhea, ear infections, gastroenteritis (stomach flu) and pneumonia. Breastfeeding has also been linked to protection from immune system related diseases such as lymphoma, Crohn disease, celias sprue, and juvenile rheumatoid arthritis [3]. Breastfeeding can even provide protection against allergies, asthma, and eczema [1]. In addition, studies suggest that infants who are breastfed have lower rates of sudden infant death syndrome (SIDS) in the first year of life [6]. Breastfeeding provides close skin-to-skin contact between mother and child and fosters an almost automatic emotional attachment [1]. In sum, the literature is clear that breastfeeding, regardless of the length of time is beneficial to both mother and child.

Brigance

▶Brigance Diagnostic Inventory of Early Development

Brigance Diagnostic Inventory of Early Development

Jana Sander
Texas A&M University Corpus Christi College of Education, Corpus Christi, TX, USA

Synonyms

Brigance

Definition

An inventory given to individual children to evaluate the development of children birth to age seven.

Description

The Brigance Diagnostic Inventory of Early Development is a readiness and screening inventory that is used

to determine the developmental level of a child ages birth through seven. The inventory consists of 200 items and usually takes between 30 and 60 min to administer depending on the number of the developmental domains evaluated. Children respond to questions by pointing to pictures, verbally responding or though written response. In addition, the examiner directly observes the child and an interview of the child's family is included to gain further information about the child. No specialized training is required for the examiner other than to have knowledge of child development and be familiar with the manual. Most items used in the inventory can be found in the typical settings of infants or young children. The 11 developmental domains covered in the inventory include: perambulatory motor, gross motor, fine motor, self-help, speech and language, general knowledge, readiness, basic reading, manuscript writing, and basic math skills.

Based upon the results of the inventory, objectives, activities and lessons can be planned to assist the child.

Broca, Paul Pierre

Matthew J. Holcomb, Andrew S. Davis
Ball State University, Muncie, IN, USA

Life Dates

1824–1880

Introduction

Paul Pierre Broca was a French-born physician who is best remembered for his major contribution to the theory of localization in regards to the area of the brain responsible for language production which now bears his name. He also had an interest in human anatomy and is considered the founder of physical anthropology [7]. In addition, Broca's early published research centered on cancer pathology, infant mortality, and the treatment of brain aneurysms.

Educational Information

Broca enrolled in college in 1841 at the age of seventeen when he entered the University of Paris to study medicine. While at the University he became a House-Surgeon in 1844, assistant anatomical lecturer in 1846, and in 1848 a Professor of Surgical Anatomy at the University of Paris Medical School, the youngest ever to hold such a position. In 1853, Broca was named a Fellow of the Faculty of Medicine in Paris, and became a member of the Academy of Medicine and Professor of Surgical Pathology to the Faculty in 1867 [7].

In addition to his work in medicine, Broca made extensive contributions in the area of anthropology. He established the Anthropological Society of Paris in 1859 and served as the secretary until his death. He founded *La Revue d'Anthropologie* in 1872 where he published much of his writing. He had a keen interest in public health and wrote several articles on issues such as infant mortality, population development, and the state of medical services provided to the French Army [2].

Accomplishments

Broca's is best remembered for his seminal finding that speech production was localized in the area of the frontal lobe which now bears his name (Broca's area). This discovery was preceded by Broca's interest in problems associated with the brain-behavior relationship. One of his patients, M. Leborgne lost the ability to produce more than a single syllable of speech at the age of 21. The only sound that was produced by M. Leborgne was a syllable that sounded like "tan." M. Leborgne would often respond using this word and therefore became known as Tan. After Tan died (April 17, 1861), Broca conducted a post-mortem examination of Tan's brain, where he found a lesion in the left frontal lobe. From this and other observations, Broca concluded that the posterior part of the left frontal lobe was intricately involved in the production of articulate speech. Broca called the region the *circonvolution du langage* in his article presenting the

case of Tan [3]. With his publication of Tan's case in 1861, Broca presented anatomical evidence of the localization of a particular brain function. Broca was not the first to propose the idea of brain localization but he pushed the idea to the forefront of the scientific community [4]. Broca's area has been linked to involvement in language processing, speech production, auditory working memory, and comprehension [1].

Broca's localization of the speech production center of the brain was certainly one of the first findings to offer firm evidence of localization of functioning within the human brain [6]. Along with this discovery, Broca also did early research into the limbic system of the brain, an area we know today is involved in emotion and memory. Additionally, Broca tied the study of anthropology to his investigations of neurological functioning. He conducted research on the brain weight of almost 350 different patients at his hospital and discovered a difference in brain weight/mass between that of the elderly and young and between men and women [5].

Broca was honored by the French Government in 1880 when he was elected as a Member for Life of the French Senate representing Science. Broca died July 9, 1880 soon after receiving this award and was survived by two sons who went on to distinguish themselves within the medical community.

Contributions

While some of his conclusions about these findings have since been proven wrong, Broca's research on the brain, and in particular with the theory of localization, render him a pioneer in the fields of neurology, neuropsychology, and psychology.

Broca's Aphasia

David Morrison, Mary Joann Lang
Azusa Pacific University, Azusa, CA, USA

Synonyms

Ataxic aphasia; Childhood aphasia; Expressive aphasia; Motor aphasia; Nonfluent aphasia

Definition

Broca's area is located in the frontal lobe of the left hemisphere of the brain and is responsible for motor speech planning. Named for Pierre Paul Broca, it was the first area of the brain to have a specified particular function.

The term *aphasia* describes a group of language disorders that are linked by a common characteristic of impairment of language processing and language production. This impairment is characterized by a combination of naming, fluency, and comprehension deficits. *Aphasia* is an acquired language disorder that results from damage to those areas of the brain responsible for the processing and production of language. For most people this occurs within the left hemisphere. *Aphasia* disorders most often occur suddenly as a result of a stroke or traumatic brain injury but can develop more slowly over time as a result of a tumor, or from infections.

Clinical Implications

Damage to Broca's area produces Broca's aphasia. The extent of the damage to Broca's area determines the extent of the aphasia. The results of this damage can be an inability to produce language of not more than a few words. In the most extreme cases the individual will not be able to express more than a single word. This inability to express words is not due to any known motor problems or impairments of the mouth or tongue. In Broca's aphasia the individual has difficulty expressing thoughts through speaking, however, the ability to understand speech remains largely intact [2].

Broca's aphasia is a non-fluent or expressive aphasia characterized by non-fluent speech, few words, short sentences, and frequent pauses. Speech lacks grammatical complexity and is described as telegraphic. For example, the individual would have extreme difficulty with adverbs, prepositions, pronouns, and conjunctions. The individual would *likely* be able to use nouns and verbs with language restricted to noun-verb combinations. The words that are produced come with great effort and often sound distorted. Speech is laborious and slow. The melodic

intonation of speech is flat and monopitched. Those affected are often frustrated due to the restricted ability to communicate their thoughts [8].

Individuals diagnosed with aphasia are generally referred to a speech pathologist or a neuropsychologist. Aphasia is commonly assessed through various standardized tests that require the individual to follow commands, answer questions, name objects, and converse. The primary treatment for aphasia is speech therapy that focuses on relearning and practicing language skills and using supplementary communication methods. The prognosis for recovery varies greatly and depends upon the severity of the brain damage and the location of the brain injury [7].

Classical Descriptions

Pierre Paul Broca, an anthropologist and surgeon from France, identified Broca's Area. He defined it as the center of articulate language in 1861. Broca had two clinical cases that defined his hypotheses about expressive language. The first case is that of Leborgne. In his role as a surgeon, he was called to treat Leborgne for advanced gangrene in his leg. During his examination of Leborgne, he discovered that the patient was unable to produce oral language due to a chronic brain lesion.

Leborgne had a history of seizure disorder since he was a child. At age 31, he lost his ability to produce oral language. Approximately 10 years later at age 41, right side paralysis developed. Pierre Paul Broca examined Leborgne and reported that he was unable to produce oral language. Leborgne often reported the word "tan" (as a result he later became known as "Tan"). Interestingly, in Broca's examination of Tan he concluded that his mouth, tongue, and larynx were intact. As a result of these findings, Broca concluded that impairment in the central nervous system was the cause of Tan's oral language difficulty. In contrast, Tan's ability to comprehend spoken language was intact. According to historical records he was able to correctly respond to questions with hand motions [4].

According to historical accounts, Tan died of gangrene. This gave Broca the opportunity to perform an autopsy on Tan. The autopsy results indicated that most of the left hemisphere of the brain was damaged. Specifically, a large lesion was found in the interior part of the hemisphere. This lesion was centered over the posterior part of the middle and inferior frontal gyri. Crank and Fox [3] notes that other parts of the brain that were involved in this extensive lesion included: (1) The anterior insula; (2) the inferior marginal gyrus; (3) the striate body. As a result of this examination, Broca hypothesized that the abnormal findings had begun in the third frontal gyrus and had progressed to surrounding tissues. Broca presented Leborgne's brain at a meeting to the French Societe d'Anthropologie.

The second case that further supported Broca's hypotheses is that of a man named Lelong. In Lelong's case, his expressive speech impairment was not confounded by other neurological symptoms. In fact, his lesion was much more localized than that of Leborgne. Specifically, the lesion was located in the third frontal convolution (posterior portion) [4].

One of the clinically significant issues in Broca's findings is that they provided evidence towards the hypothesis that mental functions were localized and lateralized in specific parts of the brain. Autopsy's conducted on twenty more cases after Leborgne further supported the original findings. Functional organization of the human brain became a main area of research after Broca's successful clinical case analyses [4, 7].

Characteristics of Broca's Aphasia outlined by the American Speech and Hearing [1] include:

- Speaks only in single words (e.g., names of objects)
- Speaks in short, fragmented phrases
- Omits smaller words like "the," "of," and "and" (so message sounds like a telegram)
- Puts words in wrong order
- Switches words and/or words (e.g., bed is called table or dishwasher a "wish dasher")
- Makes up words (e.g., jargon)
- Strings together nonsense words and real words fluently but makes no sense

Assessment and Intervention

Understanding Broca's aphasia is critical to developing an assessment plan and intervention strategies that are specifically designed for the individual student. An important issue is that the assessment be linked to intervention. Since language and communication are fundamental in a child/student's cognitive, emotional, and academic development, strategies for intervention must be integrated throughout the day for this and other types of aphasia.

An assessment for expressive aphasia should be initiated when the receptive aphasia is strongly suspected. Aphasia testing should be done for the following purposes:

(1) Diagnosis of a presence and type of aphasic syndrome, leading to inferences concerning cerebral localization; (2) measurement of the level of performance over a wide range, for both initial determination and detection of change over time; (3) comprehensive assessment of the assets and liabilities of the patient in all language areas as a guide to therapy [6, p. 1].

There are aspects of speech production that require special attention when conducting an evaluation. Goodglass [5] notes these aspects as the ease and quantity of production (fluency), articulatory error, speech rhythms and intonation (prosody), grammar and syntax, and the presence of misspoken words (paraphasias). It is important to note that while some of these aspects are always related to aphasia some may occur as speech difficulties not related to aphasia. Familiar and personally relevant stimuli will evoke the best responses.

Environment plays an important part in how much aphasia can affect the child/adolescent's daily activities. A supportive environment can help prevent further language impairment and other detriments to a person who has aphasia. Conversely, a non-supportive environment can increase the impact aphasia can have on daily routines. Teachers, clinicians, parents, and members of the child's IEP team need to take into consideration how the social environment and the process of communicating can impact the child/adolescent's daily life [6].

Broca's Area

Nickilynn Aubuchon-Endsley
Oklahoma State University, Stillwater, OK, USA

Synonyms

Brodmann's areas 44 and 45; Left inferior frontal lobe (anatomically different areas, but regarded as Broca's area by different sources); Left inferior (third) frontal convolution (gyrus)

Definition

An area of the brain within the left inferior frontal lobe that was named after Paul Pierre Broca (1824–1880) [5], that is most commonly known to play a role in speech and language processing and production (e.g., speech articulation, lexical semantics, and syntax/syntactic decoding [3, 5, 9]); but has also been shown to be related to nonverbal frequency discrimination [10]; working memory [8]; complex hand movements, associative sensorimotor learning, and sensorimotor integration [1]; imitation [4]; musical processing [6]; and hallucinations in those with *Schizophrenia* [7].

Description

Broca's area was discovered by Paul Pierre Broca in the nineteenth century as a reaction to a call for evidence for localized/lateralized neurological functioning and contributed to the development of the field of neuropsychology [5]. Broca had received a patient, Monsieur Leborgne who had lost the vast majority of his speech production abilities except for his abilities to say the word "tan" and utter an oath [5]. Leborgne ("Tan") also showed paralysis on the right side of his body, but seemed to have largely retained his intellectual abilities. Upon Leborgne's autopsy, Broca discovered a frontal lesion that he assumed was related to his deficits. After collecting eight additional case studies, converging evidence implicated the posterior third of the third frontal gyrus as being related to speech production [5]. Broca therefore concluded that language is a localized function and thus different regions of the brain have specialized functions, which may be different depending on the cerebral hemisphere (lateralization). Because of his discovery, this pattern of impaired speech production is known as *Broca's aphasia* and part of the original site of atrophy is known as Broca's area.

Subsequent reexamination demonstrated more diffuse neurological damage in several of Broca's patients, which has led to debates about the extent of localization/lateralization, especially in light of cases in which *neuroplasticity* allows for retention of particular skills (notably language) after infarction, temporal lobectomy, *hemispherectomy*, or *full corpus callosotomy* (*commisurotomy*) [2]. In addition, these findings have led to debate about the neuroanatomical demarcations that define Broca's area. Some investigators have defined Broca's area as including the entire inferior frontal lobe, while others have more strictly defined Broca's area as including one of the

following: Brodmann's area 44 and the frontal operculum; Brodmann's areas 44 and 45; or Brodmann's areas 44, 45, and 47 [9]. In addition to discoveries informing the bounds of neurological specialization and Broca's area, more recent studies have also elucidated the many functions of Broca's area beyond traditional speech and language processing and production. For example, some of the novel findings included the use of functional magnetic resonance imaging (fMRI) to demonstrate that, during a task of discrimination of relatively slow (200 ms) tonal frequency glides, adults had greater activation of the left inferior frontal gyrus than those performing an auditory control task [10]. In addition, there has been evidence that anatomically, Broca's area overlaps partially with the ventral premotor cortex and that neuroimaging studies have demonstrated the activation of these regions during complex hand movements, audiomotor and visuomotor tasks, and when watching others perform these tasks (i.e., "mirror neurons") with largely homologous activation demonstrated across primate and human studies [1]. Further neuroimaging studies have found similar activations in Broca's area related to imitation tasks (e.g., finger tapping) [4]. As a final example, several other interesting studies have noted that bilateral activation in the inferior frontal neocortex, demonstrated via magnetoencephalography (MEG), is related to detection of music-syntactic incongruities [6] and that using single photon emission tomography (SPET), researchers have found preliminary evidence of increased regional cerebral blood flow in Broca's area during auditory hallucinations within a sample of individuals with *Schizophrenia* [7].

Bronfenbrenner, Urie

Asil Ali Özdoğru
University at Albany, SUNY, Albany, NY, USA

Life Dates

1917–2005

Introduction

Urie Bronfenbrenner is a world-renowned developmental psychologist who developed the theory of ecological human development and co-founded the national Head Start program in the United States.

Educational Information

Dr. Bronfenbrenner was born in Moscow, Russia (former Soviet Union) and migrated to the Pittsburgh, United States with his parents when he was 6 years of old. After graduating from Haverstraw High School in New York, Dr. Bronfenbrenner completed his bachelor's degree in

psychology and music double major program at Cornell University in 1938. In his graduate study Dr. Bronfenbrenner received his master's degree in developmental psychology from Harvard University in 1940 and doctorate from University of Michigan in 1942.

Accomplishments

After his service in the US Army as a psychologist, Dr. Bronfenbrenner served as Assistant Chief Clinical Psychologist for Research in the Veterans Affairs Clinical Psychology Training Program in Washington, DC. Following an assistant professor of psychology position at University of Michigan for two years, Dr. Bronfenbrenner accepted a professor position at Cornell University Department of Human Development, Family Studies and Psychology in 1948 and stayed there for the remainder of his professional life.

Association for Psychological Science (former American Psychological Society) awarded Dr. Bronfenbrenner the James McKeen Catell Fellow Award in 1993. The same year Cornell's Life Course Institute was renamed as Bronfenbrenner Life Course Center. The center organized the First Bronfenbrenner Conference, Chaos and Children's Development: Levels of Analysis and Mechanisms, in 2007. American Psychological Association offered its first Lifetime Contribution to Developmental Psychology in the Service of Science and Society Award to Dr. Bronfenbrenner and renamed the award as Urie Bronfenbrenner Award in 1996. In addition to numerous national and international awards and honors, Dr. Bronfenbrenner received six honorary doctoral degrees from several institutions including major European universities.

Contributions

In over 300 hundred articles and 14 books that he published, Dr. Bronfenbrenner developed a comprehensive theory of human development and offered practical implications for public and policymakers. His seminal book *The Ecology of Human Development: Experiments by Nature and Design* that was published in 1979 laid out his ecological approach to human development, which included contextual elements from larger social environment that sociologists and anthropologists used to study. Dr. Bronfenbrenner's ecological view asserted that biological potentials can be fostered by reciprocal, long-term, and dynamic relations between developing human and objects and other individuals in different layers of surrounding environment. In the ecological theory, interpersonal relationships such as mother-child relation take place within the layers of social, cultural, economical, and political contexts that shape the development of an individual.

Dr. Bronfenbrenner was one of the founding fathers of Head Start program, which serves millions of low-income American children and their families since 1965. In line with Dr. Bronfenbrenner's ecological theory, Head Start helps not only children but also their parents and promotes parental involvement in child development. Dr. Bronfenbrenner was a frequent speaker at annual National Head Start Research Conferences showing extended support and advocacy for the program.

Bronfenbrenner's Ecological Theory

Asil Ali Özdoğru
University at Albany, SUNY, Albany, NY, USA

Definition

Urie Bronfenbrenner's ecological theory is a comprehensive system theory of human development that includes elements from social, cultural, economical, and political contexts in the development of an individual.

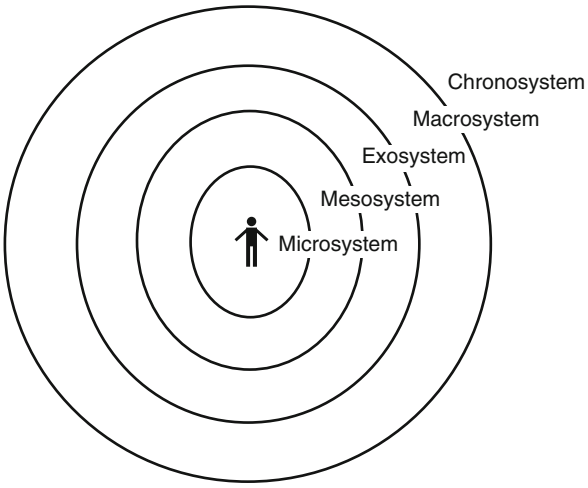
Description

In his seminal book *The Ecology of Human Development*, Urie Bronfenbrenner [3] introduced a new theory of human development that emphasizes interactive processes between the person and the environment. His ecological systems theory proposed that individual's development in any given area is primarily shaped by the interactions and relationships between the individual and different layers of surroundings. Activities, roles, and relationships of individuals in any setting constitute contexts of development. According to the ecological view, a thorough study of human development can best be achieved by the analysis of these different levels and contexts of person–environment interactions.

In ecological systems theory, nested layers of environment, like the Russian dolls, set the context for the developing human. Microsystem is the first layer of

environment in the immediate context of a child including settings like home, school, and playground. Experiences of children are affected by their activities, roles, and relationships that occur in the microsystem. For example, children's interactions with their siblings and peers, which may show contextual differences, comprise part of the microsystem. Beyond the microsystem, there are mesosystem, exosystem, macrosystems, and chronosystem with different elements of setting and appropriate analyses. The mesosystem involves interactions between microsystems or connections between different contexts such as school–home relations. The exosystem in ecological theory is the layer of social system which does not have a direct impact on the individual such as parents' workplace and community organizations. The macrosystem is the cultural environment that colors individuals' lives through beliefs, values, norms, traditions, and laws different cultures possess. The chronosystem is composed of patterns of events and transitions over time such as socio-historical circumstances on parenting styles (Fig. 1).

Bronfenbrenner later expanded his theory, which became bioecological theory, by focusing more on the active role of developing person's psychological characteristics. In essence, bioecological theory examines human development using a person-process-context-time model like other contextualist views of human development. As a dynamic systems approach to human development, ecological theory contributes a variety of principles and practices for the development of children.



Bronfenbrenner's Ecological Theory. Fig. 1 Ecological systems theory.

Relevance to Childhood Development

The most substantial application of ecological systems theory is the American national Head Start Program that Bronfenbrenner co-founded with psychologists Mamie Clark and Edward Zigler in 1965 [1]. Serving more than 900,000 preschool-age children with a budget over 6.8 billion dollars in 2007, the Head Start Program aims to help disadvantaged children to attain optimal levels of cognitive and social development through wide-ranging services in education, health, nutrition, and social services for children and families [4]. In accordance with his ecological approach, Bronfenbrenner [2] was influential in the inclusion of members and elements from different layers of the environment to achieve effective intervention practices for motivational and social aspects of compensatory education programs. Ecological systems theory emphasizes the comprehensive nurturing of a child's development with the contribution of different individuals such as peers and adults in various environments such as home, school, and neighborhood.

Brown ADD Rating Scales (BADDS)

►Brown Attention-Deficit Disorder Scales

Brown Attention-Deficit Disorder Scales

Teresa L. Davenport, Andrew S. Davis
Ball State University, Muncie, IN, USA

Synonyms

BADDS; Brown ADD Rating Scales (BADDS); Brown attention-deficit-disorder scales for adolescents and adults; Brown attention-deficit disorder scales for children and adolescents

Definition

The *Brown attention-deficit disorder scales* (Brown ADD scales) are self-report rating scales that measure symptoms of attention-deficit hyperactivity disorder (ADHD). The scales are normed for four ages groups: primary/preschool (ages 3–7), school-age (8–12), adolescent (12–18), and adult (18 and older). Rating forms are available for parents, teachers, and self-report (8+ years of age).

Description

The Brown ADD scales were developed by Dr. Thomas E. Brown from Yale University School of Medicine and Director of the Yale Clinic for Attention and Related Disorders. The Brown ADD Scales and the scoring software are published by The Psychological Corporation. The scales were first published in 1996 (Brown attention-deficit disorder scales (BADDS) and originally contained scales for students ages 12–18 and a scale for adults 18 years of age or older. The test was expanded in 2001 with the addition of scales for children 3 years of age to 12 years of age. The Brown ADD scales currently offer four scales: primary/preschool (ages 3–7), school-age (8–12), adolescent (12–18), and adult (18 and older). Forms for children 3–12 years of age include teacher and parent forms, and a self-report measure is available for children 8–12 years of age. Forms for adolescents and adults are self-report measures only, with space on the forms for input from significant others. The scales include two manuals, the Brown ADD Scales for Children and Adolescents and the Brown ADD Scales for Adolescents and Adults.

According to the test manual, The Brown ADD scales are based on a view of ADHD as a deficit in executive functions and not strictly on the criteria presented in the *Diagnostic and Statistical Manual of Mental Disorders – Fourth Edition* (DSM-IV-TR). The scales include measurements of six executive function clusters: (1) Organizing, prioritizing and activating to work (2) focusing, sustaining and shifting attention to tasks, (3) regulating alertness, sustaining effort and processing speed, (4) managing frustration and modulating emotions, (5) utilizing working memory and accessing recall. The primary/preschool and school-age forms include a sixth cluster: Monitoring and Self-Regulating Action. The scales consist of a series of behaviors which are rated by the respondent as occurring "never," "once a week or less," "twice a week" or "almost daily."

Professionals with graduate training in psychological assessment should be qualified to administer the Brown ADD Scales. Additional training in school or child clinical psychology will be helpful in interpreting the results. Protocols for the Testallow the examiner to record responses from the child and the parent(s) on the same protocol. This is consistent with administration procedures detailed in the manual, which indicate that when administering the scales to a child or adolescent, the examiner should administer the scales to the child or adolescent with the parent(s) present to offer differing perspectives, avoid exaggerated responses and to give each party present "a richer appreciation of other perspectives and experiences" [2]. The child is given the opportunity to respond to all items first. If the parent attempts to answer first or to cut-off the child, the examiner is instructed to interrupt the parent and reiterate to them that the child is to respond prior to the parent(s) response. Adults may prefer to have the scales administered to them individually; however, if he or she may invite a parent, close friend, or spouse to join them the administration of the scales in this scenario will be almost exactly as that for administering to a child. The scales contain a total of 40–50 items (less for younger children, more for older children) and the manual suggests administration will take 10–20 min for younger children and adolescents and 15–30 min for older adolescents and adults to complete. Total completion time is highly influenced by the number of items explored by the examiner and the verbosity of the client. The scales can be completed in written form by adults without the examiner present, but whenever possible should be followed up by face-to-face inquire during which the clinician asks for elaboration and examples of responses.

Clinicians may choose to use the Brown ADD scales in screenings and comprehensive evaluations for attention problems, as well as for monitoring of treatment responses in educational, clinical, and managed care settings [2].The Brown ADD Scales utilize T-scores to guide interpretation. Scores for children 3–12 years of age are divided into

four categories with four corresponding descriptions: average range, possibly significant concern;, somewhat atypical, probably significant concern; moderately atypical, significant problem; and markedly atypical, very significant problem. For adolescents 12–18 years of age, three categories are used: AD/HD possible but not likely, AD/HD probable but not certain, AD/HD highly probable. Adults are rated based upon normative results. The Brown ADD scales can be scored by hand, or by scoring software (Brown ADD Scales Scoring Assistant).

The manual reports the standardization sample used in the creation of the Brown ADD scales for children and adolescents was a stratified sample of 800 children 3–12 years of age. The sample was stratified by race and parental education, and children with a psychiatric disorder or learning disability were excluded. Participants were selected to replicate results of the 1999 U.S. Census, with 200 participants each from four geographic regions. The child clinical sample consisted of 208 children who were diagnosed with an attention deficit disorder based on multimodal assessment (DSM-IV criteria, clinical interviews with the child, his or her parents, reports from teachers, and standardized psychological assessments).

The standardization sample used in the creation of the Brown ADD scales for adolescents and adults as reported in the 1996 manual was comprised of a nonclinical sample of 190 adolescents and 143 adults and a clinical sample of 191 adolescents and 142 adults. This sample is based on U.S. Census proportions, but the sample has higher SES than the nation as a whole, and data for geographic regions are not included. The adolescent nonclinical sample had significantly more males than females (87% male), and this was also true for the clinical sample (79.5% male). The adult nonclinical sample was more balanced between males and females (49% male) and the adult clinical sample (50% male).

A review of the test manual will show that there is good evidence of adequate reliability and validity. The Brown ADD Scales were compared to other widely used measure of attention and yielded evidence of strong concurrent validity.

The Brown ADD Diagnostic Forms

The Brown ADD Scales include supplemental diagnostic forms for ages 3–12, 12–18, and 18 or older. The diagnostic form is comprised of a clinical interview, scoring summary of the scales, multirater evaluation, a screener for other learning and psychiatric disorders, an examiner's worksheet for comparing psychoeducational test scores, space for graphing test scores, and a summary of diagnostic data and impressions. Space is provided within the form for the examiner to record subject responses. The clinical interview for children and adolescents are designed to be administered to the child or adolescent, and the examiner is instructed to change the phrasing of the questions when administering to the parent(s). The multirater evaluation is designed specifically to evaluate for the presence of DSM-IV diagnostic criteria for AD/HD. The screener for other learning and psychiatric disorders will assist the examiner with determining if the individual being evaluated would also benefit from further evaluation for other comorbid psychological problems.

Educational Information

Ronald T. Brown, Ph.D., ABPP is an internationally recognized pediatric psychologist who has clinical and research expertise in the behavioral sciences, pediatric psychology, attention deficit disorders, neuropsychology, psychopharmacology, and learning disabilities. Dr. Brown earned his B.A. in Psychology from Emory University. He received his Ph.D. in Psychology from Georgia State University. Dr. Brown completed his postdoctoral fellowship at the Institute for Child Behavior and Development, Pediatric Psychopharmacology and Learning Disabilities, at the University of Illinois at Urbana-Champaign. In addition, he has completed management programs in development and leadership education at Harvard University.

Accomplishments

Early in his career Dr. Brown studied impulsivity among adolescents with oppositional, conduct, and attentional disorders. Dr. Brown investigated how specific learning disabilities and ADHD affected information processing and cognition among young children. Next, Dr. Brown studied the effects of pharmacological treatment, most notably stimulant medication, on the behavior and cognition of children and adolescents.

Dr. Brown extended is systematic research program to focus on young people in whom chronic disease has contributed to attentional problems, whether through the direct result of their primary illnesses or as an iatrogenic effect associated with treatment. His research also has explored how children and families adapt and cope with serious illness and injury.

Contributions

Many of the conclusions from Dr. Brown's early research still hold relevance today. For example, his early findings suggested that some of the impulsivity of children and adolescents could be modified through modeling, but the effects did not generalize to other classroom-related tasks. Along with other leaders in the field, Dr. Brown's research led him to conclude that ADHD does not simply resolve through maturation; rather, children with the disorder continue to have many problems during adolescence and even into adulthood. Further, Dr. Brown and colleagues found that cognitive therapy was minimally effective for children with ADHD. Instead, they concluded that stimulant medication was the most effective as long as the children remained on the stimulant regimen. Dr. Brown also was one of the first pediatric psychologists to examine cultural influences on medication response.

In research looking at fetal exposure to alcohol, Dr. Brown's team found that much of the cohort demonstrated significant problems with attention and concentration, experiencing learning disabilities in mathematics and impairments in fine motor control. This research gave impetus to a systematic line of research examining the relationship between fetal alcohol effects and ADHD. By the early 1990s, Dr. Brown became interested in ADHD and gender differences. His research data indicated that females with ADHD received considerably less attention from classroom teachers and other significant adults than their male counterparts, despite exhibiting learning disabilities and attention problems. Dr. Brown's team also found that behavioral comorbidities were more frequent in males. These findings led to the conclusion that girls with ADHD were under-diagnosed because their behavior was not as disruptive and they did not typically bother teachers and other caregivers.

Dr. Brown and colleagues made major research contributions in examining potential learning and social late effects experienced by childhood cancer survivors in the 1980s. Their findings suggested that attention difficulties frequently occurred in children who had received central nervous system treatment. They further explored the impact of cancer treatment during critical periods in brain development. Additionally, Dr. Brown and his research team supported the hypothesis that overall most families were resilient and adjusted well to their child's cancer diagnosis and treatment.

Dr. Brown continued to blaze a trail in studying the impact of chronic illness on learning and adjustment and initiated a line of research examining the impact of silent infarcts associated with sickle cell disease on executive functioning and attention. Currently, Dr. Brown is the principal investigator in a large multi-site study exploring the use of stimulant medication in addressing attentional problems in children with sickle cell disease.

Current Involvement

Currently, Dr. Brown is the Dean of the College of Health Professions at Temple University. Dr. Brown has appointments as a Professor in Public Health, Psychology, Pediatrics, and Psychiatry and Behavioral Sciences. He is a fellow of the American Psychological Society, the American Psychological Association, the Society of Pediatric Psychology, the Society of Behavioral Medicine, and the National Academy of Neuropsychology, and is a diplomate in Clinical Health Psychology of the American Board of Professional Psychology. Dr. Brown is the editor or author of nine books, and has authored more than 200 publications throughout his career. He has received over $12,000,000 in federal and foundation awards. He was editor of the *Journal of Pediatric Psychology* from 2003 to 2007, and has served on numerous National Institute of Health study sections.

Bruner, Jerome Seymour

Brenda L. Verastigi, Bernadette Hassan Solórzano
Our Lady of the Lake University Community Counseling Service, San Antonio, TX, USA

Life Dates

1915–Present

Introduction

Dr. Jerome S. Bruner is an American psychologist who has contributed to the study of perception, cognition, and education. He was one of the first psychologists to challenge behaviorism and psychophysics and created a new theory of perception. He is also known in the United States and Britain for his role in education reform.

Educational Information

Bruner completed his Bachelor of Arts Degree at Duke University in 1937. He next attended Harvard University here he earned his Master of Arts in 1939. In 1941, after writing his thesis entitled "A Psychological Analysis of International Radio Broadcasts of Belligerent Nations," he completed his doctorate of philosophy. He worked as a social psychologist exploring propaganda, public opinion, and social attitudes for the US Army Intelligence during the World War II. He returned to Harvard in 1945 to teach and became a full professor in 1952. From 1972 to 1980, he had a position as Watts Professor of Experimental Psychology at Oxford University. He moved next to New York University Law School as the Meyer Visiting Professor in 1991 and since 1998 he has held the positions of University Professor and Research Professor of Psychology.

Accomplishments

Bruner has received many awards and honors such as the International Balzan Prize, the CIBA Gold Medal for Distinguished Research, and the Distinguished Scientific Award of the American Psychological Association. He served on the President's Science Advisory Committee during the Kennedy and Johnson presidencies. In 1960, he established the Center for Cognitive Studies at Harvard University and served as its director through 1972. He was elected to serve as President of the American Psychological Association from 1964 to 1965.

Contributions

Dr. Bruner was involved in founding Head Start. He believes that people interpret the world in terms of its similarities and differences. He suggests a system of coding in which people from a hierarchical arrangement of related categories. He researched the development of children and proposed three models of representation: enactive representation (action-based), iconic representation (image-based), and symbolic representation (language-based). His theory suggests that even very young learners can learn when information is presented in an organized fashion. The Center for Cognitive Studies was a platform for those interested in the cognitive process to come together and discuss how humans store information. Bruner was convinced that the mind structures its sense of reality using cultural products like language and other symbolic systems. This led to the publication of "Narrative Construction of Reality" in 1991.

Current Involvement

Dr. Bruner is currently a senior research fellow and university professor at the New York University School of Law. He teaches courses such as Colloquium on Culture and the Law, Lawyering Theory Colloquium: Crime and Punishment, and Psychology and the Design of Legal Institutions. He has researched the Use of Narrative and Story-Telling in Law. He has authored 14 books and more than seven publications in the area of education and psychology.

Bulimia

►Binge/Purge Eating

Bulimia Nervosa

Maria Assunta Cuffaro
State University of NY: Potsdam, Potsdam
NY, USA

Synonyms

Binge/purge eating; Eating disorders

Definition

An eating disorder where people control their body weight in spite of binge overeating by purging (self-induced vomiting) or use of laxatives, diet pills or other means.

Description

Bulimia nervosa the key characteristics of this disorder include bingeing (the intake of large quantities of food) and purging (elimination of the food through artificial means such as forced vomiting, excessive use of laxatives, periods of fasting, or excessive exercise). Recurrent episodes of binge eating. An episode of binge eating is characterized by both the following: (1) Eating, in a discrete period of time (e.g., within any 2-h period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances. (2) A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating). (3) Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise. (4) The binge eating and inappropriate compensatory behaviors both occur, on average, at least twice a week for 3 months. (5) Self-evaluation is unduly influenced by body shape and weight. (6) The disturbance does not occur exclusively during episodes of anorexia nervosa. Two types: purging types: during the current episode of bulimia nervosa, the person has regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas. Nonpurging type: during the current episode of bulimia nervosa, the person has used other inappropriate compensatory behaviors, such as fasting or excessive exercise but has not regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas.

Bullies

Andrea Morillas-Brown, Grace Boyd, Brett R. Nelson
California State University, San Bernardino,
San Bernardino, CA, USA

Synonyms

Intimidators; Proactive aggressors; Tormenters

Definition

A bully is an individual who inflicts aggression, harassment, or intimidation in verbal, physical, or psychological forms to another person(s). The underlying reason for this violent behavior is usually to obtain power over another individual [4].

Description

In today's society, bullying has been found to be one of the most frequent types of violence in American schools [11]. Research has found that boys are more likely to be bullies than girls and up to 54% of children across 25 countries are engaging in the act of bullying [3].

How Bullies Evolve

There are a variety of environmental factors that are associated with becoming a bully. Family factors are one main influence that can lead to the development of a bully. The literature shows that children who experience a lack of involvement, emotional support, and low cognitive stimulation from their parents have greater chances of exhibiting bullying behavior [2]. Furthermore, if a child

experiences harsh or over controlling discipline and/or abusive experiences, he or she may be at a higher risk of becoming a bully [3, 9]. Similarly, children who either observe siblings and/or parents engaging in the act of bullying or are being bullied themselves, may be more inclined to display bullying tendencies [4]. Another important factor that influences the development of a bully is the school environment of the child. The literature suggests that children who become bullies often experience a lack of connection to their school [14] or have been inadvertently reinforced for bullying behavior because of a lack of consequences from school personnel [4]. Children's peer group factors are another major influence contributing to the incidence of bullying behavior. More specifically, the peer pressure that children experience from others, or their need to fit in with others, has been found to directly contribute to bullying behavior [2]. As a result of these factors, children may bully others as a way of feeling important and in control, something that may have been absent from his or her upbringing [4].

Relevance to Childhood Development

The act of bullying affects the development of both the bully and the bullying victim in various ways academically, socially, and psychologically [11]. In the area of academics, the literature illustrates that bullies tend to skip classes, resulting in lower academic achievement [8]. In turn, this has been found to increase the likelihood of bullies dropping out of school and ultimately impacting their ability to obtain a job [3]. Victims may also experience academic difficulties due to the high incidence of school refusal that has been documented in the literature [3]. Moreover, research suggests that both bullies and victims have reduced concentration and problem solving skills as well as an increased amount of truancies from school [13].

Socially, research shows that bullies often display little empathy for others [5], which may affect their ability to maintain interpersonal relationships [13]. As a result, bullies may resort to aggressive behaviors towards others in order to achieve social status and approval from their peers [2]. Later in life, bullying tendencies may lead these children to become abusive parents or spouses, or display criminal acts [11]. For instance, bullies frequently target victims that complain, seem weak (emotionally and physically), and are attention seeking [4]. Although the harmed individual may be repeatedly victimized by the bully, he or she may continue pursuing interaction with the bully to obtain social approval [4].

In the psychological domain, bullies can exhibit high emotionality and low self control which may result in a higher prevalence of self-destructive behaviors, such as smoking and alcohol use [8]. These behaviors may later evolve into delinquencies in adolescence and potentially a diagnosis of conduct disorder [3]. Victims, on the other hand, tend to experience unhappiness and loneliness and display behavioral problems at school [7]. Additionally, bully victimization can lead to lower social adaptation and social phobias [8]. As a consequence of continued bullying, victims may resort to extreme measures of violence [13] and ultimately attempt suicide [1]. Interestingly, bullies and victims share several psychological consequences including sleep difficulties, lowered self-esteem, and symptoms of depression and anxiety [3].

What the School/Parents Can Do

As the literature has illustrated, the prevalence of bullies is continuing to dramatically rise and is creating challenges for various individuals across different settings (i.e., school and home). As a result, necessary strategies must be considered in order to address this rising occurrence and potential challenges that can arise.

Research has proven that the most effective way to address the dramatic increase in bullying is prevention [12]. There are several prevention strategies that parents and school personnel can utilize to remediate the harmful effects of bullying. It has been found that a key component of these strategies is the implementation of parent and teacher training [4]. This training should include identifying early warning signs of bullying behavior or victimization [12], creating social support from parents, peers, and teachers [10], enforcing serious consequences for bullying behavior, and providing adequate supervision involvement at home and school [12].

In addition to the above-mentioned strategies, there are several social skills interventions that the research has found effective. An initial step in determining the most appropriate intervention is a complete assessment using multiple methodologies in order to better understand and treat the bully [10]. The literature recommends using teacher report, self-report, and behavioral observation [6] during the assessment process. Some important components in the social skills interventions include discussing the negative impacts of bullying behavior, identifying alternatives to bullying behavior, using role plays as a means to teach empathy to the bullies, teaching bullies about the respect of others and the importance of tolerance, and providing the bully with positive reinforcement for engaging in appropriate behaviors [4]. With the use of these interventions and the previously mentioned prevention approaches, it is anticipated that the development of bullying behavior will be better understood and the prevalence of bullying will decrease.

Future Directions

Currently, few prevention and intervention strategies for bullies exist in the literature. In an effort to ensure that the bullying problem continues to decline, it is essential that a more comprehensive understanding of the prevention and intervention of bullies be explored in greater depth. Additionally, in order to create more effective prevention and intervention strategies, it is important to explore different areas of research, such as the feelings of bullies [9], the efforts of social payoff [10], and the power imbalance that occurs between the bully and the victim [1] to further understand the motives behind bullying behavior [11].

Bullying

Janett M. Naylor
Fort Hays State University, Hays, KS, USA

Synonyms

Peer victimization; Peer rejection; Aggression

Definition

The abuse of power over others that is relative to cultural norms and mores; being repeatedly cruel to others who are weaker.

Description

Defining what constitutes "bullying" has been a controversial topic in research since the 1970s. Some basic definitions have focused on intention to hurt another but failed to separate bullying from aggression. Yet other definitions focused less on desire and more on actions, classifying bullying as negative behaviors not necessarily designed to hurt others. Other researchers have focused on the repeated act of bullying to further delineate bullying from one-time aggressive acts. Currently, bullying is considered an abuse of power that is defined by cultural expectations and situations. Whatever the researchers' definition, bullying is typically studied through self-reports, observations, parent/teacher reports, peer nominations, and interviews.

Bullying is not a phenomenon of only childhood; however, most research has focused on bullying in schools. In early childhood (infant-preschool years), observations during playtime reveal that children do bully for fun and not simply because they are unable to share appropriately with their peers. Although relatively few children are responsible for consistent bullying, the behaviors of targeting other children are not uncommon. A difference in power balance between peers is noticeable by teachers and parents such that researchers are able to reliably identify those children who are victimized by other children.

Peer victimization appears to decline with age such that between the ages of 8 and 11 years, percentage of students reporting being bullied weekly drop from 48 to 22.5%. The most common content of peer victimization attacks are being called hurtful names, being left out of things, and being hit or kicked. Victims vary based gender and age on their reactions to being bullied. More specifically, boys are increasingly more likely to report not being bothered by bullying between the ages of 8 and 11 years.

However, for girls there shows no developmental change in reaction to bullying. In general, victimized children are more likely to have low self-esteem and more likely to suffer from depression, sleep problems, headaches, bed-wetting, and loneliness than their non-victimized peers. In addition, boys and girls seem to be equally targeted by bullies; however, boys are more likely than girls to bully others.

Those children who perpetrate bullying show little change in their frequency of bullying others. Between 8 and 11 years, the tendency to bully others is fairly stable regardless of group size or gender. Children who bully others often blame the victim for provoking the bullying acts. The two most reported reasons for bullying others were "because they annoyed me" and "to get even" indicating that bullies often justify their actions by placing onus on the victims. Bullies are typically highly aggressive and act aggressively toward other children and adults. Bullies try to dominate others, have little capacity for empathy, and follow few rules.

Overall, programs designed to reduce bullying in school have been effective. Many methods are being used including peer counseling and training and conflict resolution skill training. The central theme, regardless of methodology, seems to be a school-wide antibullying policy and practice involving teachers, administrators, parents, and children. Incidents of bullying have been estimated from 1:5 children to 1:10 children being bullied by others.

Buoyancy

►Protective Factors

Bupropion

Synonyms

Amfebutamone; Aplenzin; Wellbutrin; Zyban

Definition

An antidepressant medication used to treat major depression and seasonal affective disorder. It is also prescribed for smoking cessation.

Description

Bupropion, an antidepressant of the aminoketone class, is chemically unrelated to tricyclic, tetracyclic, selective serotonin reuptake inhibitor, or other known antidepressant agents. Since it does not inhibit serotonin reuptake, bupropion does not cause weight gain or sexual dysfunction like the SSRI group of antidepressants. Initially researched and marketed as an antidepressant, bupropion was subsequently found to be effective as a smoking cessation aid. In 2007 it was the fourth-most prescribed antidepressant in the United States retail market, with 20.184 million retail prescriptions.

Adverse events commonly encountered in patients treated with bupropion are agitation, dry mouth, insomnia, headache/migraine, nausea/vomiting, constipation and tremor. Bupropion lowers seizure threshold however, at the recommended dose the risk of seizures is comparable to that observed for other antidepressants. Bupropion is an effective antidepressant on its own but it is particularly popular as an add-on medication in the cases of incomplete response to the first-line selective serotonin reuptake inhibitor (SSRI) antidepressants.

Café au Lait Macules

►Café au Lait Spots

Café au Lait Spots

Synonyms

Birth mark; Nevus; Café au lait macules

Definition

Café au lait spots or *Café au lait* macules are pigmented birthmark. The name café au lait is a French term for "coffee with milk" and refers to their light-brown color often associated with these birthmarks. Sometimes Café au lait spots are called "giraffe spots."

Café au lait spots do not typically cause any ailment themselves. However, having multiple spots has been linked with a number of conditions such as neurofibromatosis and the rare McCune-Albright syndrome. Specifically, having six or more café au lait spots greater than 5 mm in diameter before puberty, or greater than 15 mm in diameter after puberty, are cardinal diagnostic features of neurofibromatosis type I. Other conditions these spots are associated with could include:

- Von Hippel – Lindau disease
- Fanconi anemia
- Tuberous sclerosis
- Silver-Russell dwarfism
- Ataxia telangiectasia
- Bloom syndrome
- Basal cell nevus syndrome
- Gaucher disease
- Chédiak-Higashi syndrome
- Hunter syndrome
- Marfan's syndrome
- Maffucci syndrome
- McCune-Albright syndrome
- Peutz-Jeghers syndrome
- Multiple endocrine neoplasia type 2

Caffeine

Daniel Patanella
New York City Department of Education, New York, NY, USA

Synonyms

Guaranine; Mateine; Methyltheobromide; Theine

Sam Goldstein & Jack A. Naglieri (eds.), *Encyclopedia of Child Behavior and Development*, DOI 10.1007/978-0-387-79061-9,

Definition

Caffeine is a commonly used stimulant, usually encountered in beverages and nonprescription medications.

Description

Caffeine occurs naturally in a variety of plants; these plants are then used as components of common beverages such as tea and coffee. Caffeine usually acts as a natural pesticide and toxin, hence its evolutionary value to plants in discouraging herbivores; in human beings, caffeine serves as a mild, fast-acting stimulant and diuretic drug. As such, its effects on the central nervous system (such as increased heart rate and alertness) mimic those of other, more potent, stimulants. Its molecular formula is $C_8H_{10}N_4O_2$. There is no known dietary need for caffeine among humans, yet it is popularly consumed within hot beverages and carbonated drinks daily by many. Caffeine is also used to increase the effects of analgesic drugs such as aspirin, and some nonprescription pain relievers include caffeine as an active ingredient. As caffeine reduces appetite, it can also be found in over-the-counter weight loss pills.

When taken in moderate amounts of 250–300 mg per day, caffeine temporarily increases alertness. This amount is roughly equivalent to two or three cups of coffee per day for an adult. In larger amounts, the risks of unpleasant and undesired physical reactions exist. As with other antagonist drugs, tolerance adaptation can develop, which both reduces the effectiveness of caffeine (requiring larger dosages) and leads to underproduction of internally produced neurotransmitters. This can lead to unpleasant withdrawal symptoms such as headache, nausea, and irritability. Addiction is possible. *The Diagnostic and Statistical Manual of Mental Disorders IV* (1994) includes caffeine intoxication, caffeine-induced sleep disorder, caffeine-induced anxiety disorder, and caffeine-related disorder not otherwise specified as recognized disorders.

Relevance to Childhood Development

Caffeine is a well-researched drug, with a large body of research on its effects being relevant to those interested in childhood development. Contemporary research suggests that low daily caffeine intake by pregnant women does not lead to a significantly increased risk of miscarriage or birth defects. The American Academy of Pediatrics recommends that nursing mothers refrain from anything other than low caffeine intake, as caffeine ingested by the mother can appear in breast milk. The result of ingesting larger amounts of caffeine during pregnancy and nursing are unclear.

While a recognized stimulant, caffeine is not part of psychopharmacological treatment for ADHD and related disorders. Its effects on children's behavior are inconclusive, although there is currently concern in the medical community over high caffeine intake among children and adolescents primarily through soft drinks and "energy drinks." As with all aspects of children's health, it is best for parents to consult with a pediatrician or other health professional regarding proper use of caffeine in their children.

