Another line of inquiry has focused on the antecedents and consequences of self-talk in abnormal behavior and psychological disorders (e.g., [5, 14, 27, 36]). Studies have shown that negative self-talk in adults is related to onset and progression of depression [2], agoraphobia [6], drinking [26], and pathological gambling [11]. According to Kimberli et al. [19] studies with adolescents provide consistent findings with the adult literature. Hence, a cornerstone of cognitive-behavioral therapy of emotional disorders is the reduction of automatic negative self-talk and its replacement with neutral or positive self-talk (e.g., [18]).

Self-Understanding

Phyllis Curtis-Tweed
Medgar Evers College/CUNY, Brooklyn, NY, USA

Synonyms

Self-Knowledge

Definition

Self-understanding is the individual's cognitive representation of the self which includes awareness of one's characteristics, traits, talents and abilities, as well as thoughts and attitudes that one has about the self.

Description

Self-understanding focuses on the cognitive processes involved in personal identity and individuation as opposed to other-oriented processes of social understanding. It emerges in early childhood and develops through late adolescence as the individual has various experiences and as cognitive processes mature. Self-understanding includes self-evaluation that is foundational to self development, including self-worth and self-esteem.

Relevance to Childhood Development

Most research on the development of self-understanding focuses on early childhood through late adolescence, ages 4–18. Self-understanding emerges in childhood and develops through late adolescence as children become increasingly aware of their own characteristics, traits, talents and abilities. These self-perceptions are based on the experiences of the self in context, such as interactions with others including parents, peers or society at large. Such experiences foster positive or negative self perceptions relative to the image reflected by the other and internalized by the self.

In the nineteenth century, William James proposed that the self consisted of the "I" or subjective and "me" or objective self [2]. The subjective self embodies unconscious processes that may not be observable. The objective self is action oriented and observable. James proposed that the subjective self may be understood through its objective component. According to James, experience is the source of knowledge about the self. G.H. Mead [3] further proposed that self perception is derived from interpersonal interaction, in that one derives a sense of "me" from the perspectives of others. Experiences internalized by the subjective self inform self-understanding, and consequently impact behavior manifested by the objective self.

On the basis of the work of James and Mead, Damon and Hart developed a self understanding model in which they conceptualize individuation or the differentiation of the self from society [1]. In Damon and Hart's model (1988), self-understanding is divided into two dimensions, the "self-as-object" or the "me," and the "self-as-subject" or the "I" self (p. 10). These dimensions are further divided into seven subcomponents with four age-related organizing principles which are hierarchical in level of complexity. The dimension of self-as-subject includes perceptions of the self as physical, active, psychological, and social. The dimension of the self-as-object includes the sense of continuity, distinctness and agency. The age-related organizing principles are categorical identification in early childhood, comparative assessments in middle-late childhood, interpersonal implications in early adolescence, and systematic beliefs and plans in late adolescence. Damon and Hart stress that while the development

of the organizing principles may be age-related, all dimensions are manifested during each age period. For example, at all ages, individuals have a sense of their physical, active social and psychological characteristics. Early self-characterizations are used in increasingly complex re-conceptualized states in later age periods. For example, an individual in early childhood might describe him or herself in terms of a physical property, like being thin. However, by late adolescence, the description should include a reflection of personal or moral standards, like associating being thin with eating moderately in consideration of world hunger.

According to researchers, the attainment of higher developmental levels of self understanding provides preferable conditions for positive psychological development. Self-understanding is not synonymous with but is foundational to self-esteem, self-concept, and self-identity.

Selman's Stages of Friendship Development

Phyllis Curtis-Tweed
Medgar Evers College/CUNY, Brooklyn, NY, USA

Definition

Selman's Stages of Friendship Development describe the social cognitive development of children as they make meaning of interpersonal interactions in the context of friendship. The friendship stages are based on Selman's social perspective coordination stages, which describe children's growing ability to differentiate and coordinate social perspectives in interpersonal interaction. The stages are age-related and hierarchical in complexity.

Description

Selman's levels of friendship development describe children's increasing capacity for mutual collaboration through the processes of intimacy and autonomy that occur in the context of friendship. Friendship levels are closely related to levels of social perspective coordination which describe the child's increasing capacity to coordinate perspectives. The friendship levels may be understood as an expansion on social perspective coordination as applied to the context of friendship. The levels coordinate strongly with developmental stages so that each level is associated with an age range. The behaviors are seen typically to emerge at the lower age limit and to be crystallized by the upper age limit. The five levels begin at 0 and end at 4.

Level 0: Ages 3–6 Egocentric Understanding of Friendship

At this level, actions are often equated with physical characteristics or capabilities rather than psychological intentions. This level is associated with the least differentiated level of social perspective coordination, Level 0.

Level 1: Ages 5–9 Unilateral Understanding of Friendship

Children realize that feelings and intentions may keep together or divide friendships. However, they tend to understand these feelings and intentions from only one individual's perspective as opposed to reciprocal perspectives within a relationship. For example, Selman and Schultz [1] state that children at this level might understand not being invited to a party in terms of being denied something they want to do but not necessarily in terms of being rejected by another.

At this level of social perspective coordination, children can differentiate between physical actions and psychological characteristics, such as intentions and feelings. However, this understanding is not sophisticated enough to detect differences between outward behaviors or appearances and inward feelings. Selman and Schultz [1] state that a child at this level still interprets subjective states of others in terms of surface actions (e.g., he must be happy because he is smiling).

Level 2: Ages 7–12 Reciprocal Understanding of Friendship

At this level, children use reciprocal social perspective coordination, and conceptualize trust, jealousy, and rejection in friendship in terms of reciprocal expectations for behavior, feelings and intentions. In level 2 social perspective coordination, children can view their own actions

from a second person perspective, and understand that one person may have multiple feelings simultaneously. They also understand that inward feelings may diverge from outward experiences (e.g., a person's smile does not necessarily mean that they are happy). They also understand that one can use outward appearance to mask inward feelings and prevent others from knowing how they really feel.

Level 3: Ages 10–15 (May Start as Early as 8) Mutual Understanding of Friendship

At this level, children understand mutual commitment within a relationship, rather than simply understanding each other's perspectives. Friendship is viewed as a bond of commitment that developed over time and through mutually shared experiences. Such a bond is not easily broken. Conceptualizations of jealousy, trust, and rejection are included in the bond of commitment between friends. This level is characterized by intense exclusivity in friendships as exemplified by some strong attachments in adolescent friendships. At this level in social perspective coordination, the child can step outside the perspectives of self and other to take a third person perspective to view friendship as an ongoing system characterized by reciprocity and mutually shared experiences.

Level 4: Ages Adolescence Through Adulthood Interdependent Understanding of Friendship

At this level, individuals move beyond the exclusivity of the previous level to understand that friends may be mutually close but also autonomous and independent.

At this level of social perspective coordination, individuals also achieve a conception of the unconscious, an understanding that individuals may be affected by thoughts and feelings that are not necessarily self-reflectively or objectively perceived. There is also an awareness that the meanings of friendship may be deeply entrenched in symbolic communication and understandings developed on the basis of shared history. Therefore, in interpersonal interaction, long standing friends may be able to communicate with a simple look or other symbolic gesture on the basis of their knowledge of one another.

Relevance to Childhood Development

Robert Selman has an ongoing interest in understanding and facilitating growth in children's development of interpersonal understanding or the capacity to coordinate perspectives. According to Selman, this developing ability to differentiate and coordinate the social perspectives of self and other cognitively and emotionally is the essence of social cognitive development. Selman views progression in social coordination to be developmentally-related differentiations and integrations of meaning-making regarding children's personal experiences and social interactions. Selman has defined stages of interpersonal understanding in four domains, including friendship, peer groups, parent-child relations and individuals based on his social perspective coordination model. The levels of social perspective coordination are used to describe how children come to achieve their interpersonal understanding in the four domains.

Selman's friendship stages specifically provide a tool for the in-depth understanding and explanation of social and emotional development in the context of friendship. This model has been used in pair-therapy to help children share experiences and negotiate conflicts in dyadic relationships. It has also provided the foundation for the developmental of the interpersonal negotiation strategies model and for other intervention strategies.

Semantics

Definition

The study of meaning in language

Description

Semantics is specifically concerned with how words and sentences convey meaning. Within semantics there are two forms of meaning, denotation and connotation. Denotation is the dictionary definition of a word, and connotation is a word's emotional overtones, assumptions, and other ambiguous meanings. The combination of denotation and connotation create word meanings in different contexts. Semantics encompasses word and sentence meaning, but also extends to the understanding of discourse. Discourse is the highest level of semantics, including conversation, stories, paragraphs, chapters, and books. Also, gestures, body language, and personal space all have semantic meaning.

Sense of Self

Janet L. Etzi
Immaculata University, Immaculata, PA, USA

Synonyms

Identity; Self-Concept; Self-percept

Definition

The lived experience of being a self, and with the end of infancy and the development of a sense of a subjective self, identifying oneself as who one is.

Description

The sense of self has only recently been conceptualized in a systematic and comprehensive way by Daniel Stern [5]. Prior to Stern's work the self was discussed in the disciplines of philosophy and psychology, but without rooting it in any empirical science. Hence its usefulness was limited for psychology and for development even though it was taken for granted in many instances. For example, identity development was mapped out by Erikson [3] and identity disturbances were thought to occur in dissociative disorders [1]. However, without a systematic conceptualization or one based on empirical evidence, these phenomena only raised more questions about the role of the self or identity, rather than explaining them.

Stern delineated four major senses of the self: the sense of an emergent self, the sense of a core self (self vs. other), the sense of a core self (self with other), and the sense of a subjective self. His use of the term "sense" is deliberate and proposes an immediately lived and experienced, or sensed, self. This understanding of the self is new for psychology and due to its basis in empirical findings from infancy research, the sense of self, the subjectively experienced self, can now be studied in a more systematic and rigorous fashion. The sense of self is the subjective perspective of the human person which changes qualitatively from infancy onward.

Relevance to Childhood Development

The relevance of the sense of self as a concept to childhood development is significant in its scope and its provision of a framework for exploring subjectivity. For those disciplines studying childhood development, the concept provides a useful foundation especially for addressing the subjectivity of the self. Childhood development has been dominated by the study of measurable capacities, skills and traits which are known to undergo significant change and organization in the childhood years. Any interest in subjectivity or the experience of being a self has been relegated to philosophers and poets or perhaps clinicians and education specialists. With the grounding of a concept in empirical evidence and developmental and neurodevelopmental science, the understanding of the self and its increasing differentiation and emerging organization as it develops has increased in important ways.

The orientation to development studies referred to as life span developmental psychology [2] benefits from a rigorous conceptualization of the sense of self since it addresses developmental phenomena occurring across the life span. It can use the sense of self concept as an anchor for the many complex psychological processes being studied including resilience, wisdom, memory and the effects of trauma on identity.

Siegel [4] addresses the developing mind by integrating neuroscience and attachment theory to show the self as the integration of evolving processes of meaning making and interpersonal relationships, and that there is no self without the other. Siegel's work has brought the idea of the self to its most useful place since it is now being harnessed to the exploration of the brain/mind and the very nature of what it is to be a self.

Sensory Deprivation

Penny Stribling, Cecilia Essau
Roehampton University, London, UK

Synonyms

Restricted environmental stimulation

Definition

Sensory deprivation involves partial or complete loss of sensory stimulation, usually under involuntary circumstances. It has been associated with a number of psychological adversities but also with neural plasticity and therapeutic potential.

Description

Gathering information from the social and physical environment involves perceptual mechanisms, which in turn draw upon information supplied by the senses. Senses are cell types that have evolved to respond to different types of environmental stimuli, including vision, hearing, touch (somatic sensation), taste (gestation), smell (olfaction), balance (equilibrioception), proprioception (kinesthetic sense), and temperature (thermoception). These may be located in specialist receptor organs (e.g., nose, eyes) or located at nerve endings on the skin. The environmental data collected by these receptors are carried to the brain and cortex, where they are mediated by cognitive processes.

Sensory deprivation involves partial or complete loss of sensory stimulation, usually under involuntary circumstances. The term refers to a plurality of experiences, rather than a unitary experience. It can occur in one or more of these sensory modalities, and can sometimes be attributable to sensory overload to another modality, or sensory distortion, which prevents the individual from drawing information from the local environment. It has been associated with a number of psychological adversities (see below) but also with neural plasticity and therapeutic potential.

Types/Sources of Sensory Deprivation

One motivation for exploring the effects of sensory deprivation is to gain a better understanding of the development of human perception, and the relative contribution of nature and environment upon these processes. The main foci of developmental inquiry into the effects of sensory deprivation have focused on two main areas, firstly, the effects upon typically-developing children, and secondly those with markedly atypical development where sensory impairment or difference is a mediating factor.

Research into the first type focuses upon children whose development is unfolding in sub-optimal or inadequately stimulating environments. These sensorily-deprived environments may be a consequence of active (violent) or passive abuse (e.g., neglect), over-anxious parenting, or chronic parental illness or disabilities.

The second type of sensory deprivation is associated with a range of congenital and acquired sensory abnormalities (e.g., visual impairment or blindness). It may be acquired, possibly associated with a number of identifiable neural insults, or reflect a wide range of neuropsychological disorders. The nature of the deprivation and the developmental consequences may vary according to many factors, including the precise source of deprivation.

In recent times, interest in this area has been somewhat influenced by its perceived relevance to other debates within psychology, both in the developmental field and elsewhere. Some common sources of sensory impairment are outlined in more detail below.

Early Research

In the 1950s and 60s there was a flowering of research into artificially-induced sensory and perceptual deprivation involving adult participants, the most famous under the direction of Hebb at McGill University (for review see [31]). In adults, sensory deprivation was associated with a number of cognitive and perceptual distortions, and more latterly, which came to be associated with panic, mental confusion, time distortion, hallucinations and depression.

Ethical Implications of Researching Sensory Deprivation

One of the difficulties in understanding the role of sensory deprivation in child development relates to the potentially

detrimental effect of experimentally inducing such experiences. Some commentators consider that sensory deprivation must be experienced for a longer duration than 1 day, to avoid confounding by other effects. Clearly, a need for prolonged exposure could lead to unquantifiable harm to juvenile participants, as would withholding intervention in a non-treatment control group drawn from a population with sensory disabilities.

In the case of studies involving adults, there has been concern over the application of pure research in sensory deprivation for military purposes (e.g., [29]). Contemporary anti-terrorism practices based on sensory deprivation work have attracted considerable political controversy. For example, McCoy [13] proposes that the CIA used psychological work on sensory deprivation as the cornerstone of practices designed to precipitate psychological breakdown. This has led to the APA's [1] position statement on psychology's role in such research.

Such concerns have had severe implications for the conduct of research in this area. This has resulted in some diversification in the pursuit of evidence. Subsequent directions have included prospective research with non-human participants, and retrospective research with victims of repressive political systems or highly impoverished environments. Subsequent basic research has largely been undertaken with animals rather than humans.

Animal Studies

Animal studies allow the exploration of both the physical and behavioral consequences of early deprivation, whilst human studies tend to only provide good access to the latter. Perhaps unsurprisingly then, most developmental research has been conducted using animals, mainly, but not exclusively, mammalian species including laboratory-reared rats, cats and primates, although there are now increasing concerns about animal welfare.

Typically, such research involves comparisons between animals reared in a range of deprived conditions, and enriched conditions. This research has provided some evidence for correlations between deprivation, neural development, and behavior.

The work of Harlow and colleagues suggests that the effects of early sensory deprivation may be long-term and have severe consequences for normal social functioning. They conducted a well-known but controversial series of experiments on rhesus monkeys between 1957 and 1963 examining maternal deprivation as a source of sensory deprivation. Some monkeys were removed form their mothers and placed in various conditions involving a terry cloth "mother" representation with or without a milk dispenser, and a wire version. At times of stress, infant monkeys clung to the terry cloth models, but not the wire version, including the latter when designed to dispense milk. Harlow concluded that lack of contact comfort was psychologically stressful to infant monkeys. However it is unclear if some of the behavioral sequelae related to loss of opportunities to develop social interactional skills, or sensory deprivation per se.

There is evidence that early deprivation may have extended consequences for neural development. Rat studies have highlighted physiological correlates of early sensory deprivation, including decreases in brain volume, e.g., dendritic volume and glial density (Greenough, 1976).

In addition to psychophysiological studies, the behavioral sequelae of such impoverished environments have been explored in a number of studies. Sackett [21] observed higher levels of motor activity in dark reared rats that persisted over time, however resistance to novelty proved somewhat more amenable to change. Dodwell, Tinney, and Emerson [5] found that kittens reared in dark conditions displayed more visual stimulus-seeking behavior than controls.

Although non-human primates have many similarities in neural architecture, it remains unclear how far these findings may be generalized onto developmentally immature humans.

Developmental Studies and Sensory Deprivation

Animal studies suggest that optimal maturation of the infant's brain and the subsequent behavior of the organism is somewhat contingent on the sensory information available to it. One of the key ideas of mid twentieth century Developmental Psychology is the notion that human development is predicated on interaction with people and the physical environment to some degree (c.f. Piaget, Bowlby). In common with many areas of psychology, evidence from sensory deprivation research has been mobilized in debates between supporters of nativist (e.g., Chomsky) and empiricist (e.g., [7]) theories of brain development.

Whilst there is direct empirical evidence that sensory stimulation may enhance infant development (e.g., [22]) ethical constraints mean that there is rather less research about how sensory deprivation may negatively influence development. The available evidence is typically drawn from studies of the effects of early sensory deprivation due to sensory disability, or where development is unfolding in less than optimal circumstances during sensitive periods, or over a sustained time span. Some of the latter is principally correlational, and secondary to

the central concerns which the research was designed to address.

Studies of sensory deprivation, and variables around the onset and duration of sensory deprivation, have provided useful evidence of "sensitive" or "critical periods" in development, both in terms of the temporal correlates of consequential damage, and recovery for the adverse circumstances.

The Effects of Neglect

Important evidence has been provided by studies of children recovered from extreme deprivation and neglect, where human (in)action provides sub-optimal sensory stimulation over a period of time. This may involve familial neglect, or institutional neglect experienced by those developing in public care systems. However more can often be said about the social context in which neglecting abuse occurs, and adolescent social outcomes, than the precise nature of the sensory deprivation which is alleged to have taken place. It can be difficult to isolate the effects of other adverse life events such as poor nutrition. The potential for recovery from these adverse sensory events has proved to be a major preoccupation in this research field.

The Harlow studies (see above) linked deprivation of the mother's stimulation to poor social outcomes. Bowlby's study of children hospitalized for tuberculosis who had limited contact with their parents showed lower IQ scores in this group. However, it is difficult to partial out the effects of their illness, or the quality of care received, possible sensory deprivation, etc.

One of the best known cases where sensory deprivation had a potentially clear role is that of "Genie." She was raised in Los Angeles and experienced severe sensory and social isolation from the age of 20 months to 13 years 7 months at the hands of an authoritarian father and a visually impaired mother [4]. Although Genie did acquire some vocabulary and assembled word strings, she appeared unable to acquire standard syntax. This provides some support for Lennenberg's hypothesis that there may be critical (or at least vulnerable) periods for aspects of language learning. It was also noted that Genie displayed enhanced development in gestalt perceptual skills, considered to be a right hemisphere compensation for sensory impairment to left-hemisphere function (language experience). However, these inferences may have been confounded. There has been an ongoing controversy as to the extent to which Genie may have been globally mentally retarded.

Further evidence has come from studies of children who had been previously cared for in severely depriving state institutions in Romania. Some of these were adopted outside the country during early childhood, and future care usually took place in relatively enhanced settings. In a study conducted when adoptees were 6 years old, Rutter, O'Connor and the English and Romanian Adoptees Study Team [20] found that children kept in state institutions for up to 42 months showed a comparable rate of progress to control English children adopted before 6 months of age. A substantial minority had much poorer adjustment. Whilst it is not possible to partial out the precise contribution of sensory deprivation in these outcomes, it provides further evidence of the reversibility of effects of early deprivation.

Much research has been concerned with the behavioral consequences of early neglect or abuse later in the developmental trajectory. Early neglect or abuse has been associated with higher aggression in adolescents, for example, Bowlby's (1946) group comparisons of juvenile delinquents (thieves and non thieves) found a higher percentage of the former group had been separated from their mothers for 6 months or more within the first 5 years of life, and inferred that that maternal deprivation led to juvenile delinquency. There is some evidence that behaviors arising from early experience may be linked to vulnerability to new adversities (see [3]), perhaps by putting themselves in circumstances where sensory deprivation may be re-established.

Nevertheless, the degree to which early experience of sensory deprivation is represented in enduring change in the child's development, and the persistence of maladaptive behavior awaits further clarification. Outcomes may be open to influence by a range of variables, including time.

Neural Plasticity

Neural plasticity refers to structural cortical changes which create or modify functions in the brain in response to environmental input. It can offer the possibility of compensating for localized impairment of isolated areas of sensory processing. This is often referred to as the "Sensory Compensation Hypothesis" (e.g., [19]). There have been several empirical studies that have challenged the generalizability of this assumption (e.g., [11]).

Noting that hearing impaired individuals often develop higher visual acuity, and persons with visual impairments often display superior auditory and tactile performance, neurobiologists have been keen to explore the implications of localized sensory deprivation in their studies of brain plasticity. There has also been increasing interest in the extent to which early or later brain plasticity may influence the course of development, both within hypothesized "sensitive periods" and beyond them.

However, the benefits may be balanced by other loss of function, thus Stevens and Neville [23] characterize neuroplasticity as a "double-edged sword."

Sensory Experience in Clinical Populations with a Sensory Impairment

Sensory impairment may have a minor or profound influence on child development trajectories, which is somewhat dependent on the nature and severity of the impairment. The degree of impairment may also be associated with the context in which development is taking place, e.g., the availability of assistive technologies and early intervention. It is often difficult to precisely describe its unique influence, as a number of other variables may be in play (e.g., intelligence).

In these populations, normal stages of sensory processing from the sense organ (e.g., the retina) are interrupted at some point, either due to some congenital disorder or acquired. Sometimes this will involve multiple senses. Thus children with sensory impairments do not have the same potential for sensory experience as non-impaired individuals, regardless of any limitations upon the opportunities available to the latter group. At this stage, it becomes more useful to think in terms of restricted access to sensory experience rather than sensory deprivation.

Sound Deprivation via Hearing Loss

Deaf or hard of hearing children experience some degradation of the stimulus to the cochlear and/or some impairment in the function of the cortical regions associated with processing. The sensory deprivation involved in hearing loss may have pervasive implications for child development. Hearing losses fall into two broad categories, although there may be a mixed expression in any individual. These are firstly conductive hearing loss (where there is some impediment to the passage of sound), and secondly, sensorineural loss, which involves damage to the nerves or hair cells of the middle or inner ear. This may result in sound distortion rather than sound dampening.

Pre-lingual and early acquired deafness can have pervasive effects upon child development. Precise developmental trajectories are influenced by a number of factors, including the use of sound perception support technologies like cochlear implants and the age of implantation (for discussion see [6]).

Cognitive, linguistic and socio-communicative developmental delays can be somewhat offset by early introduction to a sign language. Children born into signing families may have no developmental delay in acquiring language. The constraints on social experience may delay the onset of Theory of Mind capacity in this population [17].

There is much evidence that hearing loss is accompanied by cortical reorganization. This may involve compensatory development and augmentation of other senses. However, such benefits may be offset by degradation or non-development of mechanisms within the affected sense. This is most relevant when the possibility exists for corrective intervention such as the use of amplification devices or cochlear implants. Earlier implantation is often associated with better outcomes, especially where there are no comorbid impairments such as general learning difficulties.

Light Exclusion and Visual Impairment

For some species, the consequences of light exclusion or diffusion for short periods are apparently negated after a period of normal light exposure. In humans, there may be temporary refocus of other sensory media which can be rebalanced. For example, Lewald [9] reported that non-impaired participants' orientation to acoustic targets were increased following 90 min of light exclusion, an effect negated after 3 h of re-exposure to normal lighting conditions.

An important source of evidence for the effects of light deprivation on human development is drawn from studies of children with visual impairments, especially those with corrected vision. The term "visual impairment" is a category descriptor for a wide range of neurobiological and physiological impairments that result in less that optimal vision. Some may experience low visual acuity, and others may be restricted to light perception only, about one in ten may have no vision at all. These impairments may be congenital, or later acquired. There may also be comorbid symptoms which further complicate the course of development.

Like deaf children, this group may be delayed in socio-cognitive development [18]. This may be related to light deprivation, in restricting access to the visual information used to manage social encounters with others such as eye gaze and gestures. There is some evidence that this may lead to pragmatic impairments in this population, although it has been unclear whether this reflects some confounding with comorbid disorders. However, James and Stojanovik (2006) observed such impairments in a small cohort of visually impaired children without co-present pathologies. Blind children are likely to require additional educational support to learn tasks commonly taught using imitation, or visual inspection, including self care routines.

Many researchers have focused upon the implication of visual deprivation for the notion of critical or sensitive periods (see above). Lewis and Maurer's [10] study of children with dense congenital cataracts has provided

evidence of multiple sensitive periods where adversity can influence visual development. Their findings suggest domain specificity, with longer critical periods being reported in terms of acuity and peripheral vision, but shorter periods of sensitivity in relation to global motion perception.

Sensory Deprivation and the Etiology of Autism Spectrum Disorders

Distinctive behaviors and socio-cognitive deficits observed in congenitally blind and deaf children can also feature in the presentation of autism spectrum disorders (ASDs). For example, the terms "blindisms," "deafisms," and "autisms" may be mobilized to refer to substantially similar stereotypical behaviors. These overlaps, together with high functioning persons' with autism own reports of sensory problems, have led some commentators to hypothesize that sensory impairment may have some etiological role in the disorder.

Treatments involving sensory deprivation or sensory substitution are sometimes used to manage the behavior of children with severe learning impairments. Zentall and Zentall [30] proposed that there may be an optimal level of sensory stimulation for "disordered" children, e.g., those with hyperactive behaviors and autism. They suggest that their "optimal stimulation model" supported by sensory interventions may offer opportunities for individuals to attain homeostasis.

A treatment approach that attempts to create an optimal sensory environment is that of the "Snoezelen" or other "sensory" room, where light levels and ambient noise may be reduced, and substituted with managed single or multiple sensory stimuli in an effort to reduce challenging behaviors or stimulate motivationally challenged or severely mentally impaired individuals. However effective these may be in addressing target behaviors, it is unclear if they provide evidence for sensory problems in these populations.

It is unclear whether the processing of available sensory information in ASD may be linked to cognitive impairment, and to what extent it may be elective, e.g., eye and ear covering to screen out unwanted stimuli. Autism may involve multiple sources of sensory deprivation, which would be quite challenging to unravel. However, in producing symptoms that have parallels with those observed in neglected or individuals with sensory impairments some possible crossover in intervention practices may be identified.

Future Directions

The early focus in the study of sensory deprivation moved from direct effects to behavioral and functional recovery (e.g., [27]). Much relied on observed correlations between behaviors, known sources of sensory impairments or life events. However, the relationships between these variables are generally not linear, and the consequences of sensory deprivation are more complex and nuanced than earlier work may have suggested. Moreover, the brain plasticity which offers scope for compensatory development may also be responsible for loss of functional capacity where very early intervention is not possible. The development of sophisticated neuro-imaging techniques will facilitate more sophisticated modeling of neural processes, which in turn should provide greater clarity about the operation of these variables.

Separation Anxiety

Robert Walrath
Rivier College, Nashua, NH, USA

Synonyms

Separation, attachment and

Definition

Behavioral and emotional manifestations of fear, worry, or upset associated with separation from home or from individuals to whom the child is attached. When symptoms are excessive or developmentally inappropriate, separation anxiety may be considered clinically significant.

Description

Separation anxiety is common throughout preschool age in children, typically emerging around 8–9 months of age. Intensity of reactions lessen over time, with developmentally normal separation anxiety typically disappearing by age 3 years, when children become capable of forming a mental image of the absent caregiver or attachment figure [2]. Length and intensity of separation anxiety reactions are often dependent on the child's temperament and age, as well as the parent's reaction to the child. Novel and unexpected separations can also cause a more intense or prolonged reaction.

Separation anxiety that is prolonged and developmentally excessive and inappropriate may lead to a diagnosis of *Separation Anxiety Disorder* [1]. These more serious reactions are often accompanied by physical complaints, nightmares, sleep difficulties, and refusal to leave home or the proximity of attachment figures for normal or routine activities.

Separation, Attachment and

Douglas K. Symons
Acadia University, Wolfville, ON, Canada

Synonyms

Separation anxiety

Definition

Separation is the physical removal of children from attachment figures, usually the caregiver to whom they are attached. *Separation and Loss* is the title of John Bowlby's second volume in his trilogy of Attachment Theory [2]. Within this book, he addresses naturalistic responses in humans to separation from an attachment figure. Normative reactions include anxiety and anger, and in more extreme forms, depression. In child development, what constitutes separation and the subsequent behavioral response changes with age, and is reflective of the relationship itself. Separation from attachment figures has also been studied across the human life-span and in non-human primates.

Description

Separation of an infant from an attachment figure typically results in a distress reaction such as crying. Around age 1, this almost always occurs, unless the attachment relationship is an avoidant one [1]. As children get older, they are capable of emotional regulation and representational thinking, and thus more tolerant of separations from attachment figures, particularly when they are predictable or explained. For example, children going to school and parents working outside the home are predictable separations that should not result in crying and distress in children once they have begun school, and if they do, there may be cause for concern that the child has separation anxiety.

In Bowlby's Attachment Theory, he described normative responses to separation from attachment figures that he observed in children that were in residential care, and thus separated from their mothers. The three phases are protest, despair, and detachment. The protest phase begins immediately upon separation, and lasts up to weeks on end. It is indicated by outward signs of distress such as crying, tantrum behavior, and searching for the return of the parent. Protest decreases during the despair phase, and children become withdrawn and helpless. The detachment phase implies loss of the original attachment, and children are emotionally distant from an attachment figure even if they returned. While these are normative responses to prolonged separation, there are also individual differences that define an attachment relationship. In Ainsworth's Strange Situation used to classify an infant–caregiver relationship, separations from and reunions with a parent are actually part of the task. In an insecure–avoidant relationship, for example, protest is minimal, as are smiling and greeting after reunion. In fact, there seems to be indiscriminate response to the parent and a stranger, and the child may even avoid the parent after the separation. In insecure-resistant infants, there is greater protest (e.g., crying, tantrums, anger), more clinging behaviour, and this distress is slow to resolve after reunion. Secure infants may protest the departure of a parent, but this distress is resolved after the separation ends. Overt behavior is also not the only way in which separation is studied. It is subject to some of the same physiological markers as other stressors, such as an elevated noradrenergic or cortisol response [3, 6].

Separation and attachment have been examined in common circumstances for children, such as family disruption in marital separation and divorce, serious illness requiring hospitalization, parents being away for extended work periods [5], children removed from parent's homes due to maltreatment and/or neglect, and children separated from parents during disasters and war-time events [7]. There is evidence that either marital separation of at least 6 months or divorce has a negative impact on teenager's attachments to parents, particularly when the separation occurs earlier rather than later in a child's life [10]. A history of child maltreatment is associated with later disorganized attachment, and this is likely due to a background of frightening parent–child experiences [8]. In this case, children may need to be taken into care and separated from the parent, although this is seen as an instance where parent–child separation is necessary and hopefully helpful for the child in the long run. These are all negative life events that include family disruption and separation from parents, and such events are associated with a decline in attachment security from infancy to adulthood in a predictable fashion [4, 9] and more normative parent–child separations such as those that come

from a parent working outside the home were initially hypothesized to result in attachment security problems for children based on Bowlby's original descriptions of separation. However, a large scale analysis of this kind of separation has not supported this hypothesis. So separation in and of itself does not have negative consequences for children, but may when combined with other negative family circumstances.

Serax®

Anisa Fornoff
Drake University, Ankeny, IA, USA

Synonyms

Oxazepam

Definition

A prescription medication FDA approved for the treatment of anxiety and management of alcohol withdrawal.

Description

This medication is a benzodiazepine, a central nervous system depressant, available in tablets and capsules.

The recommended starting dose for this medication is 10 or 30 mg taken 3 times a day to 4 times a day. Maximum suggested dose is 120 mg daily. This medication should only be taken as directed by a doctor and is usually taken only for a short period of time. This medication may become habit forming.

Some side effects are listed here: drowsiness, dizziness, memory impairment, headache, amnesia, rash, tremor, and blurred vision. Certain side effects may go away during treatment.

Relevance to Childhood Development

Serax® is not FDA approved for use in children under 12 years of age.

This medication may cause paradoxical effects in children and adolescents, meaning they may become hyperactive or show aggressive behavior. Children may be more sensitive to the side effects of Serax®.

Serotonin

Collin Davidson
Oklahoma State University

Synonyms
Neurotransmitters

Definition
A type of neurotransmitter which is involved in communication between neurons in the central nervous system.

Description
Serotonin affects areas of the brain typically involved in depression, eating, sleeping, memory, sexual behavior, and aggression. Serotonin, like other neurotransmitters, aids in communication between neurons by passing from the axon of one neuron through the synapse, or gap between neurons, to the dendrites of another neuron. Serotonin is received by 5-hydoxytryptamine (5-HT) receptors in nerve cells and most often acts as an excitatory neurotransmitter. Serotonin can be toxic in high doses which has been termed serotonin syndrome. Serotonin syndrome typically results from taking two or more drugs designed to increase serotonin and produces symptoms such as hallucinations, vomiting, diarrhea, increased body temperature and heart rate, shivering, and confusion among others. If treatment for serotonin syndrome is not sought it can be lethal [1].

Psychopathology has been related to problems in serotonergic systems of the brain such as Major Depressive Disorder (MDD) and Obsessive Compulsive Disorder (OCD) wherein individuals with such disorders tend to have low levels of serotonin. Both disorders have been found to be effectively treated using selective serotonin reuptake inhibitors (SSRIs) [2, 3] which temporarily block the presynaptic neuron from reabsorbing the serotonin, thus allowing for more serotonin to reach the receptor sites on the postsynaptic neuron. Several types of SSRIs are available such as citalopram (Celexa), escitalopram oxalate (Lexapro), paroxetine (Paxil), fluoxetine (Prozac), and sertraline (Zoloft). Research has shown that SSRIs are effective for treating depression, OCD, and bulimia nervosa.

Relevance to Childhood Development
Since serotonin has been linked to the aforementioned disorders, examination of these disorders in childhood is relevant. Treatment of children with psychological disorders such as MDD and OCD with SSRIs is fairly commonplace although warnings have been put in place due to increased risk of suicide among children, adolescents, and young adults. A cost-benefit analysis prior to the use of SSRIs in treatment and careful monitoring of individuals in this age range is recommended.

Sesame Street

Caroline McKnight
University of North Carolina, Chapel, NC, USA

Definition
Sesame Street is an educational children's television program aimed at children 3–5 years of age that is most

well-known for Muppet characters such as Big Bird, Bert, Ernie, Oscar the Grouch and others.

Description

In March 1968, Children's Television Workshop (CTW) was established through which Sesame Street was broadcast. Initially, CTW was given $8 million to fund a 2 year project with the primary aim being to enhance school readiness in preschoolers, particularly children ages 3–5 years, with minority and low-income backgrounds. Funding for the program came from the US Department of Health, Education, and Welfare, Corporation for Public Broadcasting and private foundations such as the Carnegie Corporation, the Ford Foundation and others. The principal creators of Sesame Street in 1968 were Joan Ganz Cooney, Director of CTW, Lloyd Morrisett, vice president of the Carnegie Corporation and Gerald Lesser, a professor at Harvard University. Other creators included experts in child development as well as experts from the field of commercial television. One pivotal move by the creators was using Jim Henson's Muppets as main characters on the program. Along with songs resembling commercial jingles, Sesame Street was entertaining and educational, a first in the domain of "Edu-tainment." The five broad areas on which creators of Sesame Street intended to focus included social, moral and affective development; language and reading; mathematical and numerical skills; reasoning and problem solving; and perception.

In addition to summative research, which was designed to evaluate the effectiveness of Sesame Street on children it was reaching, another major component of Sesame Street was the emphasis on formative research. Research findings have concluded that for children who were 3–3.5 years old, watching Sesame Street was a strong predictor of vocabulary development. These findings were not as significant for older children. Importantly, children's vocabulary size increased when they watched Sesame Street alone, indicating that it was not necessary for parents to view and discuss the show with their child. In addition, viewing Sesame Street has been linked to: future positive performance in reading, math and school readiness; better ability at recognizing letters and reading books at an earlier age; and better grades in science, English and math 10–15 years later.

Relevance to Childhood Development

Because of the ubiquitous nature of television, it has become an almost steady companion in children's most critical years of development. Therefore, programs such as Sesame Street, which promote positive cognitive, social and emotional development, have become crucial in meeting the needs of young children.

Severe Mental Retardation

Lindsay J. Cummings
Argosy University, Atlanta, GA, USA

Synonyms

Cognitive impairment; Developmental delay; Developmental disabilities; Intellectual disability; Mental deficiency

Definition

Severe Mental Retardation is defined by the presence of significantly subaverage general intellectual functioning as well as significant limitations in adaptive functioning (adaptive behavior) present prior to the age of 18 years. Individuals with a diagnosis of severe mental retardation generally obtain IQ scores within the range of 20–25 to 35–40 [1, 3, 4].

Description

Severe mental retardation (MR) is described by the *Diagnostic and Statistical Manual of Mental Disorders*-Fourth

Edition-Text Revision [2] as impairment comparable to a range of IQ scores that fall within the range of 20–25 to 35–40 [2]. Individuals with severe MR are limited in the areas of intellectual functioning and adaptive skills, typically exhibiting limited or absent levels of communicative speech. They are also likely to experience comparable limitation in the areas of self-care, home living, social skills, community use, self-direction, health and safety, functional academics, leisure, and work skills [2]. Symptoms are likely to manifest in both the individual's ability to master a range of cognitive skills and their ability to respond to environmental cues [5].

Individuals who fall within this diagnostic category comprise approximately 3–4% [2] of all individuals with mental retardation. Unique to this level of impairment is the strong likelihood of an identified etiology of genetic or neurological syndrome resulting in mental retardation, as well as a variety of other physical and psychological symptoms present from birth or early childhood. Concurrently, the presence of additional physical impairments such as cerebral palsy, epilepsy, and vision or hearing difficulties have been found to increase with level of intellectual impairment (intellectual disability). Co-morbid medical complications are also common.

Training typically focuses on areas of deficit such as self-care or social skills during school age and beyond. Individuals with severe MR are often able to function within a "workshop" or similar type of vocational environment. They generally adapt well to life within their family or group home environment, although some level of support and assistance will typically be necessary throughout their lives [2].

Relevance to Childhood Development

A diagnosis of severe mental retardation has weighty implications for both the child and his caretakers throughout development. Accessing services the child is entitled to often requires a working knowledge of government and school systems, including the Individuals with Disabilities Education Act (IDEA). This program provides adaptive education to all children within the least restrictive environment possible. Adaptations may also include school-provided speech, physical, or occupational therapies as appropriate. Within the family or caretaking environment, education of the parent or primary caretaker is essential regarding available resources and developmental expectations. Because the development of children with Severe Mental Retardation is significantly limited in most cases, families of children with this diagnosis should be aware of what it means for their child in particular.

Sexuality education

Definition

According to the Sexuality Information and Education Council of the United States (SIECUS), "Sexuality education is a lifelong process of acquiring information and forming attitudes, beliefs, and values. It encompasses sexual development, sexual and reproductive health, interpersonal relationships, affection, intimacy, body image, and gender roles" [6]. A sex-education program is one way by which children may learn about sexuality.

Description

In today's society, the sexual health of youth is of paramount importance. According to a recent study by The Guttmacher Institute [1], adolescents in the United States are having sexual intercourse, becoming pregnant, and contracting sexually transmitted infections (STIs). Specifically, 46% of all adolescents aged 15–19 years old have

engaged in sexual intercourse. In addition, approximately 750,000 teenage girls become pregnant each year. Of these pregnancies, 82% are unintended and over 25% are terminated by abortion. In comparison to other developed countries, such as England, Wales, Canada, the Netherlands, and Japan, this rate of teenage pregnancy ranges from twice to eight times greater. Finally, estimates of adolescent STI contraction approximate nine million new cases per year. Given the seriousness of these findings, it appears imperative that measures be taken to ameliorate these problems.

One possible solution to the sexual health problems of youth is sexuality education. Recently, Kirby [3] reviewed the effectiveness of programs for reducing teen pregnancy and STIs. Five general types of sexuality education exist: comprehensive sexuality education, abstinence-based, abstinence-only, abstinence-only-until-marriage, and fear-based programs [6]. Historically, controversy has existed regarding comprehensive sexuality education versus abstinence-only education, and this controversy has had a significant impact on federal funding of sexuality education programs [1]. That is, until recently only abstinence-only programs received federal funding. In practice, then, fewer adolescents were receiving information about birth control, and more adolescents were receiving information about abstinence. Interestingly, however, research demonstrating the effectiveness of abstinence-only education is lacking [1]. Abstinence-only education does not appear to delay the onset of engagement in sexual activities, and it may inadvertently result in an increase in unwanted pregnancies and STIs – as youth may be discouraged from using contraception.

Conversely, research suggests that comprehensive sexuality education, including an emphasis on skills building, is effective in reducing/preventing adolescent pregnancy and contraction of STIs [1, 3]. Sex-education programs are based on a model of comprehensive sexuality education emphasize abstinence is the only 100% effective method of preventing pregnancy and STIs and also address contraception, particularly for adolescents who are already sexually active [3]. The goals of comprehensive sexuality education may be viewed in terms of long-term goals and instrumental goals that work toward the attainment of the long-term goals. The long-term goals are threefold: (a) to postpone the onset of sexual intercourse, (b) to increase the use of contraception and condoms, and (c) to decrease pregnancy and birth rates. The instrumental goals of comprehensive sexuality education are fourfold: (a) to deliver correct knowledge to youth regarding human sexuality, (b) to offer a forum for youth to "develop and understand their values, attitudes, and insights about sexuality," (c) to assist youth in the acquisition and improvement of interpersonal skills, and (d) to help youth demonstrate responsible sexual behavior [6]. Comprehensive sexuality education programs do not appear to negatively influence one's age of initial sexual intercourse, the frequency with which one has sexual intercourse, or the number of sexual partners one has [3]. Rather, comprehensive sexuality education programs have been shown to help delay the onset of sexual intercourse, decrease the number of sexual partners one has, and increase the use of contraceptives [1].

Schools are advantageous settings for sex-education programs [1, 2, 4, 5]. First, schools provide a structured system that allows for sexually education programs to reach all youth [4]. Second, considering the risk factor of age, schools provide access to young students (e.g., late elementary school) who will benefit most from sexuality education [4]. Finally, being in school is related to fewer at-risk sexual behaviors and lower pregnancy rates; therefore, a sexuality education program within a school may be more effective than one outside of school [2]. SIECUS has published guidelines for content that is appropriate for sexuality education of school-aged children [6].

Despite the many advantages of providing sexuality education in schools, controversy exists [1, 5]. First, although the policy of more than 66% of public school districts includes sexuality education [1], some wonder if school is the appropriate site to teach sexuality [5]. Second, among those who agree sexuality should be taught in school, debate exists between proponents of abstinence-only education and proponents of comprehensive sexuality education programs [1, 5]. For example, of the schools that have a policy to teach sexuality education, 86% require the promotion of abstinence. Specifically, 35% require instruction of abstinence only, while 51% allow for instruction of contraception as long as abstinence is taught as the preferred method. Furthermore, 50% of southern public school districts with a policy to teach sexuality education teach abstinence only, while only 20% of northeastern public school districts adhere to the same policy [1].

Sexual Abuse

Natasha Elkovitch, David J. Hansen
University of Nebraska-Lincoln, Lincoln, NE, USA

Synonyms

Incest; Molestation; Sexual victimization; Shaken baby syndrome

Definition

The term "child sexual abuse" is complex. It is surprisingly difficult to define as operational definitions of each word in the term have varied across clinical, legal, and research contexts. Child sexual abuse is most commonly defined as sexual activity with a child where consent is not or cannot be given. This includes all sexual contact with children in which force or threat of forced is used, regardless of the age difference between participants. This also includes all sexual contact between a child and an older person (typically 5 or more years older) regardless of whether force or coercion is used.

Description

Sexual behaviors may involve contact or noncontact offenses. Noncontact offenses include genital exposure, voyeurism, showing a child pornographic material, or having a child undress or masturbate. Contact offenses include genital touching, oral sex, and digital, object or penile penetration (vaginal or anal).

Perpetrators that are a family member, including distant relations, in-laws, and step-relations are typically referred to as "intrafamilial," whereas perpetrators who are not related by marriage or blood are referred to as "extrafamilial." The majority of child sexual abuse cases involve intrafamilial perpetrators and a substantial proportion of extrafamilial offenders are known to the victim. Approximately 5–15% of offenders are strangers to the child.

Although adult men commit the majority of sexual assaults, a significant minority of sexual assaults are committed by youth. The Federal Bureau of Investigation's National Incident-Based Reporting System has indicated that youth under the age of 18 are responsible for 40% of the sexual assaults involving children under the age of 6. The majority of adolescent-perpetrated child sexual abuse involves intrafamilial victims.

It is important to note that all 50 states have laws that require certain professionals (e.g., physicians, nurses, social workers, day care workers, psychologists, and law enforcement personnel) to report suspected maltreatment. This requirement overrides professional confidentiality requirements and in most states, 24-hour reporting is available via a toll-free phone number.

Incidence and Prevalence

Child sexual abuse is an alarmingly prevalent problem in the United States. According to reports from child protective service agencies, in 2006 there were approximately 80,000 substantiated cases of child sexual abuse at the rate of 1.1 per 1000 children [6]. It is widely acknowledged that these figures do not represent accurate estimates. Many incidents of child sexual abuse, perhaps the majority, are never reported to law enforcement. Based on a comparison with retrospective reports and surveys with nationally representative samples, some reviews of research suggest that national incidence figures may represent less than one third of all occurring cases of child sexual abuse in the United States.

Child sexual abuse is pervasive across income levels and racial, cultural, and ethnic groups. The mean age of sexual abuse victims is approximately 9 years, ranging from infancy to age 17. Girls are significantly more likely to be sexually abused, although boys are more likely than are girls to be abused by an extrafamilial offender. Risk factors for child sexual abuse include physical or cognitive disability, and living with a parent whose ability to adequately nurture and supervise is compromised by substance abuse, violence, poverty, and single-parent status.

From 1990 to 2005, the number of cases of sexual abuse substantiated by child protective service agencies declined 49%. This is likely due to a combination of factors, including policy or program changes in child protection agencies, increasing awareness about child sexual abuse, improved parenting practices, economic improvements, greater numbers of agents of social intervention, and more effective treatment for mental health problems [1].

Consequences

Child sexual abuse, like other forms of adversity or trauma, does not affect children in a predictable or consistent fashion. The impact of the abuse depends not only on the severity and chronicity but also on how the abuse interacts with the child's individual, familial, and community characteristics. Further, research indicates that some youth exhibit little to no emotional or behavioral symptomatology after the abuse [2].

Nonetheless, research conducted over the last two decades indicates that child sexual abuse constitutes a major risk factor for a wide range of emotional and behavioral problems which can potentially be long-lasting. Short-term consequences include emotional distress and externalizing behaviors, including depression, anxiety, poor self-esteem, suicidal ideation, posttraumatic stress, substance abuse, self-harm behavior, sexual behavior problems, and delinquency. Further, research indicates some children exhibit difficulties with interpersonal relationships and social competence and negative or distorted attributions. However, two domains stand out as significantly more prevalent in sexually abused samples as compared to appropriate comparison groups (e.g., non-abused clinical samples). These domains are sexualized behaviors (e.g., excessive masturbation, exhibitionism) and posttraumatic stress symptomatology (e.g., reexperiencing the abuse, avoiding reminders of the abuse, and hyperarousal).

Similar to childhood consequences, long-term consequences of child sexual abuse also include emotional and behavioral disturbance, including chronic anxiety, depression, and anger, substance abuse problems, and negative or distorted attributions. Further, difficulty with interpersonal relationships and sexual problems (e.g., sexual dysfunction, sexual preoccupation) are more often reported by women sexually abused in childhood than their nonabused counterparts. Finally, women who have been sexually abused as a child are at a substantially higher risk of being physically and/or sexually abused in adulthood [3].

Treatment

There is a growing empirical literature on efficacious treatments for sexually abused and traumatized children [4, 7]. Interventions include brief psychoeducation and crisis interventions, short-term abuse-focused treatments and longer, more comprehensive interventions. Brief psychoeducation and crisis interventions are often implemented at the time of disclosure and are designed to assess the child and his/her family's needs and provide training in effective coping strategies. Brief interventions are appropriate for asymptomatic children and are intended to prevent future sexual abuse and buffer the associated risk of developing psychopathology.

Abuse-specific cognitive behavioral treatment (CBT) is the most extensively researched intervention for child victims of sexual abuse. Reviews of the treatment outcome literature indicate this treatment is an effective treatment for post-traumatic stress reactions [5]. Abuse-specific CBT utilizes principles that have been shown to be effective with a number of emotional and behavioral problems. Components of the treatment include: psychoeducation, anxiety management, exposure, and cognitive therapy. Children and parents are provided knowledge and skills related to processing the abuse, managing distressing thoughts, feelings and behaviors associated with the abuse, enhancing safety and preventing revictimization. The majority of the most rigorous studies have included non-offending caregivers in the treatment protocol [5]. Inclusion of caregivers is important to address parental reactions, distress, and supportive recovery of the sexually abused child. Furthermore, inclusion of caregivers is essential for more comprehensive intervention, which may address behavior problems (such as noncompliance and oppositionality) with behavior management techniques or sexual behavior problems with behavior management techniques and parental supervision, communication, self-control, and sexual behavior rules.

Sexual Identity

Kevin L. Nadal
City University, New York, NY, USA

Synonyms

Bisexual identity; Gender identity; Heterosexual identity; Homosexual identity; Sexual orientation

Definition

Sexual identity can be defined as the understanding of one's values, beliefs, and roles as a sexual being; this is developed through the comprehensive process of exploring, assessing, and committing to one's sexual orientation and gender identity [5–7].

Description

Sexual identity is the process of developing a personal sense of self as a sexual being and encompasses one's sexual orientation and gender identity. Sexual orientation is defined as an individual's sense of personal and social identity based on one's sexual attractions, behaviors expressing those sexual attractions, and membership in a community of others who share them [2]. Individuals may identify as homosexual (attraction to one's same sex), heterosexual (attraction to one's opposite sex), or bisexual (attraction to one's same sex and opposite sex). Gender identity is defined as an individual's personal sense of identification as male or female [7]. In accepting one's sexual orientation and one's gender, an individual is able to formulate a personal set of values, beliefs, and roles.

Sexual identity processes may differ based on one's sexual orientation and gender. For a gay, lesbian, bisexual, or other non-heterosexual individual, sexual identity is developed through acknowledging one's same-sex attractions and identifying oneself as non-heterosexual [3]. For a heterosexual individual, sexual identity is developed through acknowledging one's opposite-sex attractions and identifying oneself as heterosexual [6]. A non-heterosexual individual (e.g., gay, lesbian, or bisexual) recognizes the societal ramifications of accepting a non-heterosexual identity, including the stigma, discrimination, and marginalization that may occur. Conversely, a heterosexual individual may recognize the acceptance and privilege that one may have as a heterosexual being.

Sexual identity also includes the process of accepting one's gender identity. Gender identity is the process in which an individual identifies as male or female, regardless of one's biological sex at birth. Gender identity is influenced through biological and sociological factors (e.g., biological factors including one's reproductive organs and hormones, sociological factors including one's family influences and societal messages about gender roles). Gender identity differs from sexual orientation, in that sexual orientation refers to whom one is sexually attracted to, while gender identity refers to the gender that one identifies with. For example, an individual who was born as a biological male may identify as a woman but may be sexually attracted to women; this individual might be described as a transgender woman (gender) and lesbian (sexual orientation).

There are several models of sexual identity development that describe processes for lesbian, gay, and bisexual individuals [5, 6]. One of the earliest and most widely recognized models in psychology is Cass's [1] six-stage model of gay and lesbian identity development, which consists of six stages: (a) *Identity confusion* (questioning one's initial experiences of same-sex attraction), (b) *identity comparison* (internalizing the stigma that accompanies same-sex attractions) (c) *identity tolerance* (assuming that experiences of same-sex attraction means that one is likely gay or lesbian), (d) *identity acceptance* (identifying same-sex attraction as indicative that one is gay or lesbian), (e) *identity pride* (accepting oneself as gay or lesbian and identifying with other gay or lesbians), and (f) *identity synthesis* (integrating one's sexual orientation into one's sense of self).

Sexual identity can be influenced by a number of factors, including one's religion, culture, and family [4, 7]. Most major world religions teach negative messages about non-heterosexual orientations and/or refer to gay, lesbian, or bisexual orientations as "immoral" or a "choice." Additionally, in most cultures and societies, lesbian, gay, and bisexual individuals are stigmatized and marginalized; in some countries, homosexuality or bisexuality is illegal and prone to punishment. Finally, an individual's family may also provide messages about sexual identity to its members, particularly to one's children.

These familial messages are heavily influenced by culture, religion, and the media.

Through the development of sexual orientation and gender identity, along with messages from family, culture, and media, an individual is able to develop values, beliefs, and roles as a sexual being. Sexual identity values may include the importance of family, community, individuality, or freedom of expression in one's life. Sexual identity beliefs may include one's thoughts about equal rights, same-sex marriage, raising children, or practicing monogamy. Sexual identity roles may include how one behaves in romantic relationships, in family systems, in friendship networks, and in work settings. The cumulative development of these values, beliefs, and roles all contribute to one's personal sense of self as a sexual being.

Relevance to Childhood Development

Sexual identity development may begin during early childhood, when an individual recognizes her/his first sexual attractions to others. This first awareness of sexual attraction is often described as beginning with the Oedipus complex for boys or the Electra complex for girls. The Oedipus complex is defined as a stage in life where a boy is fixated on his mother and competes with his father for maternal attention, while the Electra complex is defined as a stage in life where a girl is attracted her father and rivals with her mother for paternal attention. Sexual identity development continues when children interact with peers for the first time and they experience sexual attractions with individuals of their same sex or opposite sex or both. These early experiences with sexual attraction during childhood may have lasting impacts on one's sexual identity during adulthood and may influence how one understands sexual orientation and to whom individuals are sexually and romantically attracted.

Additionally, children begin to learn about sexual orientation, gender and gender roles from their families, schools, religious groups, and the media during early childhood. These messages may influence one's ability to explore sexual orientation, gender roles, and gender expectations in positive and negative ways. For example, young boys may be encouraged to be leaders and authoritative while young girls may be encouraged to be more submissive or passive. Concurrently, young girls may be encouraged to be more emotionally expressive while young boys may be encouraged to repress emotions. Both groups may also learn that it is important to behave according to their gender norms and only be romantically attracted to the opposite sex.

These messages about sexual orientation and gender from early childhood may have lasting impacts on one's sexual identity as an adult. When children receive positive messages about sexual identity from their families and other role models, they are likely to gain better self-definition and positive self-esteem during adolescence; conversely, if they receive negative messages about sexual identity, they are likely to suffer other mental health consequences, particularly if they identify as gay, lesbian, or bisexual [4].

Sexual identity; Sexual labels

Definition

Sexual orientation is a construct involving sexual attraction that encompasses a variety of domains and includes behavioral, emotional, and social manifestations. Sexual orientation pertains to sexual attraction but may not result in the commission of sex acts or other sexual behavior. Despite instability in the reporting of sexual orientation or manifestations of sexual attraction over time, sexual orientation is considered to be an enduring trait that may manifest differently across the lifespan.

Description

According to the American Psychological Association (2004), "sexual orientation is an enduring emotional, sexual, or affectional attraction toward others," inherently different from biological sex, gender identity, and gender roles [1]. While many view sexual orientation as exclusively linked to sexual behavior, sexual orientation in its truest form pertains to persistent patterns of attraction across a variety of domains, regardless of whether or not the attraction results in any sexual act. Over the course of the past 50 years, heterosexuality, or attraction to members of the opposite sex, homosexuality, or same sex attraction, and bisexuality, attraction to members of both the same and opposite sex, have emerged as the most frequently researched manifestations of sexual orientation. However, though frequently conceptualized as a largely dichotomous concept, with individuals identifying exclusively as heterosexual or homosexual, and some oriented in between (bisexual), research indicates that sexual orientation is most accurately represented as a continuum of orientations [11–13]. According to Kinsey, who developed the Heterosexual–Homosexual Rating Scale [11], individuals may find that their sexual orientation is most accurately characterized by degrees of attraction ranging from exclusively heterosexual to exclusively homosexual. Specifically, Kinsey posited that sexual orientation can be described as exclusively heterosexual, no homosexual; predominantly heterosexual, only incidentally homosexual; predominantly heterosexual, more than incidentally homosexual; equally heterosexual and homosexual; predominantly homosexual, incidentally heterosexual; predominantly homosexual, more than incidentally heterosexual; and exclusively homosexual.

Kinsey's description of sexual orientation as existing along a continuum was furthered by Dr. Fritz Klein, who also subscribed to a multi-dimensional notion of sexual orientation and attraction. However, unlike Kinsey, Klein's model, operationalized by the Klein Sexual Orientation Grid, attends to the notion that sexuality is comprised of a variety of factors, including emotional, social, and lifestyle components, in addition to more traditional aspects of human sexuality, such as sexual attraction, sexual behavior, and sexual fantasies. Klein asserted that each of the aforementioned aspects of sexual orientation can change over time, conflicting with previously held notions of sexual orientation as stable and fixed, and are best evaluated by identifying past, present, and ideal descriptions of behavior. Like Kinsey's model, Klein's approach affords the option for those completing the grid to indicate a variety of interests, ranging from "other sex only" to "same sex only," as well as orientations, ranging from "heterosexual only" to "homosexual only," with a variety of response gradients in between exclusive orientations and identities. However, unlike Kinsey's model, Klein's model allows respondents the ability to differentiate between sexual behavior and lifestyle choices, thus allowing for identification of situations where respondents private sexual identity may not match their public (lifestyle) identity.

Prevalence of Nonheterosexuality

Current reported rates of homosexuality in the United States range between 2 and 4% of the total population [6]. However, methodologically, much research regarding the prevalence of homosexuality is plagued by the tendency to examine sexuality as a discrete variable, encompassing only heterosexuality, homosexuality, and bisexuality. As asserted by Diamond [7], as well as Savin-Williams and Reams [17], variations in sexual orientation are best examined by evaluating sexuality along a continuum, including same sex behavior, sexual attraction, romantic relationships, public lifestyle, emotional attraction, and fantasy. Furthermore, in accordance with Klein's suggestion that past and future sexual orientation and behavior may deviate from present orientation, Savin-Williams and Reams also suggest that self-report of sexual orientation may not be fixed, reflecting degrees of self-awareness or active engagement in same or different sex behavior, and should be investigated across time.

Holistically, research conducted over the past 10 years suggests that when the definition of sexual orientation is

broadened to include domains outside of sexual behavior, such as emotion and fantasy, rates of homosexuality or bisexuality increase significantly from established base rates in the population. It has also been found that significantly more women than men self-identify as nonheterosexual [17]. Likewise, research indicates that report of sexual orientation among nonheterosexual populations typically varies over time, while report of sexual orientation among the majority of heterosexuals tends to remain stable [17]. Consequently, research identifying instability in reports of sexual orientation among nonheterosexuals suggests that sexual orientation may be a construct that behaviorally manifests differently over time (2007).

Determinants of Sexual Orientation

To date, no research definitively identifying the cause of sexual orientation differences has been published [2, 4]. Numerous hypotheses regarding the development of sexual orientation have been tested, yielding a variety of biologically based variables correlated with sexual orientation. Possible genetic determinants related to the x chromosome have been investigated [3, 4, 8, 9, 14, 15]; as well as hypotheses involving hormonal factors [10], and differences in brain anatomy, particularly in the hippocampus and hypothalamus [5, 16, 18]. Despite a long history of competing determinants of sexual orientation, sexual identity, and attraction is primarily believed to be biologically mediated. However, social and environmental factors may serve to influence the degree to which an individual fully espouses and expresses their sexual orientation.

Sexual Prejudice

David P. Rivera
Teachers College, Columbia University, New York, NY, USA

Synonyms

Heterosexism; Homonegativity; Homophobia; Sexual stigma

Definition

Sexual prejudice encompasses all negative attitudes and assumptions directed toward an individual or group based on sexual orientation.

Description

Sexual prejudice occurs when an individual harbors negative attitudes about an individual or group based on sexual orientation [2–4]. The target of sexual prejudice can be of any sexual orientation (homosexual, bisexual, or heterosexual). However, as with other forms of prejudice, the groups that suffer most from sexual prejudice are those that have been ascribed marginal status by society.