Cardiac Disorders

Synonyms

Cardiovascular disease; Heart disease

Definition

Heart disease or cardiopathy is an umbrella term for a variety of different diseases affecting the heart. As of 2007, heart disease is the leading cause of death in the United States, England, Canada and Wales, killing one person every 34 seconds in the United States alone.

Cardiovascular disease is any of a number of specific diseases that affect the heart itself and/or the blood vessel system, especially the veins and arteries leading to and from the heart. Research on disease dimorphism suggests that women who suffer with cardiovascular disease usually suffer from forms that affect the blood vessels while men usually suffer from forms that affect the heart muscle itself. Known or associated causes of cardiovascular disease include diabetes mellitus, hypertension, hyperhomocysteinemia and hypercholesterolemia.

Children are usually thought of as having healthy hearts. Yet, eight out of every 1,000 babies born in the United States are born with a congenital heart abnormality. Nearly one million people living in the United States were born with a congenital heart defect.

Risk factors that contribute to coronary artery disease and other cardiovascular diseases (such as smoking, lack of exercise, and high cholesterol levels) often begin at an early age. Nearly half of children ages 12 to 21 do not exercise on a daily basis, and an estimated 8.8 million (about 30 percent) U.S. children ages six to 19 are obese. Some heart problems experienced by children, such as most cases of congenital (present at birth) heart defects, can be treated medically or surgically, but cannot be prevented.

Catapres® (Clonidine)

Lauren Connell Pavelka
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Clonidine (generic)

Definition

Catapres is a centrally acting alpha-agonist hypotensive agent. Clonidine is the generic form of Catapres. Catapres tablets are available in three dosage strengths: 0.1, 0.2, and 0.3 mg.

Description

Catapres is most commonly indicated in the treatment of high blood pressure. Other psychopharmacological indications of clonidine include the treatment of attention deficit hyperactivity disorder (ADHD), autism, Tourette syndrome, anxiety disorders, and chemical withdrawal.

Dizziness, lightheadedness, drowsiness, dry mouth, and constipation are common side effects that are usually mild, and diminish as the patient's body adjusts to the medication. Serious side effects are uncommon, but a healthcare provider should be notified immediately if irregular heartbeat, sudden or severe mood changes, or cold hands/ feet are experienced. Before taking Catapres, patients should discuss previous medical history (especially concerning kidney disease, heart disease, depression, and blood circulation disorders) with a physician, and note any known allergies. As little as 0.1 mg of Catapres has produced signs of toxicity in children.

This review of Catapres contains general information. For complete information about Catapres and individual use, a health care professional should be consulted.

Relevance to Childhood Development

Catapres has been used to treat ADHD, autism, and Tourette syndrome in pediatric patients, but its safety and effectiveness have not been well established in clinical trials. Catapres has been identified as a promising treatment for addressing the symptoms of Tourette syndrome.

Catell-Horn-Carroll Theory of Intelligence

Heath Marrs
Central Washington University, Ellensburg, WA, USA

Synonyms

CHC theory

Definition

A broad conception of intelligence that draws on Cattell and Horn's theory of fluid and crystallized intelligence and Carroll's three-stratum theory of cognitive abilities.

Description

The Catell-Horn-Carroll (CHC) theory of intelligence represents a combination of two previously proposed theories of cognitive abilities, the theory of fluid and crystallized intelligence (or Gf-Gc theory) associated with Catell and Horn, and John Carroll's three-stratum theory of cognitive abilities [2, 4]. Both Gf-Gc theory and Carroll's three-stratum theory are considered to be hierarchical theories of intelligence, in that they posit a broad cognitive ability with multiple, more specialized abilities at lower levels of the hierarchy. Because of the significant overlap in the main components of the two theories, an integrated theory has been proposed that combines elements of both theories to provide an understanding of the broad range of abilities that are typically thought of as representing intelligence [3]. CHC theory has been described as "the best validated model of human cognitive abilities [1, p. 140]," and it is generally viewed as a significant advance in the understanding of intelligence due to its basis in empirical research on cognitive abilities.

The earliest versions of Gf-Gc theory posited that there are two main types of intelligence, fluid intelligence and crystallized intelligence. Fluid intelligence refers to the efficiency of cognitive functioning (e.g., memory and reasoning abilities), while crystallized intelligence refers to the stored learning that a person acquires over a lifetime. For many individuals, fluid intelligence peaks in the early 20's and 30's and then gradually declines as a result of the natural aging process. In contrast, crystallized intelligence continues to increase throughout much of the life span. Later versions of the theory have retained the Gf-Gc conceptualization, while also adding a number of second-order factors similar to those identified in Carroll's three-stratum theory.

John Carroll's theory of cognitive abilities was developed after Carroll conducted a review and reanalysis of over 460 studies on human cognitive abilities [1]. Carroll [3] developed what he called the three-stratum theory of cognitive abilities, which asserts that cognitive abilities can be described by examining different levels of specificity. At the most basic level (Stratum I), Carroll asserts that there are sixty-five narrow cognitive abilities, such as general sequential reasoning, memory span, speech sound discrimination, and simple reaction time. These narrow stratum I abilities contribute to eight broad factors of cognitive abilities (Stratum II). These broad factors are fluid intelligence (G*f*), crystallized intelligence (G*c*), general memory and learning (G*y*), broad visual perception (G*v*), broad auditory perception (G*u*), broad retrieval ability (G*r*), broad cognitive speediness (G*s*), and decision/reaction time/speed (G*t*). Finally, each of these broad factors are conceptualized as contributing to an overall general intelligence (*g*).

The most direct application of CHC theory in the area of cognitive assessment is the Woodcock-Johnson III Test of Cognitive Abilities (WJ-III). The WJ-III was developed using CHC theory as a theoretical foundation [3]. The test measures abilities at each of the three stratums, including stratum I (narrow cognitive abilities), stratum II (broad cognitive abilities) [6], and stratum III (general intellectual ability). The WJ-III has been praised as a significant advance in the measurement of cognitive abilities because of its theoretical base [5]. Although the Wechsler and Stanford-Binet scales continue to dominate the intelligence testing field, the development of the WJ-III and other scales based on CHC theory has broadened the array of potential instruments for cognitive assessment. In addition, CHC theory has been somewhat influential as some of the more established instruments (WISC, SB) have been revised [5].

Caudate Nucleus

Chad A. Noggle
SIU School of Medicine, Springfield, IL, USA

Definition

The Caudate Nucleus is a mass of gray matter within the Basal Ganglia, that together with the Lentiform Nuclei, form the Corpus Striatum [3] and as a whole with other structures of the Basal Ganglia plays a vital role in the control of movement as well as procedural memory [1].

Description

The Caudate Nucleus in combination with the Putamen, Globus Palidus and Amygdala represent a collection of nuclei lying mainly beneath the anterior regions of the neocortex known as the Basal Ganglia [2]. The Basal Ganglia are a collection of deep nuclei of the Telencephalon that transmit information to and from motor areas of the cortex via the Thalamus that provide for the control of higher-order movement, particularly in initiating movement [4]. Damage to the Basal Ganglia can produce changes in posture, increases or decreases in muscle tone, and abnormal movements such as twitches, jerks, and tremors [2]. The role these structures play in aspects of movement/ motor control can be best seen in those presentations that infiltrate those structures. For example,

Huntington's Disease regularly shows atrophy of the Caudate Nucleus [1] and the Caudate as well as other structures of the Basal Ganglia have been implicated in additional movement disorders such as Parkinsonism [3]. In relationship to manifestations of more of a childhood onset, the unwanted tics and vocalizations associated with Tourette's syndrome may also occur secondary to impairments of the Caudate Nucleus [2]. In addition to the control and regulation of movement, the Caudate Nucleus, together with other structures of the Basal Ganglia, and in combination with the Cerebellum, plays a role in procedural memory, which is memory for actions or performing tasks [1].

While the Caudate Nucleus is a mass of gray matter within the Basal Ganglia as a whole, in combination with the Lentiform Nuclei, it forms the Corpus Striatum [3]. The Striatum and specifically the Caudate Nucleus receives projections from all areas of the Neocortex and sends its own projections through the Putamen and Globus pallidus to the Thalamus and from there to the motor areas of the cortex [2]. The Caudate Nucleus also demonstrates reciprocal projections (afferent and efferent neurons) to a number of Limbic, Premotor, and Prefrontal areas [4].

Central Auditory Processing Disorder

Stacy E. Levin
Argosy University

Synonyms

Auditory processing; Central auditory processes; Language disorders [3, 8]; Language impairments in children

Definition

Central auditory processing disorder (CAPD) is a deficiency in auditory mechanisms and processes, including sound localization and lateralization, auditory discrimination, auditory pattern recognition, temporal aspects of audition, auditory performance of competing acoustic signals, and auditory performance with degraded acoustic signals. It refers to weaknesses in the processing of auditory information in the central nervous system [3, 8, 9] that are not due to other cognitive or language-related disorders [2].

Description

CAPD was first conceptualized in the 1970s when studies of the central auditory nervous system were conducted on adults. Nearly 40 years later, diagnosis, assessment, and treatment of CAPD remains controversial. There is a lack of consensus among clinicians regarding identification, assessment, and treatment of CAPD [8, 9]. Theoretically, clinicians differ on whether a general auditory deficit or specific phonological deficit is the cause of auditory processing problems. Clinically, debates exist regarding identification and diagnostic criteria of CAPD. Ultimately, conflicting professional perspectives have limited the development of sophisticated diagnostic and intervention strategies [5].

Clinicians have established several behavior characteristics of CAPD, which include having normal tone-hearing thresholds, inappropriate responses to auditory stimuli, difficulty identifying the locations (localization) and positions (lateralization) of sounds, poor auditory discrimination, limited auditory and phonemic memory,

inconsistent understanding of speech in situations with elevated noise, poor listening, and required repetition of information [3, 8]. Perceptually, individuals with CAPD have trouble discriminating figure (i.e., the most relevant auditory input, such as a teacher's voice) from ground (i.e., background or ambient noise in the classroom).

Relevance to Childhood Development

Two to 3% of children, with a boy to girl ratio of 2 to 1, meet diagnostic criteria for CAPD [2]. In children, CAPD can significantly affect academic performance and result in reading, spelling, and handwriting problems. Children with CAPD can be characterized as having difficulty with: learning and language; sound discrimination; following directions; listening and attending in class; responding appropriately and consistently; and, filtering distractions. They may also frequently ask for information to be repeated [5, 9]. The effects of CAPD can intensify during particular developmental stages, such as in adolescence when teens are experiencing challenges of identity formation and social pressures [7].

Assessment

Assessment of CAPD in children should examine all auditory mechanisms and processes [1]. Children must be at least 7 or 8 years old to receive a formal audiological evaluation because of variability in brain functioning prior to this age. However, in children younger than age 8, aspects of hearing and auditory perception can be monitored [2].

Generally, teams of clinicians including audiologists, speech-language pathologists, psychologists, and teachers conduct CAPD assessments. Recommended assessments consist of a (n) collection of history and background information, observation of behaviors, administration of tests assessing general language performance, articulation, phonology, morphology, syntax, pragmatics, phonological awareness, and thorough review of sound mechanisms (i.e., temporal processes, pure tones, speech recognition, imitation, sound localization and lateralization, dichotic stimuli, binaural separation and integration procedures, and monaural speech). Audiological screening tests, such as the Screening Test for Auditory Processing Disorders in Children-Revised (SCAN-C) [10] and the Selective Auditory Attention Test (SAAT) [4], have been developed as early identification procedures for children who meet criteria for CAPD [3, 5, 9]. An audiologist must administer additional tests measuring physiological responses of the auditory system in a sound-treated room [2]. Once all assessment information has been gathered and reviewed, an audiologist – in conjunction with other appropriate professionals, can make a diagnosis of CAPD.

It is important to note, however, that results of formal testing may be lacking in ecological validity (i.e., real-life application). This is because formal testing results frequently do not consider the amount of effort a child has to exert in order to be successful. Thus, a child with central auditory processing problems may perform within the average range when he or she has the luxury of marshaling all resources, has a singular focus, and is tested in the "ideal" situation of a sound-treated room. This same child, however, may actually have significant functional weaknesses or actual deficits in auditory processing in the situations of day to day life that are less conducive to a singular focus.

Clinical Implications

Appropriate treatment can be implemented after an accurate and thorough diagnosis. Intervention techniques are highly individualized. Thus, the intensity, frequency, and type of therapy differ based on children's presenting strengths and weaknesses [2].

Because of the disagreement regarding the deficits involved in CAPD, it is premature to determine the targets and techniques of intervention [9]. However, clinicians concur that interventions should implement remediation and management techniques. Remediation involves shifting the function of the auditory central nervous system. Management encompasses behavior modification, cognitive training, and perceptual training to improve listening and learning skills in the environment [3, 5, 9]. In addition, compensatory strategies including language, problem solving, memory, and attention can lead to improvements in children with auditory deficits [2, 3, 5, 9].

Recent research has identified several specific evidenced-based remedial programs useful for children with CAPD, including Fast ForWord Language, computer-assisted language intervention (CALI), academic enrichment, and individual language intervention. Fast ForWord is a computer program which uses slow and exaggerated speech to improve children's auditory processing abilities. CALI is a computer-training program in which children receive direct assistance from a speech-language pathologist. Academic enrichment programs focus on learning, math, science, and geography. Individual language interventions involve working one-on-one with a speech-language pathologist. Upon intensive delivery of intervention (i.e., 500 min per week), all four techniques have been noted to lead to significant improvements in children's auditory processing skills [6].

Research efforts are considered necessary to examine auditory processing disorders further, solidify a definition of CAPD, establish diagnostic criteria, and assess the efficacy of intervention strategies. The approach to identification, assessment, and treatment of CAPD can be conceptualized once clinicians reach an agreement [5, 8].

Central Hemispheres

Jana Sander
Texas A&M University Corpus Christi College of Education, Corpus Christi, TX, USA

Definition

The central hemispheres are made up of the four lobes of the brain. These lobes include the frontal lobe, parietal lobe, occipital lobe, and temporal lobe.

Description

The central hemispheres or cerebral hemispheres of the brain consist of four lobes: frontal lobe, parietal lobe, occipital lobe, and the temporal lobe. The frontal lobe, located behind the forehead, is responsible for consciousness, attention, inhibition of impulses, information integration, and control of impulses. The frontal lobe is often considered to be the "home" of the personality. This is the section of the brain the enables humans to not only experience emotions but also interpret others' emotional reactions. Mood swings and changes are controlled in the frontal lobe. In addition, the frontal lobe is the section of the brain responsible for humor both expressing humor and understanding humor. Further the frontal lobe is responsible for sequencing events and actions. Due to its prominent position in the head, it is susceptible to injury.

The parietal lobe of the brain is divided into two parts and are located behind the frontal lobe and above the temporal lobe or at the back of the brain. It is

responsible for the reception and possessing of sensory information and some language function. Some of the sensory information processed by the parietal lobe includes temperature, touch, pressure, pain, taste, and visual reception. Visual reception includes the recognition of shapes and colors. If the parietal lobe is damaged the vision may be harmed.

The temporal lobe of the brain is found on either side of the brain, just above the ears. The temporal lobe controls emotions, memory, hearing, language, and learning. This lobe is accountable for interpreting and processing auditory stimuli. If the temporal lobe is damaged language may be affected. This would result in the individual being unable to verbally identify objects. In addition, visual perception, long term memory, and language comprehension would be impaired.

The occipital lobe, smallest of the four lobes, is located at the back of the brain. This lobe of the brain is primarily responsible for visual perception or sight. In fact, injury to the occipital lobe could result in blindness.

Central Nervous System

Chad A. Noggle[1], Jennifer N. Hall[2]
[1]SIU School of Medicine, Springfield, IL, USA
[2]University of Central Arkansas, Conway, AR, USA

Synonyms

Central nervous system (CNS); Nervous system

Definition

The Central Nervous System refers to the brain and spinal cord and their connections with one another.

Description

The Central Nervous System is an essential network of the human body that is the primary source, in large part, of all action and cognition. There are two main divisions involved, the Spinal Cord and the brain, that play different roles in carrying out those functions of the Central Nervous System. The Spinal Cord has 30 segments divided amongst four divisions (Cervical, Thoracic, Lumbar, and Sacral divisions) and one additional Coccygeal segment that each have a spinal nerve on both the right and left that are essential in the transmission of impulses to and from the CNS from and to the Peripheral Nervous System (nerves outside of the CNS), musculature, and other body regions and structures [2]. Damage to the Spinal Cord can lead to complete or partial loss of sensation and/or movement in those systems and areas outside of the CNS. For example, complete damage of the Spinal Cord at the Cervical level (i.e., highest level) can lead to quadrapliegia (i.e., loss of all movement and sensation below the neck).

The other division of the CNS is the brain, which itself has three divisions (the Hindbrain, Midbrain and Forebrain) organized from the bottom up. First, the Hindbrain is the site at which the brain and Spinal Cord are linked. This Brain division itself has two subdivisions, the Metencephalon and Myelencephalon [4]. The Myelencephalon is a heavily myelinated region that transmits signals between the brain and the rest of the body, but also includes the Medulla Oblongata, which regulate basic internal functions such as one's breathing and heartbeat [4]. The Metecephalon contains the Pons and the Cerebellum. The Pons serves as a relay station in which it transmits sensory information from the Spinal Cord to the Cerebellum and other brain structures, mostly via the Thalamus [3]. In contrast, the Cerebellum has been linked to the coordination and initiation of movement, although it has been implicated in addition functions, including procedural memory and language processing [3].

The second division is the Midbrain, which itself has two subdivisions, the Tectum and Tegmentum. The Tectum primarily serves in the relaying and transmission of visual information, through the functioning of the Superior Colliculi, and auditory information, through the functioning of the Inferior Colliculi [3]. While the Tectum is associated with transmitting sensory information, the Tegmentum has been linked with motor output due to

it including the Substantia Nigra and Red Nucleus which are both essential motor nuclei [3]. For example, degeneration of the Substantia Nigra has been linked to Parkinson's Disease.

Finally, the Forebrain is the division that most people think of when picturing the human brain. Commonly referred to as the Cerebrum, it is those areas, systems, and structures most important in higher functions and is composed of the paired cerebral hemispheres and the Diencephalon [4]. The outer layer of the Cerebrum is referred to as the Cerebral ortex and is characterized by numerous folds called gyri and creases called sulci [5]. The hemispheres of the brain are divided into four primary lobes, the Frontal, Temporal, Parietal and Occipital lobes. However, in addition to these lobar divisions, the Limbic System and Basal Ganglia are often discussed independently and are included in as part of the Forebrain. Each of these divisions as well as the Diencephalon are involved in different processes.

First, the Diencephalon includes the Thalamus, Hypothalamus, and Epithalamus, which each play vital roles in different actions. The function of the Epithalamus not well known; however, one of its structures known as the pineal body, assists in the regulation of seasonal rhythms [5]. In contrast, the Hypothalamus takes part in nearly all aspects of motivated behavior, including feeding, sexual behavior, sleeping, temperature regulation, emotional behavior, endocrine function, and movement [5]. It also exerts influence on the Autonomic Nervous System, which includes both sympathetic and parasympathetic branches. Finally, the Thalamus is involved in a wide variety of functions, largely related to the role the different thalamic nuclei. For example, the Lateral Geniculate Nucleus of the Thalamus is the primary relay for visual information whereas the Medial Geniculate Nucleus relays auditory sensory information [3]. Altogether, the Thalamus may be perceived as the essential relay station of all sensory information, but it has also been linked to higher-order process such as memory,

The Basal Ganglia is a group of subcortical structures that includes the Caudate Nucleus, Putamen, and the Globus Pallidus. Together, the Basal Ganglia play a vital role in initiating and modulating movement while also maintaining muscle tone and playing a role in aspects of procedural memory [6]. The second division of the Cerebrum, the Limbic System, is really a network of structures that are key to the regulation and processing of emotions, while also playing key roles in memory [5]. Finally, the four lobes of the Cerebrum, may not only be differentiated from an anatomical locality standpoint, but also from a functional standpoint. First, the Occipital lobe, which is the most posterior lobe of the cortex, houses the visual cortex and is primarily involved in the processing of visual information. The Parietal lobe is entrusted with the processing of somatosensory information, integrating sensory information, and regulating spatial cognition [5]. Next, the Temporal lobe not only houses the primary auditory cortex but is also involved in language processing and memory [3]. Finally, the Frontal lobe is the site of origin of the primary motor cortex, which functionally plans and controls movement. In addition, the Frontal lobes are essential to the modulation and regulation of behavior and personality, while also housing the executive functions.

Centration

Centration is a tendency to focus on one aspect of a situation and neglect others. This term was introduced by Swiss psychologist, John Piaget, to refer to the tendency of young children to focus their attention on only one salient aspect of an object, situation or problem at a time. This leads them to exclude other potentially relevant stimuli. In 1941, Piaget described an experiment in which he demonstrated the concept of centration as it relates to children's understanding of numbers. The child watched while a number of objects were set out in row and then moved closer together. The child was asked whether there are now more objects, fewer objects or the same number of objects. Most children in what Piaget referred to as the pre-operational stage of development, focused on the relative lengths of the rows without taking into account nothing had been added or taken away. This led them to conclude that there were fewer objects than before.

Cephalocaudal Principle

Edalmarys Santos[1], Chad A. Noggle[2]
[1]Middle Tennessee State University, Murfreesboro, TN, USA
[2]SIU School of Medicine, Springfield, IL, USA

Definition

The cephalocaudal principle refers to the general pattern of physical and motoric development followed from infancy into toddlerhood and even early childhood whereby development follows a head-to-toe progression.

Description

Cephalocaudal means head to toe. As such, the cephalocaudal principle refers to the general pattern of development seen in the earliest years of postnatal development specifically ranging from infancy into toddlerhood. The cephalocaudal principle applies to both physical and functional development. Regarding the prior (i.e., physical development), physical growth in size, weight, and feature differentiation follows this pattern of development [1]. The result of this is best seen in a comparison of the physical features of an infant compared to a toddler. In the case of the latter, the head is generally disproportionately large in comparison to the rest of the body. By the end of the preschool years most children have lost this top heavy appearance as their torso and limbs have lengthened and thus caught up with the initial surge of head growth [1].

Functionally, the cephalocaudal principle is also relevant. In terms of motor and sensory development this top down pattern plays out in the sequence of milestones accomplished. For example, control and stabilization of the head and neck tends to occur prior to an infant gaining better control of upper limb movement as well as torso control. The lower limbs are the last to come online. When played out over the first year life infants will be able to stabilize and control purposeful head movements prior to rolling over which will proceed sitting up which itself will occur prior to crawling, standing up, and finally walking.

Cerebella Cortex

Chad A. Noggle
SIU School of Medicine, Springfield, IL, USA

Synonyms

Cerebellar cortex; Cerebellum

Definition

The Cerebella cortex is the outer layer of the Cerebellum, which is a structure of the Metecephalon, an aspect of the Hindbrain that is located above the brainstem, which plays a role in the coordination of movement and balance as well as procedural memory.

Description

The Cerebella cortex is the outer layer of the Cerebellum, which is a structure of the Metecephalon, an aspect of the Hindbrain which is located above the brainstem and has direct connections with both the Spinal Cord and Forebrain [1]. Functionally, the Cerebellum's main role is in the coordination of muscular activity, both in postural and locomotor mechanisms [1]. In fact, the Cerebellum has been reported to be "phylogenetically" old, possibly being the first brain structure to specialize in coordinating motor and sensory information [3]. The role the Cerebellum plays in functioning may be best exemplified through lesions analysis. Lesions of the Cerebellum, depending on location, may cause a variety of disorder, including deterioration of coordinated movement, irregular and jerky movements, intention tremor when attempting to complete a voluntary task, static tremor when resting, impairment of alternating movements, impairment in balance, disturbances of gait, and uncontrolled nystagmic movements of the eyes [3]. In addition to those aspects of motor coordination the Cerebellum may play a role in procedural memory and learning as well [2].

While the above constitutes the functional aspects of the Cerebellum, again the Cerebella cortex refers to the outer layer of the Cerebellum. Although the Cerebellum makes up only 10% of the brains total weight, the

Cerebella cortex contains nearly 50% of the neurons of the brain [3]. Topographically, the Cerebellum is notably symmetrical and demonstrates a clearly defined morphology [3]. On inspection of the cerebella cortex, one may drastically underestimate the surface area of the cerebellum. This is due to the cortex of the cerebellum being heavily infolded with numerous sulci giving the Cerebellum a layered appearance [3]. Similar to the Cerebral cortex, the Cerebella cortex is divided into two hemispheres. These cerebellar hemispheres are connected by the vermis. Furthermore, several fissures (i.e., deeper sulci) provide divisions in each hemisphere representing separate cerebellar lobes.

Synonyms

Cerebella cortex; Cerebellar cortex

Definition

The Cerebellum is an essential structure of the Hindbrain that plays a vital role in the coordination of movement and balance in addition to being involved in procedural memory and learning [3].

Description

The Cerebellum is an essential structure of the Metecephalon, an aspect of the Hindbrain, which is located above the core of the brainstem. While the Cerebellum constitutes only 10% of the entire brains weight, it contains nearly 50% of the neurons of the brain [4]. Like the Cerebral cortex, the Cerebellum is divided into two hemispheres and can be further divided into regional domains. This is of interest as the different regions of the Cerebellum each specialize in a different aspect of motor control [2]. While the most medial parts control the face and the midline of the body, the more lateral parts are connected to areas of the motor cortex and are associated with movements of the limbs, hands, feet, and digits [2]. Finally, the flocculus receives projections from the Vestibular System and takes part in the control of balance and eye movements [2]. As a result, functional impairments of the Cerebellum largely depend on the location of the lesions.

Disorders of Cerebellar dysfunction includes deterioration of coordinated movement, irregular and jerky movements, intention tremor when attempting to complete a voluntary task, static tremor when resting, impairment of alternating movements, impairment in balance, disturbances of gait, and uncontrolled nystagmic movements of the eyes [4]. The impact the Cerebellum has on those noted functions is related to its link to other systems and structures. The Cerebellum exerts its influence on various aspects of motor control through its direct connections with both the Spinal Cord and the Forebrain as well as in combination with the gray matter nuclei in the hemispheres and the brain stem. Furthermore, there is growing evidence that the Cerebellum is involved in aspects of procedural memory [3]. That is, the Cerebellum seems to be the part of the motor system that participates in acquiring and maintaining motor skills, from riding a bike, to tracing a figure while looking into a mirror, to typing on a computer keyboard [2].

As noted, the Cerebellum's main role is to coordinate muscular activity for the purpose of movement and balance, both in postural and locomotor mechanisms [1]. The Cerebellum achieves this control by receiving somatosensory information from the Peripheral Nervous System, by way of the Spinal Cord, and Vestibular System, as well as from the visual and auditory systems [1]. In turn, it discharges out to the Cerebral cortex and back through the Spinal Cord, executing control over the timing of the execution of motor events, thus ensuring smooth, controlled, and well-organized movement [1, 2].

Cerebral Blood Flow

Marie C. McGrath
Immaculata University, Immaculata, PA, USA

Synonyms

Regional cerebral blood flow (CBF, rCBF)

Definition

Blood flow patterns in the brain that serve as an indirect measure of neuronal activity in functional neuroimaging methods.

Description

In contrast to *structural imaging* techniques, which create high-definition images of the anatomical structures of the brain, *functional imaging* techniques (including technologies such as functional magnetic resonance imaging or fMRI; positron emission tomography or PET; and near-infrared spectroscopy or NIRS) permit examination of brain activity by tracking indicators such as *cerebral blood flow* (CBF), or blood flow patterns throughout the brain. Other related indicators examined by functional imaging techniques include measures of glucose metabolism or blood oxygenation. In general, when cognitively challenging tasks are presented to an individual, CBF increases to the region(s) of the brain most closely associated with performance of those tasks; for this reason, CBF-based functional neuroimaging techniques have been useful in lateralizing and/or localizing various cognitive functions, as well as in identifying disruptions to normal patterns of brain activity. However, simple, familiar, and/or previously mastered tasks require little cognitive effort to complete, and may therefore fail to produce measurable changes (or may produce decreases) from baseline measures of cognitive activity.

It should be noted that the types of functional neuroimaging techniques described above provide measures of changes in physiological indicators of brain functioning such as CBF, rather than direct measures of neuron-level activation. However, numerous studies have established that such sequelae of cognitive activity tend to be reliable indicators of cognitive functioning. Since these techniques measure *hemodynamic* responses, or blood flow changes resulting from neural activation, they tend to have poorer temporal resolution than measures such as EEG and MEG, which more directly measure neuron-level electrical activity; a lag of one or more seconds can occur between the occurrence of an event that is likely to elicit a hemodynamic response, and the detection of that event-related brain activity by functional imaging techniques. However, functional neuroimaging techniques generally offer higher levels of spatial resolution (<2 mm) than EEG and MEG, and therefore can provide more precise information on the location of activity within the brain.

Cerebral Cortex

Chad A. Noggle[1], John Joshua Hall[2]
[1]SIU School of Medicine, Springfield, IL, USA
[2]The University of Arkansas for Medical Sciences, Little Rock, AR, USA

Synonyms

Brain; Neo-cortex

Definition

The cerebral cortex consists of those systems and structures that represent one portion of the Telencephalon, which itself constitutes one portion of the Forebrain, that are responsible for the organization of all higher cognitive functions.

Description

The Cerebral cortex represents the highest division of the brain, which together with the Spinal Cord make up the

Central Nervous System. Part of that which is known as the Telencephalon, the Cerebral cortex is that which a majority of people likely think of when picturing the brain as it is this area that makes us uniquely human [4]. In sum, the Telencephalon is responsible for the organization of all higher cognitive functions. Further specification of those functions modulated by the Cerebral cortex is best outlined through discussion of the primary divisions of the Telencephalon which consists of the hemispheres, the four primary lobes, the Limbic System and the Basal Ganglia. The Cerebral cortex is characterized by numerous folds called gyri and creases called sulci [3]. Deeper sulci are commonly referred to as fissures. Most often the various fissures of the Cerebral cortex provide the boundaries for the different lobes of the Forebrain. There are four primary lobes in all, including the Frontal, Temporal, Parietal and Occipital lobes. In addition to these lobar divisions, the Limbic System and Basal Ganglia are often discussed independently and are included as part of the Telencephalon; however, they are largely subcortical (i.e., below the surface) and are thus not viewed as part of the cortex.

As noted above, the Cerebral cortex is characterized by the four primary lobes of the two cerebral hemispheres. These lobes are not only differentiated anatomically, but also functionally. First, the Occipital lobe, which is the most posterior lobe of the cortex, houses the visual cortex and is primarily involved in the processing of visual information. The Occipital lobe is bordered by the Parieto-Occipital sulcus, which separates it from the Temporal and Parietal lobes [2].

The Parietal lobe is the second lobe of the Cerebral cortex and is entrusted with the processing of somatosensory information, integrating sensory information, and regulating spatial cognition [3]. It is bordered by the Central Fissure, Lateral Fissure, and Parieto-Occipital sulcus. The Postcentral Gyrus lays just posterior of the Central Fissure and is the location of the primary somatosensory cortex [2]. In addition to the Postcentral Gyrus, the Angular Gyrus and Supramarginal Gyrus represent other key structures of the Parietal lobe which correspond with functions such as reading, writing, and calculations [1].

The Temporal lobe is the third lobe of the Cerebral cortex and not only houses the primary auditory cortex but is also involved in language processing and memory [2]. The Temporal lobe is bordered by the Lateral Fissure and by the Parieto-Occipital sulcus. The primary auditory cortex is localized to Heschl's Gyrus which lies just below and partially within the Lateral Fissure. In terms of the Temporal lobe's role in language processing, this is related to the presence of Wernicke's area, which is the receptive language center of the brain, which connects to Broca's area by way of the Arcuate Fasciculus. The Temporal lobe is involved in memory largely through its connections with structures of the limbic system which lies subcortical to the cortical surface of the temporal lobe.

Finally, the Frontal lobes, from a functional standpoint, represent the highest-order lobes of the cortex. Anatomically, the Frontal lobes are bordered by the Central Fissure and the Lateral Fissure [2]. Just anterior to the Central Fissure lies the Precentral Gyrus which is the site of origin of the primary motor cortex, which functionally plans and controls movement. In addition, the Frontal lobes are essential to the modulation and regulation of behavior and personality, while also housing the executive functions. This is linked to the workings of the Prefrontal cortices, which include Orbitofrontal, Dorsolateral, and Medial Ventral divisions. Finally, the Frontal lobes also house Broca's area, at the location of the Frontal Operculum, which is the expressive language center of the brain.

Cerebral Dominance

►Hemispheres of the Brain, Lateralization of

Cerebral Function (Lateralization)

Matthew J. Holcomb, Raymond S. Dean
Ball State University, Muncie, IN, USA

Synonyms

Dominance

Definition

Laterality of cerebral functions is a recognition of different cognition and sensory motor functions for right and left hemispheres of the brain.

Description

Pierre Paul Broca's hypothesis that the left frontal lobe of the brain was responsible for speech production, caused a great leap forward in the idea of lateralization or hemispheric specialization, and prompted much study within the scientific community. Indeed, the idea of differentiating people into "left-brained," or "right-brained" is still a commonly held idea held by many. Yet, little conclusive evidence exists for the presence of individual brain functions that are totally localized in the left of right hemispheres.

Broca's research with a patient who had a stroke in the frontal area of the left hemisphere showed that the right hemisphere was not involved in the production of speech, which is an important finding because before Broca it was generally believed that the hemispheres of the brain were redundant in their responsibilities. After Broca many believed that the functions of the left hemisphere were in language production, which inadvertently introduced the idea of lateral dominance. Language itself is highly interdependent on temporal lobe functioning and Broca's findings dealt more with expressive speech.

It should be noted that while dominance does imply a great role of particular hemisphere on a given function, it does not necessarily mean that all aspects of a particular function are housed within one hemisphere of the brain. For example, although significant evidence suggests that speech and language have a left hemisphere dominance, research also has demonstrated that the right hemisphere is, in fact, able to perform some limited language functions such as processing of linguistic content (as long as it's simple), and in understanding [1].

Another area that is discussed at great length in the literature in regard to lateralization is handedness and laterality. Research has shown that the right hemisphere shows a greater involvement in the control of the left hand [1], where the left hemisphere is involved in the control and movement of the right hand. This finding led many, including Broca, to believe that handedness was the determining factor for brain and language dominance. However, this belief is problematic for several reasons including the continuous disagreement amongst researchers on what exactly identifies a person as right handed or left handed. Some believe that the hand a person chooses to write with is the identifying characteristic of handedness, while others prefer to look at individuals across a spectrum of activities to based handedness on. While the first definition requires a dichotomous view of handedness, the second approach places at handedness on a spectrum with each end being complete right or left handedness. Additionally, researchers have reported mixed results with regards to the belief that Broca held of language being related to handedness. For example, an MRI study [4] found that 94% of right-handed participants were left hemisphere dominant for language, with none of the participants showing right hemisphere dominance for language. Other studies looking at left handed people did not show as conclusive results as right-handed studies. For example, Szaflarski et al. [5] found that 78% of left-handed individuals as had left hemisphere lateralization for language and only 8% for right hemispheric dominance. Therefore, the empirical evidence suggests that generally the left hemisphere is lateralized for speech and language regardless of handedness.

Other Areas of Lateralization

Left Hemisphere Functions	Right Hemisphere Functions
Language – Grammar	Language – contextual
Language – Vocabulary	Language – intonation
Mathematics – direct fact retrieval	Mathematics – approximation
Mathematics – estimation	Intuition
Mathematics – numerical comparison	Imagination
Logic	Future thinking
Verbal abilities	Holistic concept formation
Analytical abilities	Intuition
Speech	Music
Movement of the right side of the body	Art
Sensation on the right side of the body	Drawing ability
Vision in the right half of the "visual field"	Movement of the left side of the body
	Sensation on the left side of the body
	Vision in the left half of the "visual field"

Relevance to Childhood Development

Research on adult's language and its subsequent lateralization appears to be consistent with research on children. Lateralization is a developing process in children. Healthy

children usually show atypical language distribution across the hemispheres, but that as they age, lateralization, including language and speech functions, becomes more pronounced [3].

Language is generally considered an important milestone in development of children. In many situations language delay is the first sign of neurological impairment or developmental delay. As such, the link between lateralization and speech is important to consider with regards to the development of children. Additionally, a number of neurological issues seen in children have been shown to directly impact language abilities and may be the only sign of neuropathology. Some of these childhood neurological problems shown to impact speech are epilepsy, stroke, tumor, or traumatic brain injury (TBI) [3].

These findings are important when considered with research suggesting that damage to the left hemisphere earlier in life may spur the brain into a reorganizing effort where language tasks may be established to the right hemisphere [4].

Cerebral Infarction

Edalmarys Santos[1], Chad A. Noggle[2]
[1]Middle Tennessee State University, Murfreesboro, TN, USA
[2]SIU School of Medicine, Springfield, IL, USA

Synonyms

Cerebrovascular accident (CVA); Stroke

Definition

Cerebral infarction refers to the sudden disruption of blood flow to areas of the brain that may lead to necrosis and/ neurological dysfunction.

Description

Cerebral infarction, more commonly referred to as stroke, refers to the sudden disruption of blood flow of one or more of the many vascular pathways of the brain. While the etiology of cerebral infarctions may vary, they are generally classified as either ischemic or hemorrhagic. In regards to the prior (i.e., ischemic), this is by far the most common form of cerebral infarction [4]. Ischemic infarctions are either secondary to an occlusion of an artery or capillary due to an embolism or thrombosis, or can also result from a sudden drop in blood pressure that prevents adequate blood flow from reaching a particular area/ region of the brain [1]. In contrast, a hemorrhagic infarction occurs when there is a bleeding out of an artery or capillary within the brain thus disrupting blood flow to areas beyond that point in the vascular pipeline. Hemorrhagic infarctions most commonly occur due to a weakening of the lining of a capillary or artery due to vascular malformations or aneurysms [4]. Trauma may also lead to hemorrhagic infarctions.

The functional impact of a cerebral infarction varies based on the location of the event, the type of infarction (i.e., ischemic or hemorrhagic), and the extent of time to which blood circulation is disrupted, which essentially corresponds with the degree of necrosis experienced. In fact, necrosis may occur within seconds to minutes of the infarction [3] which can cause permanent physical and neuropsychological deficits [2].

Although cerebral infarctions more commonly occur in the adult and geriatric populations, there are specific risk factors for children and adolescents. These include antiphospholipid syndrome, cardiac disease, drug abuse, homocystinuria, migraines, mitochondrial disorders, sickle cell disease and other blood dyscrasias, vasculitis and congenital vascular malformations.

Cerebral Lateralization

►Hemispheres of the Brain, Lateralization of

Cerebral Palsy

Jacqueline P. Parsons
St. Mary's University, San Antonio, TX, USA

Synonyms

CP

Description

Cerebral palsy refers to a number of neurological disorders appearing in infancy or early childhood that are non-contagious. The neurological disorders associated with cerebral palsy permanently affect the child's body movement and muscle coordination, but do not worsen as the child ages. Cerebral palsy is caused by abnormalities in the brain centers controlling muscle movement. It can be the result of a birth injury, brain damage, bacterial meningitis, viral encephalitis, or a head injury; but typically children are born with this brain-based disorder. Symptoms of cerebral palsy are usually evident by the time a child is 3 years old.

Classifications of Cerebral Palsy by Muscle Movement

Cerebral palsy is divided into four major classifications. These classifications describe the parts of the brain that are damaged, as well as the different muscle impairment which results. The three major classifications are:

- Spastic – Spastic cerebral palsy is the most common type of cerebral palsy. With spasticity, individuals will usually have a reduced ability to stretch their muscles, a condition known as hypertonia. People with spasticity usually have damage to the brain's motor cortex.
- Ataxic – Ataxic cerebral palsy is the result of damage to the individual's cerebellum and impacts the muscles, resulting in tremors or low muscle tone, a condition known as hypotonia.
- Athetoid – An individual has athetoid cerebral palsy when there is mixed muscle tone, both hypertonia and hypotonia, resulting from brain damage to the corpus striatum.

Classification of Cerebral Palsy by Number of Limbs Involved

1. **Monoplegia** – only one limb is affected
2. **Hemiplegia –** one entire side of the body is affected
3. **Triplegia –** three limbs are impaired
4. **Dipelia –** all four limbs are involved, with the legs being more impacted by the cerebral palsy.
5. **Quadriplegia** – all four limbs are involved.

Treatments for Cerebral Palsy

Treatment of a patient with cerebral palsy is complicated, and must be tailored for the many nuances of the disease. The best treatment plan will consist of an integrated approach, supervised by a physician or team of physicians. Many large medical centers now have integrated spasticity clinics which can bring together numerous specialists simultaneously. This is more convenient for the patient, but it also facilities vital crosstalk between the specialists.

- Physical and Occupational Therapy: Various types of physical and occupational therapy can help a patient with cerebral palsy. These therapies are often supervised by a physician who specializes in physical medicine. Physical therapy usually focuses on gross motor skills such as walking while Occupational therapy focuses on finer motor skills as they apply to daily functions such as eating dressing, and school work.
- Medical Therapy: There are numerous medications and combinations of medications which a physician can prescribe for the symptoms of cerebral palsy. In addition to treating spasticity, with medications such as botox and baclifin, the doctor can also treat problems in other organs which were indirectly caused by the muscle spasticity. For example, a patient can experience acid reflux or breathing difficulties.
- Surgery: In some cases, the long term spasticity can cause malformation of bones and tendons, and these can be corrected with surgery. Neurosurgical procedures such as the pre-selective dorsal rhizotomy may also be used to directly treat the spasticity.

- Educational Services: persons with cerebral palsy benefit from increased educational services. A good school system will integrate various types of assistance through their special education departments. They can help the student deal with cognitive problems, may provide some therapy, and can also help with the simple logistics of getting to class and going to the nurse for medications.

Cerebrospinal Fluid

Chad A. Noggle
SIU School of Medicine, Springfield, IL, USA

Synonyms

Cerebrospinal fluid (CSF)

Definition

Cerebrospinal fluid is a fluid that circulates through the ventricular system in the brain as well as surrounds the brain within the subarachnoid space offering additional protection from jarring.

Description

Cerebrospinal fluid is a salty fluid that primarily serves a protective function as it supports the brain by circulating through the ventricles of the brains and cushions the brain by enveloping the brain in fluid [1]. In addition to supporting the brain, CSF serves to help with excretion of waste products and maintaining the chemical environment for the CNS [1]. Due to its role in removal of waste products within the CNS, analysis of the CSF can demonstrate the presence of infectious processes [5]. In addition, analysis of the pressure exhibited by the CSF within the ventricular system may demonstrate the presence of Hydrocephalus, which is a condition caused by an increase in the volume of CSF within the system. Hydrocephalus may either result secondary to atrophy of the brain, thus enlarging the ventricles and, in turn, promoting increased CSF volume, or by there being an obstruction of the CSF flow leading to a build-up within the system [4]. In terms of its occurrence in children and/or infants, the latter is by far the most common etiology.

The CSF is initially produced continuously by the Choroid Plexus, which is a tissue of the ventricular system [5]. Choroid Plexus predominates in the walls of the four ventricles in the brain, thus CSF is continually produced within them all [2, 3]. The circulation of the CSF through the ventricular system follows a very specific path. The CSF initially flows from the two lateral ventricles though two interventricular foramina. The lateral ventricles are the largest ventricles in the brain and are depicted through imaging as large, hollow, C-like formations in each hemisphere [6]. From here the CSF enters the third ventricle and then passes through the Midbrain to the fourth ventricle by way of the cerebral aqueduct (Goldberg, 2007). While the lateral ventricle lies below the Cerebral cortex, the third and fourth ventricles extend into the brainstem [4]. Specifically, the third ventricle is located at the level of the Diencephalon, while the fourth ventricle lies in the brainstem, just beneath the Cerebellum [6]. The CSF then flows out of the fourth ventricle through the two lateral foramina of Luschka and the medial foramen of Magendie [4]. It is from here the CSF enters the subarachnoid space, which is the space that lies just beneath the arachnoid covering of the brain and Spinal Cord. It is the presence of CSF within the subarachnoid space that envelopes the brain and Spinal Cord that provides the protective buoyancy [2]. The CSF then eventually circulates to the vertex of the brain and is absorbed into the venous system through the arachnid villi [2].

Cervix

Pamelyn M. MacDonald
Emporia State University, Emporia, KS, USA

Synonyms

Neck of uterus

Definition

The cervix is the lower portion of the uterus that forms the neck that opens into the vagina. Cervix is the Latin word for *neck*.

Description

The cervix is the opening of the *uterus* into the *vagina* [3]. The anatomy of the cervix includes the *ectocervix*, or the part of the cervix that projects into the vagina. The narrow opening of the ectocervix is called the *external os*, oftentimes referred to as just the *os*. The part of the cervix that is connected to the uterine cavity is the *endocervical canal* and includes the *internal os*. The cervix expands, or dilates, during labor to allow for the birth of a baby [2].

Relevance to Childhood Development

At the beginning of the birth process, the cervix softens and the *mucous plug* at the external os of the cervix is expelled with a small amount of blood. In the first stage of labor, the cervix dilates to about 4 cm in diameter. As active labor progresses, the cervix dilates to 4–8 cm. The transition stage of labor is where the cervix is dilated to 8–10 cm. The baby can be born vaginally when the cervix is fully dilated at 10 cm and 100% *effaced*, or gone [3].

Complications can arise in the case of an *incompetent cervix*, or a cervix that starts to open before the baby is ready to be born [1]. Also called a *weakened cervix*, it may lead to miscarriage or premature delivery. An incompetent cervix is treated by a procedure that sews the cervix shut, called a *cerclage*. The cerclage is removed between 36–38 weeks of *gestation* before the woman goes into labor [1].

Chemical Dependency

Kasey Claborn
Oklahoma State University, Stillwater, OK, USA

Synonyms

Addiction; Alcoholism; Drug addiction; Drug habit
Substance abuse; Substance dependence

Definition

►Addiction to a mood altering chemical including drugs, tobacco, and alcohol; A physical and psychological reliance to a mood- or mind-altering chemical accompanied by the inability to discontinue use despite adverse consequences caused by their use.

Description

Chemical dependency is characterized by a maladaptive pattern of substance use including alcohol and/or drugs (prescribed or illegal) as manifested by three or more of the following problems occurring at any time in the same 12-month period: (1) taking the substance in larger amounts over a longer period than intended; (2) a persistent desire or unsuccessful efforts to cut down or control substance use; (3) spending a great deal of time in activities necessary to obtain, use, or recover from the effects of substance use; (4) decline in involvement with important social, occupational, or recreational activities; and (5) continued use despite having a persistent or recurrent psychological or physical problem that is caused or exacerbated by substance use [1, 2]. Two additional symptoms of chemical dependence include tolerance and withdrawal symptoms. When an individual becomes tolerant to a drug, they require increasing quantities of the substance in order to receive the same effects that were achieved from the original dose. Withdrawal symptoms include physiological and psychological effects that occur when chemically dependent individuals discontinue use of the substance.

The etiology of substance-related disorders include multiple factors consisting of familial and genetic vulnerability [2], environmental stressors, individual personality characteristics [3, 8] (i.e., impulsivity, risk-taking), social pressures [3], and co-occurring psychological problems. Among adolescents, substance abuse and dependence are often comorbid with conduct disorder, attention deficit hyperactivity disorder, and major depressive disorder. Although symptoms may manifest differently between genders, it appears that both male and female adolescents with substance dependence are at equal risk for having these comorbid diagnoses [6].

Relevance to Childhood Development

Adolescent drug involvement is a major health concern. Many adolescents experiment with alcohol and drugs, however, the majority do not develop chemical dependence [4]. Thus, it is important to understand risk factors associated with the development of substance abuse and dependence. The likelihood that an adolescent will abuse substances is associated with the number of risk and protective factors present in their environment. Research indicates that early onset of substance use and heavy use during adolescence are two important risk factors for developing substance dependence [2]. Risk factors for substance abuse are present within the child's community, family, school, and social environments [3]. A list of the risk factors is provided in (Table 1).

The more risk factors within an individual's environment, the greater the risk of abusing substances and becoming chemically dependent. In contrast, the presence of protective factors buffers the negative consequences of exposure to risks for two reasons: (1) protective factors reduce the impact of the risk, and (2) they change the way a person responds to the risk [3]. Protective factors include individual characteristics (i.e., gender, a resilient temperament, a positive social orientation), strong social support system, and healthy beliefs and clear standards.

Further, drug use is typically progressive in nature. Adolescents begin using substances that are legal for adults, such as alcohol, followed by marijuana use, and then other illicit drugs (i.e., ecstasy, heroin, cocaine) which may lead to the development of a substance use disorder [2, 5].