As such, those whose sexual orientation is labeled as homosexual (i.e., gay, lesbian) or bisexual are most likely to be targets of sexual prejudice. The manifestation of sexual prejudice occurs in various ways, such as heterosexuals possessing negative attitudes about homosexual behavior or expressing negative attitudes towards individuals or groups of people who are homosexual or bisexual. Sexual prejudice can be expressed through verbal statements, non-verbal facial expressions, or actions ranging from avoidance to violence, for example.

Psychologist Gregory M. Herek, a scholar of sexual orientation-based prejudice and antigay violence, coined the term sexual prejudice [2]. The term was offered as a broader way of conceptualizing the negative attitudes and beliefs directed to individuals and groups based on sexual orientation. Further, use of the term sexual prejudice may serve as a more appropriate descriptor when identifying or studying antigay attitudes, which has previously been associated with the terms homophobia and heterosexism. More specifically, use of the term sexual prejudice may be more appropriate because its use does not define the origins of antigay attitudes or beliefs.

Relevance to Childhood Development

Children can be the targets and aggressors of sexual prejudice. Issues and experiences of sexual prejudice can arise when children become aware of sexual orientation differences between themselves and others. As children begin to gain an awareness of their sexual orientation, they begin to display behaviors that can be considered gender normative, gender neutral, or gender variant. Gender normative behavior is typically displayed by children whose sexual orientation is consistent with a heterosexual orientation. However, gender neutral or gender variant behavior is likely to be displayed by children who identify with a homosexual or bisexual orientation. As children begin to engage in behaviors that are not consistent with a heterosexual orientation, the potential for being the target of sexual prejudice increases.

Childhood is full of many developmental milestones. One of the milestones salient to identity development in children is that of first awareness of sexual orientation. The first awareness of one's homosexual or bisexual orientation is believed to occur between ages 9 and 11 [6]. The behavior of children is influenced in part by their awareness of their sexual orientation. Sexual prejudice is likely to be directed towards children who begin to engage in behavior that is influenced by their homosexual or bisexual orientation. Other developmental milestones that contribute to the likelihood of becoming the target of sexual prejudice include first same-sex encounter, first self-label of gay, lesbian or bisexual, and first disclosure of sexual orientation. These milestones are reached at various ages; however, research indicates that they can all occur during the childhood and adolescent years.

Peer pressure is a psychological construct that contributes to the likelihood of a child becoming an aggressor of sexual prejudice [1]. As the child begins to notice the gender norms for his or her environment, they also begin to notice the children who are not behaving in what is considered a gender appropriate manner. Children can be greatly influenced by their peers to behave in many different ways. An environment that values and adheres to a rigid definition of gender appropriateness is likely to encourage children to adopt these same rigid values. As children begin to identify those children who are behaving in gender neutral or gender variant ways, they are likely to be influenced by their peers to think about and treat these children differently. In an environment where difference is not tolerated, the children have an increased potential for treating the children who behave in gender neutral or gender variant ways negatively.

Children who are the targets of sexual prejudice are likely to experience an array of negative experiences, which can impact their level of psychological wellbeing [5]. Children who are exposed to environments where they are made to feel inferior, deviant, and unwelcome can develop a low sense of self-worth and low self-esteem. These children can also develop higher rates of depression and feelings of hopelessness. Additionally, children who have experienced sexual prejudice can also develop a heightened level of sensitivity and awareness for their surroundings, which can increase their potential for developing anxiety disorders. All of these threats to a child's sense of wellbeing can lead to an increased susceptibility for suicidal ideation and suicidality.

In order to prevent sexual prejudice amongst children, attention needs to be placed on environmental factors [5]. Policy makers, educators, healthcare providers, and parents can take steps towards creating an environment that is more knowledgeable and accepting of gay, lesbian, and bisexual children. Since many of the peer interactions that create the potential for sexual prejudice in childhood occur in a school setting, educators can be influential in leading efforts to make schools a safer and more welcoming environment for gay, lesbian, and bisexual children. Children can be educated about sexual orientation differences. Support groups and peer ally groups can be created in the school to improve the awareness around sexual orientation issues. Mental health professionals can be made available to children who need support in processing their experiences of sexual prejudice. Parents can take

a leadership role by advocating that schools institute programs geared towards educating their children about sexual orientation issues. Preventing and dealing with sexual prejudice successfully requires the involvement of the entire community.

Sexual Relationships

Douglas K. Symons, Alicia L. Szielasko
Acadia University, Wolfville, ON, Canada

Synonyms

Intimate relationships; Mate selection; Pair bonding; Sexual intimacy

Definition

A sexual relationship is a relationship between two people that includes sexual intimacy. The main forms of intimacy are physical and emotional, but sexual relationships do not have to include both of these components.

Description

There are different kinds of sexual relationships defined by the gender of the people involved: heterosexual relationships involve a male and a female, homosexual relationships involve two people of the same sex, and people identified as bisexual typically either engage in both kinds of relationships or have a sexual attraction to people of both sexes. Sexual activity between a child and either an older adolescent or adult, or exploitation of the child for sexual gratification, is child sexual abuse defined by criminal and civil law. Age of consent for adolescents to have a sexual relationship according to law varies from country to country from age 12 to 20, although the modal age is 14 or 15 according to some sources, and subject to a variety of qualifications related to issues like permissible age differences, marital status, and what kind of activity is allowed, that again vary by country.

Relevance for Childhood Development

One third of 13 year-olds and two thirds of 18 year-olds self report having been in a romantic relationship in the past 18 months, and about half of North American high school students have experienced a sexual relationship that included intercourse. Sexual relationships are seen as a subset of romantic relationships as sex is a behavior that takes place within romantic relationships or is promised for the future, but sex can also take place outside of them [5, 7]. The evolutionary context of romantic relationships involves a combination of three behavioral systems that have been historically argued to be independent: attachment, caregiving, and sex [2, 6].

Sexual relationships have been studied for a variety of reasons in adolescence. One area of research involves risky sexual behavior [11]. Significant percentages of adolescents engage in risky sexual behavior, which includes having unprotected sex, sex while impaired, and involvement with multiple partners or at an early age. These kinds of behaviors are related to sexually transmitted diseases, involvement in unwanted sexual behavior, and teenage pregnancy. These negative outcomes have resulted in studies of motives for sexual behavior such as having sex to either gain social status or to maintain a relationship [10], as well as HIV and pregnancy prevention programs which target teenagers [8, 12]. These kinds of studies often identify populations of adolescents who tend to engage in risky sexual behavior, such as adolescents from low socioeconomic status, from single parent families, or from the inner cities. How adolescents feel invulnerable to normative risk factors (e.g., "it will not happen to me") is also an issue. Another area of concern is when sexual relationships are coercive or exploitive, which compromises consent and appropriate motivational issues regarding the sexual relationship [3].

Another area of research examines how sexual and romantic relationships arise in adolescence. For example, relationship researchers have speculated that adolescent sexual relationships arise as an extension of peer relationships, and represent a further distancing of teens from their parents [1, 4]. Sexual and romantic partners can ultimately be a new secure base to turn to when distressed, whereas parents typically are used to meet those needs in

infancy and childhood. Mate selection is another focus so that how sexual partners are selected can be understood, and it is felt that secure children make relatively healthier choices in their sexual relationships.

A final area of interest is how teenagers can best be educated about sexual relationships, risk factors, and sexuality in general. There is a presumption that education can help teenagers make better decisions in their lives. Alternatives to education, such as the "Abstinence Only" teenage pregnancy prevention campaign in the United States in the 1990s, have not been effective as they do not include an educational component. There have even been ideologically driven objections to funding research on sexual relationships in adolescence out of concerns that such research would be counterproductive to efforts to discourage casual sex amongst teens [9].

Sexual relationships in adolescence ultimately are of interest to developmental psychologists, medical personnel with a focus on prevention and community-health, family-support workers, and educators [13].

Shaken Baby Syndrome

Adeline Low
Kuala Lumpur, Wilayah Persekutuan, Malaysia

Synonyms

Battered child syndrome; Child abuse; Child maltreatment; Non-accidental trauma; Sexual abuse; Whiplash Shaken Infant Syndrome

Definition

Shaken baby syndrome (SBS) is a form of child abuse that occurs when an abuser violently shakes an infant or small child, creating a whiplash-type motion that causes acceleration-deceleration injuries.

Description

SBS, or also simply known as SBS, is becoming one of the leading issues of child maltreatment. In the United States alone, over 250 out of 1000 maltreated children die each year due to SBS. This number may be higher than reported as many cases have gone unrecorded since it was hard to properly label child abuse fatalities. Since SBS is a difficult syndrome to define, it further increases the difficulties

in determining the frequency of such cases. SBS, which causes head injuries by violently shaking an infant, is not a new type of child maltreatment. The first incomplete autopsy findings of such abuse was recorded in the year 1860, by Professor Ambrose Tardieu of the University of Paris. Although no shaking was specifically mentioned, he revealed that by investigating 32 cases of child abuse, some victims were "pulled all over the place" and had lesions at their arms and chest due to rough handling. However, it was only in the year 1946 that John Caffey coined the term Whiplash Shaken Infant Syndrome to describe 27 children with subdural hematoma, a type of brain injury, who had received whiplash shaking but had no history of trauma.

There are about 14 common signs and symptoms of SBS. Below is the list of them:

1. Apnea, an interruption in the regular rhythm of respiration
2. Bradycardia, having a heart rate of less than 60 beats per minute
3. Bradypnea, an abnormal slowness in breathing
4. Bulging fontanelle, swelling on the infant head's soft spot due to excess of fluid, blood and inflammation within the brain's substance
5. Coma, a state of unresponsiveness
6. Cyanosis, the lack of oxygen in the blood which causes the infant's lips and skin to turn into a bluish purple color
7. Eyes rolling back or staring
8. Hypothermia, abnormally low body temperature
9. Inconsolable irritability
10. Internal damage but with no external injuries
11. Lethargy, appearing sleepy, or hard to arouse
12. Seizures and status epilepticus
13. Tensing or drawing up limbs; and
14. Vomiting

Clinical characteristics of an infant with SBS may include retinal hemorrhage, subdural and/or subarachnoid hemorrhages but with no external trauma. Nevertheless, a diagnosis of SBS should not be made just by these symptoms alone, but, the combination of clinical history, diagnostic images and the abovementioned signs and symptoms.

The perpetrators of SBS can be anyone, but generally they are parents or caregivers of the child. Most often, shaking occurred not to injure the child but to control the child's behavior. There are many characteristics of SBS perpetrators, but only three will be noted here. First, SBS perpetrators were often abused as children too. Since these people grew up in a negative environment, they may believe that corporal punishment is justified, and may not see the wrong in shaking a crying child to silence him or her. Second, caregivers with psychiatric disorders show an increased probability of being a perpetrator of SBS. The psychopathology impacts the relationship between the caregiver and the child, and the caregiver has a lower ability to deal with the stress of raising a child. Third, lack of social support and social isolation has been highlighted as one of the factors that increases the risk of infant shaking. This social isolation by the caregivers increases their frustration and limits their sources to proper caregiving and child development. Abusive behaviors are found to occur especially during periods of overwhelming stress.

Relevance to Childhood Development

This syndrome is a serious form of child maltreatment because of the severe consequences it produces to the shaken infant. Vigorously shaken infants are subject to possible brain injuries. A child who experienced a minimal aftereffect of the shaking often develops attention issues and may be easily distracted. In addition, this child may develop emotional problems and attachment disorder. Normally, the conditions above happen to shaken children who were not discovered or even diagnosed. However, in severe cases, the shaken child might end up having balance problems, blindness, cerebral palsy, deafness/hearing problem, and even death. Balance problems are related to an injury to either the basal ganglia, cerebellum or the inner ear. Retinal hemorrhaging may develop as a result of SBS and this may lead to partial or total blindness while cerebral palsy impairs the child's motor skills. Since a shaken child may suffer damages to the eighth cranial nerve, bones of the inner ears and the cochlea, the child is susceptible to hearing problems or even deafness. Death often occurs due to uncontrolled increase of intracranial pressure. This is a result of injuries to the cerebral edema or hemorrhage. Shaken children under 6 months of age are exposed to a higher risk of dying.

Since SBS also leads to motor skills impairment, shaken children are also left with poor oral motor function. They are unable to chew or swallow, and might also experience gastroesophageal reflux, whereby food from their stomach is brought back into the esophagus. A SBS child might also have hydrocephalus, the enlargement of the brain due to excessive build up of fluid in and around the ventricles of the cranial space. Other complications due to traumatic brain injuries include hypersensitivity, learning disabilities, and mental retardation. Shaking could slow down the brain's rate of growth, causing the child to have microcephaly, which is defined as possessing an abnormally smaller head than the normal population.

Damage to the spinal cord can result in paralysis to the child while with severe brain injuries, the child might be left in a persistent vegetative state.

Shakow, David

Katherine E. Kiker
University of Florida, Gainesvile, FL, USA

Life Dates

1901–1981

Educational Information

Born in New York City, David Shakow attended Harvard University, where he earned his bachelor's and master's degrees in science. He began working toward his doctorate in psychology, but accepted a position at Worcester State Hospital in 1932 to support his family. In 1949, he accepted a position as professor in the psychiatry department at the University of Illinois Medical School. Two years later, he accepted a joint position to also serve as professor of psychology at the University of Chicago. In 1954, he left both of these positions to work at the National Institutes of Mental Health (NIMH). Shakow served as the first head of the Laboratory of Psychology in NIMH's Intramural Research Program. In 1966 he retired from his position, but continued as a senior research psychologist [2].

Accomplishments

At Worcester State Hospital, Shakow began his research into schizophrenia. His research helped to establish basic facts about schizophrenia and contributed to the research on the mental deterioration that accompanies the progress of schizophrenia. Additionally, Shakow helped emphasize the need to treat schizophrenics humanely [1].

During his work at NIMH, Shakow was awarded the Distinguished Scientific Contribution Award and the Distinguished Professional Contribution Award of the American Psychological Association [2].

Contribution

Shakow's dissertation (1946), *The Nature of Deterioration in Schizophrenia,* is recognized as a classic study of the disease. Shakow developed one of the nation's first clinical psychology internship programs [2].

Shakow also chaired the development of the Scientist-Practitioner Model of graduate training for clinical psychology, which was set forth at the famous Boulder Conference of 1949. Finally, Shakow's research at NIMH contributed to the areas of schizophrenia, perception, aging, childhood development, and personality [2].

Shame

Temi Bidjerano
Furman University, Greenville, SC, USA

Definition

A self-conscious emotion, evoked in situations of failing to achieve goals of personal importance and attributing the outcome to internal, uncontrollable causes such as lack of ability or intelligence.

Description

Shame is characterized as a highly intense self-conscious emotion that usually occurs as a result of failure of personal importance, such as living up to expectations or attaining personal goals and standards. It is evoked in situations in which failure has been attributed to a stable global aspect of the self (i.e., personality characteristics, ability), exemplified by the statement "I'm a stupid person." The intensity of shame is particularly strong when an individual fails an easy task. Shame is associated with feelings of helplessness, sadness, and depression; it involves a negative evaluation of the entire self and there is a great concern about the appearance of the self in the eyes of others [6, 10].

The experience of shame is accompanied by pronounced behavioral reactions such as lowering the head

and eyes, not maintaining eye contact, withdrawing from interaction, and diverting others' attention from the painful event. Physiological reactions including blushing, having difficulty breathing, and increased perspiration and heart rate. Psychological reactions include feelings of inferiority, humiliation, awkwardness, lack of confidence, loss of status, and loss of control [3, 8].

Shame could have an adaptive function as long as the recognized discrepancies between actual behavior and the ideal self serve as a motivator for change and improvement. Recurring shame, however, can result in generalized shame or a disposition for shame and as such can have devastating and de-motivating effects. Excessive feelings of helplessness, worthlessness, and incompetence across a variety of situations have been labeled a "shame-prone" style.

Relevance to Childhood Development

Shame is different from basic emotions such as sadness, as it involves a more elaborate cognitive process at the center of which is the self. Shame develops as the growing child acquires understanding of self-identity, social norms, and conventions [4, 6, 8]. Thus, shame is a higher-order, self-evaluative emotion, often considered a moral emotion as it reflects responsibility to self and others. The very first prerequisite condition for the genesis and development of shame is cognition. In order to be able to experience this emotion, children must be cognitively capable of mentally representing standards for behavior, of judging their own behavior or performance against these standards, and, in situations of failure, of reflecting upon the possible causes of their behavior which have prevented them from living up to their expectations [1, 6]. In addition to natural maturational processes in cognition, shame develops out of children's socialization experiences in the nuclear family. More specifically, shame develops as a result of parents' or significant others' use of evaluative feedback. Evaluative feedback, regardless of its valence (positive or negative), can foster the development of shame in several ways. Initially, the feedback serves to draw the child's attention to the social meaning associated with particular behavioral outcomes. Parents' frequent evaluative feedback leads to the child's internalization of parental values, norms, and standards for acceptable behavior. The perception of the social value of the outcome facilitates in turn the child's self-evaluation against the internalized standards, which are deemed to be at the center of the emotion of shame [1, 5, 6].

Shame takes different forms at different ages. Mascolo and Fischer [7] have delineated the sequence in the development of shame. The 7–9 months old infant reacts with distress when he engages in action which results in a failure to achieve a particular outcome. Between 11 and 13 months, the child's distress produced from failing a complex action is accompanied by an appraisal of other people's reactions. Toward the end of the second year of life, the child begins to attribute the negative outcomes of goal oriented behavior to the self as a cause of it. In the third year of life, the self, as a cause of the outcome, is labeled bad or poor. Preschoolers begin to judge their inadequate performance in an important area in reference to other people's performance in it. Also, they are capable of comparing their performance across different instances of the same situation and begin to generalize that they are lacking an important trait, which in turn is blamed for the failure. Between the ages of 6 and 8, children begin to judge their performance as poorer than that of other children and adults in several areas and become likely to infer that they do not possess the desirable trait to the same extent as other people do. Younger children are predominantly fearful of ridicule and embarrassment. Children younger than eight tend to explain their emotions of shame by the use of an external frame of reference, exemplified in statements such as "Mom would be ashamed of me if I did something wrong [3]." Elementary school children (10–12 years of age) become cognitively capable of analyzing the courses of ineffective actions and shame is more likely to be associated with generalized thoughts of incompetence. For example, a child can judge him/herself as lacking an athletic ability and being a poorer student comparative to other children, from which he/she concludes that in general he/she is less competent. Yet, in the adolescent years, shame could take on another manifestation: the adolescent could feel ashamed because of a characteristic or behavior of another person or group of people with identity related to theirs.

It has been argued that excessive shame reactions might originate from punitive parental socialization practices such as power assertion and love withdrawal [2, 4, 9]; that is, children whose parents rely on discipline techniques such us punishment or threat of punishment are much more likely to manifest maladaptive shame when they encounter a situation of failure [2, 9]. Moderate positive relationships have been found between maternal negative evaluations of performance and a child's expression of shame in situations of failure. In addition, it has been noted that the pattern of relationship between shame and feedback is consistent across genders. Thus, frequently communicated disappointment and criticism by parents may not only foster a child's negative self-evaluations but they also predispose that child to recurrent shame experiences. Research has also established that

girls tend to be more shame prone than boys and that mothers tend to offer more positive feedback to boys than to girls [2, 10].

Shaping

Jennifer M. Alexander, Maria G. Valdovinos
Drake University, Des Moines, IA, USA

Definition

Shaping is a procedure by which new responses are formed using differential reinforcement of successive approximations to a target behavior.

Description

Components of shaping include beginning with a response that resembles the target behavior, gradually changing the response requirement, and differentially reinforcing the successive approximations to, or changes towards, the final target behavior [1]. For example, shaping can be used to teach an infant to speak a new word. Using the word "ready" as the target behavior, running with the infant can be done contingent on their approximating the word "ready." First, the requirement might be saying "rrr." The next approximation might be "red" and the final "ready." Once the infant has mastered one response, reinforcement is withheld until the infant engages in the next approximated response. When using shaping, one needs to be mindful of the size of the change in response requirement as too large a change can result in a breakdown of the response. Shaping is often used in teaching new behaviors, sometimes within the context of behavioral intervention programs.

Short-Term Memory

Mei Y. Chang[1], Raymond S. Dean[1], Denise E. Maricle[2]
[1]Ball State University, Muncie, IN, USA
[2]Texas Woman's University, Denton, TX, USA

Synonyms

Immediate memory; Working memory

Definition

Short-term memory (STM) is conceived of as an auditory based, limited-capacity part of the human memory. It is generally agreed to be involved with the encoding to and recall from the long-term stored information. Unless information is rehearsed, information in the STM usually lasts seconds to 1–2 min, although some researchers suggest retention periods as high as 1 h–2 days. At the end of this period information either is transferred to long-term memory or is lost. Miller [18] in a study showed what has come to be known as "7 + or − 2," which related to the limited capacity of items that could be held in the normal STM (e.g., 5–9). In work by Dean and colleagues [5], the processing of the STM was shown to be associated with an auditory base while long-term memory had a longer duration and processed information conceptually. STM has been proposed as a stage that information must pass through to enter long-term memory storage, and it is into STM that long-term memories are retrieved. STM only requires material be stored and reproduced immediately without requiring that the material be transformed or manipulated in any way.

Description

Through sensory input, individuals register and hold large amounts of information briefly in sensory memory (or sensory register). If the registered information is not further processed by STM, it will decay quickly. Thus, the sensory register is a filtering device while the STM is used for processing. Long-term memory represents, with rehearsal, a relatively permanent memory storage. STM is proposed as a stage that information must pass through to enter long-term memory storage, and it is into STM that long-term memories are retrieved. Because STM is a limited-capacity system, information within STM must be transferred to long-term memory as new information replaces it; otherwise it will decay.

STM is sometimes referred to as and used interchangeably with working memory in CHC theory. For many the definition of STM does not include "the requirement for active manipulation of information," embedded in the definition of working memory. Further, STM in the past was defined as retention of information over brief periods, and working memory was a limited-capacity memory system that provided temporal storage to manipulate information for complex cognitive tasks such as learning and reasoning. In other words, working memory is a cognitive process involving both retaining information and performing mental operations on that information prior to entry to long-term memory. Working memory contains information that can be acted on and processed, not merely the result of rehearsal. Additionally, working memory ensures that information will be available until it can be effectively encoded into long-term memory. Information placed in working memory may come from sensory memory, STM, or long-term memory [17].

Historically, Atkinson and Shiffrin [1] posited a three-part model of memory (sensory memory, STM and long-term memory) where the central feature was STM. According to their model short-term memories are fragile, contain only a small amount of information that is actively being used and are lost quickly (within 30 s or so) unless they are somehow repeated. A more current model involving STM is described by Gathercole and Alloway [8]. Theirs is a working memory model that involves three components: verbal short term memory, visuo-spatial short term memory and a central executive that serves an attentional and integrative role. In their model, verbal short term memory provides for the temporary storage or retention of sound patterns and language based materials that are mediated by the left hemisphere. The visuo-spatial short term memory component is mediated by the right hemisphere and involved in recalling shape, orientation and visual features of objects, and patterns of movement. Currently, research indicates that STM passively stores information, that it is domain specific (e.g., verbal or visual) and that it can operate independently of long-term memory and working memory [12].

Neuroanatomy of Memory/Retention of Information

Studies of healthy people and patients with amnesia have revealed that memory does not consist of a single undivided whole but rather a variety of different structures, each mediated by different component processes which in turn are subserved by different neural mechanisms. Evidence from sources of functional imaging techniques and studies of patients with memory impairments and animals indicates that the medial temporal lobe (primarily the hippocampus and secondarily the amygdala) and the midline diencephalon (the dorsomedial nucleus of the thalamus) are essential brain structures for normal learning and retention. These structures permit the storage of information until consolidation is complete. Neuropsychological research indicates that left parietal-temporal lobe dysfunction disturbs short-term (and working) memory. Lesions in this area impair the ability to recall a string of digits. Left sided lesions result in verbal impairments, and right sided lesions result in STM impairments for spatial location [11].

Relevance to Childhood Development

Memory complaints are among the most frequent patient complaints in clinical neuropsychology, and STM deficits

are a common feature of many childhood disorders, including traumatic or acquired brain injury, congenital brain injury (anoxia), seizure disorders, attention disorders, autism, endocrine disorders, genetic disorders such as Prader Willi Syndrome, Turner Syndrome, XXY Syndrome, and numerous neurodevelopmental disorders such as metabolic disorders. Memory function takes precedence over acquiring new skills and directly impacts the retention of information and skills. Therefore, assessing the performance of the various aspects in the memory system is imperative in detecting and identifying possible memory disorders. Most standardized batteries of intellectual functioning in children and adults have incorporated tasks of STM. Children do not use rehearsal strategies until about age 8 or 9, so young children's STM capacity is quite limited. Most children reach adult capacities about age 10–12. Additionally, at about age 8, children develop a strong preference for using verbal STM skills when possible, even to retain visual-spatial STM stimuli because verbal STM is more accurate and efficient. The three most widely used memory batteries for children are the *Wide Range Assessment of Memory and Learning-II* (WRAML-II), *the Test of Memory and Learning-II* (TOMAL II), and the *Children's Memory Scale* (CMS).

Due to variations in etiology, age of onset, and resulting impairments of memory systems, the prognosis for improvement of memory deficits is not easily determined. There is some evidence that specific rehabilitation strategies result in improvement of memory performance. The primary focus of intervention has been on environmental compensation including mnemonic strategies, rehearsal and repetition strategies, and multimodal cueing, and the use of tools such as planners, calendars, or charts. There is considerable need for further research examining the efficacy of specific intervention strategies on various memory functions in children and adolescents.

Bashfulness; Behavioral inhibition; Reticence; Social withdrawal; Timidity

Definition

Shyness in children is a personality trait and a form of social withdrawal. Shy children exhibit wariness and anxiety when presented with novel social encounters and they show self-preoccupation when they perceive social evaluation [7, 18]. Shyness can vary in intensity from mild social awkwardness to extreme ▶social phobia [11]. Manifestations of shyness occur at the physiological, behavioral, and cognitive levels. The origins of shyness are multiply determined, and they result from a complex interplay between biology, genes, and environment [19].

Description

The biological origins of shyness appear to be linked to dysregulation of the fear system [18]. Children who become distressed and subdued when presented with novel stimuli are thought to have a lower threshold for arousal in the forebrain area, especially in the central nucleus of the amygdala. The amygdala plays an important role in fear responses. Shy children show electroencephalogram (EEG) response patterns indicative of greater right frontal brain activity. Other biological features found in shy children are elevated morning basal cortisol levels, increased heart rate acceleration in response to mild stress, and exaggerated startle responses [7].

There is a strong conceptual overlap between shyness and behavioral inhibition, a broader term used to describe a biologically based temperament trait [7]. Behaviorally inhibited children exhibit caution and wariness in unfamiliar social and nonsocial situations, whereas uninhibited children are likely to be bold and sociable. Differences between these inhibited and uninhibited children are thought to reflect variation in excitability of the amygdala and its projections to the ventral striatum, hypothalamus, cingulate, central gray matter, and medulla [13]. It is estimated that approximately 10–15% of children may be described as behaviorally inhibited.

Several other interesting biological factors are linked to shyness, such as blue eye color, blond hair, pale skin, and allergies (especially hay fever; [11]). In addition, prenatal factors also have an impact. It has been found that women who are exposed to short day length during pregnancy (especially during the midpoint of pregnancy) are more likely to have shy children. The hormone melatonin has been implicated in the link between day length during pregnancy and shyness. During the winter months when there are fewer daylight hours, the body produces higher levels of melatonin. This melatonin passes through the placenta to the developing fetal brain, where it may contribute to the development of the highly reactive temperament of shy children [9].

Shyness also shows evidence of genetic links and is considered to be the personality trait with the strongest genetic component. Shy children are likely to have at least one shy parent, or they may have other shy family members. It is speculated that genes that code for serotonin transportation likely play an important role in regulation of some components of the fear system associated with shyness. Serotonin is a major neurotransmitter that has been linked to anxiety and withdrawal [20]. It has been suggested that some shy individuals have a genetic polymorphism that results in reduced efficiency of the transportation of serotonin. Interestingly, it has been found that children who exhibit higher levels of shyness or who have one or two copies of the short allele of the serotonin transporter promoter gene show some impairment in their ability to read some facial emotions. Specifically these children have a hard time deciphering neutral and angry faces [2].

While considerable research has focused on the links between shyness and activation of the fear response region of the brain (i.e., the amygdala), less research has considered the extent to which shy individuals may show greater brain activation in areas that govern more positive emotions. Recent research found that when shy, behaviorally inhibited adolescents played games that involved winning or losing money, they showed greater activity in the striatum, the brain region associated with reward, than did adolescents who were behaviorally non-inhibited [10]. The results of this research suggest that shy children may have a greater sensitivity to a variety of stimuli, not just frightening stimuli, but rewarding stimuli, as well.

Behaviorally, among younger children shyness is manifested primarily as fear and nervousness in encounters with new people and new situations [5]. For older children, embarrassment and self-consciousness are manifestations of shyness. In free play situations with their peers, shy children tend to engage in onlooker behaviors or to remain unoccupied in both novel and familiar settings [16]. Shy children tend to withdraw from social interactions and they rarely initiate contact with potential playmates. Shy individuals tend to minimize conversation and avoid firm eye contact [14].

Self-defeating thoughts are a cognitive manifestation of shyness. These self-defeating thoughts are likely due to a fear of rejection [14]. It has been suggested that shy children may be caught in an approach-avoidance conflict. They have a desire to interact with others, but they are hesitant to do so because of a fear of adverse outcomes such as negative evaluation [14]. Shy individuals are likely to have negative biases in their self concept, such as feeling inadequate or unattractive [11].

Not all shyness is evident during infancy, and so it is important to make the distinction between early and later-developing shyness. Early emerging shyness, which typically appears during the first year of life, is described as fearful shyness. This type of shyness shows a strong genetic component, and is associated with the temperamental characteristics of wariness and emotionality. Children who show behavioral inhibition in novel social situations may be described as exhibiting fearful shyness. Beginning in middle childhood, self-conscious shyness may develop, and it is characterized by inhibition due to social-evaluative concerns [15]. It first appears around age 4 or 5, and it coincides with the child's development of a cognitive sense of self. Self-conscious shyness increases in intensity around age 8 as children begin to engage in more social comparison with their peers. Self-conscious shyness reaches a peak between the ages of 14 and 17, as the adolescent deals with imaginary audience and identity issues.