Continued hazardous use of alcohol and other drugs can result in acute and chronic consequences. A few of the long-term effects include memory loss, cirrhosis of the liver, heart attacks, respiratory depression, malnourishment, depression, and damage to fetus. Substance dependence

Chemical Dependency. Table 1 Risk factors

Risk Factors for Adolescent Substance Abuse			
Community	**Family**	**School**	**Social**
Availability of drugs	Family history of substance abuse	Early and persistent antisocial behavior	Alienation and/or rebelliousness
Community laws and norms favorable toward drug use	Poor family management practices (i.e., lack of parental monitoring of child's behavior)	Academic failure beginning in elementary school	Friends who engage in substance abuse
Transitions and mobility (i.e., when children move from middle school to high school)	Family conflict	Lack of commitment to school	Favorable attitudes toward substance abuse
Low neighborhood attachment and disorganization	Parental attitudes and involvement in drug use		Delinquency or criminal behavior
Extreme economic deprivation			

in adolescents can also cause neurocognitive deficits including poorer language skills, IQ scores, language competence, academic achievement, and visuospatial performance and executive functioning [6].

In addition to long-term consequences, some of the more immediate effects that are experienced from risky use of alcohol and other drugs include disinhibition, impairment of judgment, slurred speech, sedation, impaired immediate recall, impairment of motor skills and death from overdose. These effects may lead to accidents, violence, criminal activity, and unwanted or risky sexual behavior. In addition, family, social, occupational, and financial problems often occur among chemically dependent individuals [7].

Many individuals with a substance use disorder do not seek treatment until they are well into the alcohol or drug using lifestyle, which may be six to ten years after the initiation of drug use [2]. Treatment of chemical dependency is notoriously difficult, checkered by high rates of drop-out and relapse among adolescents [8].

There are several forms of treatment for adolescents who have a substance use disorder. It is recommended that adolescents with a positive history of substance use, but currently use low amounts of a substance or are abstinent, would benefit from an early intervention strategy. Adolescents who are experiencing problems resulting from low to moderate use of substances should seek outpatient treatment, whereas individuals who regularly use substances and are experiencing moderate to severe problems due to usage would more likely benefit from a partial residential treatment facility (or "day treatment"). Adolescents experiencing severe problems from use and live in a home environment that propagates adverse influences should seek intensive inpatient treatment [8].

Chemical Synapses

The word synapse is derived from synaptein, a term first used by Sir Charles Scott Cherrington from the Greek syn meaning together and haptein meaning to clasp. Chemical synapses are specialized junctions through which neurons signal each other as well as signaling non-neuronal cells

such as those in muscles or glands. Chemical synapses allow neurons to form circuits within the central nervous system. These are essential for all functioning, particularly those that involve perception and thought. This allows the nervous system to connect to and control other systems of the body.

At a chemical synapse one neuron releases a neurotransmitter into the synapse adjacent to another neuron. Neurotransmitters must be cleared out of the synapse efficiently so that the synapse can be ready to function again as soon as possible. The adult human brain is estimated to contain between 100-500 trillion synapses.

Child Abuse

Samantha Miller
City University of New York, USA

Synonyms

Child maltreatment; Child victimization; Physical abuse; Shaken baby syndrome

Definition

While child abuse and neglect are defined by State and Federal laws, the Federal legislation entitled The Child Abuse Prevention and Treatment Act (CAPTA) sets the following minimum standard for what States must incorporate in their definition: "Any recent act or failure to act on the part of a parent or caretaker, which results in death, serious physical or emotional harm, sexual abuse, or exploitation, or an act or failure to act which presents an imminent risk of serious harm" [42 U.S.C.A. § 5106g(2) West Supp. 1998]. For the purposes of this legislation, it should be noted, the term "child" is defined as a person below the age of 18 or, in the case of sexual abuse, the age specified by the child protection law of the State in which the child resides. For individual State standards of what constitutes an abusive act refer to www.childwelfare.gov/systemwide/laws_policies/state/. Individual state definitions for child abuse and neglect determine the legal justification for State intervention in the protection of a child's safety and welfare and guide mandatory reporters in deciding whether to report an incident to child protective services.

Description

There are four subtypes of child abuse which include (1) physical abuse, (2) sexual abuse, (3) neglect, and (4) emotional abuse. States recognize the different subtypes of abuse in their definitions and some include and define parental substance abuse and/or abandonment as child abuse in their statues.

Physical Abuse: Physical abuse is often defined as "any nonaccidental physical injury to the child" and can include striking, kicking, burning, or biting the child, or any action that results in a physical impairment of the child. In addition, in many States and territories the definition also includes acts or circumstances that threaten the child with harm or create a substantial risk of harm to the child's health or welfare. An exception to reporting laws for physical abuse occurs in the context of physical discipline in 14 States, the District of Columbia, American Samoa, and the Northern Mariana Islands, where physical discipline of a child as long as it is reasonable and causes no bodily injury to the child is not considered abuse.

Sexual Abuse: CAPTA defines sexual abuse as "The employment, use, persuasion, inducement, enticement, or coercion of any child to engage in, or assist any other person to engage in, any sexually explicit conduct or simulation of such conduct for the purpose of producing a visual depiction of such conduct; or the rape, and in cases of caretaker or interfamilial relationships, statutory rape, molestation, prostitution, or other form of sexual exploitation of children, or incest with children." All the States include a definition of sexual abuse in their child protection laws and many include sexual exploitation in their definition. It should be noted that the individual States' child protection laws specify the maximum age (not always age 18) at which it is required to report an incident of child sexual abuse.

Neglect: Neglect is often defined as a deprivation of adequate food, clothing, shelter, medical care, or supervision. In addition, the clinical literature further defines the subtypes of physical neglect and psychological neglect. In many States and territories the definition includes a failure to educate the child as required by their respective laws. In addition several States define medical neglect as a failure to provide any special medical treatment or mental health care needed by the child or as the withholding of medical treatment or nutrition from disabled infants with life-threatening conditions. About 30 States provide an exception in their definition for parents who choose not to seek medical care for their children due to religious beliefs in civil child abuse reporting laws and three states specifically provide an exception for Christian Science treatment.

Emotional Abuse: Emotional abuse is often defined as "injury to the psychological capacity or emotional stability of the child as evidenced by an observable or substantial change in behavior, emotional response, or cognition," or as evidenced by "anxiety, depression, withdrawal, or aggressive behavior." In addition, clinical literature also highlights six categories of psychological or emotional abuse. They include, spurning, terrorizing, exploiting or corrupting, denying emotional responsiveness, isolating, and mental health, medical, and educational neglect. With the exception of Georgia and Washington, all states and territories include emotional abuse or "mental injury to a child" as part of their definition of abuse and neglect.

Parental Substance Abuse: In some States parental substance abuse is included in the definition of child abuse and neglect. This subtype often includes prenatal exposure of a child to harm due to the mother's use of an illegal drug or other substance; the manufacture of a controlled substance in the presence of a child or on the premises occupied by a child; allowing a child to be present where chemicals or equipment for the manufacture of controlled substances are used or stored; selling, distributing, or giving drugs or alcohol to a child; and use of a controlled substance by a caregiver that impairs the caregiver's ability to adequately care for the child.

Abandonment: Abandonment of a child is often defined as when the parent's identity or whereabouts are unknown; the child has been left by the parent in circumstances in which the child suffers serious harm; or the parent has failed to maintain contact with the child or to provide reasonable support for a specified period of time. Many States include a definition of abandonment in their definition of abuse or neglect, while other States include a definition in their reporting laws.

Relevance to Childhood Development

Before discussing the potential impact of child abuse and neglect on child development, it should be noted that no specific behavioral symptom exhibited by a child is diagnostic, in and of itself, that a child has experienced abuse or neglect. With that said the consequences of childhood abuse and neglect are both long and short term. Areas of functioning that may be affected, include: cognitive (e.g., lower IQ, delayed emotion modulation), emotional (e.g., post-traumatic stress disorder, mood disorders, deficits in empathy), self-image (e.g., distorted body image, worthless self-concept), behavioral (e.g., conduct disorders, substance abuse), interpersonal (e.g., deficits in effective social skills, disordered attachment), psychophysiological (e.g., failure to thrive, enuresis/encopresis, somatic manifestations), socialization (e.g., negative attributions or antisocial cognitive distortions, deficits in moral reasoning and in acquisition of pro-social attitudes). Overall, the presence of particular diagnoses and the severity and extent of psychiatric symptoms in those who have suffered childhood maltreatment may depend on individual child factors, such as the child's gender and ethnicity; abuse factors, such as age at victimization, duration of abuse suffered, severity of the abuse, the child's relationship to the perpetrator, and treatment received, if any; as well as community and neighborhood factors, e.g., involvement in antisocial or criminal sub-cultures. In 2004, from a nationally representative sample of children ages 2 to 14 in the child welfare system, almost 50% demonstrated clinically significant emotional or behavioral problems, while only about 25% received any mental health treatment. This study highlights the increased prevalence of mental health problems in those who have suffered child abuse and neglect and the insufficient services that these children receive.

Child and Family Therapist

Kimberly D. Litwinowich, Amy Ball
Carrie L. Castañeda-Sound, Shannon Stovall
Our Lady of the Lake University, San Antonio, TX, USA

Synonyms

Clinician; Counselors; Marriage and family therapist; Psychotherapist

Definition

A child and family therapist is a professional who conducts psychotherapy with both children and their families, and views children and families as a transactional social system with its own set of roles, rules, and rituals.

Description

Child and family therapists come from various professional fields including, but not limited to, the following: marriage and family therapy, counseling, social work, and clinical psychology. Although credentials vary from state-to-state, child and family therapists are specifically licensed within their professional field and have been trained in individual and family psychotherapy. Most child and family therapists have graduate-level training (e.g., a Masters or Doctoral degree) and typically have a minimum of two years clinical experience before they are fully licensed and work unsupervised.

Child and family therapists are invited to work with children and families for a number of reasons. A growing number of children and families are in need of emotional help. In 2003, approximately 2.7 million children had definite or severe difficulties in emotions, concentration, behavior, or proficient social skills as indicated by parents [1]. Additional data illustrate that stressors placed upon families in growing numbers–single person parenting, lower socio-economic status, and lack of health care are factors that contribute to a growing number of emotional needs in children and their families. Fortunately, it has been found that professional counseling helps; children who receive therapy do 79% better than children who do not receive treatment [2].

In a number of cases, a child demonstrates behaviors that a parent or caregiver finds distressing or feels is an indication of a larger problem and professional counseling is sought to target behaviors or to strengthen the family's interactions. In some instances, child and family therapists are called to work with families for preventative measures in order to help the family through a difficult set of circumstances such as illness, divorce, military deployment of one or more caregivers, or other significant transitions. Still in some cases, a child or family has already experienced difficult circumstances and a therapist may be invited to help the family members work through emotions and reactions to past events.

Some commonly encountered reasons children and their families seek treatment are:

- Dealing with a medical diagnoses
- Step or blended family issues
- Behavioral or academic struggles
- Sexual or physical abuse
- Divorce
- Medical situations
- Lack of social adaptability
- Death of a loved one
- Substance or alcohol abuse
- Depression
- Self-harming behaviors
- Eating disorders
- Nightmares
- Attachment issues
- Failure to meet developmental milestones
- Parents have need for improved parenting skills
- Incarceration of a family member
- Military deployment

The manner in which a child and family therapist works will be influenced by their theoretical orientation and training. There are numerous theories of psychotherapy, but the different approaches of child and family therapy can be grouped as Psychodynamic, Experiential, Behavioral/Cognitive, Strategic, Structural, Transgenerational, Postmodern, Psychoeducational, and Milan Systemic models [3]. While a child therapist views his or her primary client as the child, a child and family therapist considers the child and family as clients. The child and family therapist might choose to work with the child alone, but will invite the family to join in subsequent sessions, or the therapist may work with the child and family jointly throughout the therapeutic process. It is difficult to accurately address a family's concern without exploring and observing how a child functions and behaves within their interpersonal relationships. This can include any or all of the nuclear or extended family system, as well as the "larger" community system (e.g., peers, teachers, etc.). Therapy sessions focus on understanding family dynamics and emphasizing the unique strengths and resources of each family member. This approach regards the family as a whole and emphasizes such factors

as relationships and communication patterns rather than traits or symptoms in individual family members.

Child and family therapists may incorporate a variety of techniques and interventions, such as play therapy, filial therapy, art therapy, or behavioral/cognitive interventions. The techniques and interventions implemented will be largely influenced by the therapist's theoretical orientation to psychotherapy [4].

A child and family therapist can work in many different locations, including, but not limited to, schools, private practices, clinics and hospitals. Each of these settings might have a different set up for the therapy room. Some therapy may take place in a play therapy room, a room designed for play. Other therapists might chose to use a more traditional office setting, or a traditional setting with some modifications to make children more comfortable. In schools and other educational settings, the therapy may occur in a classroom. In some cases a therapist might even hold a session outside or in another location than an office.

Relevance to Childhood Development

Engaging in a therapeutic process that combines both children and their families increases opportunities to facilitate the discovery of new solutions and strengthen relational bonds within the family. This can empower and validate a child and family's experience as equal participants in psychotherapy.

Child Clinical Psychology

Katherine E. Kiker
University of Florida, Gainesvile, FL, USA

Synonyms

Clinical child psychology

Definition

Child Clinical Psychology is a specialty of professional psychology that integrates the basic tenets of clinical psychology with a thorough background in child, adolescent and family development and developmental psychopathology.

Description

Overview

Child clinical psychology was recognized as a specialty of professional psychology by the Commission for the Recognition of Specialties and Proficiencies in Professional Psychology (CRSPPP) in 1998. Child clinical psychology integrates the basic tenets of clinical psychology with a thorough background in child, adolescent and family development and developmental psychopathology. Child clinical psychology is focused on understanding, preventing, diagnosing, and treating psychological, emotional, developmental, behavioral, and family problems of children. Child clinical psychology has a strong research emphasis and is committed to furthering the development of evidence-based assessments and treatments.

Populations Served

Child clinical psychologists provide services for infants, children, adolescents, and their families who have a broad range of difficulties, including psychological, behavioral, developmental, academic, health-related, and family problems. Problems can include: "high risk children compromised by biological vulnerabilities and/or psychosocial adversity and their families; children and adolescents with emotional and developmental problems, including psychotic disorders; children and adolescents with significant mental disorders as reflected in behavioral, emotional, cognitive, and/or developmental problems in family, school, childcare, juvenile justice system, and/or peer group contexts; adolescents with problems including delinquency, substance abuse/dependency, and high risk sexual behaviors; children and adolescents with signs of cognitive deficits or uneven development requiring an assessment of cognitive functioning and/or school readiness; children, adolescents, and their families coping with injury, trauma, and loss as a result of natural disasters and human-made disasters; children, adolescents, and their families in the pediatric system coping with a variety of health-related problems, including: chronic, serious, and/or life-threatening physical illnesses, adherence to medical regimens, pediatric patients with chronic pain, and amelioration of symptoms of various pediatric

conditions; children and adolescents with physical illnesses whose symptoms may be exacerbated by psychosocial factors; children and adolescents with parents who have chronic physical or mental health conditions; and children/adolescents, and families coping with developmental milestones or with the upset of divorce, single-parenting, and custody arrangements, or adjusting to remarriage and step-parenting" [1]. Services can be provided in a variety of settings, including medical clinics, schools, private practices, hospitals, and community agencies [2].

Types of Services

There are four main areas in which child clinical psychologists provide services; assessment, intervention, prevention, and consultation. Assessment techniques include using open-ended, semi-structured, and structured interviews with children and their parents/caregivers; intelligence, achievement, and cognitive testing with children; behavioral observations; and use of behavior rating scales and projective/objective personality assessment measures. Intervention encompasses a wide range of treatments for children and their families, and can include individual psychotherapy, group psychotherapy, family psychotherapy, parent training, school interventions, and psychoeducation. Child clinical psychologists that are involved in prevention aim to prevent the onset of problems and disorders in infants, children, adolescents, and families. Prevention programs can include programs to target and prevent bullying, teenage pregnancy, and substance abuse. Finally, child clinical psychologists consult with other professionals from multiple disciplines, such as child psychiatrists, neurologists, teachers, pediatricians, social workers, and other professionals who are involved with the care and treatment of children [1].

In addition to providing services in these different areas, child clinical psychologists are also active in teaching and research. Research topics are very broad and include research related to the development and validation of assessment measures, research related to the development and documentation of the efficacy and effectiveness of child treatments, research of the etiology, correlates, and developmental course of child psychopathology, and research on risk factors for child psychopathology. Child clinical psychologists that are often employed in academic settings may teach basic psychology courses and graduate-level specialty psychology courses. Additionally, they may also supervise undergraduate and graduate students in their research and clinical activities [2].

Training/Education Requirements

Training in child clinical psychology is usually pursued within an APA-approved PhD or PsyD program, and includes a year-long full-time clinical internship. Students in child clinical psychology are provided with a background in core areas of psychology, and then learn specialty-specific training [3]. Additionally, postdoctoral training with a child/adolescent focus may be received after general training in a clinical psychology doctoral program. Preparation of child clinical psychologists is characterized by: "knowledge of normal developmental processes as a prerequisite for distinguishing between normal and abnormal behavior and development, and for understanding developmental factors as they relate to assessment and intervention; normal family processes as they relate to children's development, including the impact of family dynamics, normal family functioning, and child rearing practices on normal child development and on the development of children's problems; child and adolescent psychopathology including epidemiology of children's problems, assessment and classification of problems across the age span, etiological models of child and adolescent psychopathology, research findings related to etiology, treatment options and treatment efficacy related to specific problems at different ages and knowledge of family and other problems requiring treatment; knowledge of the methods of assessment of development, intellect, cognition, personality, mood and affect, and achievement; theories and research evidence for treatments of childhood mental disorders, adjustment reactions of childhood, family problems, and adaptation to stressful conditions or to chronic illness; special ethical and legal issues in research and practice with children; appropriate appreciation for and understanding of principles of diversity and cultural contest as they relate to professional behavior and clinical practice" [1].

Child Counseling

►Child Psychotherapy

Child Counselors

Synonyms

Child therapists; Mental health counselors; Professional counselors

Definition

Licensed professionals trained at the master's or doctoral level to help children and their families cope with personal, social, career, and educational issues.

Description

Child counselors are a subspecialty of a group of professionals who focus on working with individuals, families, and groups experiencing developmental or situational adjustment issues. Child counselors have additional training and practice to better understanding and be competent in techniques for working with the unique developmental needs of children (ages 0–18) and their families. Their work is centered on both prevention and treatment of situational and long-standing problems. Counselors are rooted in development and wellness, helping children and their families to reach their highest potential and well-being.

Definition

Child development refers to the growth and development, that is, to the physical, cognitive, emotional and social changes an individual experiences from infancy through to adolescence.

Description

Principles of Development

Child development focuses on the changes that occur during childhood; some consider this to include the prenatal period because of the implications of this time on later development, and adolescence [7]. Growth is both continuous, reflecting more stable characteristics such as temperament and discontinuous, reflecting discrete changes such as the acquisition of speech. Growth may occur predictably or unevenly, and influences and is influenced by the surrounding contexts [6]. One long-standing debate is the relative contributions of heredity (nature) and environment (nurture) to the process [3, 6]. While early theorists emphasized the role of heredity, early work in the field was largely in the area of physical development where even today there is general agreement that inheritance plays a predominant role [3]. While inheritance may set the stage for the acquisition of cognitive and social behaviors there is also general agreement that experience plays an increasingly important role as children develop into social beings [2, 6]. Today most researchers agree that both heredity and environment interact; debate continues as to which is more critical in specific circumstances. And, while most researchers are from the field of psychology, child development is a truly multidisciplinary area of study [7].

Physical Development

Particularly noticeable during infancy are the tremendous physical changes an infant undergoes [2, 6]. Within a 1 year period, the infant grows from an immobile creature to a walking, talking individual. The typical baby triples in birth weight by the age of 1 and by age 2 is half as tall as she will be as an adult. This physical growth is thought to be continuous in nature involving gradual progress. Rates of physical growth slow during childhood and then increase again during adolescence, culminating with puberty or the achievement of sexual maturity.

While babies enter the world with all sensory systems such as hearing and taste intact, for the first few months after birth infants display primarily reflexive behaviors. For example, infants have a sucking reflex which is instrumental in aiding them to meet their nutritional needs.

The acquisition of voluntary motor skills is referred to as the accomplishment of ▶motor milestones [2, 6]. Locomotor skills such as sitting and standing generally occur at 6 and 11 months of age, respectively. Visual-motor

coordination is achieved through the acquisition of manipulatory skills such as reaching and grasping at 3 and 5 months, respectively. Knowledge of motor milestones is useful in determining developmental delays although there is typically a wide range of variation within the normal range of any milestone [7]. Children continue to achieve motor milestones throughout childhood. Increasingly complex motor and hand-eye coordination skills are achieved e.g., throwing and catching a ball, riding a bike, manipulating a pencil or keyboarding.

All growth and development depends on growth of the brain which at birth is 25% of its adult weight and which by age 2 years is 75% of its eventual weight [6]. The human brain is known to be quite plastic meaning that it is highly responsive to what it experiences.

Early growth is considered to be primarily maturational in nature [2, 3, 6]. ►Maturation refers to the predetermined biological unfolding of an individual due to the inherited instructions provided by the parents at conception. It is precisely because of maturational influences on development that children all over the world acquire physical skills at roughly the same age and in roughly the same order. For example, babies begin to walk at around 1 year, though some may walk much earlier and some later. Walking may be preceded by crawling but walking never precedes crawling. In this way growth is guided by an inborn or innate biological blueprint via our DNA although it can be influenced by the environment as through diet or disease.

While many early physical accomplishments are due to maturation, once the basics have been acquired new skills are largely achieved due to ►learning [2, 3, 6]. Now experience or environmental influences have a larger say in which skills are displayed. So while children worldwide all develop into walkers, swimming for example is a learned skill. Similarly while all children begin to speak despite growing up in widely different environments, only those exposed to written material, generally taught in school, learn to read. Learning then reflects relatively permanent changes in behavior due to experience. Even the acquisition of motor milestones can be impacted by the environment although this primarily affects the rate at which the abilities emerge rather than the order. The dynamic systems theory of motor development explains that motor development is an action system whereby opportunities for exploration and practice influence the development of existing motor capabilities which in turn impacts further exploration.

Cognitive Development

Jean Piaget (1896–1980) proposed one of the most influential theories in the field of child development, his theory of cognitive development [1, 5]. Cognitive development refers to the acquisition of thinking, reasoning, problem solving and other processes involved in intelligent behavior. Piaget was among the first to propose a reconciliation of the heredity and environment viewpoints; he argued that children actively create knowledge as they interact with their world, or a constructivist theory.

Knowledge construction takes place primarily through the processes of assimilation and accommodation [1, 3, 5]. In assimilation the child is able to fit new information in terms of existing parameters whereas in accommodation a new parameter needs to emerge to handle the new information [1, 5].

According to Piaget, cognitive development occurs in a sequence of four stages resulting in qualitative and not just quantitative differences between children of different ages. The first stage, the *sensorimotor* stage describes development in the first two years of life. Here the infant knows the world through her sensory and motor interactions with objects in the world. The chief advancement of this period is the acquisition of object permanence or the knowledge that objects continue to exist even when the infant is no longer looking at or actively aware of the object. Without object permanence objects simply do not continue to exist unless the infant is engaged with the object; with object permanence the infant can feel distress with the mother's absence and can use language to signify the absent object.

The preschool aged child gradually becomes less egocentric, that is, more able to take another person's perspective during the *pre-operational* stage that spans 2–7 years of age. Now the child begins to use symbols characterized by imaginary play and language to solve problems. Children then enter the *concrete operations* stage (7–11 years) and can use a variety of strategies to solve problems. For example, children begin to conserve, that is, to recognize that superficial changes in appearance do not change the quantity of an item; 10 pennies in a row are the same amount as ten pennies in a pile. By age 11 children enter the adult way of thinking, the *formal operations* stage where hypothetical, theoretical and abstract problems may be solved.

In recent years Piaget's theory has been criticized for underestimating children's abilities. Piaget likely did not adequately recognize the importance of school learning for cognitive development. He also likely placed too heavy a reliance on stages that are characterized by qualitatively different skills. Many current theorists argue that development is more continuous and gradual. An alternative viewpoint has been presented by Vygotsky who believed that children learn best in the *zone of proximal*

development where the individual still requires some assistance which is best provided by scaffolding or support to master the tasks. The information processing approach to cognitive development which likens cognition to a computer processing model has been the most successful challenger to date.

Language Development

Infants are born receptive and responsive to language [2, 3, 6]. Newborns can quickly learn their mother's voice and prefer it. They can discriminate even the smallest speech sounds of language. In general, receptive language abilities or the ability to understand language precedes and is more advanced than expressive language skills.

Newborns cry and soon begin to coo or produce vowel like sounds and later babble or produce consonant-vowel combinations. First words emerge around 12 months of age and most 2-year-olds can speak in short sentences. Using a strategy known as fast mapping, young children are able to quickly make the connection between a novel word and its meaning. Most children become near fluent in their language by around 5 years of age. They know how to create plurals and use tenses correctly and in addition are aware of the irregular nature of the English language, that is, while walk becomes walked in the past tense, teach becomes taught and not teached. In middle childhood children become more adept at using language correctly in its social context recognizing there are different requirements in formal and informal settings but most improvements are related to written rather than spoken language. These children also develop metalinguistic awareness in that they can think about language.

Emotional and Social Development

Newborns feel happiness and distress and by one year infants display curiosity, anger and fear among other emotions [4]. Self-conscious emotions such as shame and pride emerge during the toddler years as children develop self-awareness. In addition preschool children begin to develop the ability to interpret other's emotions or a theory of mind [4]. Improved language and cognitive skills assist with developing emotional self-regulation strategies and this can enhance self-esteem. Children develop the ability to deal with emotionally arousing situations and by making comparisons with peers develop the ability to understand how others view them. Play takes on a valuable role in developing emotional self-regulation as well as enhancing physical and cognitive development. Friends also become increasingly important. The primary psychosocial task of the adolescent is the attainment of an identity which can take many years [2, 6].

Relevance to Childhood Development

The field of child development is part of the broader field of human development and is also known as developmental psychology. Most theorists view development as a continual, cumulative, holistic and interactive process [3, 7]. While maturation guides the display of many initial behaviors such as walking and talking, learning explains the acquisition of most higher level skills such as reading, reasoning and empathizing. So maturation sets the blueprint but socialization or the transmission of beliefs, values and skills due to experience, defines the individual [7].

Child Maltreatment

Merith Cosden
University of California, Santa Barbara, CA, USA

Synonyms

Battered child syndrome; Child abuse; Child neglect; Child physical abuse; Child sexual abuse; Neglect; Neglected children; Psychological abuse; Psychological maltreatment; Shaken baby syndrome

Definition

Child maltreatment is the physical, sexual, or emotional abuse or neglect of a minor. Physical abuse consists of a non-accidental injury inflicted on a child by another person. Sexual abuse includes sexual assault and sexual exploitation of a child, such as rape, incest and child pornography. Emotional abuse occurs when non-physical forms of rejection and hostility interfere with the child's healthy development. Neglect refers to the omission of behaviors by a parent which, by their omission, cause harm or present a serious risk of harm to the child.

Description

Prevalence

Because perpetrators of child abuse attempt to hide their behavior from the public, the prevalence of child maltreatment is difficult to ascertain. Estimates of child maltreatment are based, in part, on substantiated reports of child abuse to state child welfare agencies, but because abuse is often undisclosed these reports underestimate the problem. Nevertheless, information obtained by the U.S. Department of Health and Human Services (DHHS) from its National Child Abuse and Neglect Data System (NCANDS) which obtains findings from each state's child welfare rolls, indicates that over 6 million children were investigated for the possibility of maltreatment in 2006, with an estimated 905,000 determined to be victims of abuse or neglect. The youngest children (from birth to age 1 year) had the highest rate of maltreatment. As has been the case in prior years, neglect accounted for the largest proportion of cases (60%), followed by physical abuse (16%), sexual abuse (9%) and emotional abuse (7%).

Estimates of the occurrence of maltreatment are also determined through retrospective surveys of adults who are asked about prior experiences of child abuse and neglect regardless of whether or not these experiences had been reported to authorities. As expected, these surveys find higher rates of child abuse and neglect than those obtained through state reporting systems; for example, in a recent national survey 19% of participants described three or more instances of neglect as a child; 14% indicated three or more episodes of physical abuse; while 4.5% disclosed that they had been sexually abused at least once by the time they entered 6th grade [4].

Risk Factors

There are a number of risk factors for child maltreatment, some related to child characteristics and others associated with family and environmental circumstances. Children with disabilities, lower intellectual ability, and difficult temperaments appear to be at greater risk than are other children for abuse. There are also differences in risk factors for specific forms of abuse, with girls more likely to be sexually abused, and boys more likely to experience physical abuse [2].

Family risk factors include high levels of familial discord and poor parent–child attachments. Children living in poverty or in single parent families are over-represented among child welfare services cases. Caution should be taken in interpreting this to mean that only low-income children are vulnerable to maltreatment, however, as families with financial means are better able to maintain their privacy from public agencies when problems occur. Nevertheless, children with one or more of these risk factors are easier targets of abuse, and less able to defend themselves or bring others to their defense when they are threatened by an adult.

Risk factors for neglect are somewhat different than those for other forms of child maltreatment. As neglect affects everyone in a family, specific child risk factors are not pertinent. Parents who neglect their children tend to have lower levels of education and income, and higher levels of depression and social isolation when compared to other families in which maltreatment occurs.

There is also a higher probability that children who have been sexually or physically abused will be re-victimized as adults and will have children who will also be abused. Explanations for this "intergenerational transmission" of abuse focus on the increased psychological vulnerability of children who have been maltreated in terms of their low self-esteem, poor affect regulation, possible dissociation under stress, and minimal social expectations. These factors put the individual at greater risk for developing unhealthy and potentially dangerous social relationships as an adult. Children who have experienced maltreatment are also likely to be impaired in their ability to form attachments to others, and to have had adult models who dealt with stress through aggression, sexual control, and denial. These factors also put maltreated children at risk as adults for domestic violence and abusive or neglectful relationships with their own children.

Identification/Characteristics of Maltreatment

Despite the untoward physical and emotional impact of maltreatment, children often do not report their abuse to others. Children maintain secrecy about their abuse for a number of reasons, including fear about the repercussions of their telling. Children worry that no one will

believe their report of abuse or neglect and that the maltreatment will increase and their circumstances become worse; they may also be concerned that if someone does believe their report they will be separated from their family, blamed for the family dissolution, and placed in a foster care home that is no better than their current living environment. Perpetrators perpetuate this fear with threats of harm to the child or others if the secret of the abuse becomes known. Children are most likely to report their abuse if there are other adults in their lives who they believe they can trust. Critical to their later healthy psychological functioning is the responsiveness of adults to children when they do report the occurrence of abuse. Children who are given support when they disclose their abuse have significantly better adjustment over time than do children who are not supported [6]. It is likely that those children who are not supported experience not only betrayal from others but also continued exposure to the danger they attempted to report.

As children are unlikely to disclose their own abuse, mandated reporters and other concerned adults need to be aware of the warning signs of abuse. There is no one cluster of symptoms associated with child maltreatment. However, certain patterns of behavior indicate a need to consider the possibility of child abuse or neglect. Foremost in these "signs" is a sudden change in the child's behavior or school performance, particularly when that change cannot easily be attributed to other causes. This change in behavior may be reflected in depression and isolation, in overly aggressive behavior, or in regression to a less age-appropriate manner of functioning. Further, children who have been maltreated are often fearful and anxious without apparent reason. Unexplained bruises or school absences to hide injuries may suggest physical abuse, while children who consistently appear unkempt, hungry or tired, or whose physical, academic or social problems go unmet despite awareness by their parents, may be experiencing neglect. Child sexual abuse is often associated with nightmares, depression and aggression, as well as sexualized responses to others. Children who have been maltreated are also more likely than others to engage in self-injurious behavior, somatic complaints, suicide attempts, drug and alcohol use and delinquent behaviors. No one behavior is a definitive sign of abuse, and the symptoms described here may also reflect other psychological conditions. However, children who evidence one or more of these behaviors over a period of time warrant an assessment to determine the full nature of their needs and whether or not maltreatment is contributing to their problems.

Despite the high likelihood of maltreated children displaying one or more of these symptoms, some children with substantiated maltreatment appear to remain asymptomatic. Even longitudinal studies on children who have been maltreated occur within a specific timeframes and with a finite number of measures; thus, it is possible that children do not remain fully asymptomatic but show symptoms of their maltreatment at a later time in their development or in ways not assessed by investigators. It is also the case however, that many children who are maltreated are exposed to multiple other risk factors, including family discord, poverty, and social isolation. Children who appear asymptomatic may be more resilient than other maltreated children because they have stronger internal coping skills and more external protective factors including social supports which help compensate for the impact of the maltreatment and provide a solid psychosocial base for their development.

Parents may also exhibit behaviors that suggest that they are maltreating their child, particularly in conjunction with observations of troubling child behaviors. For example, when parents demonstrate little concern for the child in the face of symptomatic behavior, deny the existence of problems, blame the child for family problems, talk about the child solely in negative terms, demand extremely high levels of performance, and support rigid and harsh disciplinary practices, these behaviors should be considered as possible signals of abuse or neglect.

Perpetrators of Maltreatment

Adults who engage in child abuse or neglect vary in their age, motivation, history of abuse, and relationship to the child. There is no one offender profile, although offenders are more often family members or other adults close to the child than they are strangers.

Neglect always occurs in the home as a result of parental behavior (or lack of protective behavior). Neglect can occur in both dual parent and single parent homes; however, it is more likely to occur in single-parent homes, and given the higher likelihood that women will assume the role of single parent, it is not surprising that women are more likely than men to be responsible for child neglect. Mothers who neglect their children tend to be younger, have less education, and indicate higher levels of depression, passivity, stress and social isolation relative to mothers who do not neglect their children, including those who are involved in other forms of abuse.

Physical and sexual abuse can occur at the hands of either intra-familial or extra-familial offenders. Surveys show that intra-familial abuse is more common than is extra-familial abuse, and that men are more likely than

women to be the offender. There are considerable differences in the motivations for offenders. Sexual offenders may have preferences for children at specific ages (preschool, preadolescent, or adolescent) or for a specific gender, while offenders who engage in physical abuse may have global anger management problems or focal periods of stress that results in their turning their rage more specifically on their families. Substance abuse is common among offenders, as it is a response to stress which also reduces inhibitions and may exacerbate abusive behaviors. Understanding the risk factors that trigger offenders and the interventions needed to inhibit their activities are topics outside the scope of this paper.

Legal Protection of Maltreated Children

Federal legislation to protect children from abuse and neglect is delineated in the Child Abuse Prevention and Treatment Act (CAPTA). CAPTA was passed in 1974, then amended and reformulated over the next 30 years, until its most recent re-authorization in 2003 though the Keeping Children and Families Safe Act. CAPTA provides funding to states to support services for prevention, assessment, investigation, prosecution and treatment of child maltreatment. Federal definitions for child abuse and neglect focus on actions or failures to act by parents or caregivers which result in death, serious physical or emotional harm, sexual abuse or exploitation, or which present an imminent risk of serious harm. Interpretations and augmentation of this law to identify children in need of protective services, and the development and implementation of services for maltreated children, varies across states.

Reporting Child Maltreatment

All states in the U.S. have mandatory reporting laws that identify those professionals who are required to report suspected child abuse and neglect. Mandated reporters vary, but typically include psychologists, school teachers and administrators, social workers, law enforcement officers, childcare providers and health care workers. Some states require all citizens who suspect child abuse or neglect to report it to authorities, while all states permit, but do not require, any person who suspects child maltreatment to report it. Standards for reporting vary across states. A report must be made when one has reasonable suspicion that harm to the child has occurred, or that the child is exposed to conditions under which harm is likely to occur. In a majority of states, the identity of the reporter is protected and not disclosed even when other records are made available. Reports are made to child welfare agencies, which document the call and determine whether visitation, investigation, and possible separation of the child from the family is necessary. The police may also be called to investigate and file charges as necessary.

Mandated reporters are, at times, reluctant to report suspected abuse. This reluctance may be due to lack of knowledge about the warning signs of abuse, concern about the negative impact of reporting, or a desire not to get involved in this type of problem. Mandated reporters need training to assure that they are aware of the signs of abuse and understand the importance of the requirement to report.

Prevention of Maltreatment

Two types of prevention programs have been widely utilized for child maltreatment: school-based programs, designed to educate all children about risk and safety issues, and home-based programs, focused on families that appear to be at-risk for abuse or neglect.

School-based child abuse prevention programs are available across the country, with children often participating in one or more over the course of their education. These programs can be as brief as one group meeting or involve multiple sessions over the course of weeks or months. The focus of these programs varies as a function of grade level, with different curricula implemented for children in kindergarten, elementary school, junior high and high school. At younger ages, programs typically focus on helping children identify abusive behaviors through discussion of private parts of the body and identification of "good-touch, bad-touch" from others, as well as identification of a "safety plan" if they are approached by a stranger. At older ages, other safety concepts are introduced such as the need to tell others if one is being maltreated, with many programs utilizing a "yell and tell" philosophy. Adolescent programs also include information on date rape. While these programs are effective in imparting information, it is not clear that the strategies that endorse are as effective in preventing the more common intra-familial abuse as they are in preventing the less common extra-familial abuse [5]. In particular, the traditional "yell and tell" strategies adopted to hinder stranger abuse may not work when the child is living with the abuser, as children are often reluctant to "tell" on or disrupt their families regardless of their circumstances. School-based programs are implemented because of their wide reach to children, but are not sufficient to prevent child abuse among participants.

Home-visitation programs are also implemented for families at risk for child abuse or neglect. These programs focus on families who have been determined to have multiple risk characteristics associated with child maltreatment; these might include a young parental age,

single parenting, a history of abuse or domestic violence, low income, limited or no prenatal care, and poor birth outcomes. Programs may be staffed by trained volunteers or medical or mental health professionals and involve home-based treatment including observations, modeling of healthy adult-child interactions, and information regarding medical needs, child development, and parenting skills. Many of these programs have been effective in reducing referrals for domestic violence and abuse and neglect (e.g., [3]).

Interventions for Maltreated Children

Several types of interventions have been used to help children recover from the trauma of maltreatment, including play therapy, cognitive behavior therapy (CBT) and family-focused therapy.

Play therapy is used with younger children to allow them to work through the emotional distress and confusion associated with physical or sexual abuse. Using dolls, puppets, or other toys, children can re-enact scenes of their abuse in a safe environment and reflect emotions which might be difficult for them to articulate. Through this re-enactment the therapist can help the child express and understand their feelings, attribute blame and causation appropriately and regain a sense of self-control.

Cognitive behavioral (CBT) is effective for reducing many of the trauma-related symptoms associated with child maltreatment. Trauma-focused CBT [1] was designed specifically to ameliorate the symptoms which are often associated with experience of a traumatic event. Thus, trauma-focused CBT helps reduce fear, through graded exposure and relaxation techniques; decrease cognitive distortions, such as self-blame or a view of the world as generally unsafe, through identification, evaluation and replacement of distorted and catastrophic thoughts with more accurate ones; manage stress through relaxation and thought stopping for ruminative anxieties; and reduce parental distress, through similar components of CBT as those used for the child.

Children who have been maltreated also benefit when their parents receive therapeutic interventions, as parents who are able to come to terms with the abuse are better able to help their children manage their thoughts and feelings about it. When parents are the abuser(s), they are likely to be separated from the child by the courts, for a period of time if not forever. Offending parents may also receive anger management and parenting classes, particularly if the goal is to reunite with the child. The non-offending parent also needs interventions to help reduce their distress, as this will better allow them to provide support to the child and facilitate their child's recovery. For the non-offending parent, interventions can include correcting cognitive distortions about themselves and their child; allowing them to express and work through their emotions about the abuse; and helping them to understand the abuse from the child's perspective and how to more effectively support, protect and parent their child.

Finally, many maltreated children enter foster care; children can remain in that system for shorter periods of time if their parents seek treatment, or they may remain in foster care for the duration of their childhood. While this removes the child from potential danger, it also separates them from their major attachment figures, while relocation may also mean a disruption in schooling and in peer relationships. Children who have been abused or neglected may present special challenges to foster parents as they continue to anticipate abuse from adults and respond accordingly. It is important for foster families who work with maltreated children to be trained to understand and address their special needs.

Relevance to Childhood Development

Child maltreatment can have a significant impact on many areas of child development. The impact of child maltreatment will vary based on the type of maltreatment, the age at which it occurred, its duration and its severity, the relationship of the offender to the child, and the presence of protective factors in the child's life. These protective factors include personal resilience in the form of coping strategies, the ability to regulate one's emotions and attributions of blame for the abuse to external rather than internal factors, and external supports, including the presence of positive attachment figures. Nevertheless, certain types of developmental problems appear common among children who have been maltreated. While some developmental problems are associated with specific forms of maltreatment, children who are maltreated are often exposed to multiple forms of abuse, and may, therefore, display a range of these symptoms.

Abuse and neglect can interfere with the biological and psychological development of the child. Children who are maltreated are subject to severe and sometimes prolonged stress, resulting in over-activation of areas of the brain and the limbic system responsible for responses to stress. Stress results in activation of the hypothalamus, pituitary, adrenal cortex, sympathetic nervous system, certain neurotransmitters, and the immune system. In particular, Cortisol, a hormone excreted during stress-related "fight or flight" responses is evident at higher levels and for sustained periods of time in maltreated children.

As a result of this sustained experience of stress, children can become easily agitated or numb in addressing new, potentially stressful situations and manifest difficulties in self-regulating their emotions. Relative to other children, children who have been maltreated have difficulty regulating their emotional responses and are more likely to experience dissociative responses to stress. While dissociation, the emotional separation from stressful events, is a coping mechanism, it also limits one's ability to learn to work through emotionally challenging situations, and puts one at risk for unknowingly entering other dangerous environments. Maltreatment is a risk factor for post-traumatic stress disorder (PTSD), a biologically-based, psychological disorder which includes symptoms such as anxious arousal, social avoidance, intrusive thoughts, and flashbacks to traumatic events.

Maltreatment may also affect the child's cognitive development and school performance [7]. Due to the critical role of adults in early language development, neglected children in particular often have delayed or limited language development. Children who are maltreated often have academic delays, which can be ascribed to a variety of factors. For example, children who have been sexually abused may have difficulties concentrating in school, while children who have been physically abused may be truant to avoid disclosure of bruises or other signs of abuse.

The development of social skills and social relationships are also affected by maltreatment. Maltreatment is associated with a greater likelihood of drug and alcohol use, perceptions of social stigma, and social isolation. Problems with early attachments to caregivers can leave youth mistrustful or overly compliant in future attachments, either isolating themselves or forming bonds to others without discretion. Cognitively, children who have been maltreated may misread social cues based on their expectation of abusive behavior from others. Modeling what they have observed, children who have experienced physical abuse are also more likely than children who have not been abused to respond to conflicts in an aggressive manner. Children who have been sexually abused tend to over-sexualize their relationships, and have a greater likelihood than other children of engaging in promiscuous relationships or becoming pregnant at a young age.

Finally, children who have been maltreated are more likely than children who have not been maltreated to become victimized as adults. Explanations of the relationship between early abuse and subsequent victimization focus on the increased vulnerability of children who have been abused to social exploitation [8]. This increased vulnerability can be attributed to a number of factors, including a greater likelihood of engaging in early sexual activity, coupled with poor social judgment as a result of low expectations and poor self-esteem. Further, the psychological sequala of trauma, including dissociation and depression, as well as the use of drugs and alcohol to suppress feelings of psychological distress, may also increase vulnerability to future victimization by decreasing the individual's ability to accurately judge the safety or danger of social situations.

Child Neglect

Lindsay Weymouth, Tasha R. Howe
Humboldt State University, Arcata, CA, USA

Synonyms

Child maltreatment; Neglect; Neglected children

Definition

Child Neglect is a type of maltreatment where the child's basic needs are not met.

Description

Neglect may include failure to provide educational, emotional, and/or physical necessities [1]. Educational neglect may include failure to enroll a child in school or ignoring special educational needs. Emotional neglect may include failure to provide adequate psychological support, failure to provide affection, failure to remove a child from situations of domestic violence, and/or failure to provide mental health care. Physical neglect consists of failure to provide shelter, abandonment, malnutrition, inadequate supervision, and/or failure to provide medical attention. Consideration must be made regarding a child's culture and socioeconomic status regarding failure to provide education, emotional, medical, or physical needs [2, 3]. Neglect may also occur in the presence of other forms of maltreatment such as emotional, psychological, physical, or sexual abuse.

In the United States [2], childhood neglect accounts for over half of all the documented cases of child maltreatment. Young children are more likely to be neglected than older children and adolescents. Neglect may be more common in single parent homes and in families who are poverty stricken. Mothers [2] overwhelmingly commit child neglect compared to fathers, perhaps due to their primary caregiver status.

Neglect may be chronic or acute and can have a multidimensional impact on a child's development. Young children who are neglected may show somatic symptoms such as headaches, bed-wetting, stomachaches, and enuresis. Gender may influence how older children exhibit symptoms of neglect, such as boys tending to be more aggressive and girls tending to exhibit signs of passivity and low self-esteem [2]. In general children may show physical symptoms such as failure-to-thrive, sleep disturbances, stomachaches, bed-wetting, ulcers, regression in developmental milestones, and stunted physical development due to poor nutrition. In addition to being aggressive or passive, children may also be hyperactive and show signs of incompetence. Neglected children may also show extreme dependence on teachers, lack of enthusiasm, change in academic performance, parentification of siblings, and/or learning difficulties. Cognitively, children may have delays in functioning, low self-esteem, and/or exhibit academic difficulties [1, 2]. If neglect is present at certain critical periods of cognitive development, a lack of sensory stimulation may adversely influence brain development [3]. Specifically, neglect may lead to the underdevelopment of the cortex in the brain as well as limbic system dysfunction [4].

Additionally, maltreated children may have insecure attachments to their caregivers and have problems with emotion regulation, which may lead to alterations in the hypothalamic-pituitary-adrenal axis, the stress regulation system. Poor emotion regulation may influence children to show aggressive or withdrawal patterns with their peers. Without proper intervention and treatment, children who are maltreated may be affected well into adulthood. As adolescents and adults, they may abuse substances, show symptoms of psychiatric disorders, and engage in criminal behavior [2].

Treatment for children who have been neglected is often focused on their primary caregivers. Such treatment may include training in hygiene, finance, and family competence, counseling, and referrals to resources that may help the family. In addition, treatment may include child rearing classes and stress management training. Cognitive-behavioral treatment is most commonly used to teach caregivers self-management skills and modify problematic behaviors [2].

Child Psychotherapy

Janet L. Etzi
Immaculata University, Immaculata, PA, USA

Synonyms
Child counseling

Definition
The practice of psychotherapy with children.

Description
Child psychotherapy is based on the early work of Anna Freud during World War II in England when children were gathered in safe areas, often away from their parents. Due to the trauma of war and separation from their parents, these children were observed and treated according to Freudian concepts, albeit modified and extended to meet the needs of their developmental level. A model for conceptualizing psychological development and psychopathology was established in accordance with the model for child psychotherapy itself. A key element of child psychotherapy, as conceptualized by Anna Freud and other psychoanalytic theorists, is the communication of one's inner experience and having it attended to and understood by a nonjudgmental other.

Child psychotherapy is distinguished from adult psychotherapy in that adults are generally able to verbalize their thoughts and inner experience via talk therapy or free association, whereas children express their inner experience through play, e.g., storytelling, doll play, enactments of scenes. From this fundamental understanding of how children gain insight into, and learn to master, emotional and inner experience, child psychotherapy has evolved alongside adult psychotherapy. There are now as many models of child psychotherapy and empirically established types as there are for adults, including cognitive-behavioral, psychodynamic and interpersonal therapies.

Relevance to Childhood Development
Psychotherapy with children provided a means of gaining access to children's inner psychological experience. It became possible to gain insight into their psychology in regards to both normal and psychopathological or maladaptive development, and to observe the many developmental phases, tasks or processes associated with different ages. Anna Freud [1] first conceptualized children's lines of development including id, ego, and superego development but recent models [2] comprehend adaptive and maladaptive development in relation to culture, family context, temperament and genetic predisposition.

Child psychotherapy also provided child development studies with important knowledge and insights regarding psychopathology, emotional disturbance, maladaptive cognitive and personality functioning, from clinical work with children. Child psychotherapy has provided a growing body of clinical and research literature on both normal or adaptive development and psychopathology or maladaptive development.

Parenting styles; Patterns of parental behaviors

Definition
Different styles of parenting or approaches to parenting that affect a child's social and emotional development.

Description
Developmental psychologists have long been interested in the way parenting styles affect the social development of their children. Although parents are not the only contributing agents to the socialization of children, the family has always been considered a major arena for socialization.

In the early 20th century there were two major theories that explained the role of the parents and how it affected the child's development [7, 8]. The psychoanalytic theory which believed in two major intrapsychic forces

(aggression and the libido) was mostly concerned with children's emotional states rather than behavior. According to psychoanalysts, the individual differences in the emotional relationships between parents and children are the result of different parenting attitudes.

The second theory was the behaviorist and social learning perspective which focused more on parental practices rather than attitudes. The behaviorist perspective saw parents as the teachers and children as the learners, and the differences in children's development were believed to reflect differences in the learning environment to which they had been exposed [7, 8].

Despite the challenges faced by researchers in the establishment of links between parent–child interaction and children's socialization, three kinds of parenting styles were first distinguished by Diana Baumrind: authoritarian, authoritative and permissive [1–3, 6]. Baumrind identified four parental attributes on which parents could be compared, and based on these attributes parents were placed into one of the above categories [2]. These attributes were parental control, maturity demands, clarity of communication and nurturance. Further research by Baumrind in 1971 yielded a new style of parenting which she called "harmonious" [3] while Maccoby and Martin in the 1980s suggested a fourth category of parenting style and named it the "uninvolved parents" [9].

The four parenting styles

Authoritarian parents are demanding and controlling and expect nothing less than complete obedience from the child. These parents have a set of absolute values and standards of conduct and attempt to shape, control, and evaluate the child's behavior according to those standards. Authoritarian parents do not consider the child's point of view, verbal give-and-take is discouraged, and forceful measures of punishment are used as discipline [1, 2, 5, 6].

Authoritative parents encourage verbal communication with the child and consider his/her point of view. They do believe in parental control but are not rigid, punitive or intrusive, and they share with the child the reasoning behind their rules. The authoritative parents expect mature behavior and enforce rules but they also encourage the child's independence [1, 2, 5, 6].

Permissive parents attempt to provide a non-punitive, accepting and affirmative environment, in which they consult with the child about policy decisions, gives explanations about family rules and in which children regulate their own behavior as much as possible. Permissive parents rarely use punishment or make demands of their children, are extremely tolerant, even when it comes to aggressive or other inappropriate behaviors [1, 2, 5, 6].

Uninvolved parents impose very few demands on their children, are characterized by low responsiveness and little communication with them. Although these parents fulfill their children's needs they are generally detached from their lives, and in some extreme case they may even neglect or reject their children's needs [9].

Child rearing practices and children's characteristics

Diana Baumrind conducted several studies in an attempt to show the relationship between her categories of parenting and the four parental attributes used to compare parents. According to Baumrind, authoritarian parents are high on control and maturity demands but low on nurturance and communication. Permissive parents are low on control and maturity demands and high on nurturance and communication. Finally, authoritative parents are high on all four attributes of parental behavior [1, 3]. This led Baumrind to conclude that authoritative parents are most desirable.

Further research examined parental behaviors and how these behaviors influenced children's characteristics. Children of authoritarian parents tend to be obedient but are also passive, withdrawn and distrustful, they tend not to take initiative in social situations, they lack enthusiasm and spontaneity, they tend to exhibit a low need for achievement, and girls are shy while boys are hostile [1, 3, 9]. Punitive, hostile and non-empathic disciplinary methods, used by authoritarian parents, are associated with cognitive and emotional disturbance while high demands and other manifestations of parental authority can provoke rebelliousness in children [1].

Children of permissive parents exhibit impulsivity, low self-reliance, low maturity and low self-control. They also lack in social responsibility and have higher aggression levels than children of authoritative parents. No demands, sidestepping of conflicts, offering too much help and setting low standards, all behaviors of permissive parents, can understimulate the child and as a result he/she fails to achieve the knowledge and experience necessary in the enhancement of his/her independence [1, 3].

Finally, authoritative parenting was often associated with self-assertive, independent, friendly and cooperative children, who exhibited high competence and a high need for achievement [1–3]. Emotional support, high standards, providing appropriate autonomy, being attentive and responsive to children's needs, and clear communication, all attributes of authoritative parents, have been shown to help children develop what Baumrind calls instrumental competence, which is characterized by the balancing of individual and societal needs and responsibilities [3, 7].

Although research has shown that parenting styles can affect the social development of a child, other research has pointed out how certain characteristics of a child can affect the parent's behavior. Sex seems to be a factor in the degree of punitive behavior as parents may advocate less punishment for females than for males who engage in the same behavior. The age of the child and experience in parenting (single individuals as opposed to parents, a new parent or a parent with one or more children) also played a role in the parental response [5]. Other factors like socioeconomic level, children from traditional or non-traditional families and children from one or two adult households also influenced parenting practices [4]. Biological or adoptive parents in martially intact families tended to show more positive parenting as well as coparenting practices as compared to parents in other family structures, and children from two biological parent families showed better adjustment than children from other family configurations [4].

Relevance to Childhood Development

Many researchers have been interested in the way different types of parenting might affect children's social and emotional development. By defining parenting styles and by carrying out research in this field it was possible to show the correlation between parental and child behavior as well as the typical characteristics a child develops as a result of the type of parenting style their caregiver uses. On the basis of this same research, researchers were also able to define a number of parental practices and attitudes that seem to facilitate the development of independent behavior and social responsibility in children.

[2]Texas A&M University-Corpus Christi, Corpus Christi, TX, USA

Synonyms

Age of youth; Post-infancy

Definition

Childhood is a general term that describes the years in human development between infancy and adulthood. Childhood is divided into the additional phases of toddlerhood, early childhood, middle childhood, and adolescence. During childhood, a significant amount of care must be provided by parental figures.

Description

Childhood describes the years after *infancy* (an individual who is 1–12 months old), yet prior to *adulthood* (an individual who is post-puberty). The age at which childhood ends varies among countries, but the most common age is when an individual turns 18 years old.

Childhood is divided into four stages – toddlerhood, early childhood, middle childhood, and adolescence. These four stages are described below.

1. *Toddlerhood* includes the ages between 12 and 18 months and is the stage at which individuals typically learn to walk.
2. *Early childhood* typically includes children between the ages of 2–6-years-old, which are typically associated with play.
3. *Middle childhood* includes children between 6 and 8 years old. Middle childhood is typically associated with school.
4. *Adolescence* is the last stage of childhood. Adolescence includes children at the ages of post-*puberty*.

Relevance to Childhood Development

Childhood is an eventful series of years in which much development occurs. For example, the ability to learn is inherited. In addition, the capacity to remember, process information and solve problems is apparent at basic levels throughout all stages of childhood. In addition, there are several theorists who have explored different aspects of childhood development. Some of the more read theorists are Sigmund Freud, Erik Erikson, Jean Piaget, and John Bowbly. In addition behavioral theories of children development are based upon the theories created by John B. Watson, Ivan Pavlov, and B.F. Skinner.

Childhood Amnesia

Maria Perdikogianni[1], Xenia Anastassiou-Hadjicharalambous[2]
[1]Training and Research (KESY), Nicosia, Cyprus
[2]University of Nicosia, Nicosia, Cyprus

Synonyms

Infantile amnesia

Definition

The inability to recall events from early childhood.

Description

Childhood amnesia is characterized by a relative absence of memory before the ages of 3 or 4 [1, 5]. This term does not refer to a complete absence of memories but rather a scarcity of memories during infancy, memories that can later be influenced by individual experiences and cultural factors as well as how these early events are remembered and relayed to the children by parents [2, 9]. A few people can apparently recall momentous experiences that occurred when they were as young as 2 years old, such as the birth of a sibling but not earlier. Of course we all retain procedural memories from our toddler years, when we first learned to use the spoon, drink from a cup and take our first steps, just as we can retain semantic memories acquired in early life (the rules of counting, names of people and things, etc.). However, as adults we can no longer remember being fed as an infant by our parents, taking the first steps or saying our first words. That's the result of childhood amnesia [5].

Explanations for Childhood Amnesia

Childhood amnesia was first formally studied in 1893 by the psychologist Caroline Miles [1] but it was Sigmund Freud who offered one of the most famous and controversial explanations of childhood amnesia when he tied the phenomenon in with his other psychological theories [1, 5, 8, 9]. Freud theorized that childhood amnesia is the result of the mind's attempt to repress memories of traumatic events that occur in the psychosexual development of every child. These memories, according to Freud, have disturbing sexual and aggressive content and that's why they are suppressed. This would lead to the repression of the majority of the first years of life [1, 4, 5, 7–9].

Cognitive developmentalists claim that adults have trouble recalling the events of childhood because they no longer think as children do. As adults we use very different cognitive schemas from those we use in early childhood, and these adult schemas are not useful in restructuring early events from the memories stored at that time. As preschoolers we may encode our experiences far less elaborately since our information processing abilities are still limited and thus have very few cues for retrieving early memories later on in life. Only after we begin school do we learn to think as adults do, use language to organize memories and store not only events but thoughts about those events [9, 10].

Researchers who argue that the development of the cognitive self is crucial in the establishment of autobiographical memory do not disagree that developments in language, socioemotional and memory factors are also play an important role in autobiographical memory. Research has shown that what's lacking in early infant memory is not simply a memory capacity or a language system but rather the development of self as a cognitive entity, a personal frame of reference that constitutes memory autobiographical in a unique way [5]. According to this theory, children develop self-awareness by about 2 years of age and memories are inherently associated with one's sense of self. When memories are encoded before self-awareness develops they are not comprehensible to the individual even though some information is stored in the brain.

Biological researchers believe that the brain and the nervous system are not entirely formed in young children and thus do not allow for the development of adequate memory stores and effective retrieval strategy. Evidence for this comes from three different sources. First, that the hippocampal region of the forebrain is immature in young children. Second, that the prefrontal cortex is immature at birth and undergoes a period of rapid synaptogenesis toward the end of the first postnatal year along with the improvement of other cognitive tasks. Finally, the third source states that these changes in synaptic efficiency or hormonal modulation that follow certain types of stimulation may only become functional beyond infancy [5, 7, 9].

Another explanation attributes the cause of childhood amnesia to the incomplete development of language in young children. This theory states that infants do not have the language capacity to encode autobiographical memories in such a way that their adult selves can interpret correctly. Research by Gabrielle Simcock and Harlene Hayne showed children's inability to translate early, preverbal experiences into language because they lacked the language skills to do so. As a result these experiences could not

become part of autobiographical memory since they could not be encoded [4, 8]. This theory seems to be supported by the typical process of language development. The language of 1-year olds is limited to one-word utterances and childhood amnesia predicts that adults have very few, if any, memories of this time. By the age of 3 children utter two or three word sentences and by their fifth year their speech resembles that of an adult. This language development seems to correspond to childhood amnesia because most adults' earliest recallable memories go back to the age of 3 or 4.

Recent research has found patterns in the extent of childhood amnesia and the most prominent ones are gender and race. Research has shown that in general the earliest recollections of females are earlier and more vivid than those of males, and this pattern is due to differences in how males and females interact as children, especially the types of conversations they have [3, 6].

Race has also been shown to play a role in the effect of childhood amnesia as in certain studies Asian adults reported significantly later memories than European adults, while Maori adults, whose traditional culture puts an emphasis on the past, reported significantly earlier memories than adults in the other two cultural groups. In all three cultures the memories reported by females contained a lot more information than those reported by men [6].

Relevance to Childhood Development

Childhood amnesia provides an explanation to the adults' inability to recall events and experiences from their early years. People often find childhood amnesia difficult to accept and often claim to remember events from the first or second year of life. Researchers who explore childhood cognitive development, and continue to research childhood amnesia aim to identify new characteristics and possible explanations for this phenomenon. Whatever the explanation for childhood amnesia, scientists agree that our first memories may provide some useful insight into our personalities and they prove to be an important social tool.

Childhood Aphasia

Jeremy Hertza, William Schiff
Walton Rehabilitation Hospital, Augusta, GA, USA

Synonyms

Acquired epileptic aphasia; Agraphia; Alexia; Anomic aphasia; Aphasia with convulsive disorder; Aphemia; Broca's aphasia; Central aphasia; Conduction aphasia; Expressive aphasia, fluent aphasia, infantile acquired aphasia; Isolation aphasia; Non-fluent aphasia, receptive aphasia; Sensory aphasia; Subcortical aphasia; Transcortical motor aphasia; Transcortical sensory aphasia; Wernicke's aphasia; Word deafness.

Definition

Aphasia refers to a loss or disruption of the ability to understand or produce language through spoken or written words due to injury to specific areas of the brain involved in language, almost always located in the left-hemisphere of the brain. Disruption in language due to low intellect, loss of sensation, or poor motor control or coordination of the mouth is not considered aphasia.

Description

Aphasias encompass a variety of syndromes and include specific deficits to reading (alexia), writing (agraphia), and

ability to speak and repeat words (word deafness). They also involve declines in the reception and expression of language. Aphasias affecting spoken language are often classified according to the neuroanatomical areas that are affected and can be grouped as to whether or not speech is fluent or non-fluent [7, 8].

Non-fluent aphasias are mostly related to problems in the expression of speech. ►Broca's Area (Brodman areas 44 and 45) controls language production. It lies in the opercular and triangular sections of the interior frontal gyrus of the dominant hemisphere of the frontal lobe of the brain [7]. Broca's aphasia, also known as expressive aphasia or non-fluent aphasia, presents as non-fluent speech with impaired repetition and naming, and is often characterized by short meaningful phrases spoken with great effort. Language comprehension is relatively preserved. Another non-fluent language disorder, global aphasia, involves severe communication difficulties in expression, comprehension, and repetition. Transcortical mixed aphasia or isolation aphasia is similar to global aphasia expect that repetition is intact.

Fluent aphasias involve problems with language comprehension. Wernicke's Area controls auditory comprehension and is located in the posterior portion of the superior temporal gyrus (i.e., Brodman area 22) [7]. Wernicke's aphasia, also called sensory aphasia, fluent aphasia, or receptive aphasia, is characterized by an inability to comprehend speech or to arrange sounds into coherent dialogue. Individuals with Wernicke's aphasia speak fluently but non-sensically, may create their own words, have deficits in naming and repetition, and have difficulty understanding written or spoken language. Speech is also fluent in anomic aphasia which is characterized by deficits in naming only. Transcortical aphasias are named by the neuroanatomical area associated with observed functional deficits: the motor areas or the sensory areas of the brain. Transcortical aphasia, by definition, affects the parts of the brain around either the expressive or receptive language centers; thus, transcortical motor aphasia involves problems with expressive speech while transcortical sensory aphasia involved problems comprehending language. They are fluent or non-fluent depending on location. Repetition is intact in transcortical motor and sensory aphasia differing it from either Broca's or Wernicke's aphasia. The neural pathway that connects Broca's and Wernicke's areas, the arcuate fasciculus is thought to be involved in repetition [7, 12, 13]. Conduction aphasia or central aphasia is caused by damage to the arcuate fasciculus and involves poor repetition with intact comprehension and expression. Damage to subcortical regions, such as the thalamus, internal capsule, and basal ganglia, can also cause aphasic symptoms. Subcortical aphasia can involve the full range of symptoms depending on the affected location.

Relevance to Childhood Development

Aphasia can affect individuals of all ages including children. While presenting symptoms may be similar in both age groups, there are different considerations to make when examining children and adults. Specifically, it is important to rule out factors which may have contributed to the child's presentation. Examination of developmental level (e.g., are the child's deficits due to a developmental disorder?), environment (e.g., are language deficits secondary to low levels of stimulus?), and history (e.g., any prenatal substance abuse, medical illness, psychiatric illness, etc.) may help to determine etiology.

Etiology is often the same in adults and children with symptoms frequently due to head trauma, stroke, infection, brain tumor, or other brain disorders [1, 3, 4, 7–9, 12, 13, 15]. Any condition affecting the language centers of the brain can cause aphasia, including several viruses (e.g. Epstein-Barr virus) and seizure disorders [4]. As an example, Landau Kleffner Syndrome (LKS) or infantile acquired aphasia, acquired epileptic aphasia, or aphasia with convulsive disorder, involves a slow or rapid onset of loss of the ability to comprehend or use spoken language following an otherwise normal development due to abnormal electrical discharge across the brain [1, 10].

The primary treatment of childhood aphasia is speech therapy [1]. Techniques vary according to deficits. The child may be asked to complete tasks to exercise facial muscles, repeat words, name objects, engage in activities to promote give-and-take conversation, learn sign language, use flash cards, practice reading and writing, etc. Medical treatments, such as surgery or medication, may be used to treat the primary causes of the aphasia, such as releasing cerebral pressure following traumatic brain injury or controlling seizure activity in LKS. Prognosis and outcome vary by etiology.

Childhood Disintegrative Disorder

Mark Tovar
University of Texas, San Antonio, TX, USA

Synonyms

Autism spectrum disorders; Pervasive developmental disorders

Definition

Onset of this disorder occurs after 2 or more years of normal childhood development. It is characterized by abrupt regression and loss of proficiency in cognitive, verbal, and motor skills within several months.

Description

Childhood Disintegrative Disorder (CDD) is primarily characterized by abrupt regression and loss of proficiency in cognitive, verbal, and motor skills that occurs after 2 or more years of normal development. CDD is contained within the family of Pervasive Developmental Disorders (PDDs) but differs from other PDDs such as Autism in that the symptoms appear after a period of seemingly normal development. The age of onset requirement for CDD also is different from that of Autism, as the age of onset for CDD is prior to 10 years of age. Diagnostic criteria mimic Autism in language, social interactions, and the child's self-sufficient behaviors (e.g., repetitive behaviors and fecal and bladder incontinence).

Some children experience brief traits of CDD and then become asymptomatic, however, the majority of children face atrophy of previous developmental milestones to the point of mental retardation. CDD is a very rare disorder, and diagnosis requires extensive neurological and developmental evaluations.

Childhood Leukemia

Bernadette Hassan Solórzano, Karissa M. Gilmore
Our Lady of the Lake University Community Counseling Service, San Antonio, TX, USA

Synonyms

Acute lymphocytic leukemia (ALL); Acute myelogenous leukemia (AML); Acute promyelocytic leukemia (APL); Chronic lymphocytic leukemia (CLL); Chronic myelogenous leukemia (CML); Juvenile myelomonocytic leukemia (JMML); Mixed lineage leukemia

Definition

Leukemia is a progressive cancer of bone marrow and other blood-forming organs, in which abnormal leukocytes are produced and spread to other organs of the body.

Description

Leukemia, one of the most common forms of cancer in children, can appear as soon as the age of one or as late as the early teen years. While childhood leukemia is considered to be a rare disease, it accounts for 33% of all childhood cancers. Approximately one in one thousand children will be diagnosed with leukemia by the age of 19 but it is more common in children under the age of ten. The American Cancer Society projects that three out of four children diagnosed with leukemia will have acute lymphocytic leukemia (ALL). Most of the remaining will

be acute myelogenous leukemia (AML). There are many different types of childhood leukemia which are classified as either fast-growing (acute) or slow-growing (chronic). Leukemia is defined as a cancer that attacks the early blood forming blood cells, typically the white blood cells. It begins in the bone marrow and spreads next to the blood and then the lymph nodes, spleen, liver, the brain and spinal cord and on.

ALL occurs most commonly in children between the ages of two to four years of age, while AML either occurs during the first two years of life or during the teen years. ALL is slightly more common among white, male children and AML is occurs equally among boys and girls of all races. The survival rate for ALL is now more than 80% thanks to medical advancements. The 5 year survival rates for AML are now more than 50%.

Risk Factors

While certain risk factors may increase the likelihood of developing childhood leukemia, there is no known cause. The risk factors include being born with an abnormal immune system, exposure to high levels of radiation, previous treatment with radiation or chemotherapy, or taking medications which suppress the immune system. Currently there are no tests available for early detection of leukemia so early detection of symptoms is important. Symptoms are caused by the invasion of abnormal blood cells from the bone marrow into the body. These cancerous cells affect the production of blood in the bone marrow and also affect the organs to which they spread, such as the liver, lymph nodes, or central nervous system. Parents need to be on the watch for the symptoms which include: constant fatigue, loss of color in the skin, increased bleeding (most noticeable on minor cuts), or bruising easily. Children with leukemia may also experience infections resistant to appropriate medication, high fevers, and bone pains. If the cancer cells spread to other organs, the child may have swelling of the abdomen because of an enlarged spleen or liver, swollen lymph nodes, trouble breathing, coughing, loss of appetite and weight loss. When the leukemia spreads out of the bone marrow and into the central nervous system headaches, trouble concentrating, seizures, vomiting, blurred vision and trouble with balance may occur. Children with AML may also develop swollen, bleeding, painful gums and a rash. The physician normally will obtain a thorough medical history and focus on the child's lymph nodes, the eyes and the mouth. A variety of screening tests are used for diagnosis that range from blood tests, bone marrow samples, spinal tap, and a lymph node biopsy. Imaging tests used include chest x-rays, computed tomography (CT) scans, magnetic resonance imaging (MRI) scan, gallium scan and bone scan.

Treatment

Treatment of childhood leukemia varies depending on the type of cancer, risk group, and whether or not an infection is present at diagnosis. If a child is ill or becomes ill during treatment, the infection must be cured before treatment for the leukemia can begin, or continue. Radiation therapy is one form of treatment used for leukemia. This involves the use of high-energy radiation to target and kill the cancerous cells. Chemotherapy, the most common treatment, uses several different medications to kill the abnormal blood cells. Bone marrow transplants and peripheral blood stem cell transplants are effective with some forms of leukemia when chemotherapy is insufficient. These transplants allow for a higher dosage of chemotherapy to destroy the bone marrow, the stem cells are then used to replace the bone marrow and help form new, healthy blood cells. Clinical trials testing new medications or forms of treatment can also be found. These trials are available to those children who qualify for them, but there are no guarantees as to whether or not the treatment will work.

Possible Side Effects of Treatment

One of the most common is an increased risk of infection – viral, bacterial or fungal. Some side effects do not appear until months or even years after treatment is concluded. Some of these include damage to the lungs from radiation treatment, thyroid problems, infertility and impaired bone growth. Additionally, patients who have received a bone marrow transplant may get graft-versus-host-disease which is the result of the donor immune system attacking the host.

After Treatment Ends

Following treatment, the child will continue to meet with his or her oncologist for up to 5 years. These check-ups consist of monitoring the signs of the cancer returning, examining the effects of therapy, and looking for long term and late effects of the cancer. Regular visits to the child's physician are also imperative to conduct yearly physical examinations.

Relevance to Childhood Development

A diagnosis of leukemia in a child is difficult for the child and the entire family. It is important that parents ask the doctors questions that can help clarify the process and what will happen to the child. Many different emotions arise in a family when a loved one has been diagnosed with

cancer. The child will experience a variety of emotions, including anger, fear, guilt, anxiety, and sadness. Each child handles the situation differently. While only the child carries the diagnosis, the family is impacted as a whole. While in treatment, it is helpful for the family and child to have counseling to help deal with these emotions.

Not only is a child's emotional state impacted by cancer, but also the routine of everyday living. Depending on the type and risk group of the cancer, the child may have to spend several weeks at a time in a hospital for tests and treatment, separated from his or her siblings and friends and away from school for long periods of time. In addition the child may not be strong or healthy enough to perform the regular physical activities of children. Since the child's immune system is also impacted, the entire family now is organized around taking care of the diagnosed child. Siblings may feel neglected and conflicting emotions may arise. The diagnosed child who is no longer able to do normal play and school is forced to deal with more adult emotions prematurely. Frequently, these children try to protect their parents from worrying and may not share their emotions.

Once a child is in remission from leukemia, it is important to watch for some potential long-term and late effects that can result from treatment. Some of the factors to consider are: the overall health of the child, gender, age at time of treatment, type of cancer, and duration of treatment. These effects can be psychological, physical, or cognitive. Learning disabilities may develop either during treatment or several years later. Difficulty with mathematics, spatial relationships, problem solving, attention span, as well as difficulties with fine motor coordination are not uncommon. Some physical effects include constant fatigue, growth delays, thyroid dysfunction, hearing loss, or developing a second form of cancer. Finally, the child may report changes in mood after treatment is concluded. Posttraumatic stress disorder has been found in child survivors of leukemia. An additional psychological complication results if the child is pronounced in remission but has to continue taking medications and being monitored. Medication and treatment compliance issues may result during as an additional challenge to parents especially during the teenage years.

Childhood Onset Schizophrenia

▶Childhood Schizophrenia

Childhood Psychosis

Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Synonyms

Dementia infantiles; Dementia praecossima; Disintegrative psychosis; Gross impairment in reality testing; Insanity of early life; Loss of ego boundaries

Definition

The term childhood psychosis (deriving from the Greek ψυχή "psyche," for soul or mind and -οσις "-osis," for abnormal condition) describes an abnormal condition of the mind which is characterized by disruptions in thinking and it accompanied by delusions (Definition 1: false beliefs that typically involve a misinterpretation of perceptions or experiences) and hallucinations (Definition 2: hallucinations may occur in any sensory modality (i.e., auditory, visual etc.). Auditory hallucinations are the most common and they are experienced as voices that are perceived as distinct from the individual's own thoughts.) with the hallucinations occurring without insight into their pathological nature [1].

Description

Historically, the definition of psychosis in children has been surrounded by vagueness, confusion and debate primarily because of the developmentally appropriate role of imagination in the typically developing child. Childhood Psychosis was originally conceptualized as part of the spectrum of the Pervasive Developmental Disorders. Gradually, by 1980 some degree of consensus was reached that the essential features of Psychosis hold across age.

In the most recent revision of *Diagnostic and Statistical Manual of Mental Disorders, 4th edition, Text Revision (DSM-IV-TR)*, the definitions and diagnostic features of psychosis do not differ across children, adolescents and adults. These symptoms include disorganized or disturbed thought form and thought content, disorganized speech, disorganized or catatonic behavior, flat affect, poverty of speech and lack of goal directed behavior [1].

A psychotic symptom, or clusters of symptoms are connected to a specific disorder as defined by a certain number of symptoms occurring over a specific duration of time with demonstrated impairment. Delusions (false beliefs) and prominent hallucinations (erroneous perceptions) are usually considered as the basis of diagnosis of psychosis [1].

The diagnosis of childhood psychosis remains an unresolved ongoing debate. In contrast to the diagnosis of adult psychosis which is relatively reliable since its symptoms and phenomenology are well established, in children and particularly the younger ones the diagnosis is elusive. Children in clinic as well as nonclinic populations report seeing ghosts or shapes or hearing voices and such hallucinations often do not constitute diagnostic features of psychosis. The developmentally appropriate intrusions of fantasy for the young children along with the developing cognitive abilities make the diagnosis difficult to make and often inaccurate.

Phenomenology

Childhood-Onset Schizophrenia in line to Adulthood Onset Schizophrenia is characterized by positive symptoms (that are present and should not be) and negative symptoms (that are not present and should be) [1]. Positive symptoms in children include gross disturbance of thought process or thought content, whereas delusions most possibly appear (or become apparent) with increasing age [2]. Negative symptoms include flat affect, and paucity of speech and thought [3]. Younger children with Childhood-Onset Schizophrenia are considered to have less delusions and catatonic symptoms, but they display hallucinations, disordered thought process and flattened affect [4].

Schizoaffective disorder is characterized by the positive and negative symptoms of schizophrenia as well as symptoms of a Major Depressive Episode, a Manic Episode, or a Mixed Episode [1]. These symptoms often make the diagnosis cumbersome. Especially in the initial stages of Schizoaffective Disorder in children mood symptoms may overshadow the existence of psychotic symptoms [2]. According to *DSM-IV-TR*, the phase of the illness with psychotic symptoms only must last at least for 2 weeks to distinguish Schizoaffective Disorder from a mood disorder with psychotic features. During these 2 weeks mood symptoms may be present but they are not prominent. Often it is difficult to make a determination of where to draw the line of *non- prominent* mood symptoms. For an accurate diagnosis repeated observations and multiple sources of information are necessitated [1].

The diagnosis of Psychotic Disorder Not Otherwise Specified includes psychotic symptoms for which there is not enough information to make a specific psychotic diagnosis, for which there is conflicting information or do not meet full criteria for a specific psychotic disorder [1]. The validity of Psychotic Disorder Not Otherwise Specified has been questioned and the evidence is still inconclusive.

Prevalence

The prevalence of childhood psychosis is not yet determined. Sparse epidemiological data suggest that pediatric psychosis is rare. Schizophrenia with onset during middle to late adolescence is reported to be in the range of 0.5–1.5% [1] Childhood-Onset Schizophrenia is reported to be no more than 1% [5]. With respect to ethnic origin certain population groups, for instance second generation African Caribbean's living in UK have been reported to have a far higher incidence [1]. However, the data are mixed any they may reflect biases deriving on reliance from hospitals. Further, birth cohort studies showed several geographical and historical variations in prevalence. For instance, higher risk has been reported for urban-born individuals versus rural-born individuals. Also lower prevalence has been reported for later-born versus earlier born birth cohorts [1]. The prevalence of Psychotic Disorder Not Otherwise Specified in children is hard to determine due to the vagueness of the term and the surrounded controversy over its validity.

Associated Features

Associated features of Childhood Psychosis are not yet well examined by empirical investigations. A line of evidence suggests that Childhood-Onset Schizophrenia is often associated with gross and fine motor delays, hypotonia, poor coordination, sensory integration difficulties, and significant delays and dysfunctions in language development [6] that indicate abnormal developmental of language related processes. Children with schizophrenia have also been reported to show features that are often linked with Pervasive Developmental Disorders. This symptomatology includes stereotypic behavior, such as hand flapping, preservative smelling and touching [2]. Further subsets of children with Childhood-Onset Schizophrenia

have been reported to show features associated with Attention Deficit Hyperactivity Disorder such as attention problems, distractibility, and other dysfunctions of executive functioning [7]. In addition, children with Childhood-Onset Schizophrenia score lower on IQ tests relative to the typically developing children [8]. However, neurocognitive studies suggest that these lower IQ scores may reflect primarily neurocognitive deficits [9]. Children with Childhood-Onset Schizophrenia have also shown neurobiological abnormalities such as reduced volume of the brain (frontal, temporal-limbic, thalamus, cerebellum), enlarged ventricles, altered neuronal connections, reduced brain activity, low reaction of autonomic nervous system and neurotransmitter dysfunction (dopamine, serotonin, GABA, glutamate) [10].

Socioemotional disturbances such as withdrawal, isolation, ineptness, moodiness, flat affect and lack of social interest, are also quite common in children with schizophrenia [11]. Impaired communication also is a quite common feature of childhood onset schizophrenia.

Beyond the associated features of Childhood-Onset Schizophrenia a history of developmental delays and cognitive deficits (e.g. attention, learning, abstraction) is considered to be implicated in children with other psychotic disorders such as in children Psychotic Disorder Not Otherwise Specified [12]. The scarcity of the empirical evidence however does not allow conclusions to be drawn with greater confidence.

Differential Diagnoses

Misdiagnosis of psychotic symptomatology in children is common. For instance an acute onset manic episode may be mistaken for schizophrenia, as hallucinations and delusions may be present (usually mood congruent). Psychotic symptoms in children need to be differentiated against to obsessions related to Obsessive-Compulsive Disorder, anticipatory anxiety related to Anxiety Disorders, rumination related to Depression, perseverative thoughts related to developmental disorders, disorganized behavior related to Attention-Deficit/Hyperactivity Disorder (ADHD), disorganized speech related to a Communication Disorder [1]. Further, language deficits and cognitive deficits related to mental retardation may suggest psychosis in nonpsychotic children [2]. Furthermore, nonspecific symptoms, such as anxiety, distractibility, and irritability, may precede a psychotic symptom and confound the diagnosis.

Psychotic Disorder Not Otherwise Specified is utilized to encompass psychotic symptomatology that is not adequate for diagnosis of another psychotic disorder. Nonetheless, reliable diagnosis of psychosis during childhood at present remains cumbersome.

Developmental Course and Prognosis

Psychosis in children is seldom diagnosed before the age of 7 primarily due to the developmentally appropriate fantasy lives of children. While schizophrenia sometimes begins as an acute psychotic episode in young adults, it emerges gradually in children. It is often preceded by developmental disturbances, such as lags in motor and speech/language development. Most empirical investigations on prognosis of childhood psychosis show variable course. Full recovery is very uncommon. For most children, psychosis remains lifetime condition. Most children with psychosis will enter adult life and their condition will be characterized by exacerbations and remissions. Among those whose condition persists into adulthood some will show a steady symptomatology, while others will show progressive deterioration. Empirical studies have provided a series of factors that are associated with a better prognosis. These factors include associated mood disturbance, treatment with antipsychotic soon after onset, absence of structural brain abnormalities, and normal neurological functioning [1].

Etiology

The current knowledge about the etiology of psychotic disorders focus mostly on schizophrenia and evidence derives from adult samples with only scarce studies focusing on child and adolescent samples. Most of these studies provide evidence that there is no single definite etiology of schizophrenia. The preponderance of evidence suggests that Childhood Schizophrenia evolves from a genetic predisposition, a prenatal insult to the developing brain, and stressful life events. The role of genetics has long been established. First-degree relatives of children with schizophrenia have a higher prevalence rate of schizophrenia and schizophrenia spectrum disorders. The risk of schizophrenia increases from 1% with no family history of the condition, to 10% if a first degree relative has it, to 50% if an identical twin has it. Twin data show higher concordance for identical rather than for fraternal twins Identical twins are reported to have a concordance of 45–55% while fraternal twins are reported to have a concordance of 13–17% [13]. Further to the genetic predisposition, prenatal and birth complications have been implicated in schizophrenia [12]. Prenatal adversities may include viral infections, such as maternal influenza in the second trimester [14], starvation, lack of oxygen at birth, and untreated blood type incompatibility. An increase in minor dysmorphic features indicate prenatal-onset problems. An increase in hypoxia-associated complications has been implicated in the odds of developing earlier-onset schizophrenia. Beyond genetic predisposition and

prenatal insults to the developing brain, psychosocial stress and family processes have been implicated in the development and worsening of psychotic symptomatology. For instance family communication characterized by dysfunctional thinking and attention and disturbed relationships has been linked to schizophrenia [10]. Despite the empirical investigations that determined a link between childhood psychoses and genetic predisposition, prenatal insults and stressful life events, the interaction of these factors and the possibly differentiated interplay of these factor across the life of the developing child is yet to be determined.

Treatment

To date, there are still no rigorous studies reporting on the efficacy of psychosocial treatments and pharmacotherapy specific to childhood psychosis. Early diagnosis is of crucial importance for the treatment of childhood psychoses. Children with this disorder must have a complete evaluation in order to develop a comprehensive individual treatment plan to address their difficulties.

Treatment strategies are typically recommended to focus on the clinical symptoms of the underlying disorder, while also addressing any comorbid disorders or psychosocial stressors. If there is evidence that delusions or hallucinations are the direct physiological consequence of a general medical condition then the first step is to address these conditions. For instance treating a partial complex seizure disorder, managing a metabolic imbalance, or treating an underlying infection. If it is deemed that there is no medical cause for the psychotic symptoms, then the next step is to ascertain whether the psychotic symptoms are secondary to another psychiatric condition such as Depression or Mania. If the psychotic symptoms are secondary to depression for instance the child will be prescribed with antidepressant (e.g., selective serotonergic reuptake inhibitors (flouxetine, paroxetine, sertraline, fluvoxamine, clomipramine). Often, the use of antipsychotic medications in addition to the use of antidepressants or mood stabilizers is indicated in psychosis that is secondary to depression. Medication can be helpful for many of the symptoms and problems identified [5]. Standard antipsychotic drugs appear to be effective for many schizophrenic children and adolescents. And the atypical drug clozapine is helpful for at least half of those who do not respond to other drugs. In a few cases psychotic symptoms seem to disappear entirely. However, children may be more vulnerable than adults to the toxic effects of clozapine and consequently many schizophrenic children have to discontinue its use because of the side effects (i.e., risk for seizures and serious blood abn) [5]. Newer antipsychotic drugs that may be safer and just as effective are now being tested.

While antipsychotic medications can be of value, they do not negate the need for psychosocial interventions individualized to each child's difficulties. These interventions typically include family psychoeducational approach encompassing education of the child and the parent about schizophrenia, enhancing strategies for coping with the disorder, training in family communication, training in problem solving and the provision of supportive psychotherapy during the recovery phase of the acute illness, and practical guidance of behavior [15]. Ongoing supportive psychosocial treatment helps patients with social and developmental crises. Clinicians also act as advocates with the parents for their patients with the schools and other social agencies to ensure that children with psychoses can continue their education while their specials needs will be addressed. Despite these treatment approaches that are typically generated to address psychosis in children to date there is a crucial need for methodologically rigorous controlled treatment studies that will be evaluating the efficacy and long-term outcome of the treatment approaches.

Childhood Schizophrenia

Synonyms

Childhood onset schizophrenia; Early onset schizophrenia; Schizophrenia; Schizophrenia spectrum disorders

Description

Childhood schizophrenia is a rare, chronic, and disabling mental illness in which reality is interpreted as abnormality, indicating psychosis. Individuals with schizophrenia are often paranoid and or delusional, believing people are out to get them. Children with schizophrenia also can develop auditory (hearing) or visual (seeing) hallucinations. Schizophrenia in children affects approximately 1 out of 40,000 children, with the average age of onset around nine years old. Childhood schizophrenia is essentially the same as adult schizophrenia, except that the onset is before the child's 13th birthday. Schizophrenia is a brain based disease. There is no known cause for childhood onset schizophrenia, although there is thought to be a strong genetic component to the disorder, as there is with adult onset schizophrenia. Childhood schizophrenia is typically treated with medications called antipsychotic medications. These include pharmaceuticals such as chlorpromazine, haloperidol, risperidone, and quetiapine. There are also alternative therapies including cognitive behavioral therapy, nutritional supplements, and support groups. Currently there is no cure for schizophrenia.

Symptoms and Diagnosis

Symptoms of childhood schizophrenia are identical to symptoms of adult onset schizophrenia. Symptoms are often easy is miss and might be attributed to delayed developmental patterns, especially in early childhood. With time, the symptoms often worsen, making the emerging schizophrenia more readily apparent.

Symptoms include:

- Hallucinations, both auditory and visual
- Delusions
- Disorganized or catatonic behavior
- Withdrawal from social situations, including family and friends
- Flat affect
- Strange eating patterns
- Incoherent and erratic speech
- Failure to, or loss of interest in cleaning self
- Ritualistic behavior
- Quick agitation or disturbance
- Poor academic performance

Diagnosis is never easy with childhood onset schizophrenia. Typically, a child psychiatrist will want to monitor the child for at least 6 months. In addition to monitoring, other testing is also usually performed including, but not limited to, a physical exam, blood tests, psychological consultation and other testing considered to be relevant. Typically, the child psychiatrist will look to the Diagnostic and Statistical Manual of Mental Disorders (DSM) for specific criteria. According to the DSM, when diagnosing schizophrenia, whether it is childhood or adult onset, the following criteria should be met:

A. Characteristic Symptoms: two or more of the following symptoms should be present for a significant portion of a one month period:
   1. Delusions
   2. Hallucinations
   3. Incoherent, disorganized speech
   4. Grossly disorganized or catatonic behavior
   5. Negative symptoms such as a flat affect
B. Social Dysfunction: for a significant portion of the time, there should be a marked level of dysfunction regarding the child's academic performance and interpersonal interactions.
C. Duration: the symptoms should be present for at least six months.
D. Mood disorders should be ruled out.
E. Substance/general medical condition exclusion: symptoms indicating schizophrenia should not be the result of pharmaceuticals or a medical condition.

F. If the child has a disorder falling within the Autistic Spectrum, the diagnosis of Schizophrenia is given only if delusions or hallucinations are present for at least a month.

Childhood Schizophrenia and Families

A diagnosis of schizophrenia often takes a debilitating toll on families and caregivers. Although many have heard about schizophrenia, the only information many families have been privy to are exaggerated portrayals of schizophrenia through books and Hollywood movies. When a diagnosis of schizophrenia is given, it is normal for families to have a grieving period and experience periods of guilt. It is important for families to educate themselves about the symptoms, existing treatments, and options families have regarding their family member with schizophrenia. Many children with schizophrenia live in the family home; however other residential options are sometimes available, including residential hospitals and group homes, if the illness becomes unmanageable for the family.

Definition

A benzodiazepine tranquilizer utilized in the treatment of anxiety disorders, possessing anxiolytic, muscle relaxant,

and hypnotic properties. The first drug of its class (benzodiazepines; e.g., Valium, Xanax, Ativan belong to the same class of drug and were invented after Librium) to be discovered and marketed by Roche. Librium is a controlled drug under various drug control laws (e.g., U.S. Schedule IV).

Description

Synthesized, misplaced, and then re-discovered in the laboratory of Roche chemist Dr. Leo H. Sternbach [1], Librium (chlordiazepoxide) was the first of a long line of benzodiazepine tranquilizers whose efficacy, utility, and frequent use preceded the collective entry of these pharmaceuticals into the modern lexicon. The benzodiazepines, a family of tranquilizing drugs used today to treat clinical anxiety, but prescribed more liberally before the risks of dependence became known, netted much profits and publicity for Rocheand the competition's products, but eventually triggered a public backlash among casual users of the drugs, who eventually voiced their dramatic tales of prolonged withdrawal tothe U.S. Senate.

Librium's re-discovery among Sternbach's laboratory papers, and the discovery that it possessed anxiolytic, muscle relaxant, and hypnotic properties, occurred in 1957. It wasFDA approved in 1960 [2], and soon outpaced what was then the leading tranquilizer, Miltown (meprobamate). 3 years later, Sternbach synthesized Valium.

In the U.S., Librium was written on 19.5 million prescriptions in 1974. It was prescribed for muscle pains, ulcers, and sundry diagnoses, in addition to anxiety, both clinical and normal, with such freedom that its skyrocketing popularity and public presence, along with Valium, led to increasingly ominous stories of painful drug withdrawal from some in the public, many of whomclaimed to have not been fully appraised of the possible risks when initially prescribed the drug. Media interest in these accounts of addiction and traumatic detoxification, inturn, led to law enforcement pressure to legislate the drug's use. By this time, in the early 1970s, both Librium and Valium were two of the top three most prescribed drugs in America [3]. Although Librium had its advocates among patients and doctors, accounts of tranquilizer withdrawal being "worse (more difficult) than" heroin or cocaine – especially since these drugs were touted as better than previous generations of tranquilizers, and, by the misinformed or uninformed, as relatively harmless pills – circulated through the media and by word-of-mouth.

Finally, on August 15, 1973 the newly-created DEA proposed adding Librium and Valiumto the Controlled Substances Act [3]. Previously, 7 years' worth of efforts at federal control of the drug failed, due, in part, to Roche's claims that the drug was not inherently dangerous, but only posed a risk to its users when it was misused.

This time, though, the legislation stuck as the public slowly realized that no drug is without its risks. "John R. Bartels Jr., acting administrator of the Drug Enforcement Administration [DEA], told a news conference that some people who have been issued valid prescriptions for the two drugs had been known to take 30 or 40 of the pills daily, rather than three or four as had been prescribed. 'Taking these pills is not like taking a glass of water,' he added," [3].

Today, Librium is available as a generic drug, though it is relatively seldom used – especially so in younger populations – compared to selective serotonin re-uptake inhibitors (SSRIs) (e.g., Prozac, Zoloft, Paxil) for anxiety disorders, and newer benzodiazepines (e.g., Xanax, Ativan) for short-term anxiety and panic disorder, the latter class of drugs mainly used in adults. Librium is indicated for the management of anxiety disorders or for short-term relief of anxiety, the withdrawal symptoms of acute alcoholism, and preoperative apprehension [4]. Its closely-related sister drug, Valium, has proven indispensable for treatment of anxiety and seizure disorders, and is listed on the World Health Organization's Model List of Essential Medicines [5], which are "selected with due regard to public health relevance, evidence on efficacy and safety, and comparative cost-effectiveness" [6].

As with all tranquilizers, Librium should not be used in conjunction with alcohol or other depressants, which tend to have a synergistic effect on the central nervous system.

Chorea

Lauren Connell Pavelka
University of Texas at San Antonio, San Antonio, TX, USA

Definition

Chorea ("dance") is an abnormal involuntary movement disorder, one of a group of neurological disorders called dyskinesias.

Description

Chorea is characterized by brief, irregular contractions of various muscles, and often occurs with twisting and writhing movements called athetosis. Chorea is caused by over activity of dopamine in the areas of the brain that control movement and may appear in a variety of conditions. It is a primary feature of Huntington's disease, a progressive, hereditary movement disorder that normally appears in adults. Chorea is also commonly associated with Syndenham's chorea, which occurs as a complication of rheumatic fever in about 20% of children and adolescents with the infection. Chorea can also be induced by drugs such as antihistamines, anticonvulsants, and antipsychotics, and is associated with metabolic and endocrine disorders and vascular incidents.

Treatment and prognosis of chorea depend on its type and associated disease. Because Huntington's disease is ultimately fatal, treatment is supportive. Syndenham's chorea is treatable and curable with antibiotic drugs to treat the infection. Drug induced chorea can be treated by adjusting medication dosages. Chorea associated with metabolic and endocrine-related disorders are treated according to the causes of symptoms.

Relevance to Childhood Development

Chorea in children is most commonly associated with Syndeham's chorea, or side effects from medications. Both conditions are treatable, and do not pose any serious threat to normal childhood development with adequate medical care.

Definition

The US National Center for Health Statistics defined chronic disease and chronic illness as a disease lasting 3 months or longer [6].

Description

According to the Center for Disease Control and Prevention website, common chronic health problems in adults include cardiovascular disease, cancer, and diabetes. Cardiovascular disease includes heart disease, coronary heart disease, and stroke. In 2005, cardiovascular disease was the leading cause of death in the US. Cardiovascular disease can be prevented by monitoring blood pressure and cholesterol and by having a healthy lifestyle. Cancer was the second cause of death in the US in 2005 and many people are living with cancer. Cancer can be preventative and it is treatable. Certain cancers can be reduced by having a healthy lifestyle and cancer screening helps detect the cancer at an early stage which is better for treating the cancer. A healthy lifestyle involves exercise, eating foods with vitamins and nutrition, receiving vaccinations, avoid excessive direct sun light, and no smoking. Diabetes was the sixth cause of the death in the US in 2005. Diabetes is when the body has a lack of insulin or when the body cannot use insulin. The main types of diabetes are type 1, type 2, prediabetes, and gestational. Diabetes can be preventable and controlled, but if it is not controlled it can lead to amputations, blindness, and kidney failure. The Center for Disease Control and Prevention is funding many programs to help prevent the chronic health problems in the US [5].

According to Torpy et al. [13], common chronic health problems in children include asthma, cystic fibrosis, diabetes, obesity, malnutrition, development disabilities such as attention-deficit/hyperactivity disorder (ADHD) and autism, cerebral palsy, and mental illness. According to Perrin et al. [12], chronic health problems that are on the rise in children include obesity, asthma, and attention-deficit/hyperactivity disorder (ADHD).

The Mayo Clinic Staff [11] and Perrin et al. [12] defined obesity in children as children with a Body Mass Index (BMI) of 95th percentile or above in regard to children with the same age and gender. Body Mass Index (BMI) is calculated by dividing the child's weight in kilograms by the square of the child's height in meters [7]. As seen in the Mayo Clinic website, overweight children are considered children with a BMI between 85th percentile and 94th percentile. According to Perrin et al., "obesity now affect at least 18% of children and adolescents, increasing from approximately 5% in 1971–1974" (p. 2756).

Childhood obesity has been linked to medical and psychological/emotional problems such as:

- Low self-esteem
- Eating disorders such as binge eating disorder and bulimia nervosa
- Depression

- Body dissatisfaction
- Behavior problems
- Sleep disorders
- Medical problems such as adult obesity, type 2 diabetes, skin infections, high blood pressure, asthma, liver disorders, metabolic syndrome
- Depression

Adapted from [1, 8, 11].

The Mayo Clinic Staff [10] defined asthma as the inflammation of the airways making the airways excessively sensitive causing either coughing, wheezing or breathing problems. According to Perrin et al. [12], "asthma is now estimated at almost 9% among children and adolescent in the US, doubling since the 1980s" (p. 2756). Children with asthma have been associated with medical and psychological/emotional problems such as:

- Psychological and social difficulties
- Trouble sleeping due to coughing, wheezing or breathing problems
- Coughing, wheezing or breathing problems
- Chest tightness
- Limited physical activity/exercise
- Medical expenses for medications

Modified from [9, 10, 15].