While the origins of shyness in some individuals are evident in manifestations of biologically-based behavioral inhibition in infancy, not all behaviorally inhibited infants and toddlers go on to develop shyness in childhood [14]. This suggests that biology and genetics alone are not the sole contributors to shyness. Indeed, most researchers agree that an interaction between biological and environmental factors contributes to the development of shyness [19]. Consequently, in addition to the biological factors already discussed, it is important to consider environmental factors that may contribute to shyness.

Overprotective parenting has been linked to childhood shyness [6]. Overprotective parents tend to restrict and direct their children's activities, and they discourage independence. As a result, an already temperamentally shy child may not develop important coping strategies, which may further reinforce their social wariness and shyness. Other factors within families that may contribute to shyness are frequent parental criticism, high parental control with little warmth, and chaotic family interactions [12]. Distant and rejecting parents tend to have shy and socially withdrawn children [19].

Peer relationships can also contribute to shyness. Shy and socially withdrawn behavior is increasingly perceived negatively by peers as children age. Shy and socially withdrawn children generally do not experience peer rejection in early childhood, but by mid-to-late childhood and early adolescence, many shy, socially withdrawn children experience peer rejection and may become the targets of peer victimization [17]. Peer rejection during childhood and adolescence and feelings of incompetence in comparison to peers can further exacerbate shyness.

Childhood shyness is associated with a number of negative outcomes. From middle childhood through adolescence, shyness is increasingly related to internalizing problems such as loneliness, depression, and social anxiety. Shy children may exhibit deficits in social competence and self-esteem, and they may experience peer rejection [5]. Additionally, early childhood shyness is a risk factor for later developing anxiety disorders [6], especially social phobia [16]. The negative trajectory worsens over time. That is, in middle and late childhood, social withdrawal increasingly is associated with peer rejection, loneliness, depressive symptoms, and negative self views [16].

Some research has examined long-term outcomes associated with childhood shyness through follow-up studies into the adulthood years. Long-term research on a 1920s birth cohort found that shy males married, established careers, and had children later than non-shy males. In contrast, shy women were more likely than their non-shy peers to follow a conventional pattern of marriage, childbearing, and homemaking [4]. Childhood shyness was not associated with pathological or extreme outcomes for either men or women. Similarly, a more recent long-term study found that childhood inhibition was associated with a delay in establishing a first stable career and romantic partnership, and finding a first full-time job at age 23 for both men and women. With regard to emotional consequences of inhibition, it is notable that only the most extremely inhibited showed internalizing problems at age 23 [1]. The researchers concluded that inhibited children grow up into reserved, cautious adults with minimal evidence of internalizing problems.

While it is important to acknowledge the challenges and risks associated with shyness, it is equally important to recognize that not all shy children experience negative outcomes [5]. Interestingly, language ability can serve as a protective factor for shy children. Verbal IQ, expressive vocabulary, and pragmatic language ability all facilitate social interactions for shy children, reducing their risk for negative outcomes [5].

Another factor that appears to make a difference in the outcomes for shy children is gender. Whereas shyness in girls is more likely to be rewarded and accepted by parents, being shy is especially problematic for boys in school. Shy boys in preschool have more behavior problems and are more likely to experience peer exclusion than are shy girls [5]. Throughout childhood and adolescence, shy boys continue to have more adjustment difficulties than girls do, such as more loneliness, poorer social skills, and lower self-esteem [5]. It has been suggested that cultural values play a role here, where there is greater social acceptance of shyness for girls than for boys in Western culture.

Interestingly, the role of culture can also serve to be protective factor for the shy individual. Although shyness is generally viewed as an undesirable personality characteristic in the United States, that is not the case in all cultures. For example, in the People's Republic of China, shy, reserved behavior is encouraged and accepted by mothers, teachers, and peers, and it is linked to social competence, peer acceptance, and academic success [16].

Just as family and peer factors can contribute to the risks of shyness, they, too, can serve as protective factors. Specifically, the maternal warmth, sensitivity, and supportiveness characteristic of an authoritative parenting style can help shy children develop social skills [6]. Additionally, having a high quality friendship is protective [5]. Such friendships may help provide social confidence to the child, serving as a buffer against negative emotional consequences of shyness [14]. Furthermore, children who have a closer relationship with their teacher are less likely to experience the negative outcomes associated with shyness, such as peer exclusion and rejection [5].

It is also important to recognize the positive characteristics associated with shyness. Focusing only on the problems associated with shyness can result in the view that shyness is necessarily detrimental. News stories about the use of selective serotonin re-uptake inhibitors (SSRI) or even oxytocin nasal sprays to treat shyness may communicate the message that shyness is pathological and medication is a quick fix and sure cure [20].

A more optimistic view acknowledges that some shyness attributes may be advantageous. For example, adults and children who are shy are often non-impulsive and good listeners [20]. Shy individuals are often high in empathy and sensitivity, which promotes compassion for others [11]. As noted earlier, shy children appear to exhibit increased activity in the reward system of the brain. It is quite possible, then, that shy children experience positive emotions and rewards more strongly, which may motivate the shy child to succeed.

Several intervention approaches are available to help shy children. For example, peer pairing gives withdrawn children the opportunity to participate in activities with a non-withdrawn peer, so that the more sociable peer serves as a role model, provides positive reinforcement, and increases confidence [15]. Social skills training also has been used to intervene with shy children. In social skills training, children learn and practice skills that help facilitate social interactions. Social skills training has been found to have moderate effects in increasing social interactions for shy children [15].

Another way to help shy children is to provide them with opportunities for social interaction that are related to their skills and interests. Participating in these activities expands shy children's social interactions, which in turn may enhance their communication skills and reduce social awkwardness. Activities such as group sports, acting, and dancing classes in a supportive environment can be helpful to shy children [12]. Research has found that shy children who participated in sports showed a significant decrease in social anxiety over the span of 1 year [8]. It is important to target activity participation to the child's skills and interests to maximize the likelihood that the child will have experiences of success [14].

Ultimately, parents need to adapt their parenting behavior to fit the temperamental needs of their shy child. By being patient, gradually introducing the child to new experiences, and recognizing which social experiences are a good fit for the child parents can help their shy child to achieve positive developmental outcomes.

Sibling Rivalry

Shital Pramod Gaitonde
Oklahoma State University, Stillwater, OK, USA

Synonyms

Cain complex; Jealousy complex; Sibling competition; Sibling jealousy

Definition

Sibling rivalry is a type of competition among brothers and sisters, for the love, affection, and attention of one or both parents or for other recognition or gain.

Description

Sibling rivalry often starts right after the birth of the second child, and usually continues throughout childhood and can be very frustrating and stressful to parents. It has been found that feelings of rivalry diminish in adulthood [7].

Sibling rivalry is manifested in the form of verbal or physical aggression, frustration, persistent demands for attention, or as a regressive phenomenon. Older siblings may feel lonely when the younger sibling is born and may indirectly suggest that they do not like the existence of their newborn brother or sister. Others may display frustration or demand attention when the newborn is picked up or provided more attention. Some others may hit, kick, and punch their younger sibling. Regressive behaviors such as bedwetting, thumb sucking, refusal to go to bed, insisting to be carried, and talking like babies occurs very commonly [6]. Conversely, younger siblings' feelings of jealousy may manifest as a result of the older sibling starting school before them, parents allowing the older sibling to stay up late, and having to use the older sibling's clothes and books [6].

Relevance to Childhood Development

Theories Explaining Sibling Rivalry

Different processes in sibling relationships have been identified that may explain the effect that siblings have on each other. Each child competes to define himself/herself as an individual, a process that has been described as sibling identification [1]. As they discover who they are, they try to find their own talents, activities, and interests. On the other hand, sibling deidentification has been proposed as a process whereby siblings try to distinguish themselves from their brothers and sisters and develop different

qualities and interests in an effort to avoid direct competition for resources and establish their own role and identity within the family [10]. Psychologists who support the psychoanalytic viewpoint propose that deidentification is a defense against sibling rivalry, a Cain complex [9], just as identification is regarded as a defense against the Oedipus complex.

Austrian physician Alfred Adler theorized that when a young child, initially the focus of attention, is replaced in the mother's affections by a newly arrived infant, then "dethronement" occurs. Thus Adler conceived sibling rivalry as competition between brothers or sisters for parental approval.

Factors Leading to Sibling Rivalry

Children's developmental stages affect how well they can share parent attention and get along with their siblings. Toddlers may be at an age when they are learning to assert themselves and may not like to share their toys with anyone. They may react aggressively if their brother or sister picks up their toy. In middle childhood, children often become the "fairness police," so they might not understand why siblings of other ages are treated differently. Teenagers, on the other hand, are developing a sense of individuality and independence, and might resent helping with household responsibilities, taking care of younger siblings, or even having to spend time together. All of these differences can influence the way children interact with one another.

Additionally, the emergence of sibling rivalry may depend on the temperament of the child. Specifically, young children's angry temperament can significantly predict how these young children express their jealousy feelings [11]. Furthermore, the age of the child may also determine how the child may cope with the feelings of sibling jealousy. Volling et al. [11] found that older children's understanding of emotional affect significantly predicted their behavior towards their younger sibling. Thus sibling rivalry may be less common among children over the age of 8 years. They may be better at perspective taking and thus understand why their parents are providing more attention to their younger sibling. Sibling rivalry is more common in children between the ages of 2 and 4 years [3]. Additionally, the smaller the age difference between children, the more likely sibling rivalry will occur [5].

Research has found that differential treatment (i.e., less warmth and affection, more coercion by parents) of one sibling by parents leads a child to act in an aggressive, unaffectionate and avoidant manner towards their sibling [4]. This differential treatment may also be seen in families with children with special needs. Specifically, since the child with special needs may need more attention, the other sibling may feel isolated and may develop feelings of rivalry.

Clinical Significance of Sibling Rivalry

Patterson [8] considers sibling relationships as a "training ground" for childhood aggression. Sibling rivalry, if handled properly, can help children learn social and cognitive skills important for child development [6]. Cole, Zahn-Waxler, and Smith [2] suggested that those children who interact with a jealous sibling, who is more likely to instigate conflict, may be at a high risk for development of emotional regulation disorders.

Management of Sibling Rivalry

Sibling rivalry may be minimized by preparing the child for the new baby. Involving the child in the preparations for the new baby may help him/her feel important. Providing verbal reassurance to the child that the parents will continue to love him/her after the baby arrives will address any insecurity that the child may experience. Verbal praise for caring for the baby will help the child feel like a team member in caring for the new-born child. Additionally, parents should emphasize the role of each individual within the family. Parents should avoid comparison with siblings about their intelligence, physical appearance, and achievements. Above all, parents themselves should model problem-solving skills during conflict resolution within the marital as well as family relationships [11].

Sickle Cell Disease

Anne Fierro Vanderlaan
Saybrook University, Meridian, ID, USA

Synonyms

Sickle beta-plus thalassemia; Sickle beta-zero thalassemia; Sickle cell anemia (SS); Sickle-hemoglobin C disease (SC)

Definition

Sickle Cell Disease is a genetic blood disease involving the red blood cells that produce the hemoglobins that are sickle shaped and can cause problems throughout the body. The symptoms of the disease may cause death or serious damage to vital organs.

Description

Hemoglobin carries oxygen from the lungs into the body and transports it to the organs, muscles, and tissues. Normal hemoglobin is called HbA. Hemoglobin S are red blood cells that are sickle-shaped that must pass through the blood vessels and may block the passageways and damage the tissues.

Relevance to Childhood Development

Children who have Sickle Cell disease need to make sure that the school understands the problems that they may have. Some children may have bruises on their bodies that have been mistaken for abuse. The most important consideration is for the child to be adequately hydrated and not over fatigued. Understanding the disease and watching for signs that may cause painful episodes is important. Children with Sickle Cell may experience severe pain in any part of the body due to sickling of the cells. There have been cases of people with this disease suffering heat exhaustion, dehydration, leg pain, joint pain, stomach pain, strokes, splenic infarction, stroke, and heart attacks. Diet is important and parents need to make sure the child is eating a well balanced diet. The child's immune system may be reduced which may cause more childhood illnesses. Children may also have swelling of the hands and feet.

Sickle Cell Trait

►Sickle Trait

Sickle Trait

Anne Fierro Vanderlaan
Saybrook University, Meridian, ID, USA

Synonyms

Sickle cell trait

Definition

Sickle cell trait or sickle trait is also known as hemoglobin genotype AS. Hemoglobin is the oxygen carrying protein in red blood cells. It carries oxygen from the lungs into the body and transports it to the organs, muscles, and tissues. Normal hemoglobin is called HbA. If one parent has a mutation of their hemoglobin gene and passes it on, the child will carry the defective gene, in this case, the HbS gene. In sickle trait, the individual has both HbA and HbS in about equal amounts in all red blood cells. These cells have the potential to change from round to sickle shaped red blood cells under certain conditions although they usually do not [1].

Description

Sickle cell trait needs to be understood because of the potential problems that may exist in some individuals with this genetic disorder. Most persons with sickle trait have few, if any, problems from it and are often unaware of having any abnormality. However, some persons with sickle cell trait may experience severe pain in any part of the body due to sickling of the cells. There have been rare cases of people with this disease suffering heat exhaustion, dehydration, leg pain, strokes, and splenic infarction. Some women with the trait have increased urinary infections. Hyphema or bleeding in the anterior chamber of the eye between the iris and the cornea is another problem associated with sickle cell trait. Patients with sickle cell trait have a higher incidence of gross hematuria (blood in the urine) than patients with sickle cell disease. Gross hematuria occurs from bleeding directly beneath the renal pelvic epithelium or as a consequence of papillary necrosis. Renal medullary carcinoma is a rare type of cancer that principally affects patients with sickle cell trait. A possible lethal effect of sickle cell trait is unexpected exercise-related death. A person with the trait should use caution when exercising to the limit of endurance and should take care by warming up slowly when playing sports or engaging in rigorous activity and making sure not to become overheated [2].

Relevance to Childhood Development

Although sickle cell trait originated in Africa, it has been found throughout the world among people of Greek, Italian, Indian, Hispanic and occasionally Caucasian origin. The majority of those with sickle cell trait are of African or Hispanic descent. Those from Caucasian origins tend to have more problems associated with this genetic disorder. Most children in the US are being tested at birth for this condition [3]. When a child is found to have the trait, the parent needs to be aware that most of the time children who have the trait will not have any problems, but the child might feel more pain than children without the trait [4]. Also hydration is important when the child is involved in any kind of activity [2].

Simultaneous Bilingualism

Corey E. Ray-Subramanian
University of Wisconsin-Madison, Madison, WI, USA

Definition

The development of fluency in two languages at the same time.

Description

Simultaneous bilingualism is typically the result of prolonged exposure to two languages from birth. This may result, for example, from one parent or primary caregiver speaking to a child in one language and another parent or primary caregiver speaking to the child in another language. In contrast, sequential or consecutive bilingualism is the development of fluency in a second language after fluency in a first language has been reached.

Research has shown that very young children who have developed simultaneous bilingualism are able to discriminate and switch between the two languages as appropriate to the social context. Researchers have also found that having two well developed languages is associated with increased metalinguistic awareness, communicative sensitivity, and divergent thinking skills [1].

Single Parent Families

Jennifer J. Lindwall[1], Brooke A. Bailer[1], Brian P. Daly[2]
[1]Temple University Health Sciences Center, Philadelphia, PA, USA
[2]Temple University, Philadelphia, PA, USA

Synonyms

Father only families; Lone/single parent/caregiver families; Mother only families

Definition

Single parent families are comprised of a parent/caregiver and one or more dependent children without the presence and support of a spouse or adult partner who is sharing the responsibility of parenting.

Description

Overview

During the past several decades, the number of "traditional" two-parent families has decreased while the number of single parent families has increased. For example, while only about 11% of children lived in single parent families in 1970, census data from 2000 indicate that 28% of children lived in single parent families. More recently, however, these increases have leveled off with recent rates having declined from 29% in 1997 to a slightly lower rate of 27% in 2001.

Reasons cited for single parent composition in families have varied during different decades. Specifically, death of a spouse was the most commonly cited reason for single parent families in the mid-twentieth century. In contrast, most of the rise in single parent families during the 1960s and 1970s was attributed to rising divorce rates, while increased rates during the 1980s and 1990s were due to out-of-wedlock births. The primary reason for single parent families in the early 2000s was that more and more single parents never married. Recent census data indicate that approximately one third of current births occur to unmarried women, while one fourth of children will live with a single parent. It is notable that although it has become more common for two non-married adult partners to be present in the household, the United States

Census Bureau still counts them as single parent families. Another exception that is counted as single parent families even though two married adults live in the house is military families in which one of the married partners is on extended deployment.

Because the presence of single parent families in the past was often due to death of a spouse, resulting data revealed approximately the same number of single father and single mother families [6]. Today, however, this ratio is quite different with single-parent families headed by the mother with her biological children considered to be the most common type of arrangement. In fact, data from the 2002 Census reveal that 23% of all children lived with their single mother. Although a less common arrangement, the percentage of single parent households led by a father has increased from approximately 1% in 1970 to about 5% in 2002. In 2006, there were 12.9 million single parent families, 10.4 million of which were headed by a single mother and the remaining 2.5 million that were headed by a single father [16]. In contrast to single parent mothers, single parent fathers are more likely to be divorced than never married and more likely to be sharing a home with an adult to whom they are not married.

Additional reasons for the creation of single parent families include other situations that result in the loss of a relationship (e.g., separation, abandonment by a parent) or personal choice (adoption, use of reproductive technology, or becoming or staying pregnant without a significant other) [4]. Adoption rates by single-parents also have demonstrated trend increases. For example, while only 0.5–4% of adoptive parents were single in 1970, the rate jumped to between 8 and 34% in the 1980s. This rate is likely impacted by a segment of women, often with established careers, who are choosing to have or adopt children as single mothers [12].

In the United States, there is a clear discrepancy among the percentage of single parent families within various racial/ethnic groups. For example, the proportion of single parent families by race/ethnicity is as follows: White, 22%; Black; 57%; and Hispanic, 33%.

One of the biggest problems faced by single parent families is economic hardship. Since most single parent families are headed by a female, women are disproportionately represented among the poor. Two thirds of the poor population in the United States consists of families of single mothers and their children. Reports from 1999 show that close to half (42%) of youth living in single mother families were poor compared to 18% of children in single father families and 8% of children in two-parent families [13]. The economic impact also disproportionately affects families from different racial/ethnic backgrounds. The largest group of single mother families living below the poverty line in the United States is Hispanic (51%) followed by African–American single mother families (43%) and White single mother families (31%) [13].

Impact/Stressors on Parents

Due to the fact that a single parent is responsible for all aspects of family functioning without the support of a spouse, he or she can feel overwhelmed and face a multitude of stressors [15]. In addition to being low-income, survey data suggest that many single parent families have lower parental education, a higher degree of financial difficulty, lower participation in volunteer and religious activities, and more frequent arguments between parent and child [17].

Single parent families are considered at-risk for having poorer caregiving practices compared to mother–father families. This may partly be due to the lack of resources to adequately care for their children or the stress associated with being a single parent [3]. As children get older, mothers from single parent families appear to have greater difficulty coping with behavioral issues. For example, as children develop from childhood to young adulthood, mothers in general report fewer complaints about their children's oppositional behavior. However, the decrease in these complaints happens more slowly in low socioeconomic and single parent mothers [7]. Finally, non-mother/father families also may experience higher levels of social stress and less supportive relationships with family members [1].

Impact on Youth

The experience of living in a single parent family has been linked to a number of potential youth outcomes. For example, it has been suggested that family structure is associated with children's mental health which is impacted by factors including socioeconomic status, family processes, and social stress. Research findings also reveal that young adults who grew up in single parent and step-families reported more symptoms of depression than young adults in mother–father families [1].

Children's physical health also has been demonstrated to be compromised in single parent families as compared to step-families and two-parent families. In one sample, 15.2% of children in single parent families had limiting health conditions compared to 13.6% in step-families and 8.9% in two-parent families. The same pattern also is found for behavioral well-being [17].

It has been suggested that children in various family structures receive differing amounts of time with their mothers. For example, results from a study of single

mothers revealed that these mothers only spend approximately 83–90% of the time that married mothers spend with their children. This disparity is most likely due to the fact that single mothers have less time to spend with their children given that they bear all of the parenting responsibilities in the family. However, when employment, level of education, maternal age, and age of children are held constant, single mothers spend at least as much time with their children as their married mother counterparts [14].

The research investigating potential youth outcomes within single parent families related to the parent often having to work during "nonstandard" work hours is decidedly mixed. For example, it has been suggested that nonstandard working schedules may negatively impact parents' ability to monitor their children and the closeness of the parent–child relationship. In contrast, findings from another study indicated that among single parents working nontraditional hours, the probability of parental monitoring after school is higher. On the other hand, the possibility of the parent being absent from important activities is higher as is the likelihood of the child feeling less close to his/her mother. Furthermore, in families where the single mothers are working a rotating shift there is a higher chance of adolescents participating in multiple forms of delinquent activities [11].

Due to the lack of a second parental figure, children in single parent families may have greater responsibilities in their families that include helping with the day-to-day functioning of the family. For instance, it has been suggested that children in single parent families are given the responsibility to be more involved in the decision-making processes of the family. This increased responsibility may take the form of having greater involvement in determining what purchases are made for themselves and for the family as a whole [8].

Much of the negative effects on children in single parent families are related to financial hardship. As a result, many families rely on child support payments as a supplemental form of income to help support the family. Unfortunately, many single parent families do not consistently receive child support payments in full. The discrepancy between expected and actual child support payments has been reported to predict child health outcomes, including school functioning, conduct issues, mental health problems, and participation in activities [5].

Coping and Strengths of Single Parent Families

Low-income, single parent families have reported that support from immediate family members is the most important resiliency factor in helping them to face life challenges [10]. Support from extended, "multigenerational" family members also has been reported as becoming more important with the rise in the number of single parent families [2]. Other important sources of support include friends, a style of positively approaching problems, and religious/spiritual support [10].

Despite the multitude of challenges faced by single parent families, it is important to recognize the strengths that help them to cope with stressors. For example, it has been reported that the number one strength of single parent families is having a sense of "cohesion or emotional closeness" that developed as a result of enduring family stressors. Other strengths reported include "pride/optimism," "togetherness," "open communication," and "teamwork" [15]. Furthermore, these strengths are more similar than different from those reported by two-parent families. Single parent families also have reported engaging in a number of on-going family rituals (connection, spiritual, love, recreational, celebration, and evolving) to help maintain family closeness and emphasize the family's values [15]. These research findings challenge the negative perspective that is often directed towards these families [9].

Single Subject Research Design

Gina Coffee
Loyola University Chicago, Chicago, IL, USA

Synonyms

Single-case research design; Single-participant experimental design; Time-series design

Definition

Single subject research design refers to a unique type of research methodology that facilitates intervention evaluation through an individual case.

Description

Single subject research design is a type of research methodology characterized by repeated assessment of a particular phenomenon (often a behavior) over time and is generally used to evaluate interventions [2]. Repeated measurement across time differentiates single subject research design from case studies and group designs, as it facilitates the examination of client change in response to an intervention. Although the use of single subject research design has generally been limited to research, it is also appropriate and useful in applied practice.

Single subject research designs differ in structure and purpose and typically fall into one of three categories: within-series designs, between-series designs and combined-series designs [1-6]. Within-series designs are characterized by the evaluation of data points across time and within phases/conditions (e.g., treatment vs. no-treatment conditions) [2]. Specific types of within-series designs include the simple phase-change design, the changing criterion design, parametric, and periodic interventions design. The simple phase-change design and the changing criterion design are the most common within-series designs. Parametric and periodic interventions designs are used less frequently. Between-series designs allow for the comparison of two or more conditions (i.e., baseline compared to intervention or two or more interventions) [2]. The alternating-interventions design and simultaneous-interventions design are between-series designs. As the name suggests, combined-series designs facilitate evaluation both within and between series and include the multiple baseline design, the crossover design, and the constant-series control design. Although certain studies are amenable to the crossover and constant-series control designs, they are used less frequently that the multiple baseline design – the most common type of combined-series design. The multiple baseline design's structure is a simple phase-change design in which the intervention phase is repeated across participants, settings, or behaviors. Ideally, the intervention phase is replicated across three or more different participants, settings, or behaviors, and interventions are implemented sequentially after changes are noted in the first implementation. For example, if disruptive behavior during unstructured periods of time at school is the behavior of concern, and the intervention is a positive behavior support plan individualized to the student's particular needs, the plan could be implemented first during hallway transitions, and once improvements are observed, the plan could then be implemented during lunch, and so on.

Data from single subject research designs have traditionally been analyzed through visual inspection, including the assessment of level, trend, and variability

[1-6]. However, certain nonparametric statistical tests may also be appropriate for the analysis of data collected in single subject research designs. Across all types of single subject research designs, internal validity is established by replication, and threats to internal validity can be reduced by repeated assessment, continued assessment of client variability, design flexibility, and randomization.

Single Transverse Palmer Crease

Synonyms

Simian crease; Simian line; Single palmer crease

Definition

A single crease that extends across the palm of a human hand caused by a fusion of two palmer creases (flexion creases)

Description

Palmer creases develop by the 12th week of gestation. A single transverse palmer crease appears in 1 out of 30 normal people. It is more commonly found in males, and can sometimes indicate a developmental problem, such as Down syndrome, Aarskog syndrome, fetal alcohol syndrome, Klinefelter syndrome, gonadal dysgenesis, cri du chat syndrome, pseudohypoparathyroidism, Turner syndrome, Rubella syndrome, Cohen syndrome, and trisomy 13.

Skinner, Burrhus Frederick

Steuart T. Watson, Tonya S. Watson
Miami University (OH), Oxford, OH, USA

Life Dates

1904–1990

Introduction

Skinner is considered to be the most influential psychologist of the twentieth century. His work has had dramatic impact on the fields of applied behavior analysis, the experimental analysis of behavior, education, and the analysis of verbal behavior.

Educational Information

Skinner graduated from Hamilton College with a B.A. degree in literature in 1926 with the intention of becoming a writer. After abandoning this career path, he enrolled in Harvard and earned a Ph.D. in psychology in 1931. He remained at Harvard until 1936 when he moved to the University of Minnesota. His next stop was at Indiana University where he served as department chair from 1945–1948. He then returned to Harvard in 1948 where he remained until his retirement.

Accomplishments

Quite simply, Skinner's accomplishments are far too numerous to mention within the confines of a short biography. Some of his more noted accomplishments, however, will be considered. First and foremost, Skinner is known as the father of radical behaviorism, which is the theory that behavior is determined by its consequences. He began describing his work in a 1938 book titled *The Behavior of Organisms*. His philosophy of behaviorism was more clearly explained in his 1953 book, *Science and Human Behavior*. A number of books, approximately 18, followed his treatise on the behavioral philosophy of human behavior. One of his books, *Walden II*, published in 1945, described his ideal utopian society that was built on the basic principles of behaviorism. *Beyond Freedom and Dignity*, published in 1971, described how understanding the scientific principles that guide human behavior could lead to an improved society; one without punishment and coercion. Many of Skinner's political and social views were expressed in these two novels which earned him a great deal of criticism and cynicism from his detractors. Skinner also published approximately 180 articles on topics ranging from the experimental analysis of behavior to the role of behavioral psychology in education [1].

Although a prolific author, Skinner invented a number of devices that helped to test his theories and that engendered both praise and criticism. Some of these devices included the cumulative recorder (for studying the effects of different schedules of reinforcement), the air crib (also called the "baby tender"), the operant conditioning chamber, the teaching machine, the pigeon guided missile system, and a thinking aid to help with writing [2].

He received a number of awards throughout this career, with some of the most notable being the Distinguished Scientific Contribution Award from the American Psychological Association in 1958, National Medal of Science in 1968, the Gold Medal Award from the American Psychological Association in 1971, the International Award from the Joseph P. Kennedy Foundation for Mental Retardation in 1971, the Humanist of the Year Award in 1972 from the American Humanist Society, the Award for Distinguished Contributions to Educational Research and Development from the American Educational Research Association in 1978, and the Citation for Outstanding Lifetime Contribution to Psychology from the American Psychological Association in 1990 [3].

One of Skinner's "accomplishments" was that he was roundly criticized by many who either did not understand his theories or who disagreed with him on philosophical grounds. Noam Chomsky, for instance, is a noted cognitivist who thought that Skinner's description of verbal behavior was incomplete, unscientific, and had little merit for the world beyond Skinner's laboratory. The ensuing debates between his detractors and supporters added much to the growth of behavioral psychology, and psychology in general, and still continue today [4].

Contributions

Skinner's contributions were profound in both psychology and education. His work gave rise to both the experimental and applied analysis of behavior as well as to the growth of psychology as a legitimate science. His behavioral principles influenced the treatment and care given to individuals with mental retardation and other developmental disabilities. Skinner's work directly influenced other psychologists who worked to improve education, most notably Fred S. Keller and Ogden Lindsley. Keller, along with Skinner, pioneered the Programmed System of Instruction which is used in various forms today. Lindsley based his Precision Teaching on Skinner's behavioral principles. Today, some of the major journals in psychology owe their existence to Skinner (e.g., *Journal of Applied Behavior Analysis*, *Journal of Experimental Analysis of Behavior*, *Analysis of Verbal Behavior*, *The Behavior Analyst*, to name a few). In numerous surveys, the most eminent psychologists cited Skinner and his work as their most dominant influence. Skinner is one of few psychologists whose work and influence endure far past his death.

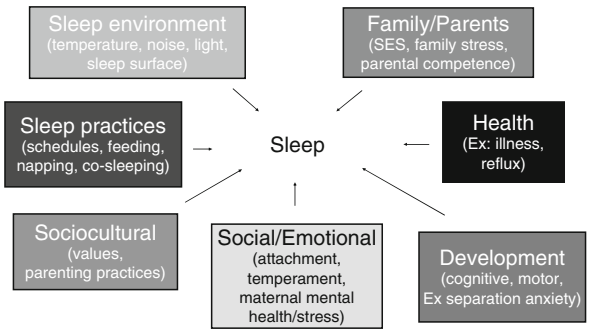
Normal sleep; Sleep architecture; Sleep stages; Sleep structure

Definition

Sleep is one of a child's primary activities from infancy to adolescence. Sleep in infancy and childhood is often thought of as a passive, inert, or isolated state, but it is actually a very active, physiological state that is influenced by a multitude of factors.

Description

Sleep is significantly influenced by a wide array of behavioral, developmental, health, environmental, social and emotional factors, and characteristics of and sleep practices of both the caregiver and child (see Fig. 1). Sleep is necessary for children to function at their optimal level, and lack of sleep can affect numerous aspects of their growth, health, behavior, and development, as well as overall quality of life.