ADHD is associated with symptoms such as inattention, hyperactivity, and impulsivity and in childhood it is considered the most common neurobehavioral disorder [2–4]. ADHD is diagnosed by the Diagnostic and Statistical Manual of Mental Disorders Fourth Edition (DSM-IV) [2–4]. In school-aged children, the percentage of children with ADHD rages from 4% to 12% [2, 3].

Children with ADHD have been linked to medical and psychological/emotional problems such as:

- Difficulty in school
- Difficulty with family and peer relationships
- Low self-esteem

Adapted from [2, 3].

Chunking

Maria Assunta Cuffaro
State University of NY: Potsdam, Potsdam, NY, USA

Definition

Chunking is an organizational process, since it combines two or more pieces of information. Chunking can organize the information in a variety of ways. For example, consider again the nine-digit string of numbers 6 3 1 9 8 0 2 5 7. One way of chunking this string is to group into three groups of three digits each. Another organizational strategy is to impose rhythm, or melody, to the numbers [1]. One can also organize the digits by attaching meaning to them-a process where your retrieve information that has been stored before in long-term memory.

Description

When studying for tests, students are often required to remember a great deal of material. This poses difficulties for those with learning or intellectual disabilities, who may have memory problems. A strategy which benefits a student, which helps them remember important content for tests. Chunking: you study a chapter, try to recall five to seven key items. These key thoughts help trigger recall of more significant details.

Cibalith-S

Synonyms

Carbolith; Duralith; Eskalith; Lithane; Lithium; Lithizine; Lithobid; Lithonate; Lithotabs

Definition

Cibalith-S contains lithium, a naturally occurring chemical used in the treatment of mania in patients with bipolar disorder.

Bipolar patients experience fluctuations in their mood which may include episodes of mania and depression. Cibalith-S is commonly used to reduce the frequency and intensity of mania commonly associated in those with Bipolar disorder. It is believed that Cibalith-S affects the transportation of sodium cells and it may also cause a change in catecholamines. Common side effects of this medication may include nausea, becoming thirsty and urination. Lithium toxicity is a common problem. Therefore, patients taking this medication must have constant monitoring.

Citizenship

►Social Responsibility

Clark, Kenneth Bancroft

Heath Marrs, Kenny Foster
Central Washington University, Ellensburg, WA, USA

Life Dates

(1914–2005)

Introduction

Kenneth Bancroft Clark was a famous African-American psychologist who is best known for conducting the "doll studies," which examined the racial identity and self-concept of African-American children in the 1940s and 1950s [5]. His research findings were prominent in the discussion of the negative effects of racial segregation in the public schools and in society in general.

Educational Information

Kenneth Clark earned a bachelor's degree from Howard University and his doctoral degree from Columbia University in 1940. He served as a faculty member at the City College of New York throughout the duration of his career, and also served as a visiting professor at Columbia University, the University of California Berkeley, and Harvard University. Together with his wife Mamie Phipps Clark, he opened the Northside Center for Child Development in Harlem, which provided much needed social and mental health services to the Harlem community (Benjamin, 2007).

Accomplishments

Along with his wife, Mamie Phipps Clark, Kenneth Clark conducted a number of studies, commonly referred to as the "doll studies," that helped to establish the negative effects of racial segregation in public schools on the self-concept and personality development of African-American children. This research was cited in the arguments for the 1954 U.S. Supreme Court case *Brown* vs. *Board of Education* case, which outlawed the practice of racial segregation in public schools.

In the "doll studies", Clark examined the reactions of black children when presented with dolls of various skin colors (light, medium, dark) to play with [2]. In analyzing the responses of the black children, Clark found that the children had developed a preference for the light (or white) dolls and negative attitudes towards the dark (or black) dolls. These responses were interpreted as evidence of the negative effects of racial segregation and prejudice in the 1930s and 1940s on the self-concept and personality development of black children.

Benjamin and Crouse [1] assert that Clark's studies are some of the most significant in the history of psychology because it marked the first time that social science research was used in the reasoning for a Supreme Court decision. They suggest that this decision validated psychological research as an appropriate foundation for issues related to public policy. A summary of the relevant research that was written by Clark was cited in a footnote of the decision as supporting evidence that segregated schools were harmful to black children [4].

In addition to his prominent work as a researcher, Kenneth Clark was active in the American Psychological Association, serving as the first African-American president of the association in 1971. He also was a prominent spokesman on issues of race, prejudice, and discrimination; he was appointed by President Lyndon B. Johnson to serve on the Kerner Commission, which examined the possible influences on the urban riots of the 1960s [4].

Classical Autism

▶Autism

Classical Conditioning

Pei-Hsuan Hsieh
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Conditioning; Pavlovian or respondent conditioning

Definition

Classical conditioning is a type of learning where an individual learns to produce an involuntary physiological or emotional response as a result of the presentation of neutral stimulus repeatedly paired with an unconditioned stimulus.

Description

Ivan Pavlov, a Russian physiologist, received the Nobel Prize for his research on the digestion. As he was studying the digestive process in canines he realized that dogs began to salivate when the lab attendants walked into the room and before the dogs received their food. Pavlov originally used the term "psychic secretions" to explain that the salivation was due to the physiological power of

the digestive system through nervous input. The secretions were considered to be a reflex mechanism of psychic operations but Pavlov continued his experimentations and was eventually able to provide support that the "psychic secretions" were actually reflexes. Pavlov continued to conduct experiments that would eventually support his hypothesis of conditioned reflexes. Pavlov had the desire to prove that the conditioned reflexes were elicited responses that could be controlled and manipulated through the pairing of two previously unrelated stimuli. Driven to verify his theory of conditioned reflexes, Pavlov created his now well-known research in which he repeatedly paired a bell with the food being give to research dogs. The dogs in his research eventually displayed an increase in salivation at the sound of the bell despite the fact that the food was no longer being presented. Pavlov noted that the dogs were not only responding to the biological necessity of hunger but they were also attempting to satisfy the newly conditioned need developed by learning.

At the core of classical conditioning are the basic tenets of the concept: Unconditioned stimulus (UCS), unconditioned response (UCR), conditioned stimulus (CS), and conditioned response (CR). The unconditioned stimulus is an object or event that automatically elicits an unlearned physiological or emotional response. The unconditioned response is the unlearned physiological or emotional response caused by the UCS. The conditioned stimulus is a neutral stimulus that when paired with the UCS causes an automatic response. The conditioned response is the learned physiological or emotional response caused by the CS. Pavlov demonstrated that classical conditioning typically occurs when two stimuli are presented at approximately the same time and is most likely to occur when the CS is presented just before the UCS so that associations can be made.

Following the experimentation on dogs and other animals, Pavlov and subsequent researchers began to study the application of classical conditioning on humans. Pavlov's research has been valuable for the treatment for insomnia, chemical dependency, dietary issues, anxiety, and a variety of other human disorders. It is also noted that classical conditioning has been used in academic settings as well as in the advertisement field.

Relevance to Childhood Development

Classical conditioning can be used to explain how children learn a variety of automatic physiological and emotional responses. Children can develop dislikes for foods, darkness, a school subject, and even school in general. In some instances, children may fear school (CS) because of a previously negative experience such as being yelled at by the teacher, being punished for speaking out in class, being ridiculed by classmates, or being reprimanded for a poor grade. School then becomes associated with these negative experiences thus learning to fear (CR).

To alleviate children's fear of school or any other negative emotions, teachers should introduce the academic subject manner in a positive climate and associate it with positive emotions. To elicit positive emotions, teachers can provide students with a safe and orderly environment. When questioning students, allow students to share their opinions and make them feel safe. This can be done by asking open-ended questions. By using these strategies, children may associate positive emotions with the class and with school.

Making association is the basis to learning in classical conditioning.

Classroom Climate

Gary Alderman
Winthrop University, Rock Hill, SC, USA

Synonyms

Classroom environment; Educational environment; School climate; Social environment; Teacher student relationship

Definition

There is a multiplicity of definitions for classroom climates that are quite varied and include a range in emphasis from the study of just one variable too many variables that make up a classroom environment. Generally the classroom climate is considered that milieu that consists of the interactions of the educational, psychological, social, cognitive, organizational, and physical variables that impact how students learn and function.

Description

The classroom climate is a conglomeration of many variables. Some of these variables have been examined in isolation in order to show any distinct impact they may have on students and/or teachers while the interaction effects on the classroom climate of two or more variables have also been studied. The study of classroom and school environments had its roots in the early study of organizational climates in the business world [1] and through initial work on perceptions of the classroom environment [13]. These early studies produced an emphasis on the measurement of environments that has strongly influenced the study of classroom climate. A number of instruments have been developed and used to measure the classroom climate. These instruments usually require that a teacher, student, parent, or some more "objective" individual complete the scale to determine what aspects of the climate are more effective than others. Some examples of the instruments used include My Class Inventory [5]; the Classroom Environment Scale [5]; the Learning Environment Inventory [5]; the Individualized Classroom Environment Questionnaire and the Modified Classroom Climate Inventory [5]; The Classroom Environment Questionnaire [15]; The Children's Classroom Environment Scale [7]; the Barclay Classroom Assessment System [2]; and the Inventory of School Climate-Student [4]. Others scales and methods for measurement are informal and are often developed specifically for the purpose of a particular classroom or school (see Freiberg's book [6]).

The many components examined to determine the impact on and the constitutions of the classroom climate are listed below as general categories most often seen in the literature. It should be noted that this list specifies those variables related to classroom climate as opposed to school environment. Assessment of the components of the school environment has some distinctive differences from the study of the classroom climate and the two are often considered separately in terms of their impact on students. Whether they should always be studied separately is somewhat controversial as some researchers believe that the confluence of the fields may be just as important as the impact of each separate area [5].

Teacher-Student Relationships

This area would include examination of variables such as positive emotional experiences; degree of positive teacher support; types of personal/supportive language used with students; students' perceptions of teachers' emotional support; sense of belonging; teachers' tolerance levels (as well as students' perceptions of teachers' tolerance); and student shared decision making.

Approaches to Pedagogy

These approaches determine the type of instructional style being used and assess the impact on climate and various student outcomes. Examples here would include authority versus democratic approaches to instruction; invitational versus moral educational practices; cooperative versus competitive structures; authority-supportive motivational teacher practices; formal versus informal learning structures; whole-group versus individualized instruction; explicit versus implicit rule structure for academics and face-to-face versus digital/virtual approaches [8].

Ecological Issues

The physical components of a classroom are considered an important part of the development of classroom climate and would include areas such as physical size of the classroom space; number of students in the class; air quality; lighting; acoustics; physical comfort; school subject; grade level; and physical arrangement of the room (e.g., furniture, organization of desks).

Impact on Various Groups

In this category the literature has examined how classroom climates effect and are created by issues related to gender, ethnicity, and disabilities, and the types of students that make up a class.

Student-to-Student Relationships

A classroom climate may have an impact on how students interact with each other and a climate may be developed based on the types of social interactions among students.

Behavior Management Practices

Although the above categories overlap with behavior management approaches (especially those involving teacher-student relationships), more specifically issues such as a teachers degree of conflict; emotional support with maladjusted behaviors in students; consistency of behavior management practices; rules and procedures; and clarity of goals are all important. Likewise, the types of student misbehaviors are important in their impact on classroom climate.

Student Self-Issues

Classroom climates can be developed by and have an impact on student "self-issues" such as motivation; self-efficacy; problem-solving; and social-emotional competence.

Relevance to Childhood Development

Fraser (5, p. 1) states that "…..(research presents) compelling evidence that the classroom environment is such

a potent determinant of student outcomes that it should not be ignored by those wishing to improve the effectiveness of schools." Much of the research on the impact of classroom climate establishes very detailed connections between climate variables and outcomes while others establish links between the quality of the climate and the effects on students, teachers, and the overall efficacy of the classroom. Although not comprehensive in its delineation of the impact of the classroom climate some of the major findings will be summarized here.

In terms of teacher-student relationships it seems clear that the stability of the relationship; the use of emotionally supportive language and practices; the provision of emotionally positive experiences; and the evidence of more tolerance with less conflict have positive impact on students. Some of the outcomes include greater academic productivity, higher student motivation, and more productive teacher-student relationships. Similarly, behavior management practices that are clear, consistent, tolerant, less punitive, and more emotionally supportive, evidence less aggression, fewer behavior problems, and more prosocial behaviors and create a classroom climate that is rated by students and teachers as being more positive and productive.

Approaches to pedagogy have been shown to have significant influence on the classroom climate. A combination of Moral and Invitational educational approaches produces classroom climates that are conducive to growth and encourage students to make decisions regarding right and wrong leading to more inviting and just classrooms [3]. Although benefits have been shown with both a competitive and cooperative approach, there are some suggestions that cooperative approaches to learning may lead to a more positive shared experience and better negotiation among students. An Autonomy-supportive motivational style of pedagogy appears to lead to greater self-determination and a stronger teacher-student relationship [14].

Ecological and social variables have also shown positive student outcomes. Class size, learning space size, acoustics and other physical variables help create a classroom environment that improves academic engagement; prosocial behaviors; student and teacher satisfaction; and overall learning [8]. In the area of social improvements, classroom climates have been found to be more productive when students improve in self-efficacy, problem-solving, and social-emotional competence [10]. Similarly, student-to-student relationships improve when the classroom climate is marked by evidence that teachers are giving high quality emotional support, respect, and evaluative feedback [12, 16]. Finally, it appears that teachers who understand equity/diversity issues create classrooms that are more equitable [9] and that student perceptions of classroom climate may be more influenced by the group of students in the classroom than by the teacher [11].

Understanding the multiplicity of variables involved in the constitution of a classroom climate is crucial to those working and consulting in the schools. Being able to manipulate many of the antecedent conditions inherent in the climate of a classroom may be more effective than trying to change student and teacher attributes that may be less malleable. Most certainly, one must also consider that a working knowledge of classroom climate could be beneficial in preventing problems related to behavior, academics, and relationships.

Classroom Integration

Molly Millians
Marcus Autism Center, Atlanta, Georgia, USA

Synonyms

Integrated education; Integrative classroom

Definition

Classroom integration refers to the process of providing age-appropriate and quality education for students with and without disabilities in a shared learning environment.

Description

Since the mid to late 1990s special education reforms have focused on ensuring that students with identified physical, emotional, behavioral, intellectual, and or academic disabilities have access to the same educational experiences as their non-disabled peers [3]. Classroom integration refers to the assimilation of students with disabilities into the general education classroom [1, 2]. Often the term classroom integration is used synonymously with the term inclusion. However, inclusion refers to the process of school-wide reforms to develop a learning community to meet the needs of all students [1–3].

In an integrative classroom, students with disabilities are provided access to the general curricula. Educators modify the curricula according to students' educational needs. Students with disabilities receive individualized educational interventions within the mainstream classroom. Additionally, an integrative classroom facilitates social interactions among students with disabilities and classmates without disabilities [2].

Studies investigating the efficacy of classroom integration in Western countries have shown inconclusive results [2]. Several studies have indicated that students with disabilities showed increases in academic achievement, task completion, and improvements transitioning to adulthood. Other studies have indicated that students without disabilities who receive instruction in an integrative classroom perform as well as students in a non-integrative setting [1]. However, the success of classroom integration varies across school districts and classrooms.

Classroom integration has been successful when instruction is provided through the collaboration of a general education instructor and a special education teacher. Also, Classroom integration has been successful when teachers receive training on ways to provide instruction to diverse learners, have access to necessary resources, such as alternative curricula, assistive technology, and materials, and are supported by administrators, therapists, and school personnel [1, 2].

Classroom integration is a practice increasing in popularity worldwide [3]. Yet, educators and advocates continue to debate the efficacy of classroom integration in meeting the needs of students with and without disabilities.

Classroom Management

Jackie Kibler
University of Montana, Missoula, MT, USA

The term classroom management refers to how the learning environment is structured and organized to optimize the on-task behavior and knowledge acquisition of students [1]. It is a term that involves the physical set-up of the room, strategies utilized by the teacher, activities given to students, monitoring of student behavior, and altering instructional practices when necessary.

Oklahoma State University, Stillwater, OK

Synonyms

Cleft

Definition

Congenital anatomical defect which may be an overt or submucous, complete or incomplete, unilateral or bilateral opening in the floor of the nose which structure also serves as the floor of the mouth. Such defect allows for inappropriate communication between the nose and the mouth. The cleft may: exist in the soft palate, (i.e., muscle and/or epithelium), only; exist in the form of an isolated hard palate cleft, (i.e., bone, muscle and epithelium); or extend through both the hard and soft palates. In addition, a combination of clefts may present in a given individual. Clefts may also involve the primary palate, (i.e., anterior portion of the palate), and/or the secondary palate, (i.e., posterior portion of the palate).

Description

Overt cleft palate is an opening in bone, muscle and soft tissue of the roof of the mouth which structure also serves as the floor of the nose. A submucous cleft palate is a defect in bone and/or muscle, however, the soft tissues (i.e., epithelium and mucous membrane) are intact, resulting in a less than obvious defect. A complete cleft palate extends into the upper alveolar ridge, preventing proper eruption and alignment of the dentition, whereas an incomplete cleft palate does not.

A cleft of the primary palate results from a failure of the left and right nasal processes and the left and right maxillary prominences to fuse in midline at approximately 6 weeks of fetal age. A cleft of the secondary palate occurs during the 11–12 week of embryonic life due to a failure of the left and right palatine processes to fuse with the vomer bone and/or failure of the muscle and epithelium of the soft palate to fuse. A theory of post-fusion rupture has also been advanced as a possible explanation of clefting, however, the theory is not well-accepted. Cleft palate may be associated with other midline defects such as heart and urogenital defects and is often associated with cleft lip. Cleft palate is associated with most cases of Pierre Robin Sequence. In addition, three hundred and fifty or more syndromes involve cleft palate, some of the more common being velocardiofacial syndrome, Van der Woude syndrome, Stickler syndrome, Apert syndrome, Crouzon syndrome, and Treacher Collins Syndrome, also known as mandibulofacial dysostosis [7]. Additionally, cleft palate defect may also occur in the absence of other anomalies. In the absence of genetic or syndromic-associated cleft palate, prenatal maternal exposure to teratogens has been offered as an explanation for the defect.

Overall incidence of cleft palate in isolation ranges from 1 in 2,500 to 1 in 3,000 live births. Incidence for cleft lip with or without cleft palate is significantly higher at 1 in 250 to 1 in 1,000 births. Incidence is higher in females for cleft palate alone and males demonstrate a somewhat higher incidence of cleft lip with or without cleft palate. Whereas cleft lip, in isolation, is more common in Asians and Native Americans than in Caucasians, and least common in blacks, cleft palate alone is equally distributed amongst Asians, Caucasians, Native Americans, and Blacks [7].

Children born with a cleft palate are at increased risk for upper respiratory and middle ear infections, dysphagia; and failure to thrive secondary to poor feeding. The ability to properly and safely feed a baby with a cleft palate can be greatly improved through positioning of the infant and use of the proper feeding apparatus. Infant mortality associated with cleft palate remains high in developing countries where a modicum of medical care is available [5].

Cleft palate is commonly closed at 9 months to 1 year of age in developed countries; however, much controversy remains as to the timing of palatal surgery. Debate continues as to the effect of early palatal closure on midfacial growth, however, the need to close the palate to allow for speech development has resulted in palatal closure during the first year of life for most non-syndromic children. The mucoperiosteum and mucosa overlying the bone is often excised, pulled over the defect and sutured closed. Cleft of the primary palate may be closed through alveolar bone grafting. Post-surgery care includes steps to prevent reopening the cleft until such time as it is healed. Foods, fingers, and instruments inserted into the mouth by the child during the post-surgical healing period can reopen a newly closed palate. Development of a palatal fistula following cleft repair is common and success of fistula repair may be dependent upon the closure technique employed [1]. A partial list of cleft palate associated surgeries includes: alveolar bone grafting; palatoplasty or palatorrhaphy; primary palatoplasty; pharyngeal flap or pharyngoplasty; and primary veloplasty. Numerous surgeries may be required, in particular when both the palate and lip are affected.

Malocclusion is commonly associated with cleft palate and involvement of dental professionals is extensive. The dental team treating cleft palate often includes orthodontists, prosthodontists, and oral surgeons. There will be extensive involvement of dental professionals throughout the childhood of most children born with a cleft palate.

Hearing loss is also commonly associated with cleft palate. Hearing loss ranges from otitis media induced conductive hearing loss to mixed conductive/sensorineural loss. Congenital sensorineural hearing loss and ear malformation are common in syndrome-associated cleft palate. The incidence of otitis media in babies with cleft palate is upwards of 90% [3] in contrast to 20% in non-cleft babies and sensorineural hearing loss in adulthood is not uncommon. Placement of pressure-equalization tubes or ventilation tubes in the tympanic membrane of children with clefts is common, but is not universally performed. Long-term follow up of children with clefts by otologists and audiologists is most often necessary.

Cleft palate is often associated with delayed and/or abnormal speech development. Problems include hypernasal speech resonance due to leakage of air into the nasal cavity. The nasal cavity is typically closed for production of all speech sounds except "m, n, and ng." In cases of cleft palate, air leaks into the nose for production of all speech sounds, both consonants and vowels. Following palatal closure surgery, continued hypernasal resonance, heard when vowel sounds are produced, may be indicative of a more pervasive issue, velopharyngeal insufficiency, inability of the soft palate and pharyngeal walls to act as a patent sphincter and separate the nasal from the oral cavity completely. This is not uncommon; velopharyngeal insufficiency following palatal closure is estimated to occur in 16% [6] to 49% [2] of cases depending upon the palatal repair technique employed. Further surgery, such as pharyngeal flap placement, may be indicated. Abnormal speech articulation is also commonly observed in children with cleft palate. Consonants normally produced at the back of the mouth, such as "k" and "g" may be produced more frontally, the pattern appropriately termed "fronting." In addition, consonant sounds may be produced through the nose resulting in inappropriate ejection of air through the nose, also appropriately termed "nasal emission." In less common cases, the inability to impound oral air pressure needed for consonant production due to leakage of air through the nose may result in compensatory impounding of air at the vocal cords. Such sounds are termed "glottals" and can be heard non-pathologically in the dialect of Cockney English. The speech–language pathologist is often involved in the care of children with clefts from birth for feeding issues and prevention of dysphagia, through early to late childhood for management of speech, and, less commonly, language issues.

Persons born with a cleft palate should be genetically counseled in adulthood as to their risk of defect transmission to offspring. The risk of genetic transmission of cleft palate ranges from 0.08% when no other family member is affected to greater than 30% when two siblings are affected [7]. Routine genetic testing of all persons with cleft palate is advocated by some [4].

Client-Centered Therapy

Tony Wu
Walden University, Diamond Bar, CA, USA

Synonyms

Humanistic therapy; Person-centered therapy; Rogerian psychotherapy; Unconditional positive regards for the client

Definition

Client-centered therapy is a modality in which client is the agent of change. The change process will take place when the therapist has created a safe, non-judgmental, and suitable therapeutic environment.

Description

Positive emotion has become increasingly important because research has shown positive feeling can enhancing human functioning [8]. It is this fundamental assumption that client-centered therapy is based. In other words, a warm, accepting, and genuine relationship will allow the client a deepening of experiences which promote integration of positive emotion and health. This ability to experience positive emotions in therapy session is a therapeutic goal; however, the ultimate goal is for the person to become fully functioning in which emotional processing is enhanced. Rogers [5] argued that client-centered therapy permits a person to become highly fluid, relativistic, genuine, and true to self. In therapy session, client-centered approach assumes that the client is highly motivated to become more balanced, mature, and self actualized; client is the main agent of change.

The term client-centered or person-centered was proposed by Carl R. Rogers in his theories of psychotherapy, group process, personality, development of pathology, education, marriage and interpersonal relationships [4, 6, 7]. There are more than 50 years of data supporting this model of positive emotional changes. For example, about half of the clients who received client-center therapy improve in their functioning [2]. These changes in psychological functioning are facilitated by the therapist's congruence, unconditional positive regard, and empathic understanding of the client's internal frame of reference, and nondirective attitude and stance [3].

In a typical psychotherapy session, the client communicates verbally to the therapist through narration and nature behaviors that mirror his or her inner state, life experiences, and current concerns and challenges. The person-center clinician listens empathically and attempts to understand client's thoughts and feelings from the client's perspective and referencing points. The therapist would reflect, summarize, and synthesize the situation in order to clarify and make sense of client's concerns [1]. It is through this empathic understanding response that the client is able to process and bring about positive changes in his or her life and become a fully functional individual.

Synonyms

Clozapine (generic)

Definition

Clozaril is an atypical antipsychotic drug and a tricyclic dibenzodiazepine derivative. Clozapine is the generic form of Clozaril.

Description

Clozaril is used to manage psychotic symptoms associated with schizophrenia or similar disorders when other treatments have failed. It is also used to treat recurrent suicidal behavior, agitation, bipolar disorder, and tremor in Parkinson's disease.

Some side effects of Clozaril may include: constipation, drooling, increased sweating, drowsiness or dizziness, sleep problems, nightmares, and weight gain. More serious side effects, which require immediate medical care include: shortness of breath, swelling of hands or feet, fever, weakness, sore throat, stiff muscles, confusion, irregular heartbeat, numbness/weakness, headache, confusion, problems with vision, speech, or balance, chest pain, wheezing, rapid breathing, pain or swelling in the legs, white patches or sores inside of mouth or lips, nausea, vomiting, loss of appetite, jaundice, or seizures.

Before taking Clozaril, patients should discuss previous medical history (especially concerning blood disorders, heart disease, irritable bowel syndrome, respiratory problems, diabetes, glaucoma, kidney and liver disease, obesity, and seizures) with a physician, and note any known allergies.

This review of Clozaril contains general information. For complete information about Clozaril and individual use, a health care professional should be consulted.

Relevance to Childhood Development

Clozaril's safety and effectiveness in pediatric patients have not been established. This medication typically is used

only when other treatments have failed because it can cause serious side effects such as agranulocytosis (impaired white blood cell count). Because of the risk of agranulocytosis, and other serious complications of the immune system, patients need to have blood tested before, and intermittently during, treatment with Clozaril.

Cocaine

Cocaine (benzoylmethylecgonine) is a crystalline alkaloid obtained from the leaves of the coca plant. The term comes from coca in addition to the alkaloid suffix - ine - forming the word cocaine. Cocaine acts as a stimulant in the central nervous system as well as an appetite suppressant. In the synapse it is a serotonin - norepinephrine - dopamine re-uptake inhibitor causing elation and a sense of heightened sensory awareness. Given its action in the synapse, cocaine is potentially addictive. The possession, cultivation and distribution of cocaine is illegal for non-medicinal and non-government sanctioned purposes in nearly every country worldwide. Despite this fact and harsh penalties for possession or distribution, the worldwide use of cocaine is widespread.

Coercion Theory

Elaine A. Thomas
Argosy University, Atlanta, GA, USA

Synonyms

Coercion model

Definition

Coercion Theory [1–3], developed by Gerald Patterson and colleagues at the Oregon Social Learning Center (OSLC), describes how aggressive and antisocial behaviors develop in children. Derived from extensive behavioral research on the moment-to-moment interactions in families, it specifies how ineffectual parental responses to problem behavior result in escalating aversive and aggressive behaviors in children in the short-term. It also describes how frequent repetitions of such coercive cycles result in a progressive worsening of aggressive behaviors in both variety and intensity coincident with lack of parental control over the aggression.

Description

The parent–child interactions that, over time, will result in increased likelihood of aggressive behaviors in the child while resulting in loss of parental control over aggressive

behaviors, and the learning principles that explain this, are outlined by the coercion model [3]. This process starts in a family where there is poor parenting in a cycle that may be described as follows. The parent gives a vague command requesting compliance from a toddler who is exhibiting some oppositional behavior. The parent repeats the ineffectual command while the toddler responds with more aversive or aggressive behaviors such as whining, crying or tantruming. The parent eventually gives in, withdraws, and does not follow through on the request. The toddler's aggressive behaviors cease while the parent obtains relief from the termination of the child's aggressive behaviors. These interactions are likely to perpetuate over time as the toddler's escalating aggressive behaviors are likely to reoccur as they terminate the parent's perceived aversive requests for compliance. At the same time the parent's acquiescence is likely to increase because it terminates the child's aversive behaviors. Strengthening of both sets of responses occur primarily through the process of negative reinforcement. Therefore, both parties actively "train" a repertoire of behaviors in the other [1, 2]. Positive reinforcement of behaviors may also occur as well, as initial parent responses may result in the child achieving a desired outcome. In families where this occurs, again due to ineffectual parenting, the child is likely to fail to develop prosocial skills and will increasingly use aversive and aggressive behaviors in interaction with others. Use of coercive behaviors becomes an entrenched style as they will also occur in other relationships such as those with siblings, peers and other adults [4].

Relevance to Childhood Development

Coercive cycles begin in toddlerhood when developmentally the child's behaviors become more challenging for parents due to autonomy seeking and independence coincident with more advanced motor, cognitive and language skills. In the face of poor or inconsistent discipline coercive cycles begin and become more entrenched over time as they typically co-occur with lack of reinforcement of adaptive and prosocial behaviors. According to coercion theory the coercive cycles are a primary mechanism producing aggressive behaviors. Coercion theory therefore describes the transactional processes that are a major precursor to a developmental trajectory of antisocial behavior.

Coffin Syndrome

▶Coffin-Lowry Syndrome

Coffin-Lowry Syndrome

Anne L. Corcoran, Maria G. Valdovinos
Drake University, Des Moines, IA, USA

Synonyms

CLS; Coffin syndrome; Mental retardation with osteocartilaginous abnormalities

Description

Coffin-Lowry syndrome was first identified as a distinct syndrome in 1966, when Coffin and colleagues noted two unrelated male patients with an X-linked disease marked by severe mental retardation (MR), short stature, skeletal deformities, and large, soft hands with tapering fingers [1]. Years later and unaware of Coffin's findings, Lowry made similar clinical observations of a large family containing ten affected members. In 1975, Temtamy recognized similarities between these two doctors' work and his own observations of eight comparable cases across three different families. Temtamy synthesized the symptoms into one syndrome, acknowledging the discoveries of both Coffin and Lowry [11].

The prevalence of Coffin-Lowry syndrome is not definitely known, but has been estimated to be about 1 in every 50,000 to 1 in every 100,000 people. However, this prevalence rate could be underestimated, due to the syndrome's resemblance of other disorders characterized by mental retardation and similar physical features, such as Williams syndrome, alpha-thalassemia with MR, Fragile X syndrome, lysosomal storage disease, and chromosomal anomalies [4, 12]. The syndrome equally affects families of European, Asian, and African origin.

Genetics

Genetic mapping has identified the p22.2 region of the X chromosome as the area responsible for Coffin-Lowry syndrome [12]. A gene corresponding to this interval of the X chromosome encodes the growth-factor-regulated protein kinase known as RSK2 (ribosomal protein S6 kinase-2), which is found in human tissues including the heart, pancreas, and skeletal muscle. The RSK2 gene is split into 22 exons and encodes a protein of 740 amino acids. The gene is activated in response to any of a series of cellular stimulations, including stimulation from insulin and growth factors, neurotransmitters and ultraviolet radiation [6, 12]. When activation occurs, RSKs regulate gene expression through phosphorylation of transcription factors, such as cAMP responsive element binding protein (CREB) [2, 6]. RSK genes have been implicated in several important cellular events including proliferation and differentiation, cell stress-response, and apoptosis. Mutations in the sequence of these genes therefore cause premature termination of translation and/or loss of phototransferase activity [14]. However, because the number and type of mutations and the associated symptoms observed in CLS are so heterogeneous, the precise effects of specific mutations remain unclear.

A significant proportion (70–80%) of individuals with CLS are probands, meaning there is no family history of the syndrome. Their mutations are considered *de novo* (novel), as compared to the other 20–30% of affected individuals who have more than one affected family member [2]. However, having a family member with an RSK2 mutation does not necessarily mean that another affected relative will have the same mutation [3].

The most recent research has reported more than 140 distinct mutations in the RSK2 gene [5, 9]. Other researchers have identified 128 mutations. Of these 37 (29%) were short insertion or deletion events in the coding sequence; 4 were large genomic deletions encompassing one to three exons; 26 (20%) were accounted for by splice alterations; 19 (15%) were nonsense mutations, and 42 (33%) were missense mutations [2]. Interestingly, 114 of those 128 mutations were found to be private mutations, occurring in only one family. This growing number of mutations, along with the absence of consistent relationships between specific mutations and severity of symptoms or expression of particular features, create difficulties when trying to systematically analyze the gene for CLS diagnosis using current techniques. Thus, many cases of Coffin-Lowry syndrome are diagnosed based strictly on the phenotypic presentation of the syndrome.

Diagnosis

Early diagnosis of Coffin-Lowry syndrome is necessary for appropriate management of the disease. Screening for ribosomal S6 protein kinase mutations and genetic counseling can help parents estimate and prepare for the severity of symptoms of their child. However, while RSK2 protein is readily detectable in cultured amniocytes, allowing for prenatal CLS screening, current genetic testing cannot detect female carriers because of random X activation. There are, however, physical signs observed during pregnancy that might suggest CLS short of genetic testing. These signs associated with CLS include: low intrauterine growth, excessive amniotic fluid, and reduced fetal movements before delivery (birth weight is usually normal) [12].

Physical Abnormalities

Typical adult male CLS patients are of short stature and have characteristic facial features such as a prominent forehead, hypertelorism, thick lips, prominent, low-set ears, and downward-slanting eyes. Dental anomalies are common and include a high, narrow palate, missing or irregular teeth, and malocclusion, Sleep apnea is a common problem when the combination of a large tongue and teeth, and small jaw occur in an individual, characterized by snoring and daytime fatigue. This has, however, been reduced when the tonsils are removed, or as the jaw shifts with age. Their large, puffy hands with tapering fingers are the most universal characteristic and are occasionally the basis for a clinician's diagnosis of CLS.

Skeletal abnormalities in CLS are common, severe, and tend to deteriorate progressively throughout life. Males have occasionally displayed hypotonia and hyperlaxity of joints before the first month. Though a delayed closure of the anterior fontanelle, or "soft spot," on the infant's head may not be observed until the age of 2, most skeletal abnormalities are not evident until after 2 years of age. The most probable early physical signs include a prominent forehead, a bulbous nose with anteverted nares, full upper lip and wide mouth, full forearms, tapered fingers, microcephaly, and possibly hearing deficits and sternal malformations.

Approximately 95% of patients are of short stature [2]. Final adult height is usually between the third and fifth percentile, or around 143 cm. However, a normal stature does not exclude a diagnosis of Coffin-Lowry syndrome [12]. Such short stature is mainly due to the spinal deformities that so frequently affect individuals with CLS. Narrow intervertebral spaces, congenital spinal stenosis, and scoliosis with dysplasia of vertebral bodies may be caused by associated ligamentous laxity and changes in the intervertebral disks [12]. A reported 80% of individuals

are affected by kyphosis or scoliosis, in which the front-to-back and side-to-side curvature of the spine is extreme and degenerative. These deformities often require corrective surgery, though determining when to have the procedure completed is a complicated issue. Typically, it is recommended that the spine not be adjusted until a person has reached puberty and the spine has undergone its growth spurt, but since individuals with CLS are often delayed in their developmental milestones, puberty may take longer to reach. Nonetheless, in many cases families have reported improvement of patients' conditions after surgery.

Brittle bones are also typical in Coffin-Lowry syndrome. In a series of experiments researchers identified one of the proteins activated by RSK2, called ATF4 [13]. They examined the effects of this protein on bone formation in cell cultures and mice. Their findings revealed that, like Coffin-Lowry patients, mice lacking RSK2 had shorter, less dense bones and bigger gaps between skull fragments at birth. Those mice lacking ATF4 had even more severe deformities, including thinner, fewer bone tissue strands called trabeculae. Following this discovery, bone-forming cells called osteoblasts were examined to determine why these deformities occurred. Findings suggested that cells lacking ATF4 are slower to differentiate and become mature osteoblast cells. In addition, these cells were unable or failed to produce sufficient Type 1 collagen, the main component of bones. This study has great implications for Coffin-Lowry, and seems to explain why the symptoms of the disease worsen over time. With less and less collagen being produced, the bone simply continues to degenerate more and more over time. This could mean, however, that corrections in the system could be encourage by something as simple as a diet rich in protein, giving hope to many affected individuals. Trials are still currently testing this theory.

Developmental Deficits and Delays

Diagnosis in childhood is more difficult compared to older patients, as most physical abnormalities are mild or unnoticeable at birth and throughout infancy. However, in the first few months growth retardations and delayed psychomotor development may become apparent [14]. Developmental milestones are often delayed. Sitting, crawling and walking take longer to master and, once developed, individuals may have an ataxic gait. Loss of strength and muscle mass is common, as well as progressive spasticity and even paraplegia, due to the calcification of the ligamenta flava and congenital spinal stenosis.

Speech delays are reported in nearly every single case of the syndrome. This is in part due to the frequency of hearing loss that occurs in many patients, but also may be caused or worsened by the severe malformation of the mouth and facial structures. It is estimated that about one third of those with CLS have significant deafness [12]. Hearing aids may be useful, but it is recommended that hearing tests be administered frequently starting at an early age, to promote language development capabilities.

Sensory integration issues also arise in early childhood. Children with CLS are noted to have trouble interpreting and organizing incoming sensory information, leading to further problems in development and behavior. For example, impairment in the tactile sensory system can cause sensitivity or aversion to touch, general irritability, and hyperactivity. Those with CLS are observed to engage in sudden "drop" episodes, which are thought to be non-epileptic and, instead, due to overstimulation of the senses such as a loud noise or an overly exciting situation.

Cognitive deficits are a common factor in Coffin-Lowry syndrome, though levels of impairment are variable and may be attributed to hydrocephaly and agenesis of the corpus callosum sometimes observed in those with CLS. Males are more likely to have moderate to profound mental retardation, with IQ scores ranging from 15 to 60, but clustering mainly in the severe range [8]. Females are often much less affected cognitively, and may appear to have normal levels of cognitive functioning and IQ, which can lead to a misdiagnosis of the individual.

Research on the range of cognitive impairments across unrelated families with the same missense mutation has shown no evidence for intellectual deterioration with age [10]. However, a distinct hierarchy of cognitive abilities has been detected across normal, to carrier, to affected individuals. Still, other findings suggest that the level of mental retardation may be influenced by the quality of care received [12]. Some reports show MR as being only moderate in those individuals who were evaluated as having been properly cared for and describe the acquisition of substantial oral communication, though this is frequently a challenging area for individuals with CLS.

Other Complications

Other complications may be present in Coffin-Lowry syndrome, including sensorineural deafness, seizures, drop episodes, and cardiac disease. Cardiac problems include mitral valve regurgitation, heart murmur, cardiomyopathy, endomyocardial fibroelastosis, and "sudden death" instances. The incidence of cardiomyopathy may be underestimated in CLS, as moderate forms of these conditions may go unnoticed by both the patient and tests such as echocardiography and myocardial biopsy [12].

Behavioral problems similar to those seen in autism and other development disorders have been occasionally reported in CLS cases such as repetitive behaviors (perseverance, echolalia), severe temper tantrums and emotional outbursts, especially when asked to shift activities (e.g., from a favorite game to some other activity). There is also a common disposition of disliking physical contact with others. Engagement in physical contact may evoke aggressive or self-injurious behavior from the individual with CLS, although, these behaviors are reported to be rare responses to physical contact. It is important to consider that some problem behaviors exhibited by those with CLS may be in response to underlying medical conditions such as stomach pain or infection as they are unable to communicate discomfort via speech. In general, however, individuals with CLS are said to have a pleasant personality.

Treatment

While strides have been made toward understanding the etiology and effects of Coffin-Lowry syndrome, there is no cure for the disease. Treatment can be symptomatic and supportive, and may include physical or speech therapy, and special educational programs. In some cases, medications have been used to lessen those symptoms commonly seen in other disorders. In particular, benzodiazapine drugs have been used as therapies for drop attacks, with variable success [7]. However, despite these treatments, the lifespan of individuals with CLS is on average, just 20 years.

Cognitive Assessment System

Jack A. Naglieri
George Mason University, Fairfax, VA, Canada

The Cognitive Assessment System (CAS; [3]) is a individually administered multidimensional test of intelligence based on the Planning, Attention, Simultaneous, and Successive (PASS) theory [1] (see ►PASS Theory). Twelve individual subtests (three per PASS Scale) are used to measure intelligence from a cognitive processing perspective for children and adolescents aged 5 to 18 years. The test is comprised of four scales that match the PASS abilities and a Full Scale score that represents overall ability. The Planning tests provide a novel problem-solving situation requiring self-regulation, flexible use of strategies, allocation of attention and memory, response inhibition, goal setting, and self-monitoring, and self-correction. The Attention tests require focused cognitive activity over time and resistance to distraction. The Simultaneous tests require the child to integrate stimuli into interrelated groups or a whole, typically using visual-spatial tests but also using verbal questions. Finally, the Successive tests require both the repetition of information in order and the comprehension of the sequence of verbal statements.

The CAS was standardized on a sample of 2,200 children aged 5–17 years who were representative of the

U.S. population at that time on a number of important demographic variables. The sample is a nationally representative, stratified sample based on gender, race, ethnicity, region, community setting, classroom placement, and parental education [3]. Information about the reliability and validity of the test is provided in the manual [3]. The CAS has been carefully studied since it was first published. There is considerable evidence that the test can be used to gain an understanding of how well the child thinks and learns, to uncover strengths and needs of children that can then be used for effective differential diagnosis, is particularly appropriate for assessment of minority children and adolescents, can be used internationally, and yield information that is useful for selection and design of interventions [2].

Cognitive Disequilibrium

Jackie Kibler
University of Montana, Missoula, MT, USA

Jean Piaget's theory of cognitive development describes cognitive disequilibrium as a state of cognitive imbalance [1]. We experience such a state of imbalance when encountering information that requires us to develop new schema or modify existing schema (i.e., accommodate). Disequilibrium is often an uncomfortable state for individuals, thus we seek to quickly return to a state of equilibrium. If we encounter something in our environment that doesn't fit our existing schema, we may devote our mental energy to developing a new schema or adapting an existing schema. For example, a child learning how to tie her/his shoes may face a state of disequilibrium as he/she works to physically maneuver the laces while thinking through the steps as he/she tries to develop a new schema for shoe tying.

Another option we have when in a state of cognitive disequilibrium is to discount the information presented in the environment and instead leave our existing schema unaltered. A child may refuse to attempt the task of tying his/her shoe, thus not exerting the mental energy to accommodate new information.

Cognitive Dissonance

Norissa Atingdui
Fordham University, NY, USA

Definition

►Cognitive dissonance is an experience in which individual's encounter psychological discomfort when they simultaneously have thoughts that are in conflict with each other. Cognitive dissonance often serves as a motivational force as it often drives them to seek to reduce discomfort.

Description

Leon Festinger, a social psychologist, is the originator of this theory and presented it in his first book on the matter in 1957 [3]. Since then he has done more research on the matter and provided a foundation for later studies in social psychology. According to Festinger, individuals seek to have psychological consistency such that thoughts, beliefs, values and actions usually coincide and are

supported by each other. This experience is termed cognitive consonance and allows for mental equilibrium. Equilibrium, a condition in which there is balance, allows for harmony, and low levels of anxiety, discomfort, shame or guilt. Unconsciously individuals aim to function in this manner. Nonetheless, there are occasions in which thoughts that one has or accepts are not consistent with the framework of thoughts traditionally and consciously held by that individual. Such mental disequilibrium is referred to as cognitive dissonance and it leaves one seeking homeostasis. When a person becomes aware of these inconsistencies it is the moment in which he or she is experiencing cognitive dissonance. Psychologically, the individual seeks to have consonance. There are many ways in which the psyche attempts to reduce discomfort and bring this about. In this way cognitive dissonance serves as a motivational force as individuals seek to have internal consistency. These ways include, but are not limited to rationalization, justification, attitude change or trivialization. Cognitions are changed to fit the actual behavior. Cognitive dissonance is a regular occurrence and can often be used as a tool for growth. It can be a byproduct of learning, challenging cultural and societal beliefs and becoming aware of logical inconsistencies in ideas. Awareness of these inconsistencies is the first step in attempting to reduce psychological discomfort caused by cognitive dissonance.

Examples

A common example that can be used to exemplify this concept is one that pertains to race. One may consciously think that all people and races are equal. Previous thoughts and actions may be consistent with this. However, if one's child is getting married to someone from another race, there may be an experience in which this individual has an issue with this union whether verbalized or not. Psychological discomfort is experienced as the individual is aware that he or she has claimed to believe that all people are created equal, but experience a feeling of resistance in this event. In order to come to terms with this and return to a state of consonance, the individual may then attempt to change these thoughts so that they occur without conflict in the existing framework of their cognitions. The individual may realize the inherent conflict in his or her thoughts and dismiss misgivings about the union or justify it by saying that he or she is not racist, but is just concerned about how the couple is received socially. Similarly, one might say, "I love gay people," but want to reject their child to some degree when they tell them of the alternative lifestyle they intend to live.

Cognitive Equilibrium

Jackie Kibler
University of Montana, Missoula, MT, USA

Jean Piaget states that as humans, we have an innate desire to maintain a state of cognitive equilibrium, or cognitive balance [1]. We like it when we experience things in our world that fit our mental understanding of the world. To be in a state of cognitive equilibrium, our brains are assimilating information more than they are accommodating information.

Cognitive Schemas

Jackie Kibler
University of Montana, Missoula, MT, USA

Description

Jean Piaget's theory of cognitive development includes discussion of cognitive schemas, or mental representations. As infants, we are born with certain innate schemas, such as crying and sucking. As we encounter things in our environment, we develop additional schemas, such as babbling, crawling, etc. Infants quickly develop a schema for their caretaker(s). Schemas are the building blocks for knowledge acquisition [1]. Using this analogy, the building blocks increase in number as we learn new information. For example, a child learns how to write his/her name, thus adding a schema. The organization of the building blocks also become more complex as the brain matures and new knowledge is gained. A child who knows how to write his/her name also learns how to write additional words. Piaget describes the concepts of assimilation and accommodation to explain how schemas develop. Assimilation involves encountering something in the environment that fits into an already existing schema. For example, some children who lived through Hurricane Katrina now experience great psychological stress if there is a thunderstorm. Piaget would explain that the children have a schema for a destructive hurricane and when they encounter a situation that is similar, they assimilate the information, thus causing distress. Accommodation involves altering a schema or creating a new one. For example, learning that not every thunderstorm is a hurricane involves the process of accommodation.

Definition

Mental abilities needed to learn something http://www.learningrx.com/cognitive-skills-faq.htm

Description

Cognitive skills involve those strategies learners employee when encountering new material that is needed to be learned. Skills such as concentration, categorization, memorization and reasoning are important.

Some strategies to improve cognitive skills include teaching the child what specifically is different about one concept or idea from another. Further, helping children to differentiate characteristics such noticing the likeness but differences between a parrot and a chicken. Further, teaching children to create a visual image of the concept in their minds assists in strengthening cognitive skills. Often repeating aloud the concept, definition or characteristics of the materials to be learned assists in the development of cognitive skills. In addition, concentration is critical to the development of cognitive skills.

Cognitive Styles

Heath Marrs
Central Washington University, Ellensburg, WA, USA

Synonyms

Learning styles; Thinking styles

Definition

"People's characteristic and typically preferred modes of processing information [5, p. 700]."

Description

As opposed to cognitive abilities, cognitive styles refer to "people's characteristic and typically preferred modes of processing information [5, p. 700]." There are a number of related terms that describe characteristics that are similar to cognitive styles, including learning styles, thinking styles, or information processing styles. Woolfolk [9] noted that educators tend to prefer the term "learning styles" while psychologists tend to prefer the term "cognitive styles." Although there is much overlap between the terms, educators tend to include a broader range of styles and preferences within the category of learning styles, while psychologists limit the term to styles that relate to differences in the ways that people process information.

Sternberg [7] describes cognitive styles as lying at the interface between cognition and personality. As indicators of cognition, they describe individual differences in how people use their cognitive abilities to solve problems and process information. As reflections of personality, cognitive styles refer to preferences for using cognitive abilities in certain ways. For example, some students may be more likely to process information by attending to the specific details, while other students may instead tend to focus on the overall picture. Witkin et al. [8] proposed a cognitive style called psychological differentiation that describes this tendency. According to this conception of cognitive style, people can be classified as either *field-dependent* or *field-independent*. People who are field-dependent have more difficulty picking out the hidden elements of a visual field than those who are field-independent. This difference may extend beyond simple visual perception to broader contexts, such as understanding social interactions or other problem-solving contexts [2].