Sleep. Fig. 1 (Adapted with permission from Jodi Mindell.)

Remarkable changes occur in sleep patterns from infancy to adolescence. In early infancy (0–2 months), the typical sleep requirement is 16–20 h per 24 h period, typically separated a period of wakefulness that ranges from 1–3 h. Sleep periods are evenly distributed between day and night. From 2–12 months of age, the typical sleep requirement is 9–12 h at night, while napping 2–4 hours per day. During this time, as nighttime sleep begins to consolidate, the frequency of daytime naps decreases from four naps to as few as one as the child gets older, each lasting 30 min to 2 h. Night feedings also decrease during this time period, and by the age of 6 months, should no longer be necessary. Between ages 1 and 3 years, the typical sleep requirement is 12–13 h per 24 h period. By age 18 months, most children have progressed from two naps to one. Typically, the morning nap becomes shorter, while the afternoon nap extends in length, until the morning nap is no longer needed. Between ages 3 and 5 years, the typical sleep requirement is 11–12 h per 24 h period. Naps decrease from one to no nap. At age 3, 92% of children still nap. At age 4, 57% of children still nap. By age 5, 27% of children still nap. For school age children between ages 6 and 12, the typical sleep requirement is 10–11 h per 24 h period. Well-rested children should no longer be sleepy during the day. For adolescents between ages 12 and 18, the typical sleep requirement is 9 to 9½ h each night. Alarmingly, most teens report obtaining 7 to 7½ h per night.

Relevance to Childhood Development

Sleep is necessary for children to function optimally. Multiple studies have shown that when children and adolescents do not obtain adequate sleep, whether from sleep restriction or due to presence of a sleep disorder, their physical, emotional, cognitive and social development are affected. Sleep is necessary for adequate cardiovascular, immune, and metabolic functioning and growth hormone production. Children who do not obtain adequate sleep are more likely to be emotionally dysregulated, impulsive, and inattentive, affecting their academic performance and social relationships.

Sleep Apnea

David J. Lozano
Children's Hospital of Alabama, Birmingham, AL, USA

Synonyms

Obstructive sleep apnea syndrome; Pediatric obstructive sleep apnea; Sleep disordered breathing

Definition

Childhood obstructive sleep apnea is characterized by repeated episodes of partial or complete upper airway obstruction that occur during sleep that are usually associated with disruption in gas exchange and/or sleep fragmentation.

Description

Introduction

Sleep disordered breathing (SDB) is a spectrum that encompasses primary snoring at the mild end of severity to classic obstructive sleep apnea syndrome (OSAS) at the more severe end. Upper airway resistance and obstructive sleep hypoventilation are part of this spectrum and are felt to be less severe than outright obstructive sleep apnea syndrome. OSAS is characterized by repeated episodes of upper airway resistance along with partial or complete airway obstruction during sleep. These episodes can be associated with ventilation and/or oxygenation disturbances. A degree of sleep fragmentation can be seen with these patients as well.

Sleep disordered breathing can occur in a child of any age ranging from neonates to adolescents. OSAS occurs in approximately 1–3% of the pediatric population. More specifically, OSAS affects up to 3% of children between the ages of 2 and 8 years old.

Pathophysiology

Obstructive sleep apnea syndrome occurs when the upper airway collapses or when the luminal cross section is reduced during inspiration. Collapsibility of the upper airway is a dynamic process that involves multiple factors such as sleep state, anatomy, respiratory drive, and neuromotor tone. The airway of the child is inherently smaller than that of an adult. As a result, size of the pharynx which includes the size of the adenoids and tonsils has long been implicated in pediatric obstructive sleep apnea. It has been shown that the site of upper airway obstruction in children with obstructive sleep apnea is at the level of the tonsils and adenoids. In normal children, it occurs at the level of the soft palate. Tonsils and adenoids increase in size from birth to 12 years of age with maximal growth appearing between the 2 and 7 years of age. However, multiple studies have not shown a strong correlation between increased adenotonsillar size and obstructive sleep apnea. Thus, pediatric obstructive sleep apnea may not be caused by adenotonsillar hypertrophy alone. Obesity can be a contributing factor in OSAS. Adipose tissue within the muscles and soft tissue surrounding the airway can narrow the pharynx. Thus, the likelihood of airway collapse is increased. Children with craniofacial abnormalities are at high risk for OSAS. Examples of conditions associated with craniofacial abnormalities include Down syndrome, achondroplasia, Pierre Robin syndrome, and Aperts' syndrome.

History and Physical Examination

Nightly loud snoring is almost universal with pediatric OSAS. In many patients, the snoring is accompanied by pauses in breathing, choking/gasping for breath, and neck hyperextension. Other associated symptoms can include sweating, restless sleep, and dry mouth. It should be noted that snoring itself is not always an accurate predictor of polysomnographic OSAS. Daytime sleepiness can be a manifestation of pediatric OSAS. However, daytime sleepiness is much more prominent with adult OSA as compared to pediatric OSAS. Physical examination of a child with OSAS is usually normal. However, children may present with adenotonsillar hypertrophy and craniofacial abnormalities which should alert a clinician to the possibility of OSAS. Obesity and failure to thrive can be seen as well. In rare instances, cardiovascular consequences of cor pulmonale and congestive heart failure can be seen in children with OSAS.

Diagnosis

Nocturnal polysomnography (sleep study) is felt to be the gold standard for diagnosis of OSAS. It is the diagnostic test that should be ordered in any child with suspected SDB. The nocturnal polysomnogram should be performed in a pediatric sleep laboratory. Adult oriented laboratories attempt to perform sleep studies in children with limited success. Other diagnostic studies have been looked at to evaluate OSAS which include symptom questionnaires and video/audio recordings. These individual studies have not shown adequate sensitivity or specificity in diagnosing pediatric OSAS.

Treatment

Tonsillectomy and adenoidectomy is first line treatment for pediatric OSAS. It is felt to be curative in approximately 80–85% of children with this diagnosis. However, a percentage of children have symptoms that persist despite adenotonsillectomy especially in children with obesity, craniofacial abnormalities, and cerebral palsy. Continuous positive airway pressure (CPAP) has been shown to be an effective therapy for OSAS in children who have either failed surgical intervention or are not good surgical candidates. Other treatment modalities include weight loss, oral appliances, supplemental oxygen, and tracheostomy.

Sleep Architecture

Kim Guion[1], Kristin T. Avis[2]
[1]Sleep Disorders Clinic, Children's Hospital, Birmingham, AL, USA
[2]University of Alabama at Birmingham, Birmingham, AL, USA

Synonyms

Sleep; Sleep stages; Sleep structure

Definition

Sleep architecture refers to the structure of sleep cycles throughout the night and the five stages of sleep including four stages of non-rapid eye movement (NREM) sleep and the fifth stage, rapid eye movement (REM) sleep.

Description

Sleep architecture allows for the quantification of sleep characteristics in order to promote accurate diagnosis of sleep disturbance or related medical or psychological diagnoses. Some relevant measures of sleep architecture include the following:

Sleep onset latency – the time between initiating sleep behavior (lights out) to onset of first sleep stage
REM latency – the time between sleep onset and occurrence of first REM period
Total sleep time – total time (in minutes) sleeping from lights out to lights on
Sleep efficiency – ratio of time asleep compared to time recording (lights out to lights on)

Measurement of sleep architecture: Sleep architecture is mapped out by the cyclic series of stages achieved during sleep. Multiple sleep cycles are achieved during the night, each lasting approximately 1.5 h. The breakdown of stages within each sleep cycle varies from the initial sleep cycle to later cycles that occur in the early morning hours. Identification of sleep stages is made using nocturnal polysomnography (overnight sleep study), which utilizes EEG data and measurements of muscle tone, eye movements, leg movements, respiratory function and patterns, and heart rate. Sleep architecture is typically depicted in a visual chart called a hypnogram (Fig. 1).

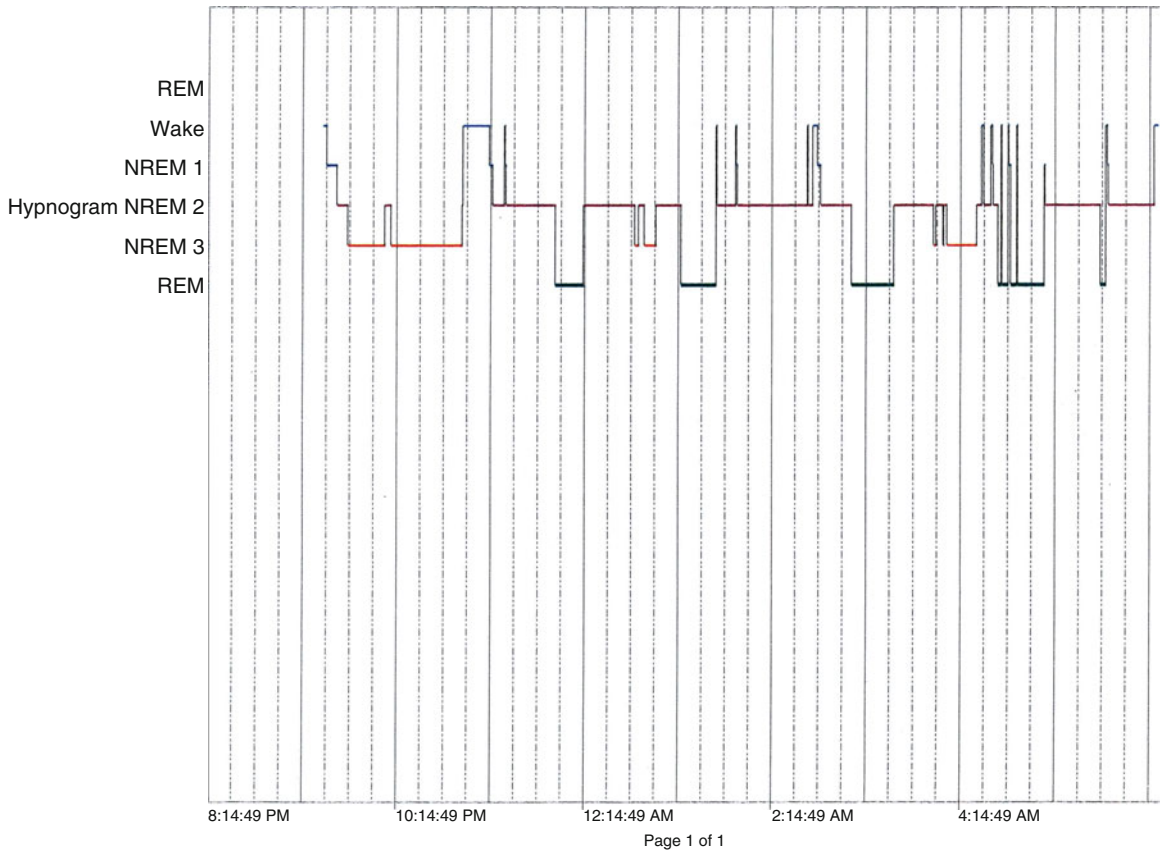
Non-REM sleep: Non-REM sleep is comprised of stages 1–4 of sleep and is characterized by relatively diminished brain activity and maintenance of voluntary motor movements [5, 8].

Stage 1: Stage 1 of sleep is considered "light sleep" and marks the transition from wakefulness to being asleep. Lasting a short period of 1–5 min, stage 1 sleep often involves muscle jerks or twitches and recall of visual images [5, 6, 8].

Stage 2: Stage 2 sleep is identified by the presence of high frequency, rapid bursts of EEG activity called sleep spindles and high amplitude low frequency waves called K-complexes. This stage is also considered initiation of "true" sleep and the initial occurrence of stage 2 lasts 5–25 min [5, 6, 8].

Stage 3/4: Stages 3 and 4 are often considered together and reflect deep sleep. They are identified as containing delta wave, or slow wave EEG activity. It is most difficult to wake people when they are in these stages of sleep. Initial occurrence period of stage 3/4 sleep is approximately 30–45 min and is typically followed by a brief arousal. Length of delta wave sleep decreases as the night progresses in healthy individuals [5, 6, 8].

REM sleep: REM is characterized by dipolar ▶saccadic eye movements, increased central nervous system activity, muscle paralysis (except for breathing and erectile function), and coincides with dreaming. REM typically occurs 70–90 min after sleep onset [6]. Length of REM sleep



Sleep Architecture. Fig. 1 Example of a normal hypnogram from a healthy child.

during each sleep cycle increases as the night progresses [6]. Initial REM periods average approximately 10 min, while REM sleep in the early morning hours may last up to 60 min [5, 6].

Disruptions in sleep architecture: Sleep architecture may be altered by a number of factors, resulting in diminished sleep quality or sleep efficiency and subsequent daytime sleepiness and problems with daytime functioning. Factors that result in disrupted or altered sleep architecture include medical health issues (e.g., seizure disorders, developmental disabilities, pulmonary disorders) [4], substance use (e.g., alcohol, cigarettes, illicit drug use), psychotropic medications, psychopathology (e.g., mood or anxiety disorders, schizophrenia, post-traumatic stress disorders), specific sleep disorders [4, 5], ▶jet-lag [4], temperature [4], or other environmental factors (e.g., household/neighborhood activity, bed-sharing) [1, 4, 5].

Periods of arousal are common throughout the night, and they are typically brief and do not disrupt overall sleep architecture. However, prolonged periods of arousal, or arousal that results in conscious wakefulness, interrupts the sleep cycle and may decrease the total amount of REM or delta wave sleep achieved, which is critical for sleep quality [4, 5, 7].

Health and sleep architecture: Increasingly, evidence for the importance of sleep (length and quality) on our health is being found. Sleep appears to impact various facets of physical health beyond daytime sleepiness and cognitive impairment. Specifically, insufficient sleep may result in dysregulation of immune function, cardiovascular disease, and endocrine functioning [3]. For example, shortened sleep time and fragmented sleep are associated with obesity, weight gain, and difficulties with weight loss. In turn, health problems may alter sleep architecture. Evidence for this with regard to respiratory disorders is widely known [4, 5, 7].

Relevance to Childhood Development

Developmental changes: Neonates and infants do not demonstrate the five stages of matured sleep structure. Instead, they demonstrate two clear sleep states referred to as "quiet" and "active" sleep, the latter reflecting cortical

activity similar to REM. Active sleep in infants comprises approximately 50% of sleep time, and this ratio decreases over the course of childhood such that by adolescence it comprises approximately 25% of sleep time. Slow wave, or delta wave sleep, predominates infancy, peaks in early childhood then declines over the course of development. In fact, minimal stage 3/4 sleep is observed in the geriatric population, which contributes to their complaints of "light" or disrupted sleep. The initial occurrence of delta waves and sleep spindles, marking different nonREM sleep stages, appear in the first year of life, and complete sleep staging is usually present by age 5 [5].

Sleep Disordered Breathing

►Sleep Apnea

Sleep Disorders

Kristin T. Avis, Aaron Davis
University of Alabama at Birmingham, Birmingham, AL, USA

Synonyms

Nocturnal disorders; Sleep disturbances; Sleep problems

Definition

Sleep disorders are common and result in insufficient amount of sleep and/or sleep of poor quality, which significantly affects daytime functioning and quality of life in children.

Description

The most commonly reported sleep disorders in children are described in detail in the following sections. Obtaining a detailed and accurate history followed by a comprehensive physical exam, including screening for developmental delays and cognitive dysfunction, appears to be a cornerstone for diagnosing pediatric sleep complaints. It is important to involve family members in the clinical interview to understand the potential etiology of sleep disturbances because children and adolescents often do not recognize nocturnal events that can disturb sleep. Developmental history with focus on sleep and wake patterns as well as potential medical illnesses that affect sleep during infancy and childhood can provide clues to the duration and degree of sleep disturbances in the child. Obtaining pertinent family history of sleep disorders is equally important given that certain conditions such as narcolepsy with cataplexy, chronic primary insomnia, restless legs syndrome, obstructive sleep apnea syndrome and advanced-sleep phase syndrome have been shown to be influenced by genetic factors [11].

Insomnia

Insomnia in children is defined as repeated difficulty with sleep initiation, duration, consolidation, or quality that occurs despite age-appropriate time and opportunity for sleep resulting in daytime functional impairment for the child and/or family. Behavioral insomnia of childhood (BIC) typically presents as bedtime refusal or resistance, delayed sleep onset, and/or prolonged night time waking that require parental intervention. BIC is classified into three categories: sleep-onset association type, limit setting type, and combined type. In the sleep-onset association type, children have difficulty initiating sleep independently and associate falling asleep with certain circumstances, such as place (couch or parent's bed), a person's presence (parent), or an activity (feeding from a bottle, being rocked, watching television). These circumstances are required for the child to re-initiate sleep in the middle of the night. In limit-setting type, the child delays bedtime with multiple requests or refusal, while the parent has difficulty setting limits, allowing bedtime to delay. If a child requires certain circumstances to initiate sleep and there are difficulties with parental limit-setting, the diagnosis is combined type.

Etiology of pediatric insomnia is usually multifactorial. Assessment should include screening for presence of concurrent medical, psychiatric and developmental disorders and associated impairments in home and school settings. It is also vital to assess for presence of underlying primary sleep disorders like obstructive sleep apnea and restless legs syndrome as possible etiologies behind a presenting symptom such as insomnia. It is also important to determine whether the difficulties with sleep onset and/or maintenance are due to inappropriate/inconsistent sleep schedules or napping schedules. For example, parents may have expectations of napping that may be outside of a child's developmental need or implement inconsistent or inappropriate naps (e.g., naps closer to bedtime), which lead to difficulty regulating the child's sleep-wake schedule. Eliminating the nap at an inappropriate age can also result in an increase in the child's behavioral difficulties at bedtime rather than helping with earlier sleep onset and/or sleep maintenance. The same issues relate to teenagers, who often have variable sleep schedules, inappropriate napping, later bedtimes, and early school start times. Subjective sleep complaints are common in children with ADHD, major depressive disorder, and anxiety disorders. This is proposed as a bidirectional relationship as unstable emotional states can lead to persistent sleep problems and chronic sleep deprivation can result in disrupted behaviors and mood.

Behavioral interventions are the mainstay of treatment of pediatric insomnia. Behavioral interventions that aim to help children initiate and maintain sleep independently, resulting in increased total sleep time and improved sleep quality, produce both reliable and lasting improvements in bedtime problems and night wakings in infants and young children. Extinction and parent education/prevention have received strongest support after empirical review. Gradual extinction, bedtime fading, positive routines, and scheduled awakenings are also strongly supported as efficacious treatments for young children. For older children and adolescents, behavioral strategies that aim to reduce arousal at bedtime are often recommended. Sleep hygiene education is particularly important. In addition, progressive muscle relaxation, stimulus control and cognitive behavioral therapy techniques such as thought stopping, increasing positive thinking, and journaling "worries" at bedtime are often recommended.

Parasomnias

Parasomnias include dysfunctions related to sleep, sleep stages, and partial arousals from sleep. The most common parasomnias include night terrors, confusional arousals, and sleepwalking and talking. There is no known etiology for parasomnias, but it is believed that they are related to maturation. Evaluation for parasomnias includes the usual time when the episode occurs, description of the behaviors and movements, the ability of the child to remember the episode, the presence of symptoms during wakefulness, and the presence of stereotypical movements during the episode. Parasomnias typically occur in the first third of the night, during which the child is inconsolable or nonresponsive for a short duration of 5–15 min with amnesia for the event the following morning. Parasomnias often increase during periods of sleep deprivation, thus it is also important to evaluate adequate sleep hygiene. The parents should avoid awakening the child since this may increase agitation and prolong the episode. Typical treatment includes reassuring and educating the child and family of the parasomnias, implementation of sleep hygiene measures, extending the sleep time, and implementation of safety measures. Depending on the frequency and severity of the episodes, medication may be given in order to prevent high risk of injury, violent behavior, or significant disruption to the family. Short-acting benzodiazepines such as Klonopin or Serax are the most common medications prescribed. They are used for 3–6 months until the episodes have disappeared. Scheduled awakenings have also been used in order to avoid prescribing medication to the child. This is a behavior modification that involves interrupting the sleep staging by waking the child about a half hour before they are most likely to experience a primary partial arousal parasomnia. This has been shown to be effective in eliminating night terrors, but may be difficult to encourage the parents to implement on a regular basis.

Night terrors are partial arousal parasomnias which are characterized by sudden arousal from slow-wave sleep accompanied by intense fear. These are usually disturbing to parents or other family members, but the child is completely unaware of his or her behavior. Around 3% of children experience night terrors, and the typical age of onset is usually between 4 and 12 years. There is a strong genetic component present in night terrors, and 80–90% of children who experience them have a first-degree relative with the same symptoms. Sleep terrors are usually characterized by a sudden onset. The child looks extremely agitated, frightened, and confused during the episode. Crying, screaming, and extreme physiological arousal are also common. The child is also usually clumsy or flailing, often pushing the parents away or behaving strangely. Diagnostic criteria include complaints of a sudden episode of intense terror during sleep occurring within the first third of the night, partial or total amnesia, onset during stage 3 or 4 of sleep, and the absence of other medical or

sleep disorders that could explain the episode. Confusional arousals are much less extreme, with the child typically sitting up in bed appearing confused or agitated, but not typically leaving the bed.

Sleepwalking is a common partial arousal parasomnia which occurs as a result of becoming caught between sleeping and wakefulness in a partial arousal state. The child's eyes may be open, and he or she may appear confused, dazed, or agitated. The child may also mumble incoherently. Sleepwalkers are also clumsy and often perform strange actions such as urinating in a closet. Occurrence can be either rare or nightly.

Between 15% and 40% of children occasionally sleepwalk while 3–4% experience weekly or nightly episodes. Average age of onset is between 4 and 6 years. Diagnostic criteria include exhibition of ambulation occurring in sleep, onset typically in prepubertal children, difficulty in arousal during the episode and amnesia following the episode, occurrence in the first third of the sleep episode, onset during stage 3 or 4 sleep, and the absence of any medical or other sleep disorders that could account for the symptom.

Safety measures may include using gates, locks on doors or windows, and alarm systems or bells to alert parents. The parents should not try to wake the child, but instead the child should be guided back to his or her bed. Benzodiazepines are also prescribed in severe cases. Scheduled awakenings have also been found to be effective in eliminating sleepwalking behavior and maintaining treatment gains.

Sleep talking, also known as "somniloquy" is a common occurrence during childhood. It includes coherent speech, incoherent mumbling, and utterances during the sleep period. Typically the child does not remember talking during his or her sleep. It usually is of no concern to parents, but occasionally significant outbursts and loud talking can disrupt parents' sleep. Sleep talking may be related to other parasomnias but alone is not associated with pathological states.

Circadian Rhythm Disorders

Circadian rhythm disorders are characterized by normal sleep quantity and quality but at the wrong time of day. The circadian rhythm is the body's "timekeeper," and it greatly affects the time of sleep onset and awakening. During adolescence, the circadian rhythm may be delayed or advanced from the desired hour of sleep or it may be out of phase with normal clock time. This occurs as a result of a combination of genetics and social norms associated with adolescence. Parents of children with circadian rhythm disorders often have the same symptoms or propensity as their child. Also, adolescents begin staying up later in order to chat online, surf the internet, talk on the phone, or hang out with friends. This causes the child to be exposed to light during the wrong time of day, which is right before or during the desired time of sleep. The light from televisions or computer screens is a common way adolescents are exposed to light.

Daytime sleepiness is a frequent result of circadian rhythm disorders. Children commonly suffer from symptoms similar to those of attention deficit hyperactivity disorder (ADHD), depression or behavioral dysregulation, and often sleep during their classes. The distinguishing feature of circadian rhythm disorders is that sleep is normal and daytime sleepiness subsides when the child is able to sleep and wake at his or her own schedule. All people have a circadian rhythm of around 24 h. This is caused to be consistent with clock time by time cues called "zeitgebers." The main example of this is light, but activity schedules, exercise and other environmental factors are included. If an individual fails to follow certain environmental zeitgebers then they can develop either delayed sleep phase syndrome (DSPS) or advanced sleep phase syndrome (ASPS). Some people's sleep phase moves progressively earlier or later and causes them to go in and out of synchrony with the environmental time of sleep. This is called non-24-h sleep-wake disorder. Circadian rhythm disorders occur in at least 10% of children. DSPS is the most prevalent, with a prevalence of 5–10% in adolescents. ASPS and non-24-h circadian rhythm are seen less frequently and occur in adolescents.

Delayed Sleep Phase Syndrome

DSPS involves a significant, persistent, and intractable shift in the sleep-wake schedules which interferes with the environmental demands of the child. The child can present with both academic and behavioral problems. Both getting the child to go to bed and waking the child in the morning are often problems. Children are lest resilient of sleep deprivation, and the delay may cause pathologic symptoms. Children with DSPS may present with problems such as bedtime struggles or difficulty awakening at the desired time, complaints of insomnia at night or excessive sleepiness in the morning, inability to wake up at the desired time, falling asleep at school. The diagnostic criteria include delayed sleep pattern by at least 1 h, an inability to fall asleep at the desired clock time and an inability to awaken spontaneously at the desired time, a presence of 1 month, normal quality and quantity of sleep when allowed to follow own schedule, later sleep on weekends and holidays with less daytime sleepiness, with no other sleep or psychiatric disorder present to cause it.

People with DSPS are referred to as "night owls" and report functioning more efficiently in the evening and at night. This may become a lifestyle for children with DSPS if their identities are found in late night activities such as chat rooms or phone calls. Children with DSPS frequently take naps during class, complain about daytime sleepiness, have poorer academic achievement and a greater number of injuries, and are more emotionally upset than other children. They are also more likely to experience academic, emotional, and behavioral problems during the morning hours, and they typically do their best work at night. Thus, circadian rhythm disorders are frequently mistaken as other sleep disorders such as insomnia (due to the difficulty falling asleep) or excessive daytime sleepiness (due to the difficulty awakening in the morning and/or resulting insufficient sleep from the necessary early rise time for school).

Treatment options for DSPS include appropriate sleep hygiene, bright-light therapy, melatonin, advancing bedtime, and chronotherapy. The beginning treatment phase is usually the most difficult and requires strict adherence to the treatment protocol. The child should also have the same bedtime and wake-up time every day. Television and computers should be avoided for the last hour before bedtime, and the child's bed should only be used for sleeping. Caffeine, if consumed, should be limited to before or during lunch. Bright-light therapy includes controlling light and dark exposures throughout the day. With this treatment, the child uses bright-light exposure during the day and avoids light exposure after sunset. Exposure to the light of dawn is important to training the circadian rhythm, and controlling the time of light and dark exposure helps produce a phase advance. There is limited evidence found on light therapy, but it appears to be a rational and effective treatment for DSPS, but family compliance may be a problem. Melatonin has been shown to be effective in altering the sleep phase. It is taken 1 h before bedtime and helps advance the timing of sleep. 1 mg is the beginning dosage given and is slowly increased to 3 mg if found to be ineffective. Bedtime and melatonin administration is then advanced by 15 min each day until the desired time of sleep onset is achieved. Chronotherapy is also used as treatment for DSPS. With this therapy, the bedtime is systematically delayed by 3 h each night until the desired bedtime is reached.

Advanced Sleep Phase Syndrome

ASPS is a disorder where the major sleep episode is advanced beyond the desired clock time. Symptoms of this include evening sleepiness resulting in the inability to remain asleep until the desired time of sleep and early awakening lasting for at least 3 months. Sleep onset times are as early as 5:00 pm but no later than 8:00 pm, and wake-up times range from 1:00–5:00 am. ASPS is more likely to occur in children who have a family member with similar symptoms. Treatment for ASPS includes bright-light therapy and chronotherapy. Bright-light therapy would expose the child to light during the early evening hours producing a phase delay. Chronotherapy would systematically delay the bedtime each night until the desired bedtime is achieved.

Non-24-h Sleep-Wake Disorder

This disorder occurs when the circadian pacemaker changes with respect to the 24-h day. Prolonged exposure to light can cause the circadian pacemaker to maintain a schedule longer than a normal 24-h day. This causes the child's sleep schedule to have no pattern, but sleep logs usually reveal a successive delay in sleep onset and wake times. This may lead to insomnia and excessive daytime sleepiness when the endogenous rhythm is out of phase with normal clock time, but when they are in phase, the symptoms are not present. Melatonin is the major treatment for this disorder. It is also important that the child is active during the wake time and in dark and quiet conditions during time for sleep.

Sleep-Related Movement Disorders

The most common sleep-related movement disorders include rhythmic movement disorder (RMD), periodic limb movement disorder (PLMD), and restless legs syndrome (RLS). In RMD, the child exhibits repetitive movements at sleep onset and following a nocturnal arousal in order to initiate sleep. Most often, the child presents with repetitive head rolling, head banging, or body rocking. RMD is very common in young children and often resolves by age of 4–5 in typically developing children. RMD is generally benign, and treatment involves parental reassurance and safety (tightening bolts on bed or crib, padding headboard to avoid bruising). In rare cases that are either severe or persist into older childhood or adolescence, treatment with benzodiazepines for a brief term may be useful.

PLMD is a movement disorder characterized by periodic limb movements in sleep (PLMS) that result in fragmented sleep of poor quality and impairment in daytime functioning due to the sleep disturbance. PLMS are brief movements (jerks) that can last up to 5 s occurring at 20–40 s intervals, typically in the lower extremities. PLMD is diagnosed by overnight polysomnography documenting the presence of PLMS. The most common cause of PLMD

is low ferritin, for which supplemental iron may be helpful. Dopaminergic agonists may be helpful in some cases.

RLS is a clinical diagnosis made using adult criteria at this time. Adult criteria include an urge to move the legs, urge to move begins or worsens when sitting or lying down, urge to move is partially or totally relieved by movement, and urge to move is worse in the evening or night than during the day or only occurs in the evening or night. Clinically, children often describe RLS using age-appropriate symptoms such as "spiders crawling," "tickles in my legs," or "creepy crawly feeling." Prevalence of RLS in children is unknown, but there is felt to be a strong family history component. RLS and PLMD are often comorbid. RLS is a clinical diagnosis, but often is associated and comorbid with PLMD documented on an overnight sleep study. However, diagnosis of PLMD is not as highly correlated with comorbid RLS. As in PLMD, the most common cause of RLS is low ferritin, for which iron supplements can be helpful. Dopaminergic agonists may also be helpful in some cases. There is a proposed relationship between ADHD and RLS, implicating a possible dopamine pathway as the common pathophysiologic link. Symptoms of ADHD have been found to improve with treatment for RLS and/or PLMD with a dopaminergic agonist.

In summary, pediatric sleep disorders are a common occurrence resulting in insufficient and/or fragmented sleep of very poor quality. The presence of untreated sleep disorders is associated with significant daytime impairments in social, academic, emotional, and neurobehavioral functioning. Pediatric sleep problems can present as the primary sleep disorder, or as a secondary consequence of underlying medical or psychiatric disorder. Children should be routinely assessed for sleep disorders, as the presence of these disorders can significantly impair their quality of life.

Sleeper Effect of Divorce

Pamela A. Sarigiani, Tiffany Spierling
Central Michigan University, Mount Pleasant, MI, USA

Synonyms

Adult children of divorce; Intergenerational transmission of divorce; Long-term effects of divorce; Sleeper influence

Definition

The sleeper effect of divorce refers to the phenomenon whereby individuals who previously showed positive recovery following childhood parental divorce later exhibit adjustment difficulties in young adulthood stemming from the earlier experience of parental divorce [1, 2]. Studies show that some children and adolescents who appear to recover and cope well after parental divorce have long-term effects in young adulthood that were not expected based on previous adjustment. Longitudinal research suggests that as children of divorce enter adulthood, they may be more likely than the general population to experience concerns about not being loved, have difficulties in relationship formation and maintenance, and have fears regarding betrayal and abandonment in romantic relationships [2]. Furthermore, in comparison to their young adult counterparts from non-divorced families, adult children from divorced families have been found to be at risk for earlier sexual activity, low self-esteem, reduced life satisfaction, and poorer psychological well-being [2–6]. Additional long-term outcomes identified in adults from divorced families include lower educational attainment, less close ties to parents (especially fathers), more marital discord, and greater likelihood of experiencing their own divorce [7]. However, a great deal of controversy exists regarding the validity and the extent of the sleeper effect of divorce and its delayed manifestations [8].

Description

The existence of a sleeper effect of divorce was first identified by Judith Wallerstein in her longitudinal study of parental divorce [1, 9]. Wallerstein's study began in 1971, and followed 131 children from 60 divorced families over a span of 25 years [2]. At the 10-year follow-up, Wallerstein observed an unexpected finding which she termed the sleeper effect. Especially evident among the young women in her sample, this delayed effect of parental divorce at young adulthood was noteworthy, as it coincided with a time in life when important decisions are being made regarding love and commitment [9]. This sleeper effect pattern was evident in 66% of the young adult women in her study between the ages of 19–23. Presumably, these young women were overwhelmed with fears and anxieties about commitment and betrayal in their own relationships as they reflected upon the lack of success of their parents' marriages. Among the 19–23 year old young men in her sample, 40% were described as having limited educational attainment, a perception of having little control over their lives, and not having clearly identified goals.

Wallerstein's research on the long-term effects of divorce has received considerable attention over the years from scholars, the general public, and the media, and her work also has influenced clinical practice and social policy [8]. While Wallerstein's study is noteworthy for directing attention to adult outcomes of parental divorce, her research also has drawn criticism for its methodological limitations. Although her use of case-studies based on in-depth clinical interviews provides vivid and rich personal accounts of parental divorce, limitations of her research include its homogeneous sample (White, middle- to upper-middle class families from California), the absence of a comparison group from non-divorced families, and the non-random sampling procedure (e.g., divorce counseling was offered as a participation incentive [8, 10, 11]). Furthermore, a significant proportion of the parents in the sample were noted to have personal histories of psychopathology [12].

At the 25-year follow-up, Wallerstein added to the original sample a comparison group of peers from the same community who were from non-divorced families [2, 13]. The addition of the comparison group addressed one methodological flaw of Wallerstein's research. Nevertheless, criticism of the conclusions drawn from her research remained. It has been argued that Wallerstein's depiction of long-term outcomes of parental divorce provides an unduly gloomy, negative and pessimistic view of parental divorce that paints a portrait of pathology [11, 14].

Hetherington and Kelly [15] emphasized that the negative long-term outcomes of parental divorce are exaggerated. Their findings from the Virginia Longitudinal Study of Divorce and Remarriage revealed that 25% of adult children from divorced families had serious psychological, emotional, or social problems in comparison to 10% of adults with continuously married parents. In other words, 75% of those who experienced childhood divorce showed positive adaptation in adulthood. When children from divorced families do not endure additional adversity, the overwhelming majority are able to cope and emerge as competent, responsible, well-adjusted adults [16]. Lansford [17] similarly summarized in her review of the literature that most individuals who experience parental divorce in childhood do not exhibit long-term negative consequences. Amato asserted that while the body of research supports the conclusion that parental divorce elevates the risk for multiple adverse outcomes for children throughout the life course, the effects are not as dramatic or pervasive as Wallerstein suggested. Rather, he concluded that the research evidence supports a moderate version of Wallerstein's perspective [8].

In the decades that have followed the initial identification of the sleeper effect, the research literature on the long-term effects of parental divorce has expanded considerably. Furthermore, through the use of carefully crafted, sophisticated methodologies, this body of research has provided a much more complex and nuanced perspective on the impact of parental divorce across the life course [11, 17]. Examination of research on the long-term effects of parental divorce follows, with a focus on three outcomes frequently identified in the literature: intimate relationships, psychological well-being, and parent–child relationships.

Parental Divorce and Intimate Relationships

Research indicates that differences in adjustment between adults from divorced and non-divorced families are often found in the realm of intimate relationships [18]. Indeed, the domain of development most frequently identified as being influenced by the sleeper effect is that of intimate relationships in adulthood. As Wallerstein [19] described:

> The central finding of our study is that, at adulthood, the experience of having been through parental divorce as a child impacts detrimentally on the capacity to love and be loved within a lasting, committed relationship. At young adulthood, when love, sexual intimacy, commitment and marriage take center stage, children of divorce are haunted by the ghosts of their parents' divorce and terrified that the same fate awaits them. These fears, which crescendo at young adulthood, impede their developmental progress into full adulthood. Many eventually overcome their fears, but the struggle to do so is painful and can consume a decade or more of their lives. (p. 410)

Wallerstein [13] reported that at the 25-year follow-up, when participants were between the ages of 28–43, 60% of the women and 40% of the men had established enduring, gratifying, and sexually satisfying relationships. She noted that some of the men appeared to avoid intimate relationships, as 42% had never married or cohabited for more than six months, whereas this was true for only 6% of men in the comparison group. In contrast, all of the women from both the divorced and non-divorced groups had been involved in brief or enduring intimate relationships.

Research which has examined intimate relationship attitudes and behaviors has provided further insight into the romantic relationship adjustment of individuals from divorced families. Adult children of divorce have been shown to display more anxious and avoidant attachments in their intimate relationships when compared to adults from intact families [20, 21]. Furthermore, adult children from divorced families report more insecurity within intimate relationships and a substantially higher incidence of trust related issues [21]. A qualitative investigation of young adults from divorced families revealed that many participants were cautious about marriage, feared they would make the same relationship mistakes as their parents, and worried about having feelings of rejection if they were to experience betrayal by their partners. These relationship fears were especially apparent among those who described distant and unsupportive parental relationships following divorce [22]. In contrast, paternal involvement has been found to ease some of these fears, as high paternal involvement predicted high levels of intimacy, commitment, and trust in intimate relationships for young adults from both divorced and non-divorced families [21].

Existing evidence indicates that individuals from divorced families are more likely to experience earlier transitions into intimate relationship behaviors and experiences. For example, individuals from divorced families initiate sexual activity at an earlier age than do those from non-divorced families [6], and they also are more likely to report having had more sexual partners [18]. A pattern of earlier intimate relationship involvement is also evident in the incidence of cohabitation. Utilizing data from the National Longitudinal Study of Adolescent Health, Ryan, Franzetta, Schelar, and Manlove [23] examined the impact of family structure history on the relationship formation behaviors of youth who were making the transition to adulthood in the late 1990s and early 2000s. They found that the more time youth spent living outside of a married, two biological-parent household, the greater the likelihood that they would form an early cohabiting union. Earlier age at marriage also is more likely among young adults from divorced families [24]. Interestingly, living in a stepfamily during childhood has been found to increase the likelihood of earlier marriage among young adults [23].

These earlier relationship transitions create risks for young adults from divorced families, as early age at marriage is one of the strongest predictors of divorce [25]. In regard to the intergenerational transmission of divorce, research reveals that adult children of divorce are twice as likely to divorce at some point during their marriage in comparison to those from intact homes [26]. In comparison to individuals from intact families, adult children of divorce are more likely to divorce when experiencing relationship problems than they are to work on issues within the relationship [26]. This may be due to the belief that commitments can be easily terminated when the relationship is no longer satisfying, which is evident

from the pro-divorce attitudes and high rates of cohabitation and divorce among adult children of divorce [3, 25]. In comparison to men, women who experience childhood divorce are more likely to have marriages that end in divorce [3].

Other research posits that later relationship difficulties for adults who experienced divorce during childhood may not be directly attributable to parental divorce per se, but to the amount of conflict within the home before, during, and after the divorce. As Amato [25] described, this may be due to a lack of positive relationship modeling by parents in unhealthy, affectionless, or high conflict marriages, which may contribute to maladaptive interpersonal communication issues for adult children from divorced families. Amato found that in comparison to adults whose parents had remained continuously married, adults whose parents had divorced were more likely to have interpersonal styles characterized by problematic communication, anger, and jealousy. These interpersonal difficulties, in turn, were found to elevate the risk for divorce.

Hetherington [18] used data from the long-term Virginia Longitudinal Study of Divorce and Remarriage to examine the impact of both parental divorce and marital conflict (without divorce) in the family of origin on marital instability in young adult offspring. She concluded that while both marital conflict and parental divorce contributed to offspring marital instability, the effects were greater for parental divorce. Furthermore, the greatest marital instability was observed among couples where both partners came from divorced families, and the difference in marital stability in that group as compared to couples where both partners came from low conflict non-divorced families was striking. However, it is essential to recognize that intimate relationship difficulties among adults from divorced families are not inevitable. In particular, Hetherington [18] found that having a supportive, well-adjusted partner was a protective factor, eliminating the difference in marital instability between participants from divorced and non-divorced families.

Parental Divorce and Psychological Well-Being

A range of adult psychological adjustment outcomes have been identified as being impacted by the earlier experience of parental divorce, with effects evident on measures of specific mental health indicators such as depression and anxiety, as well as for more global assessments of psychological well-being [3]. The focus of the review here will not be on articulating the effects of parental divorce on specific indicators of psychological adjustment. Rather, the emphasis will be on detailing the impact of divorce on psychological well-being more generally as evident in long-term longitudinal studies that have spanned decades. These longitudinal studies have helped to disentangle the complexity of effects of parental divorce on psychological well-being in adulthood.

Utilizing data from the Marital Instability Over the Life Course (MIOLC) study, Amato [8] was able to examine the psychological well-being of adults from divorced and non-divorced families, and to consider the impact of parent factors by drawing from data collected from the parents in an earlier wave of the study. Amato found that parental divorce lowered the psychological well-being of 10% of his sample [8]. In other words, 90% of adult children who experienced childhood divorce showed levels of well-being comparable to adult children from non-divorced families. Amato noted that his results suggested that divorce does not appear to reduce the percentage of children who reach adulthood with positive psychological well-being. Rather, parental divorce appears to shift some children from average psychological well-being to low psychological well-being.

Interestingly, a couple of different factors appeared to moderate the effects of parental divorce on psychological well-being in Amato's study. First, when parents reported low levels of marital discord, adult children of divorced parents had poorer psychological well-being than did their counterparts with continuously married parents. However, when parents reported high levels of marital discord, adult children of divorced parents had better psychological being than did those with continuously married parents [8]. These findings are consistent with the position that when children are exposed to chronic parental discord, they may be better off if their parents divorce. In contrast, when parents exhibit low levels of marital discord, the parental divorce may create more of a jolt for children, who may view it as an unexpected event. The second factor that moderated effects of divorce on psychological well-being was the number of family transitions that offspring experienced (i.e., parental divorces and remarriages), where more transitions were linked to lower psychological well-being. These results suggest that the accumulation of family transitions contributes to the negative effects of parental divorce.

Chase-Lansdale, Cherlin, and Kiernan [27] used longitudinal data gathered in Great Britain from the National Child Development Study to examine the long-term effects of parental divorce on the mental health of young adults (age 23). They found moderate, negative consequences of parental divorce for both men and women. Specifically, they found that the likelihood of scoring above the clinical

cutoff on the Malaise Inventory was 8% for young adults who had not experienced parental divorce and 11% for those who had experienced parental divorce. These authors concluded that while divorce raised the risk of serious emotional disorders, the large majority of individuals from divorced families did not exhibit these risks. Nevertheless, the effects on the subgroup seriously affected by divorce should not be discounted, as the proportional increase in those who may seek clinical intervention is noteworthy.

Again drawing from the National Child Development Study, Cherlin, Chase-Lansdale, and McRae [5] examined the effects of parental divorce on mental health at age 33. The authors noted that prior to parental divorce, more internalizing and externalizing symptoms were evident among individuals whose parents eventually divorced in comparison to those from non-divorced families. However, the results also indicated that parental divorce itself contributed to higher levels of internalizing and externalizing problems in adulthood. Furthermore, what is particularly noteworthy in these findings is that the gap in emotional problems between those from divorced and non-divorced families widened in adulthood. These results are consistent with the notion of a sleeper effect, whereby adjustment problems surface in adulthood. The authors suggested that parental divorce may set into motion a chain of events such as early childbearing or limited education that contribute to continued divergence in the life course for those from divorced and non-divorced families.

In summary, the results of the available body of research provide evidence for the potential for parental divorce to have long-term negative consequences on offspring psychological well-being. However, when combined with the findings of Hetherington and Kelly [15] described earlier (i.e., that 75% of adults from divorced families exhibit positive adjustment), the clear message from the research summarized here is that the majority of adult children from divorced families experience positive psychological well-being. Nevertheless, due to the small, but real elevated risk for psychological difficulties for adults from divorced families in comparison to those from non-divorced families, the impact of the divorce experience on lives of those experiencing adjustment difficulties should not be minimized.

Parental Divorce and Parent–Child Relations

As noted by Ahrons [10], parent–child relationships persist throughout the life course, and consequently, parental divorce can potentially alter parent–child relationships at any developmental transition. The available evidence indicates that parental divorce creates the greatest long-term risks for the father–child relationship. Relationships between adult children and their divorced mothers are closer than those between adult children and their divorced fathers. Furthermore, adult daughters are closer to their divorced mothers than are adult sons, and sons report somewhat more closeness to their divorced fathers than do daughters [16]. In his examination of multiple long-term outcomes of parental divorce, Amato [8] concluded that the strongest impact is on father–child relationships, where parental divorce results in poorer quality father–child relationships for approximately one-third of adult children.

Again using data from the MIOLC study, Amato [7] examined the effects of marital discord and divorce on adult children's parent–child relationships for individuals in both divorced and non-divorced families. Compared to children with continuously married low discord parents, children who experienced parental divorce reported less closeness to both their mothers and their fathers. It should be noted that children with continuously married, high discord parents also had weaker ties with fathers (but not with mothers). Additionally, the negative effects of parental divorce on father–child relationships were stronger for daughters than for sons. Children with divorced parents also had significantly poorer father–child relationships than did those children with continuously married high discord parents.

Scott, Booth, King, and Johnson [28] examined patterns of change in father–child closeness following divorce in the National Longitudinal Study of Adolescent Health, tracking youth from adolescence to young adulthood. They found that 57% of participants experienced a decline in father–child closeness over this time period. However, 25% of the participants maintained close father–child relationships, and 14% reported increased closeness with their fathers over this time period. Those participants who maintained a close father–child relationship had a stronger mother–child relationship and a greater sense of well-being prior to the divorce. Interestingly, those who experienced an increase in father closeness were less likely to have pursued education beyond high school, and were more likely to have experienced their own family transitions such as cohabitation and parenthood.

Drawing from data collected from the longitudinal Binuclear Family Study, Ahrons [10] examined family ties among adult children who were interviewed 20 years after their parents' divorce. The majority of these adult children reported that their parents currently got along with each other fairly well. Furthermore, when parents were more cooperative with each other, their adult

children reported better relationships with their parents, as well as with their grandparents, stepparents, and siblings. The desire for their parents to get along with each other was clearly evident among these adult children – they wanted parents to be cordial with each other in order that both parents could share in important events in the adult child's life, such as graduations, weddings, and the birthdays of grandchildren. Ahrons concluded that when parents are able to minimize their conflicts and co-parent effectively, their adult children are able to maintain their relationships with both parents.

The living arrangements that are established following parental divorce are important to take into consideration in efforts to understand the relationship dynamics between adult children and their fathers in divorced families. Although historically there has been an increase in shared custody arrangements in the United States, much of the available research conducted over the years has centered on families where mothers had custody and fathers were the non-residential parents [24]. Contact with non-residential fathers has been found to decrease over time [24], which can pose risks to the maintenance of strong father–child relationships.

Fabricius [29] considered the issue of living arrangements in his study of college students from divorced families. He found that these students endorsed living arrangements that would give them equal time with each parent, and the majority of the participants also believed that equal time with each parents was best for children. Furthermore, those individuals who reported having living arrangements that gave them equal time with both of their parents or a lot of time with their fathers had high quality relationships with both their mothers and fathers.

Additional findings point to the significance of both post-divorce living arrangements and parent–child conflict for father–child relationships. Specifically, the more time college students reported living with their fathers after divorce, the better their relationships were with their fathers, independent of parental conflict. In contrast, the more parental conflict they experienced, the worse their father–child relationships were, independent of time spent with father [30]. Hearing adult children's perspectives on living arrangements in these two studies sheds additional light on the importance of maintaining father–child relationships post-divorce, as revealed in the viewpoints of the children themselves.

In summary, the research reviewed here portrays a complex picture of the impact of parental divorce on parent–child relationships in adulthood. Clearly, the literature to date shows that the father–child relationship is most adversely affected by parental divorce. However, when parents are able to put aside their conflicts and co-parent effectively, positive benefits accrue for parent–child relationships. The significance of positive parent–child relationships is further underscored when the literature previously described on intimate relationships and psychological well-being is considered. It is apparent that these outcomes are all interrelated (e.g., high quality parent–child relationships are linked to positive intimate relationship adjustment).

These findings also highlight the life-long significance of the parent–child bond. Whereas most of the available literature has focused on the effects of parental divorce on parent–child relationships in young adulthood, recent research suggests that the consequences can extend later into the life course, when adult children from divorced families deal with issues such as caring for an aging parent. For example, Lin [31] found that although adult children with divorced parents were just as likely as adult children of widowed parents to provide care and financial assistance to mothers, those from divorced families were less likely to provide care for their fathers.

Conclusions

Examination of the available literature published during the last two decades on the long-term effects divorce provides some support for the existence of a sleeper effect of parental divorce, with consequences apparent for outcomes including intimate relationships, psychological well-being, and parent–child relationships. However, the strongest message that should be taken away from this analysis of the research is that the overwhelming majority of adults from divorced families show positive adaption in their adult years. Furthermore, it is important to note the limitations of this literature, as long-term longitudinal examination of outcomes of parental divorce requires decades of research. Consequently, it is important to be mindful of cohort effects, as the experience of parental divorce in the 1970s and 1980s is likely very different than today, due to changes in divorce laws and policies, the decreased stigma associated with parental divorce, and changes in family structure more generally [10]. Even so, findings from the most recent longitudinal study cited in this review (i.e., the National Longitudinal Study of Adolescent Health) are generally consistent with findings from earlier studies.

Nevertheless, acknowledging the potential significance of young adulthood for individuals from divorced families is important. As Amato [7] noted, early adulthood is a critical stage in the life course. It is a time when young people make important life decisions about education, marriage, and parenthood that can have enduring effects

on their lives. Amato further suggested that many young people are able seek guidance and support from parents as they contemplate these major life transitions. Unfortunately, youth from troubled divorced families might be at a disadvantage due to the possibility that they have weaker ties with their parents.

Wallerstein and Lewis [13] contend that parental divorce is a "life-transforming experience" (p. 367). Without a doubt, the effects of parental divorce continue to echo across the life course. Nevertheless, it would be misguided to overemphasize the consequences of the dissolution of their parents' marriage for the life course outcomes of adult offspring. Viewing parental divorce from a problem-focused "►Child of Divorce" paradigm can create fear, restrict possibilities and become a self-fulfilling prophecy for children and parents from divorced families [32]. Furthermore, Kelly and Emery [11] make the important distinction between painful memories of divorce and pathology. As young adults recall their parents' divorce, they may describe painful memories, and this is to be expected given the stressors associated with parental divorce. However, painful memories do not preclude positive adjustment – we need to recognize that lingering painful childhood recollections and adaptive functioning in adulthood can coexist. Most importantly, those who intervene with divorced families should work towards fostering protective factors known to promote resilience in both children and adults from divorced families [24]. When children from divorced families have involved parents and positive parent–child relationships, when they receive good parenting including positive co-parenting, and when they experience low parent conflict, their long-term developmental outcomes are likely to be characterized by positive adjustment.

[2]Nova Southeastern University, Davie, FL, USA

Definition

Tobacco smoking is the inhaling and exhalation of the fumes of burning tobacco which contains nicotine.

Description

Cigarette smoking is one of the most popular and persistent habits of our society. According to the American Cancer Society, each day more than 3,500 people under the age of 18 try their first cigarette, and approximately one-third will become regular daily smokers and will eventually die from a smoking-related disease. Children of smokers are much more likely to become smokers themselves as a result of observing their parents smoking and viewing their behavior as the social norm. Given that cigarette smoking remains the leading cause of preventable deaths, the decision made to smoke during the teen years has long-term consequences. Many teens begin smoking with the expectation that they will soon quit the habit but the addictive nature of nicotine leads most to continue the habit for decades. Addiction to nicotine is a common consequence of tobacco use. Nicotine addiction in teenagers is as severe as that in adults. Physiological and psychological symptoms include; hunger, dizziness, difficulty concentrating, irritability and craving for cigarettes. They also have similar difficulty in quitting tobacco as adults. Ninety percent of those who will become regular smokers start smoking before age 19 years. Knowledge of the long-term health consequences of smoking has not been a strong deterrent for use among teens, as they start smoking with recognition of the health risks but believe that they will be able to quit smoking before the health consequences become serious. There are a number of environmental factors linked to teen smoking, including parents, siblings and peers who smoke; exposure to tobacco advertising; and the portrayal of tobacco use in the media. Teens also experiment with smoking for a variety of psychosocial reasons: they want to change their self-image, look tough or grown-up, or because most of their friends smoke. Peer acceptance is a major factor for youthful smoking. Further, unlike many other drugs, nicotine enhances rather than impairs the capacity of normal people to function, and they experience primarily the pleasurable effects of smoking.

Relevance to Childhood Development

Smoking is a major health hazard to infants, children, adolescents, and their families. The U.S. Surgeon General warns that cigarette smoking is as addictive as cocaine and heroin. Research suggests that children who thought addiction happened immediately were committed to never smoke at all. Thus, the fear of addiction could be a protective factor in prevention efforts. Treatment programs for smoking have not been very successful. Three out of four smokers either wish to or have tried to stop smoking, and continue simply because they find it difficult to quit.

Supportive counseling and group interventions have been shown to be an effective part of a comprehensive nicotine treatment programs for teens. However, protective factors such as close communication with parents, high self-esteem, assertiveness, school success, social competence, and a strong sense of right and wrong, can prevent teens from smoking.

Definition

Social ►anxiety refers to an experience of anxiety (e.g., emotional discomfort, fear, apprehension or worry) regarding social situations, and the potential for evaluation in these situations.

Description

Social anxiety generally consists of three constructs: fear of negative evaluation, general social avoidance and distress, and social avoidance and distress in new situations [13]. Children with social anxiety are often mislabeled as shy (reticent in social situations). In fact, there is much overlap between social anxiety and shyness; children with either may experience similar somatic responses in social situations (e.g., heart palpitations, sweating, trembling, blushing) and similar negative cognitions (fear of negative evaluation, or of being embarrassed or humiliated). Yet, shyness that is excessive to the point of functional impairment becomes social phobia, or social anxiety disorder. It should be noted that the majority of those with social anxiety disorder have reported childhood shyness, but that shyness is not a necessary condition for the disorder [5]. The *DSM-IV* criteria that a child or adolescent must meet in order to be diagnosed with social anxiety disorder are the following: (1) a chronic, excessive fear of social or performance situations that the child fears will be embarrassing (anxiety must occur in peer settings); (2) the fear of social situations almost always triggers an anxious response; (3) the feared social situations are avoided or endured with great distress; (4) the fear or avoidance must cause significant impairment in functioning; (5) the fear or avoidance is not better explained by medication, medical condition, or other mental disorder; and (6) the symptoms must be present for at least 6 months [2].

Social anxiety disorder is one of the most prevalent childhood psychological disorders. Children may be affected with social anxiety disorder as young as 6 years of age, and the average age of onset is between 11 and 12 years of age. The course of social anxiety, if not treated, can be chronic and persist into adulthood. In addition to somatic complaints, children and adolescents may also present symptoms of irritability, crying, freezing in social situations, and inflexible temperamental styles. Children and adolescents with social anxiety disorder often exhibit comorbid disorders, the most common of which are attention-deficit/hyperactivity disorder, depression, and substance use disorders [6].

There are several theories, but no definitive explanation for how social anxiety develops in children and adolescents. From a biological view, genetics plays a role; 16%

of relatives of those with social anxiety disorder also have the disorder compared with 5% of relatives with no psychiatric disorders [9]. Children that have the early appearing behavioral characteristic of ▶behavioral inhibition are more likely to develop social anxiety disorder than those that do not. Behavioral inhibition has been linked to higher epinephrine activity and higher heart rates in novel social situations [12]. Some evidence suggests that behavioral inhibition is a genetic trait that runs in families; parents of children with social anxiety disorder have been shown to be more likely to have behavioral inhibition than the parents of children without the disorder [15]. Furthermore, studies have shown that those with high social anxiety levels have increased activity in the amygdala when presented with novel faces or faces with neutral expressions [7].

Several environmental factors may also contribute to the development of social anxiety. Along with peer rejection and victimization experiences, other life experiences that have been linked to the development of social anxiety are traumatic conditioning after experiencing panic in a social-evaluative situation [4], and maladaptive familial environments, particularly with high levels of parental criticism and overcontrol [18]. With regards to parenting behaviors, an anxious-resistant attachment is a risk factor for social anxiety disorder, while maternal warmth and secure attachment are associated with children who form healthy peer relationships [3]. Parental anxiety, rejection, and overprotection are all associated with social anxiety disorder in children and adolescents. Children may learn their parent's anxious behaviors through observational learning. Furthermore, overprotective parents may limit their children's ability to engage in social situations, thus setting up a pattern of social isolation and avoidance [5].

In most cases a combination of factors is likely present, including a biological vulnerability to anxiety and other environmental and psychological stresses that contribute to the development of social anxiety disorder [5]. For example, one theory is that social anxiety may be due to a biological predisposition for behavioral inhibition, which leads to a failure to establish peer relationships that help one to develop appropriate social skills. Lack of social skills and/or friendships cause further anxiety, insecurity, and withdrawal from social situations [17].

Concerning treatment for social anxiety, many children go without ever receiving help because they do not "act out," and thus teachers and parents may not recognize their level of discomfort. Similarly, social anxiety in adolescence is often overlooked as normal teen social insecurity. One of the most common and effective treatments for social anxiety is ▶cognitive-behavioral therapy (CBT). CBT targets three components of anxiety: physiological, cognitive, and behavioral. The physiological component is addressed through relaxation techniques. The cognitive component may include teaching children how to use constructive rather than negative self-statements. The behavioral component involves systematic desensitization to feared stimuli through imaginal as well as in vivo exposure. Some CBT treatments for social anxiety add a social skills training segment into the program. Another treatment option that has proven to be effective for social anxiety disorder is the use of psychotropic medications, including ▶selective serotonin reuptake inhibitors (SSRIs) and tricyclic anti-depressants. The SSRIs are generally the preferred drug for treating anxiety in youth [10]. The choice to use one modality (medication or therapy) over the other, or to use combined treatment, often relies on clinical judgment about individual patients. For severe cases of social anxiety in youth, a combined treatment of medication and therapy is generally used in order to increase the probability of a positive outcome [10].

Relevance to Childhood Development

Social anxiety can hinder a child's social, emotional, and cognitive (academic) development. Children with social anxiety have difficulty participating in typical classroom and school activities. They may struggle with speaking in front of the class, eating in the cafeteria, or using the public restroom. In many cases, children with social anxiety will refuse to go to school. They will often avoid social situations like talking on the phone or in person with peers, joining sports teams or clubs, and having friends to their house to play. In fact, children with high levels of social anxiety generally report fewer friendships, and perceive themselves as having a lack of social support and intimate, close relationships [13]. Socially anxious children are also less well-liked, teased more frequently, and suffer more often from peer rejection and relational victimization than non-anxious children [11]. The relationship between peer neglect/rejection and social anxiety is bidirectional; peer neglect/rejection also contributes to increases in youths' social anxiety levels [11]. Studies indicate that the effects of social anxiety are cumulative and increasingly detrimental. In one study, social isolation at age 7 predicted low levels of social competence and self-worth, and high levels of loneliness, and peer-group insecurity at age 14 [16].

With the demonstrated close links between same- and other-sex relationships, it seems likely that social anxiety would also disrupt the development of other-sex friendships and subsequent romantic relationships.

Indeed, anxiety is associated with fewer date initiation behaviors and interactions with the other sex that in turn may delay entry into romantic relationships [8]. In an analysis of retrospective reports, individuals with a history of social anxiety reported acute feelings of self-consciousness during social situations in junior high school and had fewer dating partners than a comparison group between the ages of 12 and 21 [1]. Further reflecting developmental continuity, those teens that rarely date in adolescence tend to exhibit decreased social skills, social withdrawal, and romantic dysfunction later in adulthood [14].

Definition

Social cognition refers to the ways in which individuals think about and process information relevant to their social interactions. This information includes the thoughts, feelings, motives, and behaviors of themselves and other people.

Description

Children's Theory of Mind

From very early in life, children have a *theory of mind*, which is an understanding that people have mental states, including desires, beliefs, and intentions. These mental states are not always accessible to others but serve to guide individuals behavior. As early as 2 months of

age, infants make distinctions between animate and inanimate objects, and by 6 months of age, babies know that humans behave differently toward people than toward inanimate objects. By 9 months of age, babies can discriminate between a person's positive versus negative intent (for example, offering a toy versus withholding a toy). Between nine and 12 months of age, babies begin to participate in joint attention activities in which they direct a partner's attention to objects or events. Such actions indicate that by the end of the first year, babies perceive that a social partner can understand and share their own perspectives. By 18 months of age, children can reason about other people's desires, and their behavior toward others tends to be influenced by their perceptions of these desires [13].