Other examples of cognitive styles that have been proposed in the literature are Kagan's [3] conceptual tempo (reflective-impulsive) and Sternberg's theory of mental self-government (1997). Cognitive styles may help educators understand better how children learn and how they respond to different instructional strategies. For example, a student with an impulsive cognitive style may respond very quickly to questions, while a student with a reflective cognitive style may wait before responding. These individual differences may be important for teachers to consider when trying to understand the differing behaviors of students during instruction.

The concept of learning styles has been much more prominent in education than the concept of cognitive styles. Two very popular conceptions of styles are Dunn and Dunn's [1] Learning Styles (environmental, emotional, sociological, and physical), and Kolb's [4] Learning Styles (converging vs. diverging and assimilating vs. accommodating). Although intuitively attractive, the idea of learning styles has been controversial. Many of the proposed measures of styles have limited reliability and validity [6]. With regards to measures of learning styles, Woolfolk [9] suggested that it may be more accurate to call them learning preferences rather than learning styles. In general, research has been more supportive of the concept of cognitive styles, although they have not enjoyed the popularity of learning styles.

Cognitive Theories

Synonyms

Cognitive psychology; Cognitivism

Definition

Cognitive theories attempt to describe how people think. Specifically, the field of cognitive psychology is defined as the study of how people perceive, learn, remember, and think about information.

Description

Cognitive theory or cognitive psychology is concerned with a person's thought processes and attempts to understand human behavior by analyzing these thought processes. Cognitivism is the belief held by some psychologists that much of human behavior can be explained in terms of how people think.

Cognitive psychology emerged from the broader field of psychology in response to the ideas of structuralism, functionalism, and behaviorism. Structuralism is concerned with the structure or elements of the mind and attempts to analyze perceptions into their components, while functionalism seeks to understand what people do and why. Behaviorism focuses only on the relation between observable behavior and environmental events. Early cognitive psychologists including Karl Lashley, Donald Hebb, Noam Chomsky, and Ulric Neisser rejected the ideas of strict behaviorism and felt strongly that the mind and people's thoughts should be the focus of scientific research on human behavior.

The assumption underlying cognitive theories is that humans are logical beings that make sensible choices. Therefore, cognitive psychology focuses on studying and explaining how humans come to solve problems, process and retain information, and make decisions. "Information processing" is a commonly used description of the mental process, comparing the human mind to a computer.

Cognitive Therapy

►Beck Therapy

Cognitive Therapy (CT)

Jeremy Jewell
Southern Illinois University Edwardsville, Edwardsville, IL, USA

Definition

Cognitive Therapy (CT) is a type of psychotherapy first developed by Aaron Beck that focuses on replacing cognitive distortions with more rationale thinking in an attempt to positively affect both emotions and behavior in the patient.

Description

Cognitive Therapy (CT) is derived from Cognitive Theory, which were both first developed by Aaron T. Beck [1] and later expounded upon by his daughter Judith Beck [3]. It should also be noted that many theoretical as well as technical aspects of CT are highly similar to Rational Emotive Therapy (RET) that was developed simultaneously by Albert Ellis [4]. Some consider CT falling under the larger umbrella of psychotherapies known as Cognitive Behavioral Therapy (CBT) although CT is distinguished from CBT by its exclusive focus on cognitions as the key to positive therapeutic change in emotions and behavior.

CT is based on the "cognitive model" [3] that attempts to explain the cause of dysfunctional emotions and behavior. This model explains that in any individual's life, a triggering event or situation may activate a cognitive distortion. The consequences of this cognitive distortion are dysfunctional emotions and behaviors. For example, before taking a test in school, a person may think "I'm going to fail as usual." This thought then leads to a feeling of sadness and the person may give up studying for the test. In this example, the upcoming test is the triggering event, their thought of impending failure is the cognitive distortion, and their sadness and the termination of studying are emotional and behavioral consequences of the thought. The cornerstone of this model is understanding that negative emotions and behaviors are consequences of the distorted thinking, thus the focus of therapy is on replacing these cognitions presuming that positive emotional and behavioral change will follow. Beginning stages of CT emphasize the importance of the cognitive model and direct the therapist to explicitly teach and reinforce this model with the patient [3].

CT assumes that there are three levels of belief within an individual [3], which are automatic thoughts, intermediate beliefs, and core beliefs. Core beliefs tend to be global and encompass all or most aspects of a person, such as the belief of "I am generally a good person." On the other hand, someone suffering from depression might have the core belief of "I am a worthless person." Core beliefs are often below the level of daily consciousness however, and may manifest themselves as intermediate beliefs, which are rules or assumptions one holds for oneself. For example, "nothing ever goes right for me" would be a typical intermediate belief held by someone diagnosed with depression. Automatic thoughts, on the other hand, are the most specific and frequent thoughts experienced by people and relate to specific situations, such as "I am going to fail the test on Tuesday." CT attempts to examine and change these thought processes, often beginning with automatic

thoughts, then moving to more general intermediate beliefs, and finally working toward a dysfunctional core belief.

CT is a highly standardized type of psychotherapy, which is characterized by the development and use of an agenda during therapy as well as the use of a number of specific psychotherapy techniques [3]. These techniques, as well as the theory underlying them, are rather universal in that they are applicable to a variety of problems. One such technique, and a hallmark of CT, is the continual use of Dysfunctional Thought Records (DTR) both inside and outside of therapy. The DTR is used to log dysfunctional thinking and the consequential emotions and behaviors. Part of the DTR also allows the patient to provide a "rational response" [3] to the cognitive distortion that they are experiencing. After the patient replaces the cognitive distortion with this rational response, they then re-rate their emotions related to the triggering event. One of the goals of CT is for the therapist to train the patient to become their own therapist, thus avoiding the possibility of overdependence on the therapist and ensuring continued progress beyond therapy termination [1]. As such, the use of the DTR outside of, and beyond therapy, is critical.

There are several assumptions related to the provision of CT. First, CT acknowledges that early childhood experiences lay the foundation for one's beliefs and cognitive distortions, but CT focuses on cognitions as the most expedient way to positively affect emotions and behaviors in the patient. Secondly, CT relies on the patient to be able to identify their own thinking and rationally examine these thoughts in order to replace this dysfunctional thinking. This is a point of controversy, as Albert Ellis [4] did not believe that most children or adolescents held the prerequisite cognitive skills required for this type of therapy. Additionally, Aaron Beck has written very little on how therapists might apply CT to children as most of his work has been with adults. Recent research, however, has shown that children as young as five years old possess the basic cognitive skills needed to allow them to benefit from CT [5]. Because of the standardized methods and techniques used, CT has gained a large body of empirical evidence supporting its efficacy with a variety of problems and populations and continues to gain popularity in the field of psychology.

Cognitive-Behavioral Play Therapy (CBPT)

▶Play-Group Therapy

Cognitive-Behavioral Therapy

Kristy Wakefield, Stephen D. A. Hupp
Southern Illinois University Edwardsville, Edwardsville, IL, USA

Definition

Cognitive-behavioral therapy (CBT) is a broad term covering a range of therapies that integrate cognitive and behavioral techniques.

Description

The term CBT is often also used as an umbrella term to cover many different variations of integrating behavioral and cognitive theories [11, 18] and applying those theories to effective intervention [9]. CBT has its earliest roots in behavioral theory and behavior therapy, and behavior therapy has continued to be shaped by many theoretical and empirical advances.

In his book, *Behaviorism* (1924), John B. Watson made the case that psychology should focus on observable and measurable behavior instead of consciousness [25]. Though emphasizing the importance of studying the overt actions of individuals, Watson also left room for the inclusion of some covert behavior, such as thoughts (i.e., subvocal speech), because thoughts are observable at least to the individual experiencing them. In behavioral theory, Watson frequently counters the common view of his time that heredity is the dominate force influencing most human behavior. That is, he emphasizes the important role of environmental stimuli eliciting behavior. Following Pavlov's work, Watson demonstrated how some

behaviors could be learned through the process of classical conditioning. Specifically, Watson and Watson [26] demonstrated learning by showing that an infant (i.e., Albert) had a fear response (e.g., crying) to a sudden loud noise, but he had no observable fear response when separately presented a white rat. After the rat and noise were presented together a few times, the infant began showing fearful responses to the rat alone. Watson's theory of *classical conditioning* has led to many clinical applications with children. For example, the behavioral treatment of anxiety disorders typically includes exposing the child to the feared stimulus until the fear is extinguished. In the case of a fear of white rats, the child would be exposed to the rat, without the sudden loud noises, until the child no longer demonstrates a fear response. Other examples of treatments utilizing the theory of classical conditioning include treatments for bedwetting and sleep problems.

Whereas Watson focused on the stimuli that preceded behavior, B. F. Skinner later focus on the consequences that followed behavior (see [24]). That is, he demonstrated the process of *operant conditioning* in which some consequences increase the likelihood of future behaviors (i.e., reinforcement) and other consequences decrease the likelihood of future behavior (i.e., punishment). Skinner also recognizes the importance of the role antecedents played in influencing behavior by being associated with particular consequences in the past. Some examples of the many other major contributions Skinner made to behavioral theory include: functional analysis, reinforcement schedules, shaping, and fading. Skinner also accounted for the role of cognitions in his theory by discussing both public events (i.e., overt behavior) and private events (i.e., covert behavior). Ultimately, Skinner viewed environmental stimuli as the primary force in shaping both public and private events. Since Skinner's work, his theories have been expanded and applied to children in various settings. Antecedent and consequence manipulation have become a part of many empirically supported interventions for children and adolescents [22]. For example, many empirically supported treatments make use of a token economy and other reward systems.

In the 1950s, theories began emerging which placed significantly greater weight on the important role of cognitions. Albert Ellis first termed his approach rational therapy, and later renamed it rational emotive therapy (RET) to help distinguish it from other theories. Ellis' approach focused on changing emotional and behavioral functioning through managing the individual's irrational thinking. As Ellis continued to incorporate behavioral techniques he again changed the name to *rational-emotive behavior therapy* (REBT; [14]). Essentially, REBT can be summarized by the acronym ABCDE [12, 15]. "A" in the acronym stands for the *activation* of irrational thinking by a specific event (e.g., a child is the picked last for a sports team). "B" stands for the irrational *beliefs* that follow the event (e.g., "everybody hates me"). "C" stands for the *consequences* of the irrational beliefs (e.g., anxiety, social avoidance, etc.). The therapist then encourages behavioral and emotional change through the final two steps of the model. That is, "D" represents the therapist's approach of *disputing* irrational thinking, and finally, "E" represents a more *effective* state of the individual's functioning.

Independently from Ellis, Aaron T. Beck found that his clients with depression consistently showed patterns of distorted thinking, leading A. Beck to the conclusion that depression was actually the result of distorted thinking [3]. He found that distorted thinking includes negative and unrealistic beliefs in three areas of a "cognitive triad": oneself, the future, and the world [10]. In A. Beck's later work, he expands his research beyond depression, increasing his application of *cognitive theory* to externalizing problems and anxiety [4, 5]. Through his early work [6] and the evolution of cognitive therapy through the contributions of his daughter, Judith Beck, three levels of belief have been revealed: automotive thoughts, intermediate beliefs, and core beliefs (Beck, 1995). *Automatic thoughts* are distinctive to each person or situation. *Intermediate beliefs* are assumptions or beliefs that an individual applies to their life. *Core beliefs* are comprehensive and unchanging beliefs applied to an individual's life. In the application of this theory, automatic thoughts and intermediate beliefs are viewed as a reflection of a similar core belief. Given this understanding, the theory suggests that treatment should focus on changing distorted thinking at the core belief level, while treatment would also focus on automatic thoughts and intermediate beliefs.

The work of Ellis and A. Beck focused primarily on adults; however, interventions with cognitive components have been increasingly applied to children and adolescents (and their parents) for both internalizing (e.g., anxiety, depression, etc.) and externalizing (i.e., aggression, conduct, etc.) problems. Together, A. Beck and Ellis contributed to what some refer to as the second wave of behavior therapy, also called the "cognitive revolution." As research using cognitive techniques was flourishing in the 1970s many debated the relative merits of using either behavior therapy or cognitive therapy, while others emphasized the value of an integrationist approach. Many of the integrationist approaches fall within what has been referred to as self-management. For example, D'Zurilla and Goldfried [13] presented the *cognitive problem solving model* in which a stressful situations is first identified and then

several possibilities for coping with the situation are generated. This adaptive coping response might be a behavioral response, a cognitive response, or both.

Albert Bandura also contributed an integrationist perspective based on his research on social learning (also known as modeling). Bandura [2] suggested that classical and operant conditioning did not completely account for all learning, proposing that some learning takes place without the individual needing to directly experience consequences. Bandura's bobo doll research demonstrates that children were more aggressive with a bobo doll after watching an adult's aggressive behavior with the doll [1]. Many treatments using variations of behavioral skills training include modeling the behaviors as a critical component. Over time Bandura placed greater emphasis cognitions, with the new label *social cognitive theory*. Specifically, Bandura suggests self-efficacy describes a person's beliefs that demonstrating a behavior will result in a desired outcome.

With his book *Cognitive-Behavior Modification* (1977) Meichenbaum explicitly attempts to integrate behavioral and cognitive theories into a unified approach for treating children [20]. Influenced by Bandura's early work, Meichenbaum noted that children not only learn from watching overt actions, they also imitate covert behavior. That is, children are exposed to their parental thoughts through their parent's speech (called cognitive modeling). Children then imitate their parent's speech, and soon these words can become internal speech (i.e., thought). Meichenbaum's technique of *self-instruction training* builds on his theory, by having parents model adaptive cognitive problem-solving skills. Children are then encouraged to imitate the adaptive responses aloud. Then children use whispered speech and finally subvocal speech. Meichenbaum also uses other standard behavioral techniques as part of his interventions. Distinguishing himself from Ellis and A. Beck, Meichenbaum suggests his intervention focuses on initiating adaptive cognitive responses rather than challenging maladaptive cognitive distortions.

While the "cognitive revolution" has been described as the second wave of behavior therapy, in recent years the beginnings of a third wave has also been described. Hayes [16] suggests this newest wave includes the acceptance- or mindfulness-based therapies. These therapies include many behavioral components but also incorporate teachings from Middle Eastern philosophy, such as meditation. Examples include *dialectical behavior therapy* (DBT; [19]), which has been applied to adolescents with borderline personality disorder, and *acceptance and commitment therapy* (ACT; [17]). One emphasis in ACT is the acceptance of strong emotions and cognitive distortions, rather than challenging them, as is done in the traditional cognitive approaches. The early research on ACT focused on adults; however, applications with children and their parents are growing [21].

The cognitive-behavioral therapies have been applied to a range of problems of childhood including anxiety, depression, behavior problems, attention problems, dealing with trauma, and eating disorders. In an attempt to define CBT [9] included three core features. First, *psychoeducation* is often the first phase of treatment and includes educating the child about the role of the environment and cognitions on functioning. Second, *cognitive restructuring* involves working with the child to identify and challenge maladaptive cognitions. Finally, *behavioral activation* involves helping the child increase adaptive behaviors, such as positive activity scheduling. The degree to which each of these components is utilized varies considerably from one client to the next, and many additional techniques are often incorporated. As the cognitive-behavioral approaches continue to multiply it becomes increasingly more difficult to define CBT. For example, ACT emphasizes acceptance of cognitions rather than disputing them.

Relevance to Childhood Development

Though the early cognitive approaches of Ellis and A. Beck focused primarily on adults, the integrationist approaches that followed had a much greater inclusion of children and adolescents. Hupp et al. [18] summarize some of the major differences regarding the use of CBT with adults and children. First, the child's developmental level will significantly impact the level to which cognitions can be explored during therapy [7]. For example, cognitions are not a focus of intervention with toddlers, though as children get older cognitions become of greater importance during therapy. Second, significantly others in the child's life (e.g., parents) are more likely to be directly involved during therapy. Thus, cognitive and behavioral approaches are quite often used with more than one person during therapy. Third, children are less likely to respond to the traditional "talk therapy" approaches that are often used with adults. Braswell and Kendall suggest "a therapist must be able to teach in a playful manner and play in a way that teaches" (p. 250). Fourth, therapy with children often uses the components of behavioral skills training as described by Miltenberger (2008): modeling, instructions, rehearsal, and feedback. Finally, cognitive-behavioral approaches with children often incorporate the ecological systems theory which considers the family, school, community, and culture to all have unique and

combined influences on child development [8]. As far as the effectiveness of the cognitive-behavioral therapies with children, the *Journal of Clinical Child and Adolescent Psychology* recently published a ten-year update on evidence-based treatments [23], and the many variations of CBT are well-represented.

Cohort

Audrey McKinlay
University of Canterbury, Christchurch, Canterbury, New Zealand

Synonyms

Birth cohort; Friendship

Definition

A cohort refers to a group of subjects from a given subgroup defined by a particular characteristic i.e., same year

of birth (birth cohort), same gender or same culture [1]. Researchers are often interested in cohort effects as they can have a major influence on research outcomes. Cohort effects refer to the influence of factors other than age.

For example, children born 1986 in the areas surrounding Chernobyle 1986, (in the Ukraine, then a member state of the Soviet Union) who were exposed to the radioactive material that was released when its nuclear reactor failed may be considered to be a cohort. This group would be defined by exposure to radioactive material early in life and could have particular health problems which are not related to their age.

Cohort Effect

Norissa Atingdui
Fordham University, NY, USA

Definition

The effect that having been born in a certain time, region, period or having experienced the same life experience (in the same time period) has on the development or perceptions of a particular group. These perceptions, characteristics or effects are unique to the group in question.

Description

Cohort effects are often looked at in social science research studies. Cohort effects are teased out in order to account for the prevalence or lack thereof of particular characteristics that may skew interpretations of findings in research studies. Cohort effects are often looked at in studies that look at change over time. Future studies may consider the cohort effect of individuals who were elementary age and living in New York during 9/11. This catastrophic event indubitably has shaped the perceptions and development of this particular cohort. As such, consideration of these factors is imperative to produce research that yields the most fruitful results. It may be found that there is a high prevalence of depression, or pessimism in this group. Therefore if a study was researching optimism about life in freshman and sophomore college students, a counterintuitive finding that suggests that freshman and sophomore age students are pessimistic about life may be accounted for by a cohort effect. High prevalence of pessimism could be explained by the fact that they are a part of a cohort who lived through the experience of a traumatic event that has residual effects. This example demonstrates how cohort effects can threaten internal validity, such that what one thinks is being measured is not actually being measured.

Colic

Definition

Colic is a condition characterized by recurrent episodes of prolonged crying in an otherwise healthy infant. It is usually diagnosed when the infant cries for more than three hours a day, three days a week for more than three weeks duration. In some babies, the cause of the colic is unknown, and may subside on it's own. In other babies, the cause of colic may be traced to acid reflux or a milk protein allergy.

Collectivism

Definition

Relates to a social pattern involving closely linked individuals who view themselves as parts of one or more collectives (family, co-workers, tribe, nation). These individuals tend to be strongly motivated by the norms of and duties required by those collectives, tend to put the goals of the collectives over their own personal goals, and tend to place emphasis on their connectedness to members of these collectives. Collectivism tends to be beneficial in social interaction involving families and work teams. However, some members in collectivist societies feel stifled by social demands and obligations and have a feeling of being dissatisfied.

Collectivism is usually contrasted with individualism. Individualism is a social pattern that involves loosely linked individuals who see themselves as independent of collectives. These individuals are mostly motivated by their own preferences, needs, rights, and their contract they have set up with others, tend to give priority to their personal goals over the goals of others and stress rational analyses of the advantages and disadvantages to associating with others. Individualism tends to work well in impersonal environs such as corporations and governmental hierarchies. Compared to individuals in collectivist society, members of individualist societies are more likely to feel isolated and lonely.

Research suggests that United States, Australia, Great Britain, Canada, The Netherlands, and New Zealand are considered to be individualist societies; East Asian, Middle Eastern, most Latin American, Mediterranean, and African cultures appear to be collectivist societies.

Collectivist Cultures

Silvia L. Mazzula
John Jay College of Criminal Justice – City University of New York, New York, NY, USA

Synonyms

Community-oriented cultures; Group-oriented cultures

Definition

Collectivistic cultures are characterized by a worldview that values interdependence, belonging, and group-cohesion. Members of collectivistic cultures tend to evaluate their sense of worth, well-being and satisfaction with life based on the evaluation of external sources such as social norms, family expectations, relationships and interactions with members of their group [1]. Families tend to include the nuclear unit, as well as extended family members and members of the community [2]. In contrast, Individualistic cultures are characterized by a worldview that values independence, autonomy, and self-reliance and the family is usually composed of the nuclear unit [2, 4]. African-Americans, Asian-Americans and Latin-Americans are typically considered Collectivistic cultures [1, 2] and Western or Euro-Americans are typically considered Individualistic cultures. It should be noted that Collectivism and Individualism are at the extreme poles of a spectrum and significant within-group differences are found among both of these worldviews.

Relevance to Childhood Development

Child development theories are grounded within a cultural context. Common developmental "milestones" such as a child's ability to walk by a certain age or a young adult's ability to live independently are heavily influenced by Individualistic cultural worldviews. For example, infants are expected to sleep independently within a few months of birth and adolescents are expected to be self-reliant and have the capacity to live independently when they turn 18 years of age. On the contrary, within Collectivistic cultures, it is common to have children sleep with their parents into toddlerhood and independent living is not defined by age but rather by social norms and family obligations or expectations [3]. In collectivistic cultures, children learn by observing their family and members of the community [3]. Thus, child development is heavily influenced by the development of a group identity. Moreover, a child's well-being and development falls under the responsibility of the family and the community as a whole. Therefore, depending on the cultural context, child development and child-rearing practices differ drastically. As the United States becomes a nation that is racially and culturally diverse, common notions such as developmental "milestones" need to be carefully assessed within the cultural context of that particular child.

Communication Disorders

Synonyms

Expressive language disorders; Language disorders; Receptive language disorders; Speech and language disorders

Definition

A communication disorder - speech and language disorders which refer to problems in communication and in related areas such as oral motor function. The delays and disorders can range from simple sound substitution to the inability to understand or use language.

Communication is a multidimensional dynamic process that allows human beings to interact with their environment. It is through communication that children are able to express their thoughts, ideas, needs and emotions. There are, however, a number of communication delays that can affect a child's early language development. These may include, but are not limited to: Expressive and Receptive Language Disorders, Apraxia, Dyslexia, Phonological Disorder and Articulation problems. In general, communication disorders can be broken down into two categories.

Speech disorders refer to difficulties producing speech sounds or problems with voice quality. They might be characterized by an interruption in the flow or rhythm of speech, such as stuttering, which is called dysfluency. Speech disorders may be problems with the way sounds are formed, called articulation or phonological disorders, or they may be difficulties with the pitch, volume or quality of the voice. There may be a combination of several problems. People with speech disorders have trouble using some speech sounds, which can also be a symptom of a delay. They may say "see" when they mean "ski" or they may have trouble using other sounds like "l" or "r." Listeners may have trouble understanding what someone with a speech disorder is trying to say. People with voice disorders may have trouble with the way their voices sound.

A language disorder is an impairment in the ability to understand and/or use words in context, both verbally and nonverbally. Some characteristics of language disorders include improper use of words and their meanings, inability to express ideas, inappropriate grammatical patterns, reduced vocabulary and inability to follow directions. One or a combination of these characteristics may occur in children who are affected by language learning disabilities or developmental language delay. Children may hear or see a word but not be able to understand its meaning. They may have trouble getting others to understand what they are trying to communicate.

The overall estimate for speech and language disorders is widely agreed to be 5% of school-aged children. This figure includes voice disorders (3%) and stuttering (1%). The incidence of elementary school children who

exhibit delayed phonological (articulation) development is 2% to 3%, although the percentage decreases steadily with age.

Many speech problems are developmental rather than physiological, and as such they respond to remedial instruction. Language experiences are central to a young child's development. In the past, children with communication disorders were routinely removed from the regular class for individual speech and language therapy. This is still the case in severe instances, but the trend is toward keeping the child in the mainstream as much as possible. In order to accomplish this goal, teamwork among the teacher, speech and language therapist, audiologist, and parents is essential. Speech improvement and correction are blended into the regular classroom curriculum and the child's natural environment.

Comorbidity

Douglas K. Symons
Acadia University, Wolfville, Ontario, Canada

Synonyms

Association; Dual diagnosis

Definition

Comorbidity is when two diagnostic categories tend to be associated above chance.

Description

Comorbidity is a term used in child clinical psychology when two diagnostic categories are significantly associated. These two conditions may co-exist and have a common underlying process, or they may be independent conditions that tend to co-occur [5]. For example, it is well known that children who have a diagnosed anxiety disorder according to DSM criteria have an above chance probability of having a DSM diagnosis of depression [1]. In other words, anxiety and depression are comorbid, they tend to occur together. Diagnostic categories are classified as yes/no decisions, that is, children either do or do not have an anxiety disorder, and either do or do not have childhood depression. Data illustrating this kind of pattern is contained in Fig. 1. In a non-clinical sample, a majority of children will have neither diagnoses, but comorbidity implies that some children will have both diagnoses, and fewer then chance will have one without the other. If this kind of data were collected within a child mental health clinic, the number of children with both diagnoses would be higher and the number of children with neither would be lower than a random non-clinical sample. Because clinical diagnoses are classified as yes/no decisions, these data are nominal, and a chi-square statistic could be used to examine for significant associations.

Comorbidity implies that children are in two categories at the same time. For example, in models of the development of juvenile delinquency, children with a diagnosis of attentional problems such as Attention-Deficit Hyperactivity Disorder (ADHD), and behavior problems such as in Oppositional-Defiant Disorder

Comorbidity. Fig. 1

(ODD) are at elevated risk for later delinquency [2]. In fact ADHD and ODD are also comorbid as they tend to occur together [4]. ADHD is also comorbid with Learning Disorders. The co-occurrence of clinical disorders that revolve around acting out may reflect a broader behavioral problem called externalizing behavior problems. In the example of anxiety and depression, psychological distress is turned inwards, and this comorbidity reflects a broader problem called an internalizing behavior problem or emotional distress.

Comorbidity does not have to be examined only in mental health diagnoses [6]. Medical diagnoses may be used also. For example, a history of chronic inner ear infections is *otitis media*, and this medical condition is more likely in children with ADHD than not [3]. In fact, because of comorbidity, this medical condition can actually be used to assist in a diagnosis of ADHD, as a parent having a child repeatedly on antibiotics for inner ear infections is a fairly salient and concrete event for parents to report to a clinical or developmental psychologist. Although comorbid, the common process is less clear, although it is likely children with ADHD may have specific hearing deficits associated with their chronic ear infections. Comorbidity studies are common in child-clinical and pediatric literatures, but they have relevance in child development research as there may a common underlying developmental process between both conditions of interest.

Comprehensive Assessment of Spoken Language

DaNella Knight
Argosy University

Synonyms

CASL

Definition

The CASL is an individually and orally administered assessment of oral language development for children and adolescents ages 3 through 21 years. It can be used to assess language comprehension, expression, and retrieval across the following four categories of oral language: Lexical/Semantic, Syntactic, Supralinguistic, and Pragmatic. Administration of the core battery can be completed in approximately 30–45 min. Scores yielded include age and grade-based standard scores, age and grade equivalents, percentiles, normal curve equivalents, and stanines.

Description

The CASL was developed by Elizabeth Carrow-Woolfolk, Ph.D. based on her Integrative Language Theory (ILT), which suggests language is founded on two basic dimensions. According to ILT, language knowledge, the structure of language, and language performance, the process of comprehending and expressing language, provide the basis of spoken language. The battery was nationally standardized on a sample of 1,700 individuals, stratified by gender, race, ethnicity, geographic region, socioeconomic status, and special education according to the 1994 U.S. Census data [1].

Early criticism of the CASL suggested further research was needed to determine concurrent validity, or the extent to which CASL scores correlate with other language assessment tools [3]. The Pragmatic Judgment and Inferences tests of the CASL have since been found to discern

CASL test	Age range
Basic concepts	Core: 3–4
	Supplementary: 5–6
Antonyms	Core: 5–12
	Supplementary: 13–21

Ambiguous sentences	Supplementary: 11–21

difficulties in the adaptive use of language for communication in individuals with Autism Spectrum Disorder [2]. The CASL is used both as a research tool and for the clinical assessment of language disorders. However, researchers have advocated against using only cutoff scores to diagnose specific language impairment, as most children with impaired language scored within one standard deviation of the normal mean distribution [4].

The CASL is composed of 15 tests measuring language processing skills (i.e., comprehension, expression, and retrieval) across four structural categories of oral language. The four oral language components assessed in this battery are as follows: lexical or semantic, syntactic, supralinguistic, and pragmatic. Core subtests can be used to estimate a global language composite while supplementary subtests yield additional diagnostic information regarding language delays, oral language disorders, dyslexia, and aphasia.

Lexical/Semantic

Lexical/Semantic aspects of language refer to the comprehension of single words and phrases. CASL tests measuring lexical/semantic components of language development focus on the knowledge and ability to appropriately use individual words and make word combinations. These tests include: Basic Concepts, Antonyms, Synonyms, Sentence Completion, and Idiomatic Language.

Syntactic

The syntactic component of oral language development refers to the knowledge and use of grammar. Syntactical assessment focuses on the structure of sentences and paragraphs. The CASL tests measuring syntax include: Syntax Construction, Paragraph Comprehension, Grammatical Morphemes, Sentence Comprehension, and Grammaticality Judgment.

Supralinguistic

Development of supralinguistic abilities involves understanding complex language whose meaning must be inferred from the given context. This component of language facilitates the comprehension of implied meanings that are not directly apparent based on lexical and syntactic combinations, such as figurative speech, sarcasm, and ambiguous statements. The CASL tests assessing supralinguistic abilities include: Nonliteral Language, Meaning from Context, Inference, and Ambiguous Sentences.

Pragmatic

The pragmatic component of language refers to the ability to use language appropriately and modify responses across varying contexts. Pragmatics encompass a wide range of conversational behaviors, such as selecting appropriate conversational topics, taking turns during dialogue, and using language to express emotions. The Pragmatic Judgment Test of the CASL primarily focuses on the expression of language; however, some emphasis also is placed on comprehension and the awareness of appropriate actions in a given context.

Relevance to Childhood Development

The CASL can be used to record oral language development in children from preschool through the postsecondary years. It is also a useful tool to aid in the diagnosis of autistic spectrum disorders and specific language impairments, as well as to gauge recovery and guide remediation in children who have had traumatic brain injuries or other medical conditions that affect language (e.g., childhood stroke).

Computation

►Computational Skills

Computational Fluency

►Computational Skills

Computational Skills

Molly Millians
Marcus Autism Center, Atlanta, Georgia, USA

Synonyms

Arithmetic operations; Calculation; Computation; Computational fluency; Mental computation

Definition

Computational skills are the selection and application of arithmetic operations to calculate solutions to mathematical problems.

Description

Arithmetic encompasses a set of mathematic processes that include number sense, the understanding of mathematic principles such as the associative and commutative properties, and computational skills. Specifically, computational skills are defined as the abilities to calculate basic addition, subtraction, multiplication, and division problems quickly and accurately using mental methods, paper-and-pencil, and other tools, such as a calculator. This requires the selection of the appropriate arithmetic operation. Also, computational skills require the execution of the steps to calculate the solution. The term computational fluency expands the definition to include the flexible application of calculation strategies and the automatic recall of basic number facts.

Efficient computational skills require a sold understanding of the number system. Young children learn about numbers through interactions with their environment. Children begin to count and to share sets of objects while playing, assisting caregivers with chores, and other activities. As children receive formal mathematics instruction, they begin to use small blocks, beads, and other manipulatives to explore ways amounts can be combined or altered. Learning activities that provide a concrete demonstration of a skill contribute to the acquisition of the concepts and procedures associated with addition, subtraction, multiplication, and division operations.

In elementary school, children learn the steps or algorithm to compute problems. Children are taught to represent mathematic information using symbols in a standardize format using a mathematical expression or equation. Children learn to integrate number concepts, such as shifting and renaming numbers for borrowing and carrying, with the procedures to compute multi-digit by multi-digit problems. Children are provided frequent written computation practice. The repeated exposure and practice solving mathematic problems facilitates registration and recall of facts in long-term memory. Efficient fact recall supports problem solving in higher level mathematics.

Often children's mathematic skills are assessed by the speed and accuracy of computing arithmetic problems. However, measures of calculation skills assess children's working memory and fact knowledge. This provides a narrow view of mathematical abilities. Children's conceptual understanding, sequencing of information, translation of verbal information into mathematical symbols, and processing of visual-spatial information need to be assessed when investigating overall mathematic abilities.

Computation is one component of the skills needed to be proficient in mathematics. Children need to understand the underlying mathematical concepts to support computation and problem solving. Also, children need to select and apply procedures and strategies flexibly to compute problems accurately. Lastly, children need to understand the purpose and usefulness of computation as subset of mathematical knowledge.

Computerized Assessment of Attention and Self Control

►Gordon Diagnostic System

Computerized Axial Tomography

Lauren Connell Pavelka
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

CAT; Computerized tomography (CT)

Definition

Computerized axial tomography (CAT) is a noninvasive diagnostic procedure that uses x-ray equipment to obtain three dimensional pictures of organs, bones, and tissues.

Description

CAT uses large amounts of ionizing radiation to scan cross-sectional images of the human body. Though CAT scanning is noninvasive and efficient, its radiation exposure, which is associated with increased risks of cancer, is higher than traditional x-rays. Similarly, a recent study presented at the American College of Radiology suggested that pediatric patients, especially those receiving pelvic or abdominal scans, are at twice the risk of radiation exposure as adults. However, because benefits of CAT scanning often outweigh its risks, the decision to use CAT scanning – even with pediatric patients – is often necessary. With children and adolescents, CAT scans are typically used to detect cancer, infectious or inflammatory disorders, causes of abdominal pain, and results of injuries, especially from car accidents. In the case of head injuries, for example, CAT can quickly display serious complications such as brain hemorrhaging or forms of brain damage.

Relevance to Childhood Development

CAT scanning is a tool that physicians may use to diagnose and treat problems with pediatric patients.

Definition

Concepts are the foundation of knowledge. They allow people to classify and organize information.

Description

As children grow and develop they form concepts through the interactions with others and from experiences. Young children generally form concepts through the use of their senses. When a child forms a concept they must isolate characteristics of experiences based on similar attributes ([3], p. 3).

Concept formation begins in infancy. Through their senses of touch, smell, sight, hearing, and taste children take in information. When infants look around their environment they gain a sense of size, weight, and shape. They learn that many things are heavier than they are able to lift through their experiences. Shapes of objects are learned from the experiences of touching [3].

According to Swartz (http://www.allkindsofminds.org/ArticleDisplay.aspx?articleID=18), there are five different types of concepts. These are: concrete concepts, abstract concepts, verbal and non-verbal concepts. Concrete concepts examples would include desk, bird, boat, and seasons. Conversely, abstract concepts would not have sensory input. Examples of abstract concepts would be: love, hate, or beauty.

Verbal concepts are those that are best learned and comprehended through the use of language as a vehicle for explanation. Some examples of these would include

sarcasm, humor or sadness. Often verbal concepts are also abstract concepts (http://www.allkindsofminds.org/ArticleDisplay.aspx?articleID=18).

Representing mental pictures often is one of the best ways to understand non-verbal concepts. The mental picture can correspond to the most significant characteristics of the concept. Diameter, circumference, volume and mass are examples of non-verbal concepts (http://www.allkindsofminds.org/ArticleDisplay.aspx?articleID=18).

When introducing a child to a new concept it is helpful to first label the concept and then tie the label to actions. This could result in a demonstration of the actions of the object of your action upon the object ([2], p. 75).

Concerta

►Stimulant Medications

Concerta® (Methylphenidate)

Lauren Connell Pavelka
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Methylphenidate (generic)

Definition

Concerta is a central nervous system stimulant that increases the release of norepinephrine and dopamine in the cerebral cortex. The generic form of Concerta is Methylphenidate.

Description

Concerta (or other medications based on the generic Methylphenidate), along with psychological, educational, and social interventions, is used to treat attention deficit hyperactivity disorder (ADHD). It may also be used in patients who have narcolepsy or certain mood disorders.

Common side effects include: abdominal pain, decreased appetite, headache, dry mouth, nausea, insomnia, anxiety, dizziness, decreased weight, and irritability. Rare but more serious side effects include: rapid/irregular heartbeat, fainting, fever, sore throat, skin blistering/peeling/rash, aggression, restlessness, hallucinations, unusual behavior, motor tics, bruising, blurred vision, confusion, chest pain, shortness of breath, and seizures. Methylphenidate also can provoke mixed/manic episodes in patients with comorbid bipolar disorder.

This review of Concerta contains general information. For complete information about Concerta and individual use, a health care professional should be consulted.

Relevance to Childhood Development

Concerta is a well-established pharmacological treatment for the symptoms of ADHD (inattention, impulsivity, hyperactivity) in children and adolescents. At the same time, pharmacological treatment of ADHD may be needed for extended periods, but the effectiveness of methylphenidate in long-term use has not been systematically evaluated. Further, the safety and effectiveness of this drug in pediatric patients younger than 6 years have not been established.

Conditioning

Daniel Patanella
New York City Department of Education, New York, NY, USA

Synonyms

Classical conditioning; Habit; Instrumental conditioning; Learning; Operant conditioning; Respondent conditioning

Definition

Conditioning refers to any process by which an organism acquires new behaviors through repeated experience.

Description

There are two main types of conditioning. The study of the first, known as classical or respondent conditioning, originated in the early twentieth Century work of the Soviet physiologist Ivan Pavlov (1849–1936) and the American psychologist Edwin B. Twitmyer (1873–1943); it found its best-known adherent in John B. Watson (1878–1958), who popularized the term "behaviorism." The study of the second, known as operant or instrumental conditioning, primarily derives from the works of B. F. Skinner (1904–1990). Both forms of conditioning were extensively researched in laboratory work using not only humans but also other living creatures such as pigeons, rats, and dogs. While the distinction between the two major types of conditioning is very clear within experimental research, it is important to remember that in the real world, both forms of conditioning may operate simultaneously to influence the behavior of all living things. Although the biological predispositions toward certain types of conditioning and the potential limitations of conditioning to explain aspects of cognition have been touted by physiologically and cognitively oriented psychologists [3, 5], the utility of conditioning as a means to understand behavior through a mechanistic perspective certainly remains strong.

Classical Conditioning

Classical conditioning is a form of learning in which an organism comes to associate one stimulus with another, prompting a behavior previously associated only with the first stimulus. In the terminology of classical conditioning, those stimuli that an organism does not need to learn to respond to are called "unconditioned stimuli." Those stimuli which an organism learns to respond to are called "conditioned stimuli." If the unconditioned and conditioned stimuli are reliably presented in a predictable sequence in which the conditioned stimulus appears immediately prior to the unconditioned stimulus, over a period of trials the organism can learn to respond only to the conditioned stimulus. These responses are referred to as "conditioned" because even though they are the exact same behaviors elicited in response to the unconditioned stimuli, they are being evoked by a conditioned stimulus.

In Pavlov's seminal research, for example, dogs were trained to salivate to the ringing of a bell. Salivation is a naturally occurring response to a stimulus such as presentation of food, and does not need to be learned. By reliably pairing the ringing of a bell to the presentation of food, Pavlov was able to elicit the salivating behavior even when the food was no longer reliably presented immediately after the bell was rung. Twitmyer performed a similar experiment in which human participants learned to associate the ringing of a bell to being struck on the knee with a hammer, and therefore were conditioned to exhibit the patellar reflex in response to the sound of a bell.

Much of classical conditioning, as is evident from the examples given, is concerned with the elicitation of reflexive physical behavior in response to formerly novel or neutral stimuli. These reflexes include blinking, salivating, and swallowing. As Watson's theorizing matured, he preferred to conceptualize the learning occurring in classical conditioning as the formation of habits. Watson also demonstrated that classical conditioning can also be used to influence behavior that is not purely reflexive, as in the controversial "Little Albert" study he published with Rayner (1920), in which an 11-month old child was conditioned to become fearful of a white rat to which he previously exhibited no negative reaction.

Should the association between the conditioned and unconditioned stimuli become weakened, a phenomenon known as "extinction" occurs. The organism no longer reliably exhibits the conditioned response (although it will still reliably exhibit the reflexive, unconditioned response to the unconditioned stimulus). Such behaviors are said to be "extinguished." However, if the relationship between the stimuli is re-established, the organism will relearn the behavior at a much faster rate than before, suggesting that the behavior was never completely unlearned. This rapid relearning is called "spontaneous recovery."

Operant Conditioning

Operant conditioning is not as dependent upon reflexive behavior as is classical conditioning. Instead, operant conditioning is primarily concerned with the effects of reinforcement and punishment upon behaviors. Rather than focusing on stimuli, operant conditioning focuses on the

consequences of behaviors, and what makes learned behaviors stronger or weaker. We should not misconstrue operant conditioning as being a technique which somehow transcends the biological hard-wiring of instinctive behaviors; as early as 1961, Skinner's former students Keller and Marian Breland, described the tendency of animals with strong instinctive behaviors to revert to these behaviors even after being successfully trained via operant conditioning, a phenomenon the Brelands termed "instinctive drift."

In operant conditioning, "reinforcement" refers to anything that makes a behavior more likely to occur. We can distinguish between positive reinforcement, which is analogous to a reward, and negative reinforcement, in which something unwanted or undesirable is removed as a result of a behavior. Giving a dog a treat for obeying commands is a good example of positive reinforcement, whereas turning an alarm clock off to stop the loud, unpleasant ringing of bells is a good example of negative reinforcement. Behaviors commonly associated with negative reinforcement are termed "escape" and "avoidance" because the organism is rewarded for escaping from or avoiding an unpleasant stimulus. Reinforcements can also be described as "primary," in which case they satisfy a basic biological need, or "secondary" in which their value is learned. Money, for example, is something we can use to buy food and drink and therefore is a secondary reinforcement. In general, reinforcements have a stronger effect on behaviors when they appear relatively soon after the behavior. Behaviors that are not reinforced tend not to be repeated.

Ferster (1922–1981) and Skinner are credited with distinguishing among four different schedules of reinforcement in the landmark book *Schedules of Reinforcement* (1957). These schedules are known as variable interval, fixed interval, variable ratio, and fixed ratio. "Interval" refers to the amount of time a behavior continuously occurs. "Ratio" refers to the actual amount of the behavior. "Fixed" means that the schedule is predictable, and "variable" means that the schedule is unpredictable. Due to their unpredictable nature, learning tends to occur slowly with variable ratio schedules, yet the very unpredictability of reinforcement under this schedule also means that behaviors reinforced using variable ratio schedules are highly resistant to extinction and will continue long after reinforcement has ceased. These schedules of reinforcement have been observed in both the laboratory and the real world. Being paid a set salary weekly, for example, is an example of a fixed interval schedule and being paid a set amount based on the amount of work completed is an example of a fixed ratio scale. Gambling behaviors such as playing slot machines are prime examples of reinforcement on variable ratio schedules and are quite difficult to extinguish.

Both in the laboratory and in the real world, operant conditioning can be used to train exceptionally complex behaviors through a technique in which organisms are first reinforced for performing a task that only vaguely approximates the desired behavior. Gradually, the reinforcements are given only when the organism's behaviors more closely approach the desired behavior and finally, the reinforcements are given only when the exact desired behavior is exhibited. This is referred to by conditioning researchers as "shaping through successive approximations" and explains how complex behaviors that are unlikely to emerge fully-formed can eventually become as deeply-ingrained as simpler behaviors.

Operant conditioning also elaborates upon "punishment," which is anything that causes a behavior to decrease in frequency. In this sense, the word "punishment" has a very close meaning to its English vernacular. Punishment is effective in getting an organism to immediately cease a potentially dangerous behavior. However, research demonstrates that such behaviors are not extinguished but merely suppressed, and not only do such behaviors re-emerge in the absence of the punisher but undesirable side-effects such as displaced aggression often appear in the punished organism. Skinner himself vocally opposed punishment on both humanitarian and practical grounds Thus, for durable long-term changes in behavior, conditioning researchers and practitioners usually recommend the use of both positive and negative reinforcement to promote desired behaviors that are incompatible with the undesired behavior.

Relevance to Childhood Development

Despite often being misconstrued as a purely experimental laboratory science, from almost the beginning behavioral scientists specializing in conditioning have sought out real world applications for their work, particularly in relation to childhood development and associated spheres such as education and the remediation of developmental delays. Watson and Rayner's "Little Albert" study, while often written about from the perspectives of those who rightly deplore the study's ethical lapses, also deserves attention for being one of the earliest attempts to apply the basics of laboratory science to understanding childhood development. This was not an anomaly for Watson, who earlier penned the broad "Psychology as the Behaviorist Sees It (1913)," and would later popularly publish childrearing advice for parents in *Psychological Care of Infant and Child* (1928).

Skinner conceptualized developmental changes in behavior as the accumulation of responses largely learned through operant conditioning, providing a mechanistic alternative to the largely biological and psychodynamic schools of development that were in the mainstream for much of the twentieth Century. As an empiricist and theoretician, Skinner deplored what he viewed as inconsistent reinforcers and inefficient environmental controls in the classroom, and advocated self-paced learning with contingencies similar to Skinner's schedules of reinforcement; not only did Skinner provide the groundwork for what he called "teaching machines," but he also collaborated with other authors on self-tutorial textbooks such as *The Analysis of Behavior* (1961). Skinnerian principles of reinforcement provide the backbone of the field of behavior analysis, which has numerous implications not only for everyday classroom management but also for remediation and training of social skills for children with special needs. Stuttering, asocial behavior, below-average academic performance, and hyperactivity are all areas that can show tremendous improvement using programs grounded in conditioning theory.

Conduct Disorder

Tony Wu
Walden University, Diamond Bar, CA, USA

Synonyms

Aggressive behaviors; Behavioral disorders; Behavioral disturbances; Defiance and norm violation; Severe emotional and behavioral problem

Definition

Conduct disorder is a mental health disorder in which there is a significant repetitive and persistent pattern of anti-social, rule-breaking, and norm-violating behaviors.

Description

According to the Diagnostic and Statistical Manual of Mental Disorders IV-TR [1], the main characteristic of conduct disorder is a persistent and recurring behavioral pattern of rights violation of others, ruling breaking, and infringement of social norms. These behaviors can include but are not limited to aggressive conduct that instigates physical harm to people and/or animals, actions that cause property damage, and larceny. These behavioral disturbances must create significant functioning impairment in social, academic, or occupational domain. Conduct disorders are usually diagnosed in childhood or adolescence, but may be diagnosed for adults when the individuals do not meet the criteria for Antisocial Personality Disorder.

Typically, children with conduct disorder display aggressive behaviors toward others. They bully, threaten other children; they engage in fights and use weapons. In severe cases, they would taunt their victims, or even force someone into sexual activity. Studies have estimated the prevalence of conduct disorder has increased with higher occurrence in urban areas. Depending on the samples and methods, for boys under the age of 18, it is reported to be between 6% to 16%, while it is estimated from 2% to 9% for girls in the population. Given its high prevalence rate,

conduct disorder is a common diagnosis for children and adolescent in mental health facilities [1].

Twin and adoption studies have provided evidence of both genetic and environmental factors in the development of conduct disorder. For example, the risk for conduct disorder increases when a child's caregiver has Antisocial Personality Disorder or when siblings have similar emotional behavioral problems. Other disorders that have been linked to conduct disorder include Alcohol Dependence, Mood Disorders, Schizophrenia, and Attention-Deficit/Hyperactivity Disorder [1]. Other studies have offered similar findings. For example, parents' antisocial personalities are associated with children's conduct problems [5]. Additionally, in an Epidemiological Catchment Area study, with 20,000 persons, conduct problem prior to age 15 is highly associated with schizophrenia than the general population [7].

In terms of long-term outcomes for individuals with conduct disorder, studies have painted a somewhat bleak picture. Children with conduct disorder have poor prognosis in later years; they are more likely to have criminal history, mental and medical problems, domestic violence and financial problems. When conduct problem occurs before the age of 10, children may have lower IQ, ADHD, poor temperament, neglect, and low socio-economic status [6]. Correspondingly, the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) produced similar results. This study looked at 56 sites in the United States and found that three-quarters of men who had childhood onset conduct disorder had more aggressive behaviors when compared to others [9]. Other studies showed that adolescents with conduct problems use more alcohol and drug [2] at a younger age than their peers [8]. One interesting note is Blair and Coles [3] found that children with conduct disorder are less likely to identify sadness and fear expressions in laboratory test. Other attempts to investigate child conduct difficulties have converged on the adequacy of parenting [4].