There are great advances in children's theory of mind between the ages of 2 and 5 years. Young children know that others cannot observe their thoughts, and that as a result they have access to information that others do not. By about 4 years of age, children understand that people are likely to act on the basis of false beliefs. Children may use their knowledge about false beliefs to their own advantage by deliberately deceiving their partner. They may give false clues about where an object is hidden or blame someone else for a transgression that they committed that was not witnessed by others [13].

Person Perception

With the development of theory of mind, children are gaining insights regarding other people's desires and beliefs. However, children continue to have much to learn about the personalities and behavioral tendencies of themselves and their social partners. Children younger than about 7 or 8 years of age tend to describe themselves and others in terms of concrete, observable features. Nevertheless, even though young children may not spontaneously use personality traits, they do show some psychological self-awareness. For example, children ages 3-1/2 to 5 years old do characterize themselves along psychological dimensions, such as aggressiveness and sociability, when asked to respond to forced choice options regarding their personality traits. Furthermore, their characterizations are stable over time [4]. In addition, even if preschoolers do not yet use personality traits when describing others, they do show an understanding of the ways in which their closest companions typically behave. By 5 years of age, children make trait-like inferences, for example assuming that someone who has been aggressive in past peer interactions will continue to be aggressive. Moreover, 4 and 5 year olds can use trait labels to predict others' trait-relevant behavior [9].

Between the ages of 7 and 16 years, children increase their use of personality traits when describing others, though they continue to include concrete attributes in their descriptions. Person perception becomes even more complex during adolescence, as individuals are increasingly aware that their own and others' behavior can be impacted by situational factors that may lead them to act "out of character" [13].

Social Perspective Taking

An important aspect of social cognition is being able to understand the social partner's point of view, including the partner's thoughts, feelings, beliefs, motives, and intentions. According to Selman [11], children develop social perspective taking skills across five stages. In the first stage, Egocentric or Undifferentiated Perspective Taking (approximately ages 3–6 years), children are generally egocentric and thus are not aware of any perspective other than their own. In the second stage, Social-Informational Role Taking (approximately 6–8 years), children begin to recognize that others can have different perspectives from their own but believe that this occurs only because these individuals have access to different information. In the third stage, Self-Reflective Role Taking (approximately 8–10 years), children recognize that their own and others' points of view may conflict even if they have received the same information. At this point, the child can consider the other person's point of view and can recognize that the partner also has an understanding of the child's point of view. However, the child has difficulty considering his own perspective and the perspective of the partner simultaneously. In the fourth stage, Mutual Role Taking (approximately 10–12 years), the child can consider his own perspective and that of the partner simultaneously and realizes that the partner can do the same. The child can also assume the perspective of a disinterested third party and anticipate how each person will react to one another. Finally, in the fifth stage, Societal Role Taking (age 12 and older), individuals expect others to consider and adopt perspectives that most people in their social group would assume. Children proceed through these stages of social perspective taking in a fixed order, though the rate at which they do so may vary based on cognitive skills and social experiences.

Adolescent Egocentrism

As adolescents become capable of formal operational thinking, in which they are able to reason about abstract concepts and hypothetical events, they often overextend this ability when thinking about themselves and their social world. This leads to adolescent egocentrism, where

the adolescent's thoughts may reflect a great deal of self-absorption. Adolescent egocentrism seems to contribute to two distinct types of thinking [5]. The *imaginary audience* is the belief, brought on by the heightened self-consciousness of adolescence, that everyone is watching and evaluating the adolescent's behavior. The adolescent has a sense of constantly being "on stage," and seems to think that others are as preoccupied with his or her appearance and behavior as he or she is. The second belief is the *personal fable*, in which the adolescent focuses on the uniqueness of oneself and one's thinking and tends to think that no one can possibly understand his or her experiences or emotions. The personal fable contributes to beliefs that one is invincible, and thus appears to play a role in adolescents' greater tendency to participate in risky behaviors given their propensity to believe that negative consequences could not possibly occur for them.

Models of Social-Cognitive Processing

In addition to studying general types of changes in social cognition across development, researchers have focused on individual differences in children's social cognition as they respond to specific types of social situations. Quite often social situations are ambiguous in nature, and individuals vary in their interpretations and motivations during social interactions. Indeed, individual differences in social-cognitive processing help to explain why children confronted with the same social situation, such as having milk spilled on them by a peer, may choose to act in very different ways (e.g., retaliating vs. cleaning up the mess). A variety of models have been proposed to describe specific social-cognitive processes that underlie children's behavioral choices, and several of the more prominent models are described below.

One of the most influential models of social-cognitive processing was proposed by Crick and Dodge [3]. According to this model, as individuals interact with others they bring to the situation their own social knowledge, schemas (e.g., scripts for how to deal with conflict), and a database of memories of past social experiences (e.g., memories of frequently being victimized by peers). They then receive as input a set of social cues (e.g., a peer tripping them), and their behavioral response is a function of how they process those cues. The model proposes that there are six steps of processing that occur: (1) encoding of external and internal cues, (2) interpretation of those cues, (3) selection of goals, (4) response access, (5) response decision, and (6) behavioral enactment. To illustrate, a child who is tripped by a peer and has a history of being victimized by peers may attribute the action to hostile intent rather than to accidental circumstances. That child then selects a goal, perhaps retaliation or avoidance. The goal that is given priority is likely to influence the types of social responses generated (e.g., aggressive vs. passive behaviors). As children make a decision about how to respond, several social-cognitive constructs are likely to come into play. Children's self-efficacy perceptions are important, given that children are most likely to select behaviors they think they would be able to produce successfully. Outcome expectations also play a significant role, as children tend to choose behaviors they feel will result in a positive outcome. In addition, children should view the response as being appropriate according to their own moral rules or values (e.g., beliefs about the legitimacy of aggressive behavior). Thus, children who believe that they are good at being aggressive, that aggressive behavior will bring positive results, and that aggression is legitimate are quite apt to decide that aggressive behavior is an appropriate response.

Notably, the Crick and Dodge model is circular in nature, such that each step of processing may influence the others through a series of feedback loops. For example, whereas a child who attributes a protagonist's action to hostile intent may be more apt to select a retaliation goal, it is also possible that a child who generally gives high priority to retaliation goals (Step 3) may be especially primed to attribute any harm caused by the protagonist to hostile intent (Step 2). Notably, though each of the social-cognitive variables may predict behavior, behavior is best predicted by multiple variables.

Another important social-cognitive theory is Weiner's attribution theory [14]. This theory emphasizes that during social interactions, individuals are concerned with determining the perceived causes of behavior and events. Three underlying dimensions of causes are proposed. The first is *locus*, in which the individual must decide whether a cause is internal (e.g., lack of social ability) or external (e.g., bad mood of the interaction partner). The second dimension is *stability*, which identifies a cause as constant or changing over time. The third dimension is *controllability*, or whether a cause is subject to volitional influence. The attributions a person makes can have a strong impact on factors such as behavioral choices, expectancy of success, and emotion. For example, an individual who is not invited to participate in a special activity with peers may attribute this incident to external, stable, and uncontrollable factors. In turn, the individual may decide to withdraw socially, expect future rejection, and feel hopeless.

Selman's Interpersonal Negotiation Strategies (INS) model [12] asserts that four information processing issues are central as individuals engage in social problem solving. First, the individual must define the specific problem and

evaluate it in terms of the social relationship (i.e., whether the problem is a mutual one, or whether the focus is on one person). The second process focuses on the action to be taken (i.e., the strategy or strategies suggested to deal with the dilemma). The third process involves considering the consequences of the solution proposed, including consequences to the protagonist, the significant other, and the relationship between the two people. In the fourth process, the individual considers the effect of the solution on the emotions of those involved. According to this model, the individual's use of strategies may vary depending on the context (e.g., status difference between interaction partners, type of relationship).

Finally, Bandura's [1] self-efficacy theory proposes that individuals' level of confidence in their ability to successfully perform a certain behavior will impact whether they choose to enact that behavior, how much effort they will exert, and how long they will attempt the behavior in the face of challenge. Bandura asserts that expectations of personal efficacy come from four primary sources of information, including performance accomplishments, vicarious experience, verbal persuasion, and emotional arousal. Bandura distinguishes self-efficacy perceptions from outcome expectations, which are defined as an individual's estimate that a given behavior will result in a particular outcome. Indeed, although a person may believe that a specific behavior may lead to a certain consequence, that person may not think he or she could be successful at enacting that behavior. For example, the individual may believe that using negotiation strategies would result in the peaceful resolution of a conflict, but she may think that she is not a very effective negotiator. In contrast, a person may believe that she could effectively perform a behavior but may expect that action would not result in a desirable outcome. Ultimately, both self-efficacy perceptions and outcome expectations impact individuals' behavioral choices.

Each of these theoretical models highlights specific types of social-cognitive variables that may operate as individuals decide how to respond to social situations. The models differ in the specific variables they emphasize, but across these models various social-cognitive processes are viewed as playing significant roles in predicting individuals' social behavior. These variables include attributions of hostile intent, attributions for social success or failure, social goals, strategy knowledge, self-efficacy perceptions, outcome expectations, and beliefs about the legitimacy of aggression.

Relevance to Childhood Development

A great deal of research has shown that children's social-cognitive processes are related to their psychosocial adjustment. Among young children, those who show more sophisticated knowledge about theory of mind display more advanced social skills and are more highly accepted by peers compared to age mates. Gains in person perception abilities across childhood into adolescence can contribute to greater understanding and intimacy in social relationships. In addition, children with more advanced social perspective taking skills are more likely to experience empathy for others and are more apt to engage in prosocial behavior [13]. Although advances in most social-cognitive processes are associated with positive outcomes, it should be noted that adolescents' strong endorsement of personal fable beliefs is correlated with a greater likelihood of engaging in risky behaviors, including dangerous driving and unprotected sexual interactions.

Children's social adjustment is also related to individual differences in their social-cognitive processes as they respond to specific types of social situations. Specifically, children who are aggressive and/or highly disliked by their peers tend to show a variety of social-cognitive deficits or distortions. For example, rejected-aggressive children are apt to display a tendency to make attributions of hostile intent and, in turn, to endorse aggressive responses to provocations [10]. Such behavior often leads to further rejection by peers (and reinforces children's interpretations that others have hostile intentions) and leaves children vulnerable to a variety of negative outcomes, including loneliness, depression, delinquency, and school dropout [8]. Other social-cognitive processes are similarly associated with maladaptive behavior and peer rejection. Aggressive children are more apt to endorse retaliation goals and tend to generate primarily aggressive responses. They tend to have high confidence in their ability to carry out aggressive behaviors and low self-efficacy regarding their ability to enact prosocial responses. Moreover, aggressive children expect positive outcomes for their use of aggression, including gaining material rewards, status, and power, and tend to have little regard for the suffering of their victim. Aggressive children also believe that their choice of aggressive behavior is morally legitimate [6].

Behaviorally withdrawn children similarly appear to have a specific social-cognitive profile that underlies their behavior. Like aggressive children, they may also show a hostile attributional bias, but they are more apt to endorse socially avoidant goals and strategies and think they are better at carrying out these behaviors than at being aggressive or prosocial [7]. Socially withdrawn behavior is often associated with being overlooked, or neglected, by peers during the childhood years. However, as children approach adolescence, withdrawn behavior is increasingly associated with overt rejection, and such rejection can

leave the child vulnerable to a variety of negative outcomes, including loneliness, depression, and social anxiety.

Research has shown that the most socially adjusted children are those who make attributions to accidental circumstances, endorse relationship-oriented goals, and select prosocial strategies [7]. Children who are better accepted by their peers tend to have high self-efficacy for their ability to act in prosocial ways and expect positive outcomes that will enhance relationships. Those children with more adaptive social-cognitive functioning tend to engage in more prosocial behavior. This behavior, in turn, contributes to greater acceptance by the peer group and a higher likelihood of being involved in friendships. These positive social experiences are associated with adaptive psychosocial adjustment.

Traditionally, social skills intervention programs have focused on teaching children specific social behaviors, such as sharing and initiating social interactions. Increasingly, however, intervention programs are beginning to target social-cognitive processes as well. For example, some interventions have focused on teaching children to make nonhostile attributions when the intent of the actor is ambiguous, to give higher priority to prosocial goals, and to generate more prosocial strategies [2]. By addressing the social-cognitive processes that underlie children's behavioral choices, children may be prompted to engage in more prosocial behavior that in turn will increase their acceptance in the peer group and decrease their risk for poor psychosocial adjustment.

Social Cognitive Learning Theory

Social learning theory

Definition

Albert Bandura's social cognitive theory conceptualizes cognitive, vicarious, self-regulatory, and self-reflective processes as they relate to human motivation and behavior.

Description

Social cognitive theory was founded on the social learning theory proposed by N. E. Miller and J. Dollard in 1941 [8]. Early social learning theorists were heavily influenced by behaviorism and drive reduction principles. In 1963 Albert Bandura and Richard Walters extended social learning theory by stressing that observational learning is a natural occurrence. They also stressed that reinforcement controls performance, not learning, and that learning can happen vicariously. Bandura's work also developed the importance of self-beliefs in learning behaviors. With the 1986 publication of his book *Social Foundations of Thought and Action: A Social Cognitive Theory* [2], Bandura made a clear distinction between his theory, which emphasizes the important role of cognition in human behavior, and other social learning theories [7].

Social cognitive theory is grounded in the belief that humans are unique in our ability to symbolize experiences, to develop forethought about consequences for our actions, to learn vicariously through the actions of others, to be able to change our behaviors through self-regulation, and to self-reflect. Bandura is most widely known for his contributions of reciprocal determinism [2] and self-efficacy [1].

Reciprocal Determinism

One unique contribution to the social-cognitive framework is the concept of *reciprocal determinism* (also called *triadic reciprocality*). Other theorists have speculated about the role personal factors (cognition, affect, and biological events) and environmental factors (both social and physical) play in the human behavior. However, Bandura's theory proposes complete interactionism among personal factors, behavior, and environmental factors, whereby people are both products and producers of their environments and social systems. In this model, not all sources of influence are equally strong. Additionally, the effects are not always seen immediately, but may develop over time (Fig. 1).

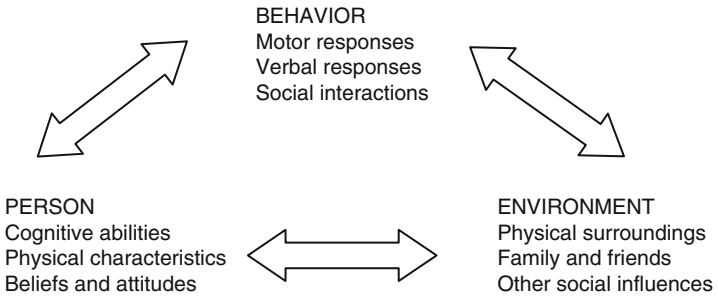
Self-Efficacy

Self-efficacy beliefs are judgments people make about their ability to do something. Self-efficacy beliefs are not global – they are task-specific and may change depending on contextual factors. According to Bandura, "people's level of motivation, affective states, and actions are based more on what they believe than on what is objectively true" ([5], p. 2). Self-efficacy beliefs are established through four sources of information and they are most easily shaped during the development of self-beliefs. It is much harder to change a person's self-efficacy beliefs once they have become firmly established.

Mastery experiences provide the most authentic evidence of whether or not a person can perform a task. If a task has been successfully performed in the past, it increases the likelihood that a person may be able to do it again in the future. How a person remembers experiences is also important. If a person selectively remembers the one mistake made in an event that was successful overall, it can negatively affect the person's efficacy for that task. Alternately, remembering the accomplishments made in a task that was not successful can improve a person's efficacy for the task. Mastery experiences and their interpretation are particularly important when developing self-efficacy for a task. However, once self-efficacy beliefs have become firmly established mastery experiences become less important.

Vicarious experiences allow a person to learn a novel behavior without performing it. Vicarious learning is less powerful than mastery experiences in creating self-efficacy beliefs, but it is useful when a person has little prior experience and when a person is unsure of their ability. In some cases, vicarious learning serves to protect people from harmful behaviors. For example, the consequences of a motorcycle accident in which the driver was not wearing a helmet or protective clothing is likely to affect the future safety behaviors of other motorcyclists who witnessed the event. In other cases, it allows us to learn situational social norms. For instance, weather to raise one's hand in the classroom to get permission to use the restroom or if it is acceptable to discreetly leave without overt permission.

Vicarious learning also allows a person to assess their task capabilities in relation to the attainment of others. Self-efficacy for a task is most strongly influenced when the models are people relatively similar to one's self. For example, watching someone else learn how to swim may increase a person's belief that they too, can learn how to swim – particularly if there are other commonalities such as age and gender. This experience would likely have a stronger impact on one's efficacy beliefs about learning to swim than watching Olympian Michael Phelps win a gold medal. Vicarious learning is also often referred to as modeling or observational learning.



Social Cognitive Learning Theory. Fig. 1 Reciprocal Determinism.

Social persuasion also contributes to the development of self-efficacy beliefs. This happens when other people provide verbal judgments about one's ability. When others cultivate positive beliefs combined with realistic assessments of success, the social persuasion can encourage positive self-efficacy beliefs. However, negative appraisals can serve to weaken self-efficacy beliefs as well.

Physiological and affective states, including anxiety, stress, and moods also provide information about efficacy beliefs because they provide cues about anticipated success or failure. Low self-perceptions may trigger more stress or anxiety about a performance, which can lead to a negative outcome. Negative affective states also divide a person's focus. By focusing on feelings such as an upset stomach or tension, focus is directed inward and taken away from task performance. Alternately, if a person feels confident in their ability to perform a task, they are likely to have lower stress and anxiety and be able to focus completely on the task without diverting attention to inner feelings.

It is the combination of the information and interpretation (e.g., symbolization, self-reflection) of that information that contribute to judgments of self-efficacy.

Relevance to Childhood Development

Social cognitive theory continues to be a useful lens through which to explore child development and provides an alternate explanation to Piaget's stage theory of cognitive development. Social cognitive theory uses reciprocal determinism as a way to explore cognitive and linguistic aspects of development. It also contributes to the fields of cognitive-behavioral therapy and healthcare [4, 6].

Bandura's famous bobo doll experiment in the early 1960s demonstrated the powerful effect of behavior modeling on children. The experiment demonstrated that children who witnessed aggressive behaviors by adults (particularly when the aggression was demonstrated by the same gendered adult) were more likely to demonstrate those behaviors than children who did not witness aggressive behaviors. Currently, Bandura's work is often used as a foundation for research on violence in the media. He asserts, however, that the social impact of observational learning is largely a function of a person's exposure to other information about reality. The more a person's image of reality depends on the media's symbolic environment, the greater the social impact [3, 9].

Social Construction of Memory

Alandra Weller-Clarke
Benedictine University, Lisle, IL, USA

Definition

Theoretical perspective in which memory is created by collaborating with and observing others.

Description

Social construction of memory has its roots in social cognitive theory that includes a blend of ideas from behaviorism and cognitive psychology. Albert Bandura [4–6, 8–10] is the main architect of the theory as it pertains to learning, and he explains that when students learn, they cognitively represent or transform their experiences. Five major assumptions of social cognitive learning include learning by observing, learning as an internal process that may or may not be reflected in behavior, goal directed behavior, self-regulated behavior, and indirect effects of reinforcement and punishment [15]. According to social

cognitive theorists (e.g., [3, 4]), both reinforcement and punishment influence learning, behavior and memory in several ways.

First, children form expectations about the likely consequences of future responses based on how they remember previous responses as reinforced or punished. Secondly, children's expectations are influenced by their observations of the consequences that follow other peoples' behaviors, in other words, by vicarious experiences. These expectations or memories regarding probable future consequences affect how children cognitively process new information and store it into memory. These memories alter children's expectations and also influence their decisions about how to behave.

Some examples of social cognitive learning that create memories in children include observational learning and/or modeling.

Observational learning involves acquiring skills, strategies, and beliefs by observing others. It involves imitation but is not limited to it. What is retained or remembered typically is not an exact copy of what is modeled, but rather a general strategy that the observer often applies. The capacity to learn behavior patterns by observation and modeling eliminates trial-and-error learning. Models can be live or symbolic, and teach children all sorts of behaviors. Considerable research has been conducted concerning the impact of modeling in three areas: academic skills, aggression, and morality.

Academic skills are learned by children more effectively when others demonstrate how to do something and how to think about something. In other words, a teacher might use cognitive modeling to show the thinking processes involved in a long division problem, thus making the information more meaningful and easier to retrieve from memory later on.

Numerous studies indicate that children become more aggressive when they observe aggressive or violent models [2, 12, 13]. Whether children learn aggression from live or symbolic models they see in person, or in films, on television, or in video games [1], their imitations take the remembered forms as the aggression they have seen and processed [7, 14].

Many aspects of moral thinking and behavior are influenced by observation and modeling. Children watch, retain to memory, and mimic examples of moral judgment, sympathy, sharing, and generosity [11]. Children who watch generous models are more likely to donate their time or possessions than children who observe selfish models. Even in cases where an experiment is repeated months afterward, children repeat the behavior from the initial session because it has been committed to memory.

Social Learning Theory

Tonya R. Hammer
University of Houston Clear Lake, Houston, TX, USA

Synonyms

Imitation; Modeling; Media influence; Observational learning; Social cognitive learning theory

Definition

Social learning theory states that norms, attitudes, expectations, and beliefs arise from an interaction with the cultural or social environment around an individual.

Description

Albert Bandura, the leading theorist in social learning theory, proposed that people learn from their observations of individuals or models. Bandura believed that behavioral theories presuming that environment determines one's behavior were too simplistic in nature. In response he presented the idea of reciprocal determinism, meaning the environment and one's behavior cause each other. As the theory developed the term prosocial behavior was coined. Prosocial behavior has been defined by theorists as "helping behavior that benefits others" [3]. The premise behind social learning theory, unlike operant or classical conditioning, is that the behavior does not have to be performed or reinforced directly for others to benefit from the positive reinforcement. Children learn behavior by observing others or ►models, and if the models receive positive reinforcement for their actions, the observers seek to imitate the behavior in order to obtain the positive rewards as well. However, the behavior modeled does not have to be positive for the observer to imitate it. Positive *and* negative behavior can be socially learned. In order for the behavior to be repeated several conditions are necessary. First, the

observer must pay attention to the behavior of the model. Secondly, the observer must recall or remember the behavior. Subsequently, the observer must reproduce the behavior accurately and finally the observer must be motivated to learn and carry out the behavior.

Current Research

While in the past Bandura's theory has primarily been applied to parents, teachers, peers and other authority figures as models, one of the greatest sources for observational learning is the media. For example, studies have found that the concept of social learning is at play in the smoking behaviors of adolescents. According to a study by [2], a correlation between smoking in the movies and adolescent smoking behaviors exists. Additionally, images in the media are modeling certain behaviors that are proving to be detrimental to teenage girls and in some instances boys. Numerous studies have been conducted on the influence of the media on body image. [7], found that "exposure to idealized images (in the media) led to increased body shame and appearance anxiety" (p. 89). In sum, current literature clearly indicates that the media significantly influences society in various facets of life ranging from smoking to body image.

Social anxiety; Social anxiety disorder

Definition

According to DSM IV [3] social anxiety disorder is "a marked and persistent fear of one or more social performance situations in which the person is exposed to unfamiliar people or possible scrutiny by others." It is a disorder with a very broad range of implications as most of our daily activities revolve around social encounters. It is especially debilitating because seemingly routine tasks become an ordeal for the individuals suffering from the disorder.

Description

Social phobia is a common disorder with vast implications; its effects range from interpersonal problems to inability to meet developmental milestones. The socially anxious youth struggle with the inherent anxiety as well as the social implications of their anxious behavior.

Ford [6] in a personal account of social phobia described her experience in the following way

> In first period chemistry, I was up to my ears in dread-dread of having to say 'here' when my name was called, of getting back yesterday's assignment, of looking as if I didn't fit in. I glanced around the room to compare my notebook, pencils, clothes, jewelry, hairstyle, backpack, and pile of textbooks with everyone else's. The corners of my notebook lacked the lazy scribbles from a friend.

Imagine a young person going through the day this way with a pervasive sense that all eyes are on her. Socially phobic youngsters believe they are on display and any mistake or flaw is readily apparent. Further, they predict that others will ridicule, embarrass, and humiliate them due to this flaw. It is like stage fright gone terribly awry. Indeed, this is a distressing experience.

Social phobia is a prevalent and debilitating condition. Beidel and Turner [5] report prevalence rates of approximately 8% for children and 4% for adolescents. Additionally, they cited data indicating that between 15 and 18% of

children referred to an anxiety disorder clinic were diagnosed with social phobia. Social phobia transcends normal shyness and is marked by young people's profound dread of social/performance situations where unfamiliar people are present and may negatively evaluate them. Finally, social phobia compromises children's emotional well-being, completion of developmental tasks, and academic achievement.

Signs and Symptoms

The DSM-IV [3] defines the essential feature of social phobia as "marked and persistent fear of social and performance situations in which embarrassment may occur." Social phobia may be specific or generalized in which case fears are related to most social situations. Thus the symptom profile is vast and encompasses a large variety of presentation styles. For the purpose of clarification, the symptoms are divided into the following categories:

Physiological/biological: Socially anxious youth experience somatic arousal while engaging in or anticipating social encounters. The salient features are physical symptoms such as heart palpitations, flushing or chills, trembling, sweating, blushing, fainting, shaking and headaches; mediated by the beta-adrenergic system [9].

Behavioral: Behavioral symptoms include hallmark avoidance behaviors such as shying away from typical childhood activities (parties, dating, sports, school, clubs, etc.). Avoidance behaviors may be overt, dramatic or subtle. Generally unstructured social and/or evaluative situations and encounters precipitate avoidance behaviors [1]. These may include refusal or avoidance of eating or drinking in public, initiating or maintaining conversation, and avoiding using public restrooms. Moreover, worry about taking tests, giving oral reports in the classroom, participating in gym as well as working in groups is typical behavior for these children and adolescents [6]. Socially anxious youth are reluctant to seek help from their peers or teachers [1]. Other likely behavioral manifestations include stuttering, poor eye contact, mumbling, nail biting, and a tremulous voice. Socially anxious youth frequently avoid answering the telephone or doorbell [1]. Moreover, many children and adolescents preoccupy themselves with hobbies reflecting isolative interests which are different from those of their peers. Finally, children with severe social fears act stubbornly, oppositional, non-compliant, and occasionally they become outright defiant [9].

Cognitive: Cognitive content reflects the way youngsters mentally package their experiences. Fears of negative evaluation mark socially anxious youth's cognitive content. They predict others will harshly judge them ("They will think I am a dork") and dread potential embarrassment / humiliation ("They'll see me blush and mock me"). Cognitive content may include thoughts of escape from the social situation ("The best way to cope with my anxiety is avoid it"), lower perception of social competence ("I'm not one of the cool kids. I don't fit in."), and self criticism ("I'm a misfit").

Developmental factors must be considered when evaluating a child or adolescent [9]. The capacity to express cognitive content of the disorder may be correlated with psychological maturity and mediated by chronological age. Older and emotionally sophisticated children may be better able to put their thoughts into words and describe their cognitions.

Emotional: Emotional symptoms generally include sadness, excessive worries, irritability, social distress, poor self esteem, feelings of inadequacy in interpersonal relationships and high degree of loneliness [5].

Interpersonal

Typical interpersonal symptoms include restricted peer interactions, fewer friends, social withdrawal, reluctance to participate in family gatherings and social isolation. Finally, the play activities of these individuals are sometimes unusual which further socially isolate them. This lack of common interests may be because of limited opportunities for social interactions due to their social anxiety and avoidance [5].

Treatment

Pharmacological Treatment

Currently, ▶selective serotonin reuptake inhibitors (SSRIs) are the mainstay of pharmacological management for youth. Currently available SSRIs include Fluvoxamine (Luvox), Fluoxetine (Prozac), Paroxetine (Paxil), Citalopram (Celexa), Sertaline (Zoloft), and Escitalopram (Lexapro).

Behavioral Treatment

Social Effectiveness Therapy for Children (SET-C) is a comprehensive behavioral treatment modality which has been specifically designed to reduce social anxiety and enhance children's interpersonal social skills. SET-C focuses on helping children reduce their avoidant and inhibitory behaviors in socially evaluative and interpersonal contexts. SET-C consists of social skills training (SST), Exposure and programmed practice with peers to provide real life coping experience [5].

Cognitive Behavioral Treatment

Cognitive behavioral therapy is a form of psychotherapy which hypothesizes that individuals' problematic emotions and dysfunctional behavior is shaped by misinterpretations of themselves, other people and their experiences. The most widely used CBT protocol for childhood anxiety is Phillip Kendall's Coping Cat Program [8]. This protocol is administered for children ages 7–16 years. The approach can be utilized for both individual and group treatments.

Albano et al. [2] adapted group cognitive behavioral therapy for adolescents ages 13–17, which involves 16 group sessions incorporating psycho-education, skills training and behavioral exposure.

Conclusion

Social phobia is a common and complex disorder which comes at considerable costs to young people. Proper identification and treatment is crucial. Fortunately, there are multiple promising therapeutic options. Hopefully, future research will facilitate advances in the detection and treatment of social phobia.

Definition

Social problem solving is the process by which individuals identify and enact solutions to social life situations in an effort to alter the problematic nature of the situation, their relation to the situation, or both [7].

Description

In D'Zurilla and Goldfried's [6] seminal article, the authors conceptualized social problem solving as an individuals' processing and action upon entering interpersonal situations in which no immediately effective response is available. One primary component of social problem solving is the cognitive-behavioral process of generating potential solutions to the social dilemma. The steps in this process were posited to be similar across individuals despite the wide variability of observed behaviors. The revised model [7] is comprised of two interrelated domains: problem orientation and problem solving style. Problem orientation describes each individual's meta-cognitive schema, which tends to be a stable approach to understanding problems. Problem orientation has been defined in two primary ways, positive and negative. Individuals with a positive problem orientation believe that problems are challenges to be solved rather than threats. This positive orientation has been associated with more rational and adaptive problem solving efforts and adjustment. In contrast, a negative orientation is

characterized by beliefs that social problems represent major threats to well-being, that one lacks self-efficacy to solve problems, and that one will experience emotional distress when confronted with problems. This negative orientation has been associated with dysfunctional social problem solving styles and problems in adaptation (i.e., anxiety, depression, and conduct problems).