Conformity Among Adolescents

Ashlea Smith
Phoenix College, Phoenix, AZ, USA

Synonyms

Compliance; Conformists; Obedience; Peer groups; Peer influences; Peer pressure; Social competence; Social influence

Definition

Conformity among adolescents refers to the degree of compliance (e.g., peer pressure or fitting in) with peer defined socially acceptable norms on how to act, think, and feel.

Description

During the early 1950s and 1960s a new concept that dominated the field of psychology was formed called; "social psychology" that emphasized that all people have a desire to essentially fit in with a group or follow socially accepted norms to avoid being labeled as an outcast [4]. The world is filled with people who long to feel a sense of belonging to a group or a relational connection with other people. Those whom are unable to achieve this need to fit in may then start to feel socially excluded, oppressed, rejected, or regarded as social deviants. This need to fit in or be accepted by peers typically is most prevalent in the adolescent years of development (ages 11–17). Adolescence is a period of human development when someone is no longer considered a child, but has not yet reached adulthood.

Adolescent years are filled with many potential stressors such as: peer pressures, physiological and emotional changes associated with puberty, an increase in one's autonomy, the need for close peer relationships, and the development of one's identity. All of these events in some shape or another are molded by the level of peer group acceptance or conformity by teens. The term conformity, defined as the degree to which individuals follow the socially accepted rules for behavior set by peers or parents, is commonly used when describing adolescents preferably using the word, "conformists" [1]. This trend is also referred to as peer pressure which becomes visible when evaluating how groups of adolescents adhere to peer established group norms defining one's clothing selection, body shape or size, hairstyles, demeanor, etc. to name a few. On the other hand these peer established group norms or rules can also be characteristics targeted by bullies [3]. John [2] original motion picture, *The Breakfast Club*, so eloquently illustrated the concept of conformity among adolescents, by using five characters to depict five different peer groups and the common stressors that adolescents face [2]. This film portrays the adolescent stereotypes of the prom queen (Molly Ringwald), the jock (Emilio Estevez), the nerd (Anothy Michael Hall), the misfit (Ally Sheedy), and the criminal (Judd Nelson), but in the end shows that each character's original perceived differences that initially separated each character from the other; really made them realize just how similar they really were in the end of the film. The characters actually became friends and developed a relational connection that would always be remembered from their experience together in detention.

One of the most important ways to buffer the bullying experienced by some adolescents is to have close peer relationships or friendships. Adolescents typically select friends that share common interests, values, and attitudes. [1] described how adolescents with stable peer friendships often achieve higher academic performance, adapt to their environments, and exhibit less signs of problematic behavior than those youth who do not have stable peer relationships. These intimate friendships are highly influential in the personal lives of adolescents and hold true for both males and females. Additionally, adolescents with intimate friends are more likely to be sensitive to other's feelings, engage in altruistic behaviors, and show a mutual understanding and relational connection with each other [1].

Relevance to Childhood Development

As children progress to the adolescent years of development they begin to seek a greater sense of autonomy from parents and other adults. This new found sense of autonomy and need for more responsibility and freedom lures adolescents to pursue the comfort and acceptance from peer groups. The adherence to these peer defined norms of behavior (conformity) causes adolescents to become more susceptible to peer pressures which impact the development of one's identity.

Conners' Parent Rating Scales – Revised

Jessica R. Gurley
Argosy University, Arlington, VA, USA

Synonyms

Conners' teacher rating scale – revised; Conners-wells adolescent self report scale personality testing

Definition

The Conners' Parent Rating Scale – Revised is a parent report scale appropriate for parents with children between the ages of 3 and 17.

Description

The Conners' Parent Rating Scale – Revised (CPRS-R) is the parent form of the Conners' Rating Scales – Revised (CRS-R). The CRS-R were designed to address the need for a multimodal assessment of children and adolescent's behavioral difficulties and contain a parent form, and teacher form, and an adolescent self report form. The parent form, the CPRS-R, is appropriate for use with parents of children and adolescents ages 3 through 17. There are two forms of the CPRS-R: the Long Form (CPRS-R:L) and the Short Form (CPRS-R:S). The Long Form contains 80 items and can be completed by most parents/guardians in approximately 20 minutes; the Short Form contains 27 Items and can be completed in 5 to 10 minutes. On each form, the parents/guardians rate how often their child or adolescent engages in the behaviors listed on a form based on a four point scale. The scale ranges from Not True at All (Never) to Very Much True (Very Often) [1, 2, 4, 5].

The CRS-R system is useful when assessing children and adolescents for Attention Deficit/Hyperactive Disorder (ADHD). The items on the measures are face valid and very similar to the diagnostic criteria for ADHD in the DSM-IV [1, 3, 5].

Scales

Both forms of the CPRS-R have a variety of scales. The raw scores from the items on the CPRS-R are converted into T-scores [1].

The 80 items on the CPRS-R:L can be used to calculate seven subscales, an ADHD Index, three Conners' Global Indices (CGI) and three DSM-IV Symptom Indices. The seven subscales assess for a variety of behaviors that have been associated with behavior problems in children and adolescents, including Oppositional, Cognitive Problems/Inattention, Hyperactivity, Anxious-Shy, Perfectionism, Social Problems, and Psychosomatic. The ADHD Index is useful when identifying children and adolescents who may meet DSM-IV criteria for ADHD. There is strong evidence for ADHD when the ADHD Index, the DSM-IV Symptoms Indices, the Hyperactivity Subscale, and the Cognitive Problems/Inattention Subscales are all elevated [1].

The CGI-Total is comprised of the CGI Restless-Impulsive and the CGI Emotional Lability. The CGI-Total is best described as a general measure of psychopathology. The CGI Restless-Impulsive is associated with symptoms of hyperactivity while the CGI Emotional Lability is associated with mood swings [1].

The three DSM-IV indices were designed to determine how many DSM-IV criteria for ADHD the child or adolescent being assessed meets. The three DSM-IV indices are divided into a DSM-IV Total, DSM-IV Inattention, and DSM-IV Hyperactive-Impulsive. These indices can be scored dimensionally (e.g., transformation into T scores) and categorically (e.g., counting the number of items endorsed as occurring "Often" [1]).

The CPRS-R:S contains 28 items that can be used to calculate three scales (Oppositional, Cognitive Problems/Inattention, and Hyperactivity) and the ADHD Index. The manual reports the short form should be used over the long form when there is not enough time to complete the long form or when the clinician plans to administer the test numerous times to the same individual [1].

Scoring

The CPRS-R can be scored by hand in approximately 10 minutes. The raw scores for each index are transformed into T scores on the scoring sheet. There are separate scoring sheets for males and female children/adolescents. Additionally, each scoring sheet contains five different sets of norms for different age groups.

Unlike other personality tests, the CPRS-R:L and CPRS-R:S do not have formal reliability and validity scales. Instead, the manual recommends that the mental health professional using the CPRS-R examine the protocol for random responding by assessing for an overabundance of one particular answer and zigzag patterns. Additionally, the mental health professional should examine the protocol for inconsistent responses [1].

Psychometric Properties

The CRS-R was standardized on over 8,000 individuals between the ages of 3 and 17 in the United States and Canada. The standardization sample was representative of sex and age. Additionally, the manual notes that minority groups were well-represented. The internal consistency of the CPRS-R:L is good and range from 0.772 (Psychosomatic – Male) to 0.936 (ADHD – Male). The internal consistency for the CPRS-R:S was similar, ranging from 0.857 (Hyperactivity – Female) to 0.938 (ADHD – Male). The test-retest reliability for the CPRS-R:L ranges between 0.47 (Anxious-Shy) and 0.85 (Hyperactivity) while the test–retest reliability for the CPSR-R:S ranges from 0.62 (Oppositional) to 0.85 (Hyperactivity) [1, 2].

Relevance to Childhood Development

The CRS-R can be used to screen children and adolescents for symptoms of ADHD [1, 6].

Definition

The Conners' Teacher Rating Scale – Revised is a teacher report scale appropriate for teachers of children and adolescents between the ages of 3 and 17.

Description

The Conners' Teacher Rating Scale – Revised (CTRS-R) is the teacher form of the Conners' Rating Scales – Revised (CRS-R). The CRS-R were designed to address the need for a multimodal assessment of children and adolescent's behavioral difficulties and contain a parent form, and teacher form, and an adolescent self report form. The teacher form, the CTRS-R, is appropriate for use with teachers of children and adolescents ages 3 through 17. There are two forms of the CTRS-R: the Long Form (CTRS-R:L) and the Short Form (CTRS-R:S). The Long Form contains 59 items and the Short Form contains 28 Items. On each form, the teachers rate how often their students engage in the behaviors listed on a form based on a four point scale. The scale ranges from Not True at All (Never) to Very Much True (Very Often) [1, 2].

The CRS-R system is useful when assessing children and adolescents for attention deficit hyperactive disorder

(ADHD). The items on the measures are face valid and very similar to the diagnostic criteria for ADHD in the DSM-IV [1, 3].

Scales

Both forms of the CTRS-R have a variety of scales. The raw scores from the items on the CTRS-R are converted into T-scores [1].

The 59 items on the CTRS-R:L can be used to calculate six subscales, an ADHD Index, three Conners' Global Indices (CGI) and three DSM-IV Symptom Indices. The six subscales assess for a variety of behaviors that have been associated with behavior problems in children and adolescents, including Oppositional, Cognitive Problems/Inattention, Hyperactivity, Anxious-Shy, Perfectionism, and Social Problems. The ADHD Index is useful when identifying students who may meet DSM-IV criteria for ADHD. There is strong evidence for ADHD when the ADHD Index, the DSM-IV Symptoms Indices, the Hyperactivity Subscale, and the Cognitive Problems/Inattention Subscales are all elevated.

The CGI-Total is comprised of the CGI Restless-Impulsive and the CGI Emotional Lability. The CGI-Total is best described as a general measure of psychopathology. The CGI Restless-Impulsive is associated with symptoms of hyperactivity while the CGI Emotional Lability is associated with mood swings.

The three DSM-IV indices were designed to determine how many DSM-IV criteria for ADHD the student being assessed meets. The three DSM-IV indices are divided into a DSM-IV Total, DSM-IV Inattention, and DSM-IV Hyperactive-Impulsive. These indices can be scored dimensionally (e.g., transformation into T scores) and categorically (e.g., counting the number of items endorsed as occurring "Often" [1].

The CTRS-R:S contains 28 items that can be used to calculate three scales (Oppositional, Cognitive Problems/Inattention, and Hyperactivity) and the ADHD Index. The manual reports the short form should be used over the long form when there is not enough time to complete the long form or when the clinician plans to administer the test numerous times to the same individual [1].

Scoring

The CTRS-R can be scored by hand in approximately 10 min. The raw scores for each index are transformed into T scores on the scoring sheet. There are separate scoring sheets for males and female children/adolescents. Additionally, each scoring sheet contains five different sets of norms for different age groups.

Unlike other personality tests, the CTRS-R:L and CTRS-R:S do not have formal reliability and validity scales. Instead, the manual recommends that the mental health professional using the CTRS-R examine the protocol for random responding by assessing for an overabundance of one particular answer and zigzag patterns. Additionally, the mental health professional should examine the protocol for inconsistent responses [1].

Psychometric Properties

The CRS-R was standardized on over 8,000 individuals between the ages of 3 and 17 in the United States and Canada. The standardization sample was representative of sex and age. Additionally, the manual notes that minority groups were well-represented. The CTRS-R:L was standardized on teacher ratings of 1,983 children and adolescents when the CTRS-R:S was standardized on the ratings of 1,897 children and adolescents. The internal consistency of the CTRS-R:L is good and range from 0.773 (CGI Emotional-Labile – Female) to 0.958 (DSM Total – Male). The internal consistency for the CTRS-R:S was similar, ranging from 0.882 (Cognitive Problems/Inattention – Male) to 0.952 (ADHD – Male). The test–retest reliability for the CTRS-R:L ranges between 0.47 (Cognitive Problems/Inattention and DSM-IV Hyperactive-Impulsive) and 0.99 (Anxious/Shy) while the test–retest reliability for the CTSR-R:S ranges from 0.72 (Hyperactivity) to 0.92 (Cognitive Problems/Inattention) [1].

Relevance to Childhood Development

The CRS-R can be used to screen children and adolescents for symptoms of ADHD. It can also be used as part of a comprehensive psychological evaluation to diagnose ADHD.

Definition

Conners-Wells Adolescent Self Report Scale is a self-report scale of symptoms appropriate for adolescents between the ages of 12 and 17.

Description

Conners-Wells Adolescent Self Report Scale (CASS) is the adolescent form of the Conners' Rating Scales – Revised (CRS-R). The CRS-R were designed to address the need for a multimodal assessment of children and adolescent's behavioral difficulties and contain a parent form, and teacher form, and an adolescent self report form. The adolescent self-report form, the CASS, is appropriate for use with adolescents ages 12 through 17, although some studies have examined its utility with children younger than 12 [1, 2]. There are two forms of the CASS: the Long Form (CASS:L) and the Short Form (CASS:S). The Long Form contains 87 items and the Short Form contains 27 Items. Both forms were written to be at a sixth grade reading level and can be completed quickly (e.g., less than 20 minutes for the long form). On each form, the adolescents rate how often they engage in the behaviors listed on a form based on a four point scale. The scale ranges from Not True at All (Never) to Very Much True (Very Often) [1, 3].

The CRS-R system is particularly useful when assessing children and adolescents for Attention Deficit/Hyperactive Disorder (ADHD). The items on the measures are face valid and very similar to the diagnostic criteria for ADHD in the DSM-IV [1, 3]. Additionally, the CASS can be used to help identify adolescents who may benefit from additional evaluation or intervention.

Scales

Both forms of the CASS have a variety of scales. For all of the CRS-R forms, the raw scores from the items are converted into T-scores [1]. The CASS differs from the teacher and parent version of the CRS-R because it does not provide the Conners' Global Indices.

The 87 items on the CASS:L can be used to calculate six subscales, an ADHD Index, and three DSM-IV Symptom Indices. The six subscales assess for a variety of behaviors that have been associated with behavior problems in children and adolescents, including Family Problems, Emotional Problems, Conduct Problems, Cognitive Problems/Inattention, Anger Control Problems, and Hyperactivity. The Family Problems scale is unique to the CASS and identifies adolescents who are experiencing difficulties within their family system. The ADHD Index is useful when identifying students who may meet DSM-IV criteria for ADHD. There is strong evidence for ADHD when the ADHD Index, the DSM-IV Symptoms Indices, the Hyperactivity Subscale, and the Cognitive Problems/Inattention Subscales are all elevated [1, 4]. This is especially true when these elevations are consistent across raters (e.g., the adolescent, parents, and teachers).

The three DSM-IV indices were designed to determine how many DSM-IV criteria for ADHD the adolescent being assessed meets. The three DSM-IV indices are divided into a DSM-IV Total, DSM-IV Inattention, and DSM-IV Hyperactive-Impulsive. These indices can be scored dimensionally (e.g., transformation into T scores) and categorically (e.g., counting the number of items endorsed as occurring "Often" [1]).

The CASS:S contains 27 items that can be used to calculate three scales (Conduct Problems, Cognitive Problems/Inattention, and Hyperactive-Impulsive) and the ADHD Index. The manual reports the short form should be used over the long form when there is not enough time to complete the long form or when the clinician plans to administer the test numerous times to the same individual [1].

Scoring

Similar to the other instruments that comprise the CRS-R system, the CASS can be scored by hand in approximately 10 minutes. The raw scores for each index are transformed into T scores on the scoring sheet. There are separate scoring sheets for males and female children/adolescents. Additionally, each scoring sheet contains two different sets of norms for different age groups.

Unlike some instruments for adolescents, the CASS:L and CASS:S do not have formal reliability and validity scales. Instead, the manual recommends that the mental health professional using the CASS examine the protocol for random responding by assessing for an overabundance of one particular answer and zigzag patterns. Additionally, the mental health professional should examine the protocol for inconsistent responses [1].

Psychometric Properties

The CRS-R was standardized on over 8,000 individuals between the ages of 3 and 17 in the United States and Canada. The standardization sample was representative of sex and age. Additionally, the manual notes that minority groups were well-represented. The CASS:L was standardized on 3,394 adolescents when the CTRS-R:S was standardized on 3,486 adolescents. The internal consistency of the CASS:L is good and ranges from 0.743 (Hyperactive-Impulsive – Female) to 0.894 (Conduct Problems – Male). The internal consistency for the CASS:S was similar, ranging from 0.753 (ADHD Index - Male) to 0.849 (Conduct Problems – Male). The test–retest reliability for the CASS:L ranges between 0.73 (Cognitive Problems/Inattention) to 0.89 (Emotional Problems) while the test–retest reliability for the CASS:S ranges from 0.72 (Conduct Problems) to 0.87 (ADHD Index) [1].

Relevance to Childhood Development

The CRS-R can be used to screen children and adolescents for symptoms of ADHD. The CASS can be used to identify adolescents who are experiencing symptoms consistent with ADHD (e.g., difficulty sustaining attention) and to identify adolescents who may benefit from additional assessment or intervention [4, 5].

Consequences

Nina Foster
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Effect; Outcome

Definition

Within the context of behaviorism and learning theory, consequences are outcomes that follow a behavior.

Description

A consequence is the outcome or effect that follows a behavior. A consequence indicates the importance or significance of the behavior that immediately preceded the consequence. The repetition or non-repetition of the behavior is determined by the conditions of the consequence. It is a learning, or cause and effect, relationship [1].

Related to Behavioral Therapy

The focus on consequences of behavior, in order to change the behavior, is utilized in the behavioral therapy approach and there are numerous techniques used within this theoretical orientation. Positive reinforcement involves providing a consequence that supports the behavior. It is utilized to increase the probability of the behavior occurring again. Negative reinforcement involves the removal of an aversive stimulus in order to increase the likelihood of the behavior. Punishment techniques are used to decrease the behavior by applying aversive consequences immediately following the behavior. Thus, behavioral therapy uses different types of consequences to either increase desirable behaviors or decrease undesirable behaviors. Along with reinforcements and punishments, skills training and practice can be used as well.

Related to Rational Emotive Behavior Therapy

The central concept of Rational Emotive Behavior Therapy (REBT) is ABC: Antecedents, Beliefs, and Consequences.

In this theoretical approach a consequence is a result of the belief about the antecedent, which may be an event, experience, thought, or emotion. The consequence can either be adaptive or maladaptive. When the consequences are primarily unhealthy, creating negative emotions and self defeating behaviors, different techniques are utilized to produce a more rational thought process. "Disputing" is the primary technique utilized to produce a healthier consequence for the individual [2]. Other techniques include role playing, rational-irrational dialogues, reinforcements and penalties, homework, shame attacking, and skills training.

Solitary constructive play

Definition

Constructive Play is the using or manipulating of objects with creation or construction of something as a purpose. Constructive play is the use of materials by children to achieve a specific goal in mind that requires transformation of objects into something new.

Description

This type of play typically emerges in children around the age of 2 and will be the dominant type of play from the age of 3 and on [1]. The primary goal of this type of play is not the having of the object, but the creation of the object [2]. This type of play also allows the child to develop their own working theories about the natural, social, material, physical worlds through enquiry research, exploration, generation, and modification [4].

Relevance to Childhood Development

Over the years, early childhood researchers have found that constructive play is essential for children as a building block and critical component of the foundation researchers feel children need to lead happy, healthy, and productive lives. Experts agree that constructive play is safe, wholesome, and non-violent and that it stimulates children to develop skills and positive relationships. According to researchers, constructive play also inspires children to learn more about themselves and the world around them and it enables children to fully realize their potential. Researchers also agree that constructive play encourages creativity and helps develop a child's personality and makes learning fun [5]. Research has also focused on solitary constructive play with children and the positive benefits or outcomes of solitary constructive play. Some positive outcomes solitary constructive play has for children are emotional development, physical skills, language development, and social information processing abilities, and from the first to the third grade, relatively lower levels of social problems [3]. Researchers have also found that solitary constructive play behaviors have been related to happier moods and increased alertness and rather than immaturity or dependence, solitary constructive play has also been found to be related to maturity and independence [3]. Types of solitary constructive play is described as the repetitive movements of muscles with or without the use of an object and includes activities such as creating artwork, attempting and/or completing puzzles, and construction using blocks [3]. As they create, children begin to understand the nature and properties of a range of materials through constructive play. Constructive play also promotes the development of spatial understandings, including an awareness of how objects can be fitted together and move in space. Children develop mathematical concepts such as numbers, length, weight, volume, shape, and pattern for meaningful and increasingly

complex purposes through constructive play. During constructive play, children have many opportunities to re-create experiences and express their own ideas about the world [4].

Constructivist Family Therapy

►Constructivist Psychotherapy

Constructivist Psychotherapy

Bernadette Hassan Solórzano
Our Lady of the Lake University Community Counseling Service, San Antonio, TX, USA

Synonyms

Constructivist family therapy; Developmental constructivism; Narrative therapy; Personal constructs; Postmodernism; Relativistic philosophy; Social constructivism; Systemic therapy

Definition

Constructivist therapies are theories of change that place clients in the role of meaning makers and active participants in their own lives. There are multiple ways of understanding any one given situation [1]. How each person interprets a situation is influenced by their previous life's experiences. Even then, it is possible to focus on one piece of a situation and apply meaning, but if you change focus, a completely different meaning may be discovered. Constructivist therapies moved away from the deficit model that labels and pathologizes. The therapist's role shifted from an expert, didactic position to one of collaboration and exploring to assist the client in uncovering their strengths and resources. The role of language and meaning making is a large part of the therapeutic process. Lynn Hoffman [5] defined it best.

> In contrast, social construction theory posits an evolving set of meanings that emerge unendingly from the interactions between people. These meanings are not skull-bound and may not exist inside what we think of as individual "mind." They are a part of a general flow of constantly changing narratives. Thus, the theory bypasses the fixity of the model of biologically based cognition, claiming instead that the development of concepts is a fluid process, socially derived. It is particularly helpful for the therapist to think of problems as stories that people have agreed to tell themselves. . .Many styles of doing therapy that would otherwise compete can crowd together under its broad rim, as long as their practitioners agree that all therapy takes the form of conversations between people and that the findings of these conversations have no other "reality" than that bestowed by mutual consent.

Some of the theoretical models based on social constructivism are strategic therapy, solution focused therapy, narrative therapy and collaborative therapy. Jerome Bruner [2] encouraged us to teach our children "an appreciation of the fact that many worlds are possible, that meaning and reality are created and not discovered" (p. 149) Mahoney [7] emphasized that constructivism provides "a metatheoretical home for diverse approaches to psychotherapy." (p. 307) The concept that meanings are created within each of us individually as well as in interactions with others, influences how individuals make meaning of themselves and their lives. The constructivist therapist will work in a non-hierarchical relationship with clients to develop new understandings that will highlight the strengths, resources and talents of each person. As individuals recognize these qualities, the prospect of a more positive future is created. Social constructivists frequently emphasize that small change leads to bigger change [6].

Description

A hallmark of constructivist therapy is that the therapist is not looking for the "real" truth or the need to find the "why" that a problem has occurred. The therapist is an expert in asking questions and being curious. In finding a way to ask circular questions that will in turn lead to

more questions, new perspectives and possibilities emerge. It would be naïve to say that the therapist has no impact on the creation of new understandings. The very act of what the therapist chooses to be curious about creates a certain amount of influence [3]. Many times, clients have created a reality of their situations in their lives and see no other options or solutions. They become stuck and continue to apply the same sort of understandings and solutions to the problems which then escalates the problem, convincing them that there are not other choices and the situation becomes hopeless [8].

An important aspect of beginning the session is to understand that the person is not the problem, the problem is the problem. Thus, it is important to starting with the smallest goal, staying in the present and obtain a clear, concrete, measurable, positive goal that is within the client's control establishes a success strategy. Constructivist therapists believe that each human creates their own meanings both within themselves and in interactions with others. It is important to consider cultural influences, gender and age along with family dynamics as impacting how each person understands their situation. The goal of the constructivist therapist is to empower the client. When considering the aspect of the narrative, the client is creating a reality in how they understand their lives, it is as if they are no longer the hero of their own story. The ability for them to reclaim that leads to self-empowerment. The therapist wants to ensure that the client takes ownership of their own solutions and not credit the therapist. It is also important for the therapist to be open to self-evaluation to avoid imposing their own values on the client [9].

Relevance to Childhood Development

Constructivist therapeutic approaches are an excellent fit for children and their families. Michael White and David Epston developed the narrative approach and utilized externalization as a tool to place the problem outside the child. This means that the therapist is no longer working with an "ADHD child" or "depressed child" or an "angry child." By shifting the language to a "child dealing with anger" or "sadness" or "problem sitting still and paying attention," the therapist has introduced that the child is not "broken" and now the entire family can join forces to help the child overcome the problem [1, 4, 10]. This also introduces the fact that the child no longer has an excuse for the behavior but has to look at taking responsibility for the choices made. Since no problem occurs all the time, the therapist can help the child and family look at times when the problem could have occurred but did not. Frequently this reveals an existing solution that can be utilized consistently. Since developmentally, children have wonderful imaginations, White and Epston documented many cases working with life threatening eating disorders very successfully with this approach [4, 11].

Constructivist View (Piaget)

Kathleen Brown
Niagara University, NY, USA

Definition

Constructivism is considered to be a theory of learning, illuminating the processes by which students respond to instruction, and, organize information into individually relevant schemata [1].

Description

Although Jean Piaget (1896–1980) is associated with education and developmental theory, he obtained his doctorate in natural sciences. His work in this field led him to the awareness that biological development was due to environmental variables, as well as heredity. This grounding in science led him to conclude that cognitive development was grounded in environmental adaptation and

organization, and also that cognitive development and biological development share the same basic principles. Human beings have both biological and intellectual components. Both are required in order to organize the experiences of adapting to environmental stimuli [2].

Piagetian nomenclature lists four basic cognitive structures that exist in man – schema, assimilation, accommodation and equilibrium. The use of all four structures is necessary for cognitive development [2].

Schema

Schema is the intellectual counterpart of biological adaptation. Schemata can be likened to categories. New information is constantly being processed and assigned categories. As children grow and develop more, schemata are added based on their experiences. Schemata are constantly being refined and adapted [2].

Assimilation

Assimilation is a cognitive process whereby children attempt to fit new theories and experiences into existing schemata. If a child's first view of an animal was a "cow", henceforth whenever she encountered a new animal, she would say "cow". Parents would present new information – correct name of new animal – which would then be assimilated into the animal schemata. In this way the child classifies new animals into her existing schemata. Assimilation is thus an ongoing process and part of the child's development. Children adapt to, and organize, their environment based on their individual experiences [2].

Accommodation

Accommodation refers to the increase of a child's individual schemata in response to new experiences or information. First, children try to assimilate new information into existing schemata, but if they cannot do this, they create a new schemata, either by modifying an existing schema or creating a new one [2].

Equilibrium

Balance is needed between assimilation and accommodation. Assimilation without accommodation would result in a few very large schemata. The child would have difficulty detecting differences. Accommodation without assimilation would result in a large number of very small schemata. Either extreme is undesirable. Equibrilation is a self-regulated process that uses both assimilation and accommodation to achieve equilibrium [2].

Relevance to Childhood Development

Piaget believed that when new information is connected with prior knowledge and experience, learning occurs. Individuals can also learn and create new knowledge by reflecting on past actions [1]. In a constructivist view, learning is not a direct line from ignorance to knowledge, with knowledge being acquired by having someone in authority deliver facts. This type of acquisition of knowledge exists in a non-constructivist classroom when students memorize facts so that they may regurgitate them on exams. In a constructivist classroom, there would be more active engagement and less "drill and skill" types of learning.

True knowledge, versus data memorization, is not something a student receives from an all-knowing, all-powerful teacher. Rather, a constructivist teacher would create an environment in which the student could explore, investigate and create new constructions under the guise of 'answers'. Presenting students with questions to answer or problems to solve creates disequilibrium. Will this new knowledge fit an existing schemata (assimilation), or, will the student be required to either modify a schemata or create an entirely new one (accommodation) in order to maintain their equilibrium?

As new information is constantly being acquired, the twin processes of accommodation and assimilation occur, leading to cognitive development. Human beings create knowledge and refine it. An example would be the process by which individuals came to learn that the sun did not revolve around the earth, rather the earth revolves around the sun. Scientific data required revised schemata because existing schemata were inconsistent with new information. In constructivism, it is expected that learners will encounter problems they cannot solve with existing schemata [1].

Constructivist strategies that promote cognitive development include cooperative learning, curriculum mapping, anticipatory sets, multiple intelligences, exploratory activities, active discussions, journal writing, and portfolio assessment.

In a constructivist classroom, both teachers and students learn to effectively critique their own ideas and those of others. The shift from traditional to constructivist teaching requires the teacher to spend less time judging answers and more time helping students to become better critics of their own thinking. One goal in a constructivist classroom would be students who would be able to accurately assess themselves. Knowledge is not static but is revised based upon new information that is assimilated by the active learner [1].

Constructivist practice integrates assessment into instruction. Exploration, comparison, evaluation, and analysis are terms often used in constructivist assessment. Skill acquisition and restatement of fact are terms more common to pre-constructivist practice. Student reflection is also part of constructivist practice. Students are given choices of how to demonstrate their understanding, leading to measures of individual growth rather than competition [1].

Continuous Performance Task

►Continuous Performance Test (CPT)
►Gordon Diagnostic System

Continuous Performance Test (CPT)

Synonyms

Continuous performance task

Definition

A psychological test which measures an individual's sustained and selective attention, and impulsivity response patterns

Description

A CPT is commonly used in a battery of other measures to diagnose attention deficit/hyperactivity disorder (ADHD). There are a variety of different CPTs, the two most common are the Conner's CPT-II and the Test of Variables of Attention (T.O.V.A.). Both the Conner's CPT-II and the T.O.V.A are administered on a computer and are fairly simple to administer. The Gordon Diagnostic System (GDS) is also a CPT; however, it is not done on a computer but rather is a computerized machine where individuals have to respond by pushing a button when they see a certain stimulus. In general, a CPT measures correct detection, reaction time, omission errors, and commission errors.

Conventional Level

►Conventional Moral Reasoning

Conventional Moral Reasoning

Amie Senland
Fordham University, Bronx, NY, USA

Synonyms

Conventional level

Definition

Conventional moral reasoning is the second of three levels of moral reasoning in Kohlberg's Structural Theory of Moral Development, where people have internalized the rules and expectations of those closest to them and generally make moral judgments based on the norms and expectations of their reference group (e.g., family, friends, etc.) [1–4].

Description

Conventional moral reasoning is the second of three levels of moral reasoning in Kohlberg's Structural Theory of Moral Development, a cognitive-developmental approach to moral development that describes six invariant, sequential, universal, and progressively complex structural stages of moral judgment across the life-span [3]. Kohlberg's theory of moral development suggests that as people mature cognitively, they develop an increasingly complex and inclusive view of who deserves justice. The level of conventional moral reasoning follows the level of preconventional moral reasoning and precedes the level of postconventional moral reasoning. There are two stages in the conventional level of moral reasoning, the first of which consists of a less complex and advanced sociomoral perspective than the second [3].

The first stage of conventional moral reasoning, Good-boy/Good-girl Orientation (also known as Mutual Interpersonal Expectations, Relationships, and Interpersonal Conformity) is Stage 3 in Kohlberg's theory of moral development [3, 5]. At this stage, individuals operate from a social perspective of being in relationship with others and focus on prioritizing shared feelings, expectations, and agreements over personal interests. People at this stage do what is right to maintain relationships and live up to the expectations of those closest to them. Following the principles of trust, loyalty, concern for others, and gratitude is perceived as important for maintaining mutual relationships [3, 5]. For example, an adolescent might respond to those within his or her social group or clique with acts of caring, loyalty, and trustworthiness but might not extend such prosocial acts to those outside his or her social circle, potentially teasing and excluding those in another social group or clique.

The second stage of conventional moral reasoning, Authority and Social Order Maintaining Orientation (also called Social System and Conscience) is Stage 4 in Kohlberg's theory of moral development [3, 5]. At this stage, individuals distinguish between a broader societal point of view and interpersonal agreements, as well as understanding the social system as defining and generating rules and roles that apply to everyone. People at this stage focus on doing right by fulfilling their duties and obligations, obeying laws and rules except under extreme circumstances, and contributing to society in order to avoid the breakdown of the social system as a whole [3, 5]. For example, at this stage, an individual would understand the underlying reasoning behind rules, comprehend that rules such as speed limits are in place to maintain order in society, and obey such rules to maintain the organization of society as a whole.

Relation to Childhood Development

Conventional moral reasoning is used by most adolescents, particularly at the high school level. Kohlberg also worked to apply his moral development theory to moral education and educational interventions, with the aim to help children progress to higher stages of moral development. At the high school/conventional level, two relevant applications of Kohlberg's theory include dilemma discussions and Just Community Schools [5, 6]. Dilemma discussions are hypothetical moral dilemmas used in classrooms or peer groups to foster growth in moral reasoning by creating dissonance between one's current stage and a higher stage of moral reasoning [5, 6]. Just Community Schools are small communities that offer high school students an opportunity to participate in a democratic school environment, including community meetings, where students and faculty are given equal voting power on real-life moral issues related to school rules and discipline [5, 6]. Using Kohlberg's theory as a guide, cognitive-developmental moral education interventions provide guidelines for fostering moral growth in students at conventional levels of moral reasoning, as well as other levels of moral reasoning.

Cooing

Meredith L. McKee
Washburn University, Topeka, KS, USA

Synonyms

Gurgle; Soft cry

Definition

Cooing is a stage of infants' *prelinguistic* speech development and consists of the production of single syllable, vowel-like sounds.

Description

The verbal behavior of infants during the first year of life is termed the *prelinguistic period* because it does not contain actual words [2]. Common noises during early infancy include crying, cooing, and variations in patterns of intonation. Emerging between 6 and 8 weeks of age, cooing is a stage of prelinguistic speech that is characterized by infants' first noncrying verbal behavior [3]. Consisting of brief, vowel-like utterances, such as "oo," or "aa" sounds, or consonant-vowel combinations such as "goo," cooing provides vocal practice and entertainment to infants, and aides in the development of motor control over vocalizations [1].

Relevance to Childhood Development

Cooing is a spontaneous vocalization behavior that infants typically engage in when they are in a comfortable state, and is also used by infants as a noncrying means to communicate to caregivers [2]. As infants grow older their vocalizations change in both pitch and intensity. At about 3 or 4 months of age, cooing develops into a wide array of repetitive sounds, vowels and consonants, called *babbling*, which is the next stage in the prelinguistic period [1].

Cooperative Integrated Reading and Composition (CIRC)

►Cooperative Learning

Cooperative Learning

Janet Ward Schofield
University of Pittsburgh, Pittsburgh, PA, USA

Synonyms

Complex instruction (CI); Constructive controversy (CC); Cooperative integrated reading and composition (CIRC); Group investigation (GI); Jigsaw classroom (JC); Student teams achievement divisions (STAD); Team assisted individualization (TAI); Teams-games-tournaments (TCT)

Definition

Cooperative learning is a generic term referring to a number of approaches typically designed to foster student learning through creating positive interdependence between students while at the same providing individual accountability.

Description

During the past 50 years, a wide variety of approaches to increasing student learning through the use of carefully planned cooperative activities have been developed and tested in both laboratory and school situations [1–3]. These approaches vary in a number of ways. For example, some are very concrete "recipe-like" procedures designed to be easy for teachers to learn and to implement, whereas others are much more abstract and require considerable work on the teacher's part to adapt and implement in specific classroom situations. Also, some are designed for students of a particular age and for a particular subject, whereas others can be adapted for use across a wide range of age groups and curriculum areas. Finally, some of these approaches combine in-group cooperation with out-group competition, but others do not.

However, cooperative learning approaches also have much in common. First, they typically foster cooperation in small face-to-face groups rather than in entire classes of students. Also, when the composition of the larger class allows it, these small groups are commonly composed of individuals from heterogeneous social backgrounds and with varied ability levels. In addition, cooperative learning approaches emphasize promoting positive interdependence between students. Thus, typically they create situations in which an individual student's success is dependent, to at least some extent, on the success of others in his or her small group. Some approaches emphasize goal interdependence, meaning that students cannot learn what they need to unless others in their group learn what they need to. Others emphasize reward interdependence, in which case students' grades or their attainment of other desirable rewards are influenced not only by what they learn but also by what others in their groups learn. Resource interdependence, in which students must share information or other resources to succeed, and role interdependence, in which students have complementary roles within their groups, are also commonly part of cooperative learning techniques.

Finally, cooperative learning approaches typically include elements intended to provide individual accountability. Mechanisms for achieving this include giving individual tests to students, having students teach what they have just learned to others, and having one group member engage in procedures designed to ensure that all group members understand what is occurring in the group. Conscious efforts are also commonly made to foster effective group functioning. These include specific instruction regarding roles, responsibilities, and appropriate modes of interaction as well as the allocation of class time for discussion, reflection, and feedback on how individual groups are functioning.

Based on a substantial body of research, a consensus has emerged that cooperative learning, when properly implemented, typically yields better learning outcomes than either individualized or competitive approaches [4]. Improved achievement is sometimes found primarily for initially low-achieving or minority students, although many studies suggest learning benefits for students from various backgrounds and with varying levels of initial achievement. Cooperative learning approaches are effective with elementary school children as well as with middle school and high school students, in spite of the fact that young school children may lack important social skills and/or have difficulty understanding the perspective of others.

Cooperative learning strategies often have social and personal benefits in addition to academic ones [5]. One of the most researched of these is cooperative learning's tendency to foster positive relations between students from diverse backgrounds compared to individualized or competitive modes of instruction.

Although the effectiveness of cooperative learning approaches has been clearly demonstrated, it should be emphasized that merely requiring students to work together is not sufficient to dependably yield academic and social benefits. Sometimes students do not have the skills to work well together. Also, diffusion of responsibility and social loafing can cause problems, which can result in little being accomplished or in some students doing a disproportionate amount of work while others do and learn little, if anything. Thus, the actual benefits gained from cooperation depend to a large extent on how the cooperative activities are structured.

Relevance to Childhood Development

Well-implemented cooperative learning strategies are likely to be useful in fostering students' academic and social development, although properly implementing such approaches can take considerable training and effort. In a world in which the ability to work effectively with individuals from different backgrounds has become a sufficiently important skill to be recognized as such in U.S. government reports, cooperative learning approaches are likely to be useful in preparing students to function effectively in the workplace as well as in other realms of life.

Cooperative Play

Jordan Luther
Niagara University, Niagara, New York, USA

Definition

The term "cooperative play" was originally coined by Mildred Parten in 1932 to describe the "highest level of social play" between young children. This genre of play is considered the highest level of play as both participants combine their efforts, as well as their feelings and ideas, towards a common goal in a "give-and-take interaction" [2].

Description

In the late 1920s, Parten began to observe the free play behaviors of preschool children between the ages of 2 and 5 [1]. She eventually devised a scale of social participation to rank six categories of social behavior. These categories were "unoccupied behavior, onlooker behavior, solitary independent play, parallel activity, associative play, and cooperative play" [1]. Cooperative play occurs in cyclical stages, as one child's behavior acts as a stimulus for the play behavior of their playmate and vice versa [3]. Therefore, each member of the cooperative play team is adapting to their partner's actions and is aware of their progress towards accomplishing the goal of the play situation. Cooperative play is more advanced than imitative

play because each child produces novel responses to the stimuli of their peers, as opposed to merely copying their peers' actions [3].

Relevance to Childhood Development

Cooperative play generally occurs between the ages of 3 and 4 and is reflective of a certain level of social, cognitive, and language development [3]. For example, children must be able verbally describe play behaviors and also be able to react to the verbal descriptions of play from their play partners [3]. Therefore, aspects of both expressive and receptive language communication are used by each child. Cooperative play also requires a certain degree of organization, as members are assigned different roles to complete relatively complex tasks [6]. According to Weininger [6], children can gain an understanding of their self in relation to other children through cooperative play by virtue of the tasks they are assigned (or the tasks they assign themselves), and in the reciprocal interactions they have with other children [6]. As well, through cooperative play, children can learn to predict the "actions, behaviors, or feelings" their play partner expects of them, which is an important skill fostering safe relationships with others in the future [6].

Unfortunately, cooperative play is less likely to occur among children who have certain disabilities. Specifically, disabilities which affect the ability to express/receive verbal messages, moderate emotive responses, read the affective cues of others, and engage in complex behaviors may decrease the likelihood an individual will engage in cooperative play [2]. Children who have not reached a certain level of language development may also have difficulty engaging in cooperative play with other children. For example, children who have an Autism Spectrum Disorder may have difficulty engaging in cooperative play due to their delays in language development, and therefore may not be able to express their feelings and/or ideas to their playmate(s) [4]. Children with mental retardation may not have the verbal and/or non-verbal intelligence to communicate and/or perform the actions necessary to complete the tasks of cooperative play.

Fortunately, cooperative play can be taught to children, including children who have disabilities. Jahr and Eldevik [3] found that if cooperative play was modeled, along with verbal descriptions of the specific behavioral steps taking place, preschool children, including children who have Autism, can learn these skills and generalize them to their own novel situations of cooperative play. Children with disabilities, as well as students without disabilities, can also learn important language, self-help, and communication skills from the behavioral and verbal modeling which occurs during cooperative play [3].

Cooperative play is especially important for children who are disabled as it allows for positive peer interactions with other disabled and non-disabled peers. It is crucial to include children with disabilities in all the social situations experienced by non-disabled children to help them acquire important social skills and allow them to experience the satisfaction of being included in regular peer groups [5]. Social isolation of children with disabilities should be prevented, reinforcing the importance of inclusive classrooms. As children with disabilities mature, it is increasingly relevant that efforts be made to accommodate their need for acceptance and inclusion by their non-disabled peers [5].

In light of the importance and utility of cooperative play, it should be encouraged whenever possible. Several studies indicate that the likelihood of cooperative play occurring between young children depends upon the type of toys which are present in their play environments [2]. For example, "social toys", such as "dress-up clothes" and "giant pillows", are more likely to elicit cooperative play amongst its users than "isolate toys", such as "puzzles" and "toy animals" [2]. Therefore, adults who work with young children and want to encourage cooperative play can do so by providing social toys. Even among preschool children who are disabled, the specific "social" toys selected can influence the degree of cooperative play they engage in with both disabled and non-disabled peers [2]. These social toys lend to ideal situations wherein cooperative play can occur. Ivory and McCollum [2] believe that the cooperative play induced by social toys in inclusive classroom settings can generalize to other aspects of the child's social and cognitive development as well.

Conclusion

Cooperative play is a relatively complex form of social play between preschool children who have reached a certain level of social, cognitive, and language development. While cooperative play may be less likely to occur amongst certain populations, various strategies can be used to teach and encourage these children to engage in cooperative play.

Coping

Steven L. Proctor
Louisiana State University, Baton Rouge, LA, USA

Synonyms

Resilience; Stress

Definition

Coping is the act of managing events or situations deemed as taxing or exceeding one's own personal resources in an attempt to alter the meanings or reduce the ill effects of ►stress.

Description

Literature surrounding the topic of coping follows one of two perspectives; the trait approach and the process approach. The trait approach to coping assumes that an individual's specific response to a stressful encounter can be understood independent of the situational context. The trait approach ignores such important features as individual characteristics and the changing demands of the stressful situation. Studying coping following the trait approach can be better understood as being more heavily concerned with what an individual usually does in stressful situations and maintains that coping is a more static or stable process. A second approach to studying coping is to conceptualize it as a process. The process approach to coping accounts for such individuality and is concerned with what an individual actually does in a specific situation. The process approach to coping maintains that to speak of a coping process implies change. Change not only refers to the adjustment of selected coping acts and behaviors but to the stressful encounter as it unfolds. Lazarus and Folkman [4] stated that coping is a "shifting process" in which the individual must constantly alter his or her position and modify his or her deployed coping responses as the person-environment relationship changes (p. 142).

Once an individual's well-being is threatened the cognitive process of secondary appraisal determines the degree of threat and coping responses are then activated [3]. Researchers have continued to agree upon three higher-order coping dimensions that categorize the different coping strategies. The most frequently used coping dimensions have been problem-focused, emotion-focused, and avoidance coping. Problem-focused coping refers to an individual's deliberate attempt to alter or manage the current problem (e.g., communication, planning, increasing effort, seeking information). Emotion-focused coping on the other hand tends to refer to an individual's attempt to alleviate distress associated with the situation or the emotional resultant of the problem (e.g., self-blame, acceptance, wishful thinking, avoidance, relaxation). Finally, Avoidance coping refers to the individual's behavioral or psychological efforts to disengage from the stressful situation (e.g., walking away, blocking, suppression).

Healthy coping styles are a fundamental component to a healthy lifestyle both physically and psychologically. An individual's chronic inability to cope effectively with stress can lead to a number of pathogenic effects [6]. One reason for this relationship is that the emotional response followed by a stressful encounter can trigger physiological responses which may ultimately lead to an increased vulnerability to a disease. Stress has been linked as a probable etiological agent in instances such as atherosclerosis (e.g., [5]), hypertension (e.g., [2]), coronary artery disease (e.g., [7]), psychological disorders (e.g., [6]), and even death (e.g., [8]). Although all three coping strategies may prove useful in reducing stress, researchers have continued to establish a negative relationship for problem-focused coping and negative affect, as well as a positive relationship for emotion-focused coping and negative affect. This means that the use of problem-focused coping strategies may result in a more positive emotional state and that the utilization of emotion-focused coping strategies may contribute to a generally negative emotional state. These correlations suggest that focusing on the emotional aspects of stressful situations can produce negative affect whereas utilizing coping skills related to problem-solving can prove adaptive thus resulting in a more pleasant affect ultimately reducing the risk of depression.

Coping–Skills Training

David Hackett
Argosy University, Atlanta, GA, USA

Definition

Social skills training (SST) is a behavioral intervention used to enable children to acquire a repertoire of developmentally appropriate verbal and nonverbal interpersonal skills so as to enhance successful outcomes in a variety of social situations [4, 5, 7]. Social skills training is often used in the treatment of many psychological and interpersonal difficulties, such as schizophrenia, social anxiety (i.e., ►social phobia), aggression, and depression. SST is delivered in a variety of settings including school-based programs, day treatment facilities, individual, and group settings [1].

Description

The acquisition of social skills follows a basic behavioral process whereby direct observation and ►modeling are typically utilized when first introducing the targeted social behavior to the child. Subsequently, psychoeducation is often presented in conjunction with modeling of the particular skill, be it eye contact, initiating conversation or the like. Psychoeducation and modeling are utilized to provide the child with the necessary information regarding how to perform the social-behavioral response, as well as the rationale regarding the importance of this response in the context of successful social interactions [3, 5]. The use of video or peer-models may be used in this phase of social skill acquisition as learning is typically more likely to occur when the model is of a similar age and background as the child trainee [7]. Ideally, modeling of the social skill should be as realistic as possible, and as with the acquisition of any complex human behavior, it is important to break down the behavior into its sub-component parts in order to facilitate learning. Next, mastery of the particular social skill generally occurs through shaping and behavioral rehearsal, typically employing a variety of techniques such as ►role-playing [1, 3, 5]. Throughout this process of rehearsal, the therapist provides immediate, corrective feedback following deviations from the social skill being enacted. Effective corrective feedback is given in a constructive manner, whereby the therapist/instructor emphasizes positive aspects of the performance in addition to those areas in need of change. Positive reinforcement is an essential component to this corrective process and should follow the successful performance of the given social skill being rehearsed as well as any approximations towards the enactment of the target behavior. Lastly, to increase generalization of social skills to other contexts, the child typically practices these skills in vivo through real-world experiments [3, 6, 7].

In general, social skills refer to a complex set of behaviors utilized within a social context, in which an individual interacts in some manner with his or her environment. These skills are considered vital in both the initiation and maintenance of interpersonal relations [2]. Social skills typically taught are numerous and may include, but are not limited to, communicating needs, cooperating with others, responding in a prosocial manner to peers and adults, making friends, conflict resolution, and assertiveness [2, 5, 7]. In particular, the specific social behaviors taught may include maintaining eye contact, approaching unfamiliar individuals, initiating a conversation, and increasing the child's awareness regarding acceptable personal space. Typically, the set of social skills targeted for change are unique to the child in need of social skills training, as assessment is utilized to identify those particular social delays and/or deficits in the child's behavior repertoire [2].

Relevance to Childhood Development

The child's developmental level must be taken into account during the implementation and selection of target behaviors. Social skills selected for acquisition should be consistent with developmental theory as well as the child's capabilities. A thorough assessment of social development should be conducted prior to skills training. A child's social competence is a significant and ongoing developmental task, present throughout all stages of childhood

development. Consequently, deficits in a child's repertoire of social skills can result in poor developmental outcomes [4, 5]. For instance, deficits in social skills and overall social competence may manifest as a feature of many childhood disorders, as well as exacerbate other disorders common among children [3, 6].

Copycat Suicides

David N. Miller
University at Albany, SUNY Division of School Psychology, Albany, NY, USA

Synonyms

Suicide contagion; Suicide epidemic

Definition

Copycat suicides refer to two or more suicides that occur in close temporal proximity and are presumably related.

Description

The notion of copycat suicides developed from research indicating that suicide can be "contagious" in the sense that exposure to suicidal behaviors can influence others to copy these behaviors. Much of the debate regarding this issue concerns the relationship between the media and suicide. Research suggests that the extent of media contagion is modest, although the media can play a crucial role in the decision-making process of vulnerable individuals, particularly in cases involving non-fictional presentations of suicide. Media-related suicide contagion appears more likely to occur when there is a feeling of identification with the suicide victim, when the method of suicide is specified, when a suicide is reported or displayed prominently or dramatically, and when suicides of celebrities are reported.

Given that children and adolescents may be particularly vulnerable to media influences, providing guidelines to the media about the appropriate portrayal of suicide is critical. Some of these recommended media guidelines include (a) avoid sensationalistic coverage of the suicide; (b) avoid glorification or vilification of the victim; and (c) do not provide excessive details regarding the suicide. There is currently inconclusive evidence, however, as to whether media guidelines have had a significant impact on the behavior of media professionals or on attempted or completed youth suicide rates.

Copycat suicides involving children and adolescents may be of particular concern in schools, especially when a student commits suicide. In this situation, two groups of students may be at particular risk for engaging in copycat suicides. The first group consists of students who have engaged in previous suicidal behavior, regardless of whether or not they knew the victim. The second group consists of close friends of the victim. These two groups should be carefully assessed and monitored by school personnel to decrease the risk of suicide contagion.

Corporal (Physical) Punishment

Stephanie Dvorak, Tasha R. Howe
Humboldt State University, Arcata, CA, USA

Synonyms

Corporal punishment; Harsh discipline; Physical discipline; Physical punishment; Spanking

Definition

The use of physical pain, without intent to injure, as a means of stopping or changing undesirable behavior.

Description

The use of corporal punishment can be found in schools and homes around the world. Studies have shown rates of corporal punishment in the home to be about 90% for toddlers [1]. This number declines throughout childhood, but over 50% of adolescents receive physical punishment in the home [1]. Data from the 2006–2007 school year show that over 200,000 children in the United States received corporal punishment in schools and there were over a million reported incidents of its use every year. There are currently still 23 states that allow the use of corporal punishment in the schools [2]. Two states, Ohio and Utah are sometimes found on the list of states not allowing physical punishment in schools, but Utah will allow it if parental permission is given for its use and Ohio has specific laws regarding school board voting wherein parents may request it not be used in school districts where it is allowed [2].

Physical punishment takes many forms including spanking, slapping, punching, kicking, pinching, shaking, shoving, and the use of a variety of objects such as belts and paddles. The majority of people (over 80% of American parents) support the idea that physical punishment is "sometimes necessary." However, most scientific studies assert that corporal punishment can potentially lead to psychological or behavioral problems later in life [1]. Corporal punishment has been linked to increased risk for depression, suicidal ideation, alcohol and drug problems, and spousal or child abuse [3]. Most data are correlational, however, and more longitudinal studies are necessary to ascertain definitive long term effects of corporal punishment [1]. Parents should be aware, however, that large meta-analyses and studies on thousands of representative households find a significant relationship between alcohol abuse, depressive symptoms, suicidal ideations and the experience of corporal punishment in childhood [3]. Also, much research suggests that physical punishment often unintentionally escalates into abuse. Therefore, organizations like the American Academy of Pediatrics and the American Psychological Association argue against any use of physical punishment with children.

Corpus Callosum

Tracey McLellan
University of Canterbury, Christchurch, New Zealand

Definition

The corpus callosum is a bundle of fibres that connect the left and right hemispheres of the mammalian brain. In the eighteenth century, the corpus callosum was considered the sight of the soul. In the early twentieth century, it was thought the function of the corpus callosum was to stop the two hemispheres from collapsing together.

Description

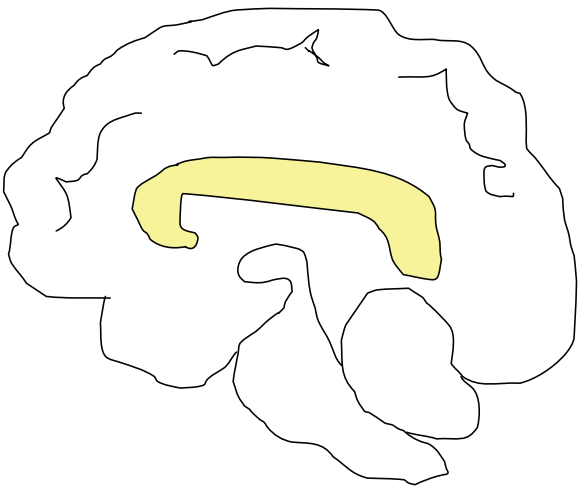
The corpus callosum is a white matter bundle of 200–250 million nerve fibres that allows for rapid interhemisphere communication. It is in the longitudinal fissure and it is the largest white matter structure in the brain (see Fig. 1).

The corpus callosum is made up of four parts; the rostrum, genu, body and splenium. While the corpus callosum is not the only path connecting the two hemispheres, it is the most important. Roger Sperry earned a Nobel Prize when he and his team explored the behavior of individuals who had undergone a surgical procedure to cut the corpus callosum. The rare opportunity to conduct research on the independent functioning of the left and right hemispheres informed much of our understanding about the specialization of the human brain. For example, a blindfolded split-brain participant was unable to name an object when touched with the left hand, but could when the object was touched with the right hand. Each hemisphere controls the opposite side of the body. The right hand is connected to the left hemisphere that is most responsible for language. Although the participant had registered the information when using the left hand, he/she was unable to access the language capabilities required to name the object. Thus, each hemisphere specializes in certain types of information, such as language and spatial perception. It is important for effective functioning that the hemispheres communicate with each other.

Relevance to Childhood Development

Typically, the corpus callosum develops 12–16 weeks after conception and the fibres continue to become more efficient so that by approximately 12 years of age the structure functions as it will in adulthood [5]. There are several related disorders of the corpus callosum that are relevant to childhood development. Agenesis of the corpus callosum (ACC) is complete or partial absence of the corpus callosum [1]. Estimates vary greatly regarding the frequency of ACC, however, it is suggested that it occurs in about 1:4,000 children [5]. Furthermore, 2:100 children with developmental disabilities may have the condition [4]. Hypoplasia of the corpus callosum is a disorder characterised by a thin or underdeveloped corpus callosum and Dysgenesis of the corpus callosum is characterised by malformation of the structure. Disorders of the corpus callosum are diagnosed by brain structure rather than behavior, although there are several common characteristics shared by children with ACC. Typically, individuals with ACC suffer delays in achieving motor, language and cognitive developmental milestones [3]. In addition, they often have a high tolerance to pain, have poor motor coordination, are sensitive to some tactile sensations like food texture and touch, have difficulties with social information like facial expressions and have limited insight into their own behavior. There is no single cause of disorders of the corpus callosum, although disruptions likely occur between week 5 and week 16 of pregnancy [4].

The corpus callosum may also be relevant to the development of children with epilepsy. In rare cases of intractable epilepsy, a child or infant may undergo a corpus callosotomy, in which the corpus callosum is surgically sectioned to control seizures and prevent neuronal deterioration [2]. Research has shown this to be an effective means to stop drop attacks and improve psychomotor functioning. These children may experience limitations in their speech, movement or behavior as a result of the surgery.



Corpus Callosum. Fig. 1 Sagittal view of the brain featuring the corpus callosum in gray.

Correlation

Synonyms

Correlation coefficient; Correlational statistics; Correlativity

Definition

Correlation refers to a mutual relation of two or more things or parts. Specifically, in statistics it is defined as the degree to which two or more attributes or measurements on the same group of elements show a tendency to vary together.

Description

Correlation is one of the most commonly used statistics, describing the degree of the relationship between two variables. When correlations exist they are classified as either positive or negative. Positive correlations exist when as the value of one variable increases, the value of the second variable also increases, or when the value of one variable decreases, the value of the second variable also decreases. In positive correlation the two variables increase or decrease together, such as weight and height. Typically as a person's height increases so does their weight. A negative correlation exists when the values of one variable increase while the values of the second variable decrease, or vice-versa. This is sometimes referred to as an "inverse" correlation. An example of this type of correlation can be seen with time spent watching TV and grades. Typically, students who get higher grades spend less time watching TV. In statistics, correlations are reported with correlation coefficients commonly symbolized by ρ or r. These coefficients range from -1.0 to 1.0 and indicate both the direction and strength of a correlation. Values close to 0 indicate the absence of a correlation, while values closer to 1.0 indicate stronger levels of correlation or stronger relationships. The negative or positive sign simply indicates the direction of the correlation, positive or negative. Correlation itself does not indicate the presence of a cause and effect relationship. A popular phrase in science is "correlation does not imply causation", which means that one cannot assume that the relationship between two variables is causal simply due to the presence of a significant positive or negative correlation.

Correlation Coefficient

Synonyms

Coefficient of correlation, Correlation

Definition

A statistic that express the degree of the correlation between two measures or variables.

Description

Typically correlations coefficients are symbolized by ρ or r and range from −1.0 to 1.0. When variables are completely unrelated the coefficient will equal zero, while values approaching 1.0 indicate strong relationships. The sign, negative or positive, indicates the direction of the relationship (see *correlation*). The most commonly reported correlation coefficient is the Pearson's product-moment correlation coefficient and is obtained by dividing the covariance of the two variables by the product of their standard deviations. This statistic is used with interval or ratio data. The formula for calculating Pearson's r for a sample is written $r_{xy} = \frac{\sum_{i=1}^{n}(x_i-\bar{x})(y_i-\bar{y})}{(n-1)s_x s_y}$. When working with at least one dichotomous variable the Point-biserial correlation coefficient is the statistic of choice and is calculated as follows: $r_{pb} = \overline{s_n}\sqrt{n^2}$. Rank coefficients, including Spearman's and Kendall's rank correlation coefficient, express the extent to which, as one variable increase, the other variable tends to increase or decrease independent of whether the relationship is linear. Other types of correlation coefficients include Phi and Tetrachoric coefficients. The phi coefficient is use to express the degree of association between two binary variables. The tetrachoric coefficient is a correlation coefficient computed for two normally distributed variables that are both dichotomous in nature.

Counselors

Synonyms

Child and family therapist; Mental health counselors; Professional counselors; Therapists

Definition

Licensed professionals trained at the master's or doctoral level to help persons cope with personal, social, career, and educational issues.

Description

Counselors are a group of professionals who focus on working with individuals, families, and groups experiencing developmental or situational adjustment issues. Their work is centered on both prevention and treatment of situational and long-standing problems. Counselors are rooted in development and wellness, helping individuals to reach their highest potential and well-being.

Craniosacral Therapy

Synonyms

CST

Definition

Craniosacral therapy is a gentle, hands-on method of evaluating and enhancing the functioning of a physiological body system called the craniosacral system - comprised of the membranes and cerebrospinal fluid that surround and protect the brain and spinal cord. This non-invasive form of body work is beneficial for a wide range of health challenges from minor aches and pains to severe conditions.

CST is a healing technique that is practiced by chiropractors, osteopaths, massage therapists, and other health care professionals. The practitioner "listens" with their hands to the subtle rhythms of the body, detecting restrictions and imbalances in the tissues and fluid movement. Using a soft touch generally no greater than 5 grams, or about the weight of a nickel, practitioners release restrictions in the craniosacral system to improve the functioning of the central nervous system. This enhances the natural healing ability of the body.

Creativity

Megan E. Tudor, Tessy T. Pumaccahua
Bethany A. Pritchard, James C. Kaufman
California State University, San Bernardino, California, USA

Synonyms

Adaptability; Creativeness; Divergent thinking; Imaginativeness; Innovation; Originality; Novelty; "Thinking outside of the box"

Definition

Although a variety of definitions of creativity have been published, commonalities among these many viewpoints state that creativity is the ability to generate high-quality ideas that are both original and useful [14].

Description

Despite creativity's straightforward definition, the collective conceptualization, measuring, and understanding of the subject is rather complex. Much like the concept of intelligence, creativity is regarded as a challenge to consistently define, assess, and understand. Creativity differs among individuals and an unlimited number of means creative expression exist. Creativity is commonly associated with the arts, but is actually reflected in all areas wherein problem solving may occur and therefore has been studied in a plethora of contexts. For these reasons, a dearth of perspectives and measurements of creativity have been adopted and expounded upon since creativity research began to thrive in 1950 [23].

Creative Thinking

A distinguishable characteristic of creative thinking is the intentionality involved when producing a novel thought. Thus, by this definition novelty involves the subject purposely and knowingly creating a novel product. If the subject has prior knowledge of the production of something "novel" and still produces/replicates it, such production cannot be considered creative. Furthermore, creativity is not accidental; a subject that accidentally creates a product that is believed by others to be "creative" cannot be considered to be creative under the definition given above of what "creativity" involves. Once a novel product is produced, does that automatically make the product a creative one? Some researchers argue that novelty is not or should not be the main and only distinguishable characteristic of a creative product. They argue that though novelty is essential, the value of the creative product is also as important. Not all researchers agree with such a stand, due to the socially based meaning and changeability of what value constitutes [31]. Creativity is viewed in two different ways: domain general or domain specific. There is a major debate in the field of creativity as far as where domain creativity stems from. Domain general creativity, as the name suggests, is a type of creativity that is not restricted to one area, but is instead a skill that can be applied widely across many areas, problems, and situations. The second perspective, domain specific creativity, is a type of creativity that can be mainly applied to one particular field, such as an area of expertise. For instance, Pablo Picasso

had a domain-specific creative strength in art. Research evidence suggests that creative performance is connected to expertise in a specific area; however, other research in the field also suggests that both positions are partially right [30].

Models of Creativity

Creativity is a field of many theoretical standpoints and ideologies. There is no singular model that encompasses the many facets present in creativity study. Some models and theories; however, have served to be quite influential and enduring; the précis to follow summarizes these ideas in a manner as to provide a brief account of the conceptualization of creativity and some of the prominent theories that have aimed to understand it.

In 1904, Spearman presented the concept of general and specific intelligence, which has remained central to intelligence theory, and has also strongly influenced the study of creativity [21]. General intelligence, referred to as *g*, represents an underlying mental capacity that drives mental task performance. This type of intelligence; however, lacks an adequate depiction of one's abilities across different areas and subjects. Specific intelligence, referred to as *s*, represents ability in a particular mental task. For example, success in verbal comprehension may cohabitate in an individual that shows weak performance on quantitative tasks. Analyzing separate s factors yields an individual's g; general intelligence cannot be measured without taking into account the areas in which the individual has specific intelligence. The research of Gardner [6] has further propagated and made famous the concept of unique talents and abilities in the individual, with the theory of multiple intelligences. Gardner currently recognizes eight special intelligences that are present at varying levels among individuals: musical, bodily-kinesthetic, logical–mathematical, linguistic, spatial, interpersonal, intrapersonal, and naturalist [7]. Such perspectives are fervent in creativity study, with the belief that creativity is not necessarily an all-encompassing general ability but can also be specific to certain areas; creativity can manifest itself differently and uniquely among people.

In acceptance of the idea that intelligence is multifaceted and specific, Sternberg [22] presented the triarchic theory which included creative ability. The triarchic theory holds that there are three main divisions of intelligence: analytical, practical, and creative [31]. While the analytical and practical components deal with information processing and environmental adaptability, the creative component deals with reactions to novel tasks. Creative intelligence, is described as one's ability to transfer knowledge across situations and activities, in order to make it useful in new ways. A person may be able to easily memorize information or successfully fit in unfamiliar settings, having analytical and practical intelligence, but if they are unable to use their acquired information in a variety of unrehearsed ways, they would therefore lack creative intelligence. According to this theory creativity is an imperative subcategory of overall intelligence and can be displayed in a myriad of ways. Further research has focused on what variables creativity is actually dependent on.

Four ideas, known as the "four Ps": person, process, product, and press, have provided a guideline for creativity research since Rhodes presented them in 1962 [17]. Each dimension: person, process, product, and press, represents a crucial component of the creative process. Person refers to all of the internal processes and characteristics of the individual involved in the creative thinking. Such an idea encompasses biological and personality traits of the individual. Process refers to the actual manner and development of the creative idea, and may research in this area may focus on the stages of the creative process and ways in which to enhance the process. Product considers the actual outcomes and results of the various people and processes that create them. Finally, press refers to all of the environmental factors that are external to the person involved. Press can include a range of variables from governmental restrictions to the temperature outside. These four Ps serve as a model for four broad categories of creativity research: creative people, creative processes, creative products, and effects of pressures on creativity.

Simonton [18] proposed a theory that has emphasized both the importance of the person and external pressure on creativity is that of "little-c" and "big-c" creativity [19]. Little-c creativity is the ability to generate original and useful ideas for everyday problems and situations. Such creativity is considered a component of typical, healthy mental function. Big-c is not a common form of creativity, but a type reserved for those that generate in ways that are remarkably groundbreaking, for example Albert Einstein and Leonardo da Vinci. It is strongly suggested by some researchers that creativity should not be reserved only for the big-c genius, but can be seen in everyone [4].

An early contribution to creativity research was Wallas' 1926 description of the four distinct stages of the creative process: preparation, incubation, illumination, and verification [29]. Preparation refers to one's initial consideration of a given problem as well as their first premature ideas as to how to solve it. After pondering the question, one then leaves the problem and spends their time and attention elsewhere in the incubation stage. After incubating, the illumination stage takes place wherein a new perception or insight about the problem, sometimes

suddenly, is attained. Lastly, the creative process is complete through verification, putting the decided idea or solution in action to solve the original problem at hand. Support for this theory is principally introspective report from people heralded for their creative thinking, but it is seemingly implausible to verify the creative process through applied research.

A famously pioneering contribution to creativity research has been the idea of convergent and divergent thinking by Guilford [10]. These terms embody two dissimilar thinking styles, which lead to dissimilar creative products. Convergent thinking is thinking that linearly derives a clear-cut objective result. For example, the question, "Where is the Eiffel tower located?" is a query that yields one distinct answer, any other answer would be incorrect. Divergent thinking is not linear, but opens many avenues for creative thought. Answers to a question such as, "What are all the ways you can use a bucket?" can lead to an unlimited number of responses that are not restrained by objective correctness, but are more subjective in nature. As answers become more divergent, unusual, or abstract, for example, "A drum in a chipmunk band" and less convergent, for example, "To carry water long distances" the thinker has demonstrated more of an ability to use information in novel and useful ways, and would be considered highly creative by the expert rater.

Creativity according to Guilford [9] was comprised of four basic components including "sensitivity to problems, an ability to produce many novel ideas or solutions, a flexible approach to solving problems, and the capacity to analyze and synthesize a complex collection of ideas." He and his colleagues developed tests to measure such qualities [12].

Another central tenant of creativity research has been the Investment Theory by Sternberg et al. [25]. This theory revolves around an analogy to financial investment. Wise investors are frequently thought to be foolish when buying seemingly unprofitable stock, until the price suddenly rises and then everyone else wishes they had done the same. As such, creative persons are often unappreciated when creating, but when the merit of their effort is finally observed, many people desire the product or idea themselves. The theory applies the old adage, "buy low and sell high" as a term for creativity investment. The creative person is considered creative because they were the first to risk the novel idea, and will already be moving on to a new idea by the time others are clamoring to what may have previously ridiculed.

The aforementioned theories and models of creativity are just some of the bases for which research on creativity and application of creativity is founded. Also pertinent to the subject of creativity is the measurements thereof, cultural influence, neurology studies, and its relationship to intelligence.

Culture and Creativity

Despite the prominence of Western-based study of creativity, creativity study exists around the world and has revealed distinct global patterns as well as variations and similarities across cultures [13]. Creative thinking has been proposed to be, in part, a product of culture, including one's region, language, religion, education, and government.

An example of research conducted regarding creativity and cultural influence is that by Adams in 1976. Participants were presented with the problem of how to remove a ball that is stuck in a tube embedded in cement, with six other people in the room and eight household items [1]. The results of this study led to a conclusion that people have "cultural blocks" that hinder may hinder their creativity in solving problems. For example, certain answers, such as urinating in the tube to allow the ball to float to the surface may not be generate by people whose cultures would deem such an act publicly inappropriate. Also, answers may be culturally driven in how they perceive each household item as a tool, or perhaps the familiarity of items on the list, such as a wire coat hanger or Wheaties cereal, could be in question due to one's upbringing, and therefore people from different backgrounds could solve the problem quite differently.

Although creativity research in a given country is dependent upon the institutional support and cultural perception therein, commonalities among all creativity research have been identified: creativity is the generation of useful and novel ideas or products, that are interesting in some manner; creativity is in some ways general, but with information-acquisition is specific in precise areas; to certain extents, creativity can be assessed and judge; it is possible to develop creativity; and although theory suggests high reward for creativity, this is not always supported in practice [13]. Also, creativity research is homogenous across countries in that it is very underrepresented worldwide. This is suspected to be a result of little governmental support, complexity and difficulty of study, lack of popularity, a rigorous process to becoming a creativity research, and a perception of creativity research as being non-scientific [13].

Relationship to Intelligence

Given that the definition of creativity stipulates an ability to generate high-quality, novel, and useful ideas, one might infer that a strong ability to reason would warrant

stronger creativity. Some studies have shown very weak correlational relationships between creativity and intelligence [15]. Others have shown that creative people are, indeed, more likely to have an above-average IQ; however, people that have IQs of 120 or higher are not necessarily equally gifted in creativity [24]. One can improve intelligence by emphasizing strategies such as combining ideas, breaking through pre-existing cognitive sets and recognizing unexpected relationships which is the basis of increasing one's creative thought processes. Intelligence has four main properties which can be linked to creativity including: complexity, which involves bringing the elements of a set of information into relationship with one another, plasticity refers to the changing of existing cognitive structures, totality, as seen in the relating of new material to existing mental structures, and fluency, consists in moving freely from one idea to the next. Creativity can be thought of as a style of applying one's intelligence [13].

Signs of Creativity in Children

Creativity in a child developmental context is viewed as an essential component of childhood thought processes. Research in the field demonstrates that children's ordinary thoughts and actions have a degree of creativity. Preschool children exhibit creativity through a variety of ways, such as language and ordinary pretense play [8]. First language development in the pre-school years comes not from acquiring a large selection of sentences but instead from the ability to generate an infinite assortment of sentences based on a linguistic rule system that is learned through out. In this way attaining language skills can be seen as a creative process [3]. Children at this stage are likely to use language metaphorically through the creation of new words, and may construct categorical generic phrases. Children's language is considered to be creative if its content and significance are contextually and age appropriate. The use of overextensions in children's language, such as calling a ball a moon, can be a characteristic of a child's creativity. However, it may be the case that such overextensions of language are the result of incomplete knowledge. Nevertheless, if overextensions are deliberate, meaning that the child knows what the name of an object is, yet still calls it something different, this might suggest creativity. Creating generic categories for phrases or the simple act of generalizing are both creative, for they both involve the child to produce new and useful ways to cognitively organize and understand information. Pretense-play also entails a level of creativity, because it not only involves the child to distinguish reality from pretense, but it also allows the child to change reality in unique ways [8].

Further research also suggests that playfulness is a distinguishable characteristic of creative children. Creative children tend to be more playful than the average child, and playfulness is displayed by the child's level of curiosity. Curiosity is viewed as the satisfaction gained by interacting with various new ideas, being able to have a multidimensional perspective on things, and not accepting the obvious as obvious by searching for explanations. These are all viewed as characteristics of creative thinking. It is suggested that a way to enhance creativity in children is by fostering curiosity [28].

Autism research has undergone tremendous growth in recent years due to the surge in diagnosis of the disorder in children. Within this research, the study of this developmental disability and creativity has not been neglected. Findings; however, have proven enigmatic. There are suggestions of both a lack of creativity and imaginativeness in children and adults with autism [2]. Possibly due to irregular integration of social and communicatory information, persons with autism are described as overly literal and concrete thinkers. In contrast, a variety of research also indicates adult men with autism to be more likely to possess creative genius [5]. These incongruous findings may be a result of limits of conventional creativity measures in relation to populations with disabilities.

Development of Creativity

Research evidence suggests that creativity and intelligence are two independent realms, with each possessing their own individual differences [30]. A child with a wide variety and large quantity of schemata, images, concepts, and rules is considered to be intelligent, whereas a child who uses these in an original and even constructive way is regarded as being creative [16]. No direct association has been found between a child's intellectual/academic performance and his/her level of creativity [30]. This in a sense means that anyone can be creative. One does not necessarily have to be intelligent to be creative nor does one need to be creative to be intelligent. These qualities are unique and unrelated to each other [27]. In a study conducted by Howard Gardner, he examined the lives and the work of creative individuals in different fields. These were Pablo Picasso, Albert Einstein, Mohandas Gandhi, Igor Stravinsky, T.S. Eliot and Martha Graham. None of these highly creative individuals, with the exception of Picasso, was a child prodigy. In fact, they all demonstrated intellectual weaknesses at an early age (i.e. Picasso exhibited poor academic performance). The findings of the study suggest that despite these individuals' intellectual weaknesses, each possessed an outstanding domain-specific cognitive strength associated with each

of their specific fields. Additionally, cognitive precocity was not found to be a distinguishable characteristic of children that are likely to produce elite creative works [4].

Present day classroom teachers face many restrictions regarding creative teaching methods. With current laws in place, teaching is based on standardized testing, which results in children being encouraged to memorize and repeat information, with little room of creative expression [4]. Such environmental situations have led to more speculation of an age-old question: can creativity be fostered, developed, and/or taught? Is it possible to encourage creativity in our children?

When considering theories of creativity that suggest that creativity is a result of culture and environment, the answer is surely, "yes". Hayes' model purports that the following steps are necessitated to enhance creativity: development of a knowledge base, a creativity-conducive environment, and searches for analogies [11]. Development of a knowledge is necessary to provide the individual with various sources of information. The ability to draw from diverse fields results in a greater ability to integrate seemingly unrelated information and create novel ideas. Creativity-conducive environments are environments wherein individuals are free to share and express thoughts, to be free to take risks without fear. For example, brainstorming sessions that encourage all possible solutions to a problem to be shared, creates an environment in which novel ideas are likely to occur. Searching for analogies represents the requirement to recognize similarities amongst varying contexts. With search of analogies enabled, the individual constantly relates dissimilar information, making connections wherein others would not see any similarity, and then using those connections to create and solve familiar problems in new ways.

The label of being "gifted" is often given to children with markedly high intelligence and creativity. Gifted and Talented Education (G.A.T.E.) state-regulated programs exist in private and public schools across the United States for the privilege of those that attain an adequately high score on an IQ test or that have demonstrated exceptional creative ability [32]. Some researchers strongly hold that creativity is not just for an exceptional minority, but for all people, and can be fostered in the development of all children [4]. It is contended that although there are not direct methods of teaching creativity, creativity should be modeled for and reinforced in young children, especially in the classroom setting [26]. It is asserted that creativity can be nurtured by helping shape a creative attitude in children: not fearing rejection or resistance from others for their ideas, willingness to take risks and understanding that ideas may not succeed, and accepting creativity as eternally in progress and worth the challenges it presents [20].

Creativity Assessment

Ryan Holt, Megan E. Tudor, James C. Kaufman
California State University, San Bernardino, California, USA

Synonyms

Creativity measure; Creativity test; Divergent thinking task; I.Q. assessment; Psychometric study of creativity; Torrance tests

Definition

Creativity assessment attempts to measure an individual's potential for creativity, which is defined as one's ability to generate novel and useful ideas. There is no single defining test used to measure creativity.

Description

One way to measure creativity is through self-assessment – simply asking people how creative they are (e.g., Refs. [6, 9]). Many of the major self-report personality tests (e.g., the California Psychological Inventory; Myers-Briggs Type Indicator) include creativity indexes, and the Five Factor Model's conception of Openness to Experience is highly related to creativity [16]. Biographical data can be recorded through self-report measures, asking people to list their creative accomplishments [14]. Self-assessment is appropriate for non-professional creativity situations, but is not considered appropriate for professional situations. Self-assessment is advantageous in that it is quick and easy. However, one disadvantage of self-reporting is the possible falsification of responses by examinees. Furthermore, it relies entirely on personal perceptions, which always contain elements of unreliability. In sum, persons may report themselves much more or much less creative than they are.

A different method that uses personal information to study creativity is the historiometric method, which examines past creative performance. Typically this research is conducted at the eminent level, and focuses on such sources as awards [8], length of career [5], age at accomplishments [19], as well as influence, productivity, and international recognition [15].

Another popular method of creativity assessment is the Consensual Assessment Technique (CAT), developed by Amabile [1]. This method relies on experts of a given field to assign ratings to creative products (such as poems or a collage). These experts tend to agree with each other, thus providing a high level of inter-rater reliability. This technique opens up research beyond self-assessment, but is not wholly conducive for use in most educational contexts. It provides only comparative measurements within the group of products evaluated by a specific group of experts (novices do not work at the same level; see Ref. [12]). It has been shown that the CAT can be extended to creative products produced under both diverse and ecologically valid (as opposed to experimentally controlled) conditions, which potentially expands uses for the CAT [3].

Divergent thinking tests remain the most popular of creativity assessments, with the most-used instrument being the Torrance Tests of Creative Thinking (TTCT; Ref. [20]). The TTCT measures creativity conceptualized as divergent production (e.g., Ref. [7]). The TTCT items revolve around responses to questions with no single specific correct answer. Verbal-oriented questions may ask for different uses of an egg carton or what might happen if all people were born with three arms. Figural-oriented questions might ask someone to modify a circle into an illustration or to finish an incomplete drawing. A participant's responses would then be scored on fluency (how many different responses were produced), flexibility (how many categories of responses were produced), originality (how novel and unique the responses were), and elaboration (how much detail and development was present in the response). The Torrance tests have made a large impact on creativity research as the most-used creativity tests across the world [11, 13, 18, 21]. Although the influence of the TTCT has declined slightly in the last 2 decades, one survey has found that the Torrance tests have been used in three-quarters of all published studies of creativity involving elementary and secondary school students, and nearly half of all creativity studies with college students and adults [21].

The TTCT's reliability and validity have been challenged and debated with scholars arguing both in favor [17] and against (e.g., Refs. [2, 4]). There are issues with the TTCT in that it assumes a creativity-general perspective, meaning

that by measuring creativity on problem-solving type items, we can make assumptions about someone's overall creativity. An alternate perspective is that creativity is domain-specific (e.g., [10]), which proposes that creativity in one area, such as problem solving, does not necessarily translate to creativity in other areas (such as art, and math). At the everyday creativity level, the TTCT's focus may be general enough not to matter. At the non-professional level and higher it may be problematic since it does not allow evaluation into a specific domain that the CAT allows.

While divergent thinking tests offer much to creativity research, additional tests created for a fuller battery of creativity assessment similar to IQ tests would benefit researchers. However, the unanimous acceptance of a single creativity assessment tool is not expected in the near future, given the extensive debate remaining over what an ideal assessment would entail.

Crime, Adolescence

Jessica R. Gurley
Argosy University, Arlington, VA, USA

Synonyms

Adolescent offending; Juvenile delinquency; Juvenile offending

Definition

Crime in adolescence is adolescents violating the law. Adolescents can be charged with both violent and nonviolent offenses, similar to adults. Unlike adults, adolescents can also be charged with ►status offenses.

Description

Recent estimates indicate that at least 50% of all adolescents are involved in some violation of the law each year, ranging from very minor crimes (e.g., truancy) to very serious crimes (e.g., murder). Violent offending is prevalent, with approximately 40% of adolescents reporting

they have engaged in a violent offense (e.g., assault). Approximately one-quarter of those adolescents who have offended violently have multiple violent offenses. Although the majority of adolescents will violate the law, only a percentage will be arrested and prosecuted. Additionally, only a small minority of adolescents are repeat offenders. Even a smaller percentage of adolescents who offend as juveniles go on to offend as adults [1–3].

There are a number of factors that increase the likelihood that an adolescent will violate the law and become involved in the juvenile justice system. First, it should be noted males are arrested more often than females, even though survey data indicate females offend nearly as often as males. Additionally, there is an overrepresentation of ethnic and racial minority adolescents in the juvenile justice system; although, survey data indicate no significant difference in adolescent crime rates between racial and ethnic groups. Other factors that contribute to adolescent crime and adolescent arrest are difficult temperament as an infant, poor parent–child relationships, not having both parents in the home, poor school achievement, the presence of cognitive deficits, hyperactivity, and social disadvantage (e.g., low socioeconomic status) [1–3].

Relevance to Childhood Development

Although most individuals will commit some violation of the law during adolescence, only a small percentage of adolescents will commit multiple crimes during their adolescence. These "repeat offenders" represent between five and ten percent of all adolescent offenders, depending on the type of crime being examined (violent versus nonviolent). Additionally, only a very small percentage of adolescents – approximately two percent – will have multiple offenses that include both violent and nonviolent offenses. The rate of reoffense in adulthood is low, even for repeat adolescent offenders; almost 90% of repeat adolescent offenders do not reoffend as adults. Even adolescents who offend both violently and nonviolently, putting them at an increased risk of reoffense, tend not to reoffend as adults. Approximately three-quarters of the individuals who offend both violently and nonviolently as adolescents do not reoffend as adults [1].

Data indicate it is commonplace for adolescents to violate the law and the majority of adolescents who violate the law will not continue to do so as adults [1, 4, 5]. Consistent with these data, Moffitt has identified a few distinct groups of criminal offenders based on their pattern of offending during childhood and adolescence, including the life-course persistent and the adolescent limited offenders. According to Moffitt's research, there are a small percentage of individuals – life course persistent – who begin to offend criminally as children. These individuals tend to continue offending criminally throughout their adolescence and adulthood. The adolescent limited offenders, on the other hand, offend criminally only during their adolescence. These individuals tend not to reoffend as adults. She posited that the adolescent limited offenders engage in violations of the law in response to their extended period of adolescence. Previously, once individuals were of a certain age, they were given the same responsibilities as adults. In current society, the age at which individuals attain the responsibilities and benefits of adulthood is later in life, therefore extending adolescence. It is in response to this extended period of adolescence that adolescent limited offenders violate the law [4]. Moffitt's work has been confirmed by other researchers [6].

There are a number of risk factors that have been associated with adolescent crime. These include the presence of cognitive deficits, poor academic achievement, difficult temperament as an infant, hyperactivity, poor parenting, poor parent–child relationship, social disadvantages, having antisocial peers, psychological problems such as PTSD, and previous history of arrest. It should be noted that most of these risk factors are static and thus, cannot be changed. Not surprisingly, treatment for juvenile offenders often focuses on altering the dynamic risk factors, such as academic achievement and the parent–child relationship. Another focus of treatment is the adolescent's mental health, as many adolescents involved in the juvenile justice system have psychiatric diagnoses [1–3, 7, 8].

One of the most controversial risk factors associated with adolescent crime is juvenile psychopathy. The adult literature has consistently indicated that individuals with the personality and behavioral traits considered to be indicative of psychopathy are at an increased risk of reoffense [9]. Some researchers have extended the construct of psychopathy to adolescents and have attempted to identify juvenile psychopaths or fledgling psychopaths [10]. There are multiple measures that have been created to identify juveniles with psychopathic traits, including the Psychopathy Check List – Youth Version (PCL-YV) and the Antisocial Processes Screening Device (APSD). Others have used existing measures of personality, such as the Millon Adolescent Clinical Inventory (MACI) in an attempt to identify adolescents with psychopathic traits [11]. Nonetheless, there are significant risks with identifying adolescents as fledgling psychopaths, including the possibility of a labeling effect and self-fulfilling prophecy.

There is also a concern that research has not shown conclusively that adolescents with traits consistent with psychopathy will go on to become adult psychopaths [12]. Thus, the identification of adolescent psychopaths remains controversial.

Consequences of Adolescent Offending

The initial purpose of the juvenile justice system in the United States was to provide treatment and rehabilitation for the juveniles who offended; it was not meant as a punishment [1]. However, in the past 50 years, the juvenile system has moved away from the treatment model and towards a punitive, adult-like model. This includes trying juveniles in adult courts. For example, all 50 states and the District of Columbia provide for ways for juvenile justice cases to be transferred to adult criminal court. Transfer to adult court was intended for only the most violent and severe adolescent crimes (e.g., murder) and results in adult-punishment for crimes. For example, prior to 2005, juveniles ages 16 and 17 who had committed a murder were able to be sentenced to death [1–3]. Now, with the passage of the Adam Walsh Act, juveniles age 14 and above who offend sexually can be placed on a sex offender registry for a period of 15 year to life depending on the severity of the sexual offense. Thus, adolescent criminal offending, at least adolescent sexual offending, can have life-long consequences [13].

Critical Thinking

Héfer Bembenutty
Queens College of the City University of New York, Flushing, NY, USA

Synonyms

Information processing; Logical reasoning; Memory; Metacognition; Problem-solving; Rationalizing; Reasoning; Reflective judgment; Thinking

Definition

Critical thinking refers to individuals' ability to engage reflectively in high-level information processing and entails producing, evaluating, and reflecting on the evidence, facts, syllogisms, and reasoning.

Description

Thinking involves the process of perceiving, storage, processing, transforming, retrieving, remembering, and using information storage in the memory. The process of thinking starts with perception of stimuli, processing the information in the working memory, storage them in the long-term memory, and retrieving the information when it is needed. Individuals think about actual objects such a dog or imaginary objects such as Peter Pan. However, thinking reflectively and evaluating evidence is a unique characteristic of human beings. Children and adults do not act only based on impulse and instincts; rather, they think reflectively and productively. They could evaluate their own thinking as well as those of others presented to them in written, verbal, concrete, or abstract formats.

Critical thinking is an ability that could be learned and taught by caregivers and teachers. However, a controversy related to critical thinking is whether teachers could indeed teach critical thinking [6]. According to supporters of teaching critical thinking, it fosters reading, writing, speaking, listening, metacognitive skills, comprehension, and achievement [4]. In contrast, Hirsch [1] proposed that critical thinking should not be thought because those skills do not transfer and learners continue falling into logical fallacies.

According to King and Kitchener [2], *epistemic cognition*, which is the ability to identify ill-structured problem related to beliefs, values, assumptions, and misconceptions, is the foundation of critical thinking. The process of critical thinking takes place in *inductive reasoning*, which is reaching conclusions by building new knowledge, or by *deductive reasoning*, which is reaching conclusions by previously known information. According to Piaget [3], critical thinking skills mature during the concrete operational stage of development, in which children are able to solve concrete problem in a logical manner. However, critical thinking flourished during the formal operational stage, in which adolescents are able to solve abstract problems and their thinking follows. Zimmerman and Rosenthal [7] demonstrated that critical thinking skills could be acquired through social learning and modeling at an earliest age than the one proposed by Piaget.

Relevance to Childhood Development

Caregivers and teachers help children to explore situations, engage in questioning assumptions, or evaluating problems to deal with hypothetical or real situations for which they will need to use all-important information available to them. Critical thinking skills rely on criteria provided to the individuals or are self-generated. The process of critical thinking is self-corrected, and is sensitive to context, beliefs, values, and history of successes.

Critical thinking involves more than just remembering the information. According to Santrock [5], during childhood, this reflective process involves asking how and why information is obtained and a situation interpreted. It examines whether facts are sufficient to support conclusions and whether the arguments are substantiated enough. Critical thinking entails the possibility that there is more than one point of view or explanation and it compares multiple positions in order to reach the most solid conclusion and alternative. During adolescence, maturity of critical thinking skills is essential. However, critical thinking skills that are not developed during childhood may not mature during the adolescence. During adolescence, it is observed an increase in capacity for processing information, greater domain of knowledge, ability to use learning strategies, logical thinking, and reasoning.

Cross-Cultural Research

Cecilia A. Essau, Harshad C. Keval
Roehampton University, London, UK

Definition

Cross-cultural research is used to refer to the systematic comparison of two or more cultures.

Description

Although culture is a widely used term, its definition is still controversial. As early as 1952, Kroeber and Kluckhohn [18] had already listed 160 definitions of culture found in anthropological literature. This is not surprising because culture is an abstract term covering various types of phenomena and preferences regarding its definitions are related to the investigator's theoretical orientations.

Culture can be defined as a "learned and shared pattern of behaviour which is characteristics of a group living within fairly definite boundaries ... interacting socially among themselves" [2, p. 9]. Culture may be explicit, as shown by observable behavior or by the use of valued objects, and implicit as manifested through values, beliefs, and attitudes. Cross-cultural psychology may generally be defined as an area of psychology which includes culture as one of the variables, or more specifically it can be defined as the method by which psychological phenomena can be compared systematically in different cultures [29]. Although it only emerged as a discipline in psychology about 50 years ago, its origin can be traced back to the nineteenth century. Wilhelm Wundt, the founder of experimental psychology, directed psychologists' attention to the importance of ethnographic factors for a better understanding of the thought, belief and action of man, through his work on Voekerpsychologie (Ethnopsychology). He believed that the study of psychological processes should be done outside the laboratory. Wundt also stressed that thinking is heavily conditioned by language, customs and myth.

Cross-cultural psychology is of great importance because it helps us "check the generality of our existing psychological knowledge, theory, laws and propositions and help to decenter psychology and to dethrone its Euro-American, White and middle-class ethnocentricity" [3, p. 5]. It is important for other reasons such as (a) investigating the cultural basis of psychological processes; (b) examining the possibility of applying psychological knowledge of one culture to another, and identifying the problems involved in the process; (c) testing the usefulness of standardize instruments for use in different cultures and finally (d) improving the validity of these instruments.

Problems of Cross-Cultural Psychology

Doing cross-cultural research is not without methodological problems. While some problems may differ from one study to the other or from one culture to the other, others are common across studies and cultures.

Emic-Etic Distinction

The emic-etic dichotomy, coined by an anthropologist linguist – Kenneth Pike (1966) comes from the suffixes of the word phon*emics* with is the study of units of sound having discrete meaning within a language, and phon*etics* which is the study of elements of sound found in the language of the world. The emic approach is cultural specific since it deals with the meanings and patterns of behavior within a single culture based on its own rules and values. The etic approach is cross-cultural because it focuses on behavior from a universal perspective by applying the same concepts and methods to different cultures and is aimed at generating a general hypothesis or theory [6]. Some authors [22] have suggested that both etic and emic items be included in the instruments used for cross-cultural research because investigators who use the etic approach may run the risk of using stereotypes of the dominant culture; other authors however do not consider the emic-etic distinction as important because the differences are often abstract and unclear [13].

In terms of creating instruments which allow the integration of emic and etic concepts within cross cultural research and analyses, the EMIC (Explanatory Model Interview Catalogue) has been established in cultural epidemiology over the past two decades (see [21], 1997, 2001). This framework based on Kleinman's [17] notions of explanatory frameworks grounded in medical anthropological work in health and illness experience across cultures pulls together several conceptual and methodological strands. Conceptually it performs the function of integrating the emic and etic distinctions – essentially drawing on Pike's (1966) work, so that within research on for example illness experiences, it is possible to gain insights not only from the "externally" sourced set of ideas which are often imposed on research participants, but also the "culturally inside" informed view of the experience. As such, instruments such as the EMIC, which have been tested and used in a variety of epidemiological arenas globally have yielded important and insightful information about how illness is perceived, help may be sought, and crucially for stigmatizing conditions such as mental illness, how people react to the disclosure of such conditions [23; Weiss et al. 2001]. Cross culturally of course this is useful because research can gain an empirical foothold in understanding conditions across several cultures, by integrating etic and emic understandings and ensuring that concepts used are both locally pertinent and valid, and can also be framed within larger epidemiological arenas, thus facilitating illness intervention. Methodologically it functions as an epistemological bridge allowing the integration of quantitative and qualitative measures.

This is carried out by the establishing of an instrument which queries categories of illness experience in a quantitative fashion, along the lines of conventional quantitative field survey methods (apart from the fact that the categories used are informed and indeed created on the basis of field work and ethnographic studies prior to the study), but then using narrative queries and qualitative analysis therein, allows a more in depth elicitation of information to occur. These quantitative and qualitative elements are connected so that it is possible to gain a picture of the extent of a particular dimension of an illness within and across groups, but it is also possible to gain a qualitative insight into the specific components of this data for a qualitative understanding.

Equivalence

If comparisons are to be legitimately made across cultures, equivalent bases (defined as the similarity in quantity, value and meaning between assessment procedure) upon which to make such comparisons should be established [20]. There are four kinds of equivalence: (1) Functional equivalence refers to the relationship between specific observations and the interferences made from these observations; (2) conceptual equivalent refers to the meanings individuals attach to specific stimuli or concepts; (3) metric equivalence is related to establishing equivalent scores obtained with an instrument in one culture to those obtained in another cultures; and (4) linguistic equivalence is related to the language used and hence to translation.

The key to establishing linguistic equivalence includes the use of the bilingual approach, the committee approach, pretesting, and back translation techniques [6]. (a) In bilingual approach, the participants (who are bilinguals) complete both language versions of an instrument so that the discrepancies and non-equivalent meanings can be identified; (b) The committee approach involves having a committee of bilingual consultants evaluate the translated questionnaires. This approach however does not control for shared misconceptions and the fact that some consultants are hesitant to criticize the suggestions of other consultants. (c) In the pretesting techniques, the investigators randomly select items from the translated instrument and ask a probing question about each of these items. This approach tends to be expensive when several language translations are used; (d) Back translation is the most commonly used method for establishing linguistic equivalence because it does not have the problems inherent by a bilingual translator (language A to language B) and then by another bilingual person who blindly translates it back into the original language (language B back to language A). Both the original and back translated versions of the instruments are then evaluated for equivalence to ensure that they are meaningful to target language monolinguals. Differences in responses to the items of the original and back-translated versions of the instrument signal the need to examine the translated items.

Types of Cultures

A major distinction between individualistic and collectivistic cultures is the hierarchical relationship between the self and the society [11]. In individualistic cultures high emphasis is placed on the self (i.e., by being independent) and that social behavior is largely regulated by personal goals, likes and dislikes. Conflicts and confrontations within the group are acceptable and are seen as desirable because they "clear the air." The main aim of the socialization is the promotion of individualism, including independent, freedom and autonomy.

In collectivistic culture, high value is placed on kinship, conformity and submissiveness. Social behavior is largely determined by group norms; should a conflict between personal and group goals arise, it is socially desirable to give priority to the group goal over the personal goal for the sake of preserving group integrity and harmonious relationship among group members [28]. Harmony and face-saving are important attributes among collectivists. The main aim of socialization is the maintenance of harmony and cooperation.

The individualism-collectivism distinction has been criticized because, by focusing on the different emphasis regarding personal and group goals, the dichotomy may overlook certain values that serve both personal and group interests [25]. Moreover, placing people on the individualistic or collectivistic dimension can be misleading because it assumes that each pole represents certain values that are in opposite directions [25].

While the notion of cross cultural research can and indeed has been taken as a taken for granted conceptual "package," it is certainly the aim of critical social and psychological analyses to explore the constructions and employment of "culture" and "cross-cultural."

We can therefore take cross-cultural research at its most reduced and simple level – that groups of people who are in a series of ways categorized as belonging to specific cultural groupings can be accessed and researched in comparison to other groups. This then is the most basic level of description we can work with, and raises several important issues. Firstly, sociological, cultural and anthropological theorizing has made the very definition of culture a problematic enquiry, and within the context of post-colonial discourse has endeavored to ensure that

when "culture" or "cross-cultural" is involved in discourse, there is an engagement with the socio-historical, political and cultural constructions.

When notions of moving across cultures are invoked, there must be clarity therefore in defining what exactly is being referred to in the terms "culture," and as Williams (1983) has stated, it is one of the most complicated words in the English language – the situation has changed little in the several decades since. What has changed however is the progress made by various academic and intellectual arenas in ensuring that its usage is purposeful and analytically clear, as well as retaining all the fluidity it requires to express its location in lived, everyday social and cultural lives. As Bockock [5] illustrates, the emergence of the term culture as a symbolic dimension and social practice (i.e., culture as something that is *done*, rather than something that *is*. This has particular relevance in relation to the points above regarding language equivalence in cross cultural research. Culture therefore involves the idea of language being a crucial social practice allowing people to share a commonality in communication systems, in other words, people can communicate meaningfully with each other.