The cognitive and behavioral skills that comprise individuals' general responses to stressful or novel problems characterize their problem solving style. The three styles outlined by D'Zurilla and colleagues [6, 7] include rational, impulsive/careless, and avoidant styles. Classification into a problem solving style is based on the utilization of the four major problem solving skills: problem definition and formulation, generation of alternative solutions, decision making, and solution implementation and verification. Rational problem solving is characterized by a planful and systematic use of these skills to solve problems. In contrast, impulsive/careless and avoidant styles are considered dysfunctional because individuals classified into these categories do not systematically process each step of the model. Instead, the impulsive/careless problem solving style attempts to utilize problem solving strategies, but does so in an incomplete and inadequate manner. The avoidant problem solving style is characterized by passivity, procrastination, and avoidance.

The model presented by D'Zurilla and Goldfried was primarily developed with attention to adult problem solving processes to explain variations in social behavior. Their model was applied and expanded by Spivack and Shure [14] to explore developmental factors that influence problem solving. The authors examined social problem solving (called interpersonal cognitive problem solving skills) that would distinguish maladjusted children from their well-adjusted peers. Spivack and colleagues [13, 14] posited several prerequisite cognitive skills that were necessary for effective problem solving; specifically, the abilities to consider step-by-step plans, think causally, develop alternative solutions, anticipate consequences, and understand the motives of others. In a series of studies, Shure and Spivack [13, 14] identified the relationship between interpersonal cognitive problem solving skills and normative age-related changes. Moreover, the authors illustrated that deficiencies in these skills were related to problematic social skills, impulsiveness, and withdrawn behavior in preschool to elementary school aged children [13].

Crick and Dodge [3] provided a comprehensive review and model of the social cognitive processes leading to maladjustment in childhood. Again, these authors proposed that when faced with a social problem, children engage in a number of steps before implementing a response and that differences in these processes may account for the differences observed in children's social behavior. Similar to the D'Zurilla and Goldfried model, Crick and Dodge [3] suggested the essential steps in social problem solving included encoding the problem, interpreting cues in the social situation, clarifying goals, generating possible responses, selecting a response, and enacting the behavior. In an important distinction from the D'Zurilla and Goldfried model, the authors suggested that differences in processing styles may be most predictive of differences in social behavior and could be illuminated at each step in the problem solving process. The Crick and Dodge reformulation included an explicit emphasis on the importance of the interaction between individuals' internal processes, developmental changes (i.e., increased in experiential knowledge; improved attention, memory, and organization; and increased speed of processing information) and environmental factors on problem solving efforts (e.g., emotion processes; access of social scripts, schemas, and knowledge in memory).

In a model similar to Crick and Dodge's [3] reformulation, Rubin and Krasnor [11] focused on the development of automaticity to account for the stability and change in the development of social behavioral patterns. Specifically, the authors suggested that children learn standard scripts for common and routine social situations. The scripts are stored and cued by internal or external stimuli and are easily and unconsciously accessed in familiar social situations. However, when in novel situations, situations that violate expectations, and situations that have been unsuccessful in the past, children are required to deviate from script-driven behavior. Rubin and Krasnor classified such situations as "social problems." Once a social problem is encountered, children must select the social goal, examine the task environment (the social status, familiarity, type of relationship, age of others); generate, retrieve strategies, and select strategies (automatic or deliberate), implement a strategy, and examine the outcome.

The four models presented for social problem solving have several common elements. The seminal social problem solving model [6] and the revised models all share core steps in the problem solving process, including recognizing the problem, generating alternatives, deciding on an action, and implementing the action.

Relevance to Childhood Development

Development of Social Problem Solving Abilities

The attention to developmental factors highlighted by Spivack and Shure [14], Crick and Dodge [3] and Rubin

and Krasnor [11] represent significant steps toward understanding social problem solving processes in youth. The majority of research has emphasized the importance of social influences on the development of effective social problem solving skills. The following sections describe influences including attachment relationships, parenting practices, and peer influences, and cultural context on these skills.

Socialization

Attachment and Parenting

Classic attachment theory emphasizes the importance of children's relationships with their primary caregivers and the manner in which those relationships affect future relationships [1]. In the attachment framework, early relationships provide children with internal working models, which serve as guides for subsequent social interactions. Applied to the study of social problem solving, secure attachments have been frequently emphasized as essential to the transmission of social information and the development of effective and appropriate levels of independence and social competency [12]. Within the context of their attachments to caregivers, children are believed to engage in social learning processes (e.g., observation of models) through which they internalize strategies for managing ambiguous social situations. It has been suggested that secure attachments are more likely to foster adaptive social problem solving, whereas insecure attachments may be associated with maladaptive strategies [12].

Although few data are available to elucidate the relationship between child attachments and social problem solving, a significant body of research exists to support a more general connection between parent–child relationship patterns and children's social competence, with maternal nurturance and authoritative parenting correlated with prosocial problem solving skills [9]. Significant parental stressors, such as parental psychopathology (e.g., depression), may also negatively impact child adjustment by interfering with effective parenting behavior [5].

Peer Influences

Beyond the home environment, various aspects of children's broader social ecologies appear to be linked to social problem solving abilities. Socially accepted, rejected, and neglected children differ in their social problem solving abilities at each step of the social problem solving process. Research has documented that children who experience relational problems have difficulties interpreting the actions of their peers, when compared to socially-accepted children [3]. Indeed, socially-rejected children appear more likely to make attributional errors regarding peers' intentions in social situations and are more likely to infer hostile or negative intent. When generating behavioral response options, children who experience social rejection are also more likely to identify avoidant or aggressive strategies to solve social problems. In contrast, socially-accepted children tend to generate behaviors that are competent and effective rather than incompetent or aggressive.

Community and Cultural Context

Beliefs about the appropriateness of different problem solving strategies are also rooted in community norms and cultural values related to assertiveness and individualism. Relative to more individualistic cultures, adolescents living in cultures that endorse collectivistic values may be more likely to use the tactic of withdrawing to deal with social conflicts. In addition, experiences such as exposure to community violence have been associated with beliefs about the appropriateness of aggressive problem solving strategies. Nevertheless, the extent to which aggressive responses are actually detrimental to youth functioning may be moderated in part by the cultural acceptability of aggression versus disengagement as a problem solving strategy [2].

Relationship Between Social Problem Solving and Psychopathology

There is a substantial literature investigating the interrelationship between social information processing, effective social problem solving, and adjustment across development. Specifically, both internalizing and externalizing type childhood disorders have been found to have elements of ineffective social problem solving skills. Disorders such as oppositional defiant disorder, conduct disorder, and depression have been found to be associated with unique pathways in the development of social problem solving deficits. In the following sections, the primary disorders will be discussed as well as potential treatments targeting these deficits.

Externalizing Disorders

Research investigating the social problem solving abilities of children with externalizing disorders and maladaptive behaviors found in non-clinical samples, including aggression, delinquency, and substance abuse support the notion that these problems are associated with a variety of deficits in implementing each step of the social problem solving process. Specifically, aggressive children, when compared to non-aggressive children, demonstrate deficits in encoding social cues, and a "hostile attribution bias" in which they tend to attribute hostile intent in ambiguous

situations [8]. Moreover, aggressive children tend to generate fewer and lower quality solutions to social problems and evaluate aggressive solutions as more effective.

As the reviewed literature illustrates, aggressive behavior is associated with a variety of deficits in each of the social problem solving steps; however, research suggests that the relationship between social problem solving and aggression may be dependent on whether the aggression is reactive or proactive. Research that has examined subtypes of aggression has found that reactive-aggression is associated with deficits in the earlier steps of social problem solving, including deficits in encoding of cues and increased rate of hostile attributions, whereas children with proactive aggression were not found to have such deficits [4].

Internalizing Disorders

Research on child depression has suggested that depressed children exhibit less effective social problem solving than their non-depressed peers across most steps in the social problem solving process. Studies indicate that depressed children may experience difficulties with correctly encoding relevant information about the problem, exhibit a negative problem orientation, generate fewer solutions and problem responses that are less assertive and irrelevant to the problem, and evaluate ineffective solutions (e.g., withdrawal) more positively than do their non-depressed peers [10].

Social problem solving abilities have been investigated to a lesser extent in anxious children. However, the literature suggests that early fearful and isolative behaviors are significantly associated with less flexible problem solving style and greater use of adult resources rather than using independent strategies [12].

Intervention

Social problem solving has been a primary focus of childhood intervention since D'Zurilla and Goldfried [6] proposed their initial model. The basic problem solving framework has been applied to teach problem solving skills as a means of clinical intervention as well as prevention of future deficits. Although each of the social problem solving interventions is uniquely designed to address the needs of specific groups across distinct developmental stages, a common element among the interventions is explicit teaching of the problem solving steps. Many of the programs use developmentally appropriate teaching strategies that include skill modeling by an adult leader, opportunities for children to role play the newly learned skills, opportunities to practice the skills in vivo, and feedback when skills are implemented.

Prevention Programs

The majority of prevention programs are implemented in the school setting with small groups of children. To enhance efficacy of treatment, parents are typically involved in the programs. The Interpersonal Cognitive Problem Solving Program, Promoting Alternative Thinking Strategies (PATHS), Social Relations Program, and The Coping Power Program prevention treatments are empirically supported and have been shown to result in significant improvements in children's social problem solving abilities following the intervention.

Clinical Interventions

Unlike prevention programs, clinical interventions provide treatment for targeted clinical groups. These interventions have included multimodal approaches, which incorporate problem solving skills training (PSST) as a component of a broader intervention, as well as other more "pure" social problem solving therapies that primarily target deficits in social problem solving skills. PSST and Incredible Years Classroom Social Skills and Problem-Solving Curriculum are two empirically supported intervention programs that rely on social problem solving techniques as a core component. A variety of other interventions have also incorporated components of social problem solving into their treatment approach.

Social Referencing

Matthew J. Hertenstein

Definition

Social referencing refers to the process wherein infants use the affective displays of an adult to regulate their behaviors toward environmental objects, persons, and situations. Social referencing represents one of the major mechanisms by which infants come to understand the world around them.

Description

In the last quarter of the first year, infants become capable of integrating interpersonal communication with objects and situations in the environment. Infants in this period are capable of viewing their parents as teachers and sources of knowledge about the environment; thus, there is true two-person communication about third events, including people and objects in the environment, which yields meaning about the world to the infant [2]. With newly acquired knowledge about environmental events, infants are capable of regulating their behaviors toward people and objects in accordance with the appraisals given them by caregivers.

Social referencing is perhaps the emotional cornerstone of this developmental period because it both broadens and deepens the infant's emotional life [3, 11]. Social referencing refers to the process wherein infants use the affective displays of an adult to regulate their behaviors toward environmental objects, persons, and situations [1]. In one of the most common paradigms used to study social referencing, an ambiguous and novel object is introduced to infants between the ages of 9 and 18 months. Upon the introduction of the object, an adult emotes, via facial and vocal modalities, either a positive or a negative signal to the infant. Of interest is (a) how the child's emotional displays are regulated and (b) how the child's instrumental behaviors, such as reaching, are regulated as a function of the adult's emotional displays. If, for example, a mother displays disgust in relation to a novel object, an infant tends to avoid the object and express negative emotions, but in the context of a happy display from the mother, the infant tends to readily approach the object [2]. Social referencing represents one of the major mechanisms by which infants come to understand the world around them [2].

The most powerful regulatory effects of social referencing were demonstrated using a visual cliff paradigm [8]. In this experiment, the investigators placed the infant on the shallow side of a visual cliff, and the mother stood at the deep side (30 cm) in front of the infant. The mother coaxed the child to the edge of the cliff and when the infant looked up at her, she posed 1 of 5 facial displays (happy, interest, fear, anger, and sad). When 12-month-old infants approached the edge of the cliff and saw their mothers pose a "fear face," none of the 17 infants crossed, and when they saw an "angry face" only 2 infants crossed. In contrast, 14 of the 19 infants in the happy face condition and 11 of the 15 infants in the interest condition crossed the cliff after referencing their mothers. Finally, infants showed mixed responses to their mothers' sad facial displays (6 of the 18 infants in the sad face condition crossed the cliff, the other 12 infants did not).

The findings concerning the regulatory effects of a variety of emotions on infant behavior in social referencing paradigms have been extraordinarily consistent [2, 7]. Four general conclusions emerge from the literature. First, the emotional expressions of others appropriately elicit approach and withdrawal behavior in a variety of settings. Second, vocal expressions alone, and together with the face, regulate infants' behaviors more powerfully than facial expressions alone [6, 7, 10]. Third, negative emotional displays elicit withdrawal from objects more readily than displays of joy elicit approach [3, 6, 9]. Finally, infants regulate their behavior in accordance with emotional displays from either the mother or another adult [4, 5].

In sum, social referencing represents one of the most significant milestones of emotional development in infancy. Many questions remain unanswered, however. For example, how does social referencing develop

over time? What individual differences exist in social referencing? What cognitive and perceptual skills enter into the development of social referencing? Future research holds the key to these questions.

Social Responsibility

Kristy M. Kelso
Western Carolina University, Cullowhee, NC, USA

Synonyms

Citizenship; Public duty; Societal obligation

Definition

An ethical theory in which it is believed that those in need of assistance should be helped, even if the costs outweigh the benefits. The theory also conveys the belief that every individual has the responsibility of acting when a need for help arises, because it is in the best interest of society.

Description

The social responsibility norm is an expectation that if help is needed, it is the responsibility of anyone who sees that need to provide help regardless of potential risks to the person helping. Thus, helping others is seen as a social responsibility, and if properly carried out will ultimately be in the best interest of the society as a whole.

Relevance to Childhood Development

Social responsibility is an idea that is taught to children at a very early age. Whether it is through a religious affiliation, a school, or a club, community service is very much encouraged. Volunteering within the context of community service may instill work ethic and promote a sense of appreciation. Social responsibility taught at a young age could potentially prepare children for greater academic and career opportunities as adults, as universities and employers tend to seek appreciative individuals who are willing to work hard and contribute to the larger community.

Social Skills

Robert Walrath
Rivier College, Nashua, NH, USA

Synonyms

Interpersonal skills; Pragmatics

Definition

A set of verbal and nonverbal behaviors, cognitive and language abilities, and attention that facilitates situation specific, appropriate and reciprocal interaction and communication with others.

Description

Social skills are culturally specific behaviors, learned over time, that are influenced by group membership, environmental factors, social status, and individual characteristics, as well as reinforcement or lack of reinforcement from others. The interactive and reciprocal nature of social skills suggests a developmental learning process to obtain social skills. Social skill difficulties can be skill based (lack of learning of appropriate skills) or performance based (inability to apply previously learned skills appropriately).

Social Skills Training

Tabitha Bond
Scott Center for Autism Treatment, Melbourne, FL, USA

Synonyms

Natural environment training

Definition

Social skills training is comprised of techniques and methods utilized to assist individuals with various social interaction deficits.

Description

Social skills training is an area of behavior modification therapy, utilized by educators and therapists, to strengthen socialization and play skills required to succeed in a social environment. This type of treatment, also known as natural environment training, provides a setting similar to those found in scholastic programs allowing for a higher probability of generalizing skills [1]. Many individuals benefit from social skills training; however, these programs are particularly designed for individuals with attention deficit disorders, autism spectrum disorders, psychiatric conditions and learning disabilities. Within these disabilities, training focuses on deficits in generating and maintaining social relationships with peers [3]. Other deficits include a low level of social interactions, few initiations in conversations or compliments, lack of orientation towards peers, and minimal eye contact [1].

The level of training and types of techniques utilized in social skills programs vary depending on the deficits of the individual and training of the professional. Common similarities between programs involve specializations in social interactions, communication, eye contact, conversation skills, verbal and nonverbal social cues, and conflict resolution skills [3]. These programs are taught within individual or group treatment sessions. Individual social sessions focus on strengthening environmental social skills or skills required to participate in an academic program. Examples include listening, eye contact, and following group instruction. Group social sessions strengthen social interaction skills or skills that generate and maintain conversations and communication. Within these two treatment categories, several methods are utilized to focus on individual skill deficits. School programs, play dates, peer modeling, peer tutoring, sibling training, video feedback, social stories, social songs and social scripts are a few of the many components of social skills treatment [2].

Research studies have indicated social skills training programs to have a positive influence on social interactions and communication in individuals with social deficits [4]. Further studies have indicated that individuals with untreated social deficits may develop depression and a lack of responsiveness to peers. Within adulthood, deficits maintaining intimacy and relationships with individuals develop resulting in loss of friendships, limited employment opportunities, and eventual isolation.

Social Validity

James K. Luiselli[1], Derek D. Reed[2]
[1]The May Institute, Inc., Randolph, MA, USA
[2]University of Kansas, Lawrence, KS, USA

Synonyms

Acceptability; Intervention satisfaction; Subjective assessment

Definition

Social validity refers to the acceptability of and satisfaction with intervention procedures, usually assessed by soliciting opinions from the people who receive and implement them.

Description

Intervention procedures for child behavior are socially valid when people judge them as being acceptable. Typically, social validity assessment is conducted by questioning the recipients of intervention and the individuals responsible for procedural implementation. For example, a child who receives a school-based intervention might be asked about the appropriateness of the procedures that were used by the classroom teacher (e.g., did they make the student "stand out" among other students?). In turn, the teacher might be queried about the complexity of the intervention procedures, time required for implementation, and satisfaction with the outcome. The information gathered from social validity assessment enables professionals to select intervention procedures that will be well received and in consequence, will be applied accurately.

Social validity assessment can be conducted through interviews, surveys, and rating scales. Questions usually are posed with a positive valence such as, "The classroom plan I used with John helped him complete more academic assignments." Respondents reply to such questions by endorsing one of several numerically anchored options: (1) I strongly disagree, (2) I disagree, (3) I have not opinion, (4) I agree, (5) I strongly agree. An average score is derived as a global measure of acceptability and satisfaction.

There are other areas worthy of social validity assessment. For example, the consumers of intervention may be asked to what extent the selected objectives are consistent with community standards (*norm referenced criteria*). Or, experts in a particular area of child development may be requested to comment about the purpose and components of an intervention plan (*expert validation*). Finally, professionals have been advised to correlate the results of social validity assessment with direct measurement of observable behaviors.

Relevance to Childhood Development

Parents, teachers and therapists are frequently given advice about child development. The effectiveness of recommended child rearing practices notwithstanding, it is desirable to know whether the methods suggested by professionals are judged positively by consumers. Procedures with poor acceptability will likely not be adopted. Other procedures may be implemented successfully but judged poorly because they are too difficult to apply consistently. Accordingly, validating the social acceptability of procedures should be an emphasis in the child development literature.

Society for Research in Child Development

Agnieszka K. Serwik
University of Maine, Orono, ME, USA

Definition

The Society for Research in Child Development (SRCD) is an international organization for researchers and practitioners working in the domain of child development. SRCD, as a not-for-profit entity, seeks to support communication and cooperation among professionals across different disciplines to serve the promulgation of research on development and its utilization to address child welfare issues [5]. The organization sponsors a biennial research conference during odd numbered years and publishes several highly regarded journals and a newsletter, including *Child Development, Child Development Perspectives, Monographs of the Society for Research in Child Development,* and *Social Policy Report.*

Description

SRCD was founded in 1933, with Robert S. Woodworth as chairman [3]. It evolved from and later replaced the Committee on Child Development (CCD), which had been founded in 1924 as an offshoot of the National Research Council [4]. Numerous societal factors converged to influence the formation of an organization devoted entirely to research with children. First, the social sciences were now recognized within academics [4] and several notable figures in the field, such as Sigmund Freud, John Watson, Jean Piaget, and Arnold Gesell were proposing theories and completing research that had important implications for child development [2]. Second, during the early 1900s following World War I, public and government attention had shifted to exploring the childhood contributions for why many youth had been disqualified from enlisting in the armed forces due to physical or mental concerns [1]. Finally, during this early period private funding sources and public focus turned to preventative measures to reduce social problems and a new mission to enhance the health and well-being of children [4].

Until the formation of the CCD, the topic of child development was not considered to be a legitimate scientific pursuit across many different disciplines. Thus, the formation of an organization devoted exclusively to research and early recruitment that focused on increasing male membership was one way to prioritize and elevate the study of children into the sphere of science, rather than laypeople's interest [1]. After the formation of CCD, interest in child development grew, as did the membership and productivity of the committee [5]. Despite this successful beginning, the onset of the Great Depression reduced the availability of funding, new child-focused organizations began to compete for recognition, and disagreement occurred within and outside the committee regarding scope and purpose [4]. The founding of SRCD represented a recommitment by CCD members to child development topics, in addition to a new agreement by members that research and application are inseparable [3].

Since its inception, SRCD has grown and changed in membership, productivity, and scope, becoming a premiere multidisciplinary association for the study of children. From an initial group of 125 people [3], the organization now claims a national and international membership of approximately 5,500 professionals who pay its annual dues [5]. Although still committed to the interdisciplinary investigation and application of developmental issues, the composition of SRCD membership has changed drastically. From initial demographics at inception indicating only 25% of members identified as psychologists, current members are overwhelmingly represented from the field of psychology [2]. Within the realm of publication, SRCD at its founding had acquired journals in danger of discontinuation and frequently needed to implore members to submit articles for publication [3]. As of 2002, given the influx of publications, *Child Development* no longer had to ask for articles and instead demonstrated a 75% rejection rate [2]. In addition to furthering these initial goals, SRCD has also expanded its interests to include a focus on diversity in both membership and research population, taken a major role in national policy development on children's issues, and remains a leader in formulating and imposing ethical guidelines for research on a child population [5].

Relevance to Childhood Development

SRCD remains a central source for the sharing of research results for all fields within the scope of child development and the cooperation of the professionals involved. In addition to encouraging research through funding, publications, and conferences, SRCD is concerned with transmitting the newest in research results to inform the public and benefit children around the world.

Sociometric Techniques

Alana M. Burns, Cynthia A. Erdley
University of Maine, Orono, ME, USA

Definition

Sociometric techniques are methods that qualitatively measure aspects of social relationships, such as social acceptance (i.e., how much an individual is liked by peers) and social status (i.e., child's social standing in comparison to peers).

Description

Sociometric techniques have been used since the 1930s, when Moreno proposed that two dimensions of interpersonal relationships (attraction and repulsion) and the perceptions of individuals involved in relationships combined in various ways to determine nine dimensions of interpersonal relationships (e.g., attracted, attractive, rejected, isolated) [10]. Over subsequent decades, statistical techniques became more complex, and there was increasingly recognition of the importance of distinguishing between the low status categories of rejection and neglect. An important advance in sociometric measurement occurred in 1979, when Peery proposed a classification system that included both social preference (i.e., liking) and social impact (i.e., visibility) dimensions [14]. This classification system became a model for the current classification systems employed in the study of children's peer relationships [5]. Currently, the two most common sociometric techniques used within peer relations research are the peer nomination technique and the peer ratings technique.

Peer Nominations

The peer nomination sociometric technique is one method used to determine a child's social status. Commonly, peer nominations are obtained in school classroom settings where children are asked to select from a class roster the three classmates they like the most (positive nominations) and the three classmates they like the least (negative nominations). Although the use of limited nominations has been typical, some researchers allow children to make unlimited peer nominations. For younger children, peer nominations are often obtained by asking children to select from a set of class photographs the classmates they like most and like least [4]. Sociometric categories of social status are determined by the relative number of positive nominations and negative nominations children receive from their peers. Children are classified into one of five sociometric categories of social status: popular (many positive, few negative nominations), rejected (many negative, few positive nominations), neglected (few positive and few negative nominations), controversial (many positive and many negative nominations) and average [7]. Research has shown that sociometric classification systems developed for use with the peer nominations technique have good reliability and validity in classifying children's social status [7, 11, 15].

Another use of peer nomination techniques has been to measure perceived popularity, or the child's level of social visibility within the peer group. Students are typically asked to identify the most popular people in their class; thus, this technique is employed as an index of social reputation, whereas sociometric popularity is an index of likeability. Children who are perceived as popular are not necessarily well liked by the peer group as they are more apt to engage in antisocial behavior than children who are sociometrically popular [6].

Peer nomination techniques have also been used to identify children's friendships. Typically, children are asked to nominate their three best friends. If two children nominate one another, then they are considered friends. In some cases, children are also asked to indicate a very best friend, and if that friendship is reciprocated, then the particular dyad is considered to be very close friends [3].

Peer Ratings

The peer rating sociometric technique is used to determine a child's level of social acceptance. Children are asked to rate an aspect of peer interaction (e.g., how much they like to play with a specific classmate), typically on a 5-point Likert-type scale (e.g., 1 = *not at all*; 5 = *a lot*). For younger children, a 3-point Likert-type scale with

visual aids (e.g., faces ranging from frowns to smiles) is often used, along with photographs of the classmates to be rated [4]. The mean peer rating received is used to determine a child's level of acceptance in the peer group (i.e., low, average, high). To eliminate the possibility of children being inaccurately classified, most rating scales include a "don't know" option for children to choose if they do not know a classmate.

In contrast to peer nomination techniques, peer rating techniques do not allow distinctions to be made among the low status groups (i.e., rejected, neglected, controversial). Nevertheless, peer ratings have high levels of reliability and validity [2]. In fact, peer ratings yield more reliable data than nominations given that each child is rated by all participants [13], whereas peer nominations provide information only on participants who are nominated by their peers. In addition, rating scales are better able than nomination techniques to detect even subtle changes in the level of a child's acceptance by the peer group.

Ethical Issues Related to the Use of Sociometric Techniques

Not surprisingly, some school personnel and parents have raised concerns about the appropriateness of having children report how much they like their peers. Examination of the impact of having children complete sociometric measures has revealed that participation in these tasks does not appear to have negative effects on children [8]. After completing sociometric measures, children do not tend to change their social interaction patterns. Indeed, children tend not to play with peers they dislike either before or after responding to sociometric measures. Furthermore, children's feelings of loneliness do not increase, even among the low-accepted groups, and children generally report that they enjoy completing these measures and sharing their feelings. Of course, it is important to emphasize to children that researchers will keep their responses confidential, and children are strongly encouraged not to discuss their responses with peers. Interestingly, however, girls have been found to be more likely than boys to discuss their responses, though they are much more apt to seek out someone to whom they gave a positive, versus a negative, evaluation. The likelihood of children discussing their responses can be decreased if sociometric measures are administered before other structured activities, such as a math lesson, and not before unstructured time, such as recess. Despite findings that participation in sociometric tasks does not adversely impact children, researchers have investigated alternative techniques that do not involve the use of negative nominations, which seem to be the most controversial. Specifically, data from positive nominations and rating scales have been combined, with low ratings being used as a substitute for negative nominations. This system accurately identifies rejected status children when circumstances do not allow for the use of negative nominations [1].

Relevance to Childhood Development

Sociometric techniques have been important tools for identifying how successful children are within their peer group. A valuable contribution of sociometric measures is that they have enabled researchers to develop profiles of the types of behaviors that are associated with children being liked, disliked, or overlooked by the peer group. For example, prosocial behaviors are correlated with popularity, aggressive and disruptive behaviors are predictive of rejection, and social withdrawal is associated with peer neglect [12]. The use of sociometric techniques has also revealed that the relation of specific behaviors to status sometimes varies as a function of the child's gender, developmental level, or social context. For example, withdrawn behavior is increasingly associated with peer rejection as children get older, and this is especially true for boys. Research using sociometric techniques has indicated that particularly those children who are rejected by peers are at risk for a variety of negative outcomes, including loneliness, depression, delinquency, and academic difficulties [9]. Given the risks associated with rejected status, researchers have focused on trying to improve the acceptance of rejected children as a means to reduce their vulnerability to maladaptive outcomes. Information about how specific behaviors are related to peer status has been important for informing the design of social skills intervention programs. Such programs tend to be based on the premise that rejected children are often deficient in critical social skills, and within these programs children receive coaching on and practice those skills that have been found to be associated with peer acceptance.

Sociometric techniques have been used effectively to identify children who are having difficulties in the peer group and who may benefit from social skills intervention programs. Moreover, these measures are important for assessing the impact of such interventions. It should be noted that peer ratings seem to be more sensitive to detecting changes in peer status following interventions than are nomination techniques. Although post-intervention, a child may still not be nominated among peers' top three choices as a most liked student, a rating scale can reveal whether there have been even subtle improvements in the peer group's liking of that student. Overall, sociometric techniques are useful tools for understanding

children's social relationships, identifying children who may be at risk for later maladjustment, and assessing the effectiveness of social skill interventions.

Sociopathy

Rania D. Hadjicosta, Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Synonyms

Antisocial personality disorder; Dissocial personality disorder; Psychopathy

Definition

Sociopathy is a term used to describe certain personality characteristics including lack or impaired conscientiousness, lack of future orientation, lack of interest in goal-directed activities [15], egocentricity, callousness, impulsivity, exaggerated sexuality, excessive boasting, risk taking, inability to resist temptation, antagonistic and deprecating attitude toward the opposite sex, and lack of interest in interpersonal bonding.

Description

The concept of psychopathy was introduced in the literature by Cleckley around the 1940s [20]. Sociopathy was once considered as a distinct cluster of personality disorders, namely the Sociopathic Personality Disturbances (SPD). SPD was recorded in the first edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-I; 1952) as a cluster of personality disorders encompassing two distinct personality disturbances, antisocial and dyssocial personality reaction and reflected specific types of social deviance [1]. In the second edition of the DSM (DSM-II; 1968), the category of SPD along with the dyssocial reaction component were discarded, though the antisocial reaction component remained, reflecting a distinct personality disturbance. The antisocial component was retained throughout the following editions of the DSM, i.e., DSM-III (1980), DSM-III-R (1987), DSM-IV (1994), and DSM-IV-TR (2000); however, since the 1980s it has been considered as a distinct personality disorder, namely Antisocial Personality Disorder (APD), which fell under the umbrella of Cluster B personality disorders [17].

The concept of Dissocial Personality Disorder (DPD) is currently used by the World Health Organization (WHO) to describe personality disturbances characterized by disregard for social obligations, and callousness. Moreover, within DPD there is gross disparity between behavior and social norms, and the behavior does not

seem to be modifiable by adverse experience or punishment. Individuals diagnosed with DPD show low tolerance to frustration and a low threshold for discharge of aggression, and are characterized by the tendency to blame others and the use of rationalizations to explain behavior that has brought the person into conflict with society (http://www.who.int/classifications/apps/icd/icd10online/?gf60.htm+f60.2).

Since the abandonment of the SPD concept in 1968 and the introduction of APD, little work has been done engaging the concept of sociopathy. Nonetheless, contemporary research and practice uses the terms sociopathy, psychopathy, DPD, and APD interchangeably. However, Lykken [15] argues that even though the most recent editions of the DSM treat the APD as a single entity, experience in the field denotes that APD is a heterogeneous category, constituted by subcategories among which are sociopathies, the major subcategory of antisocial personalities, and psychopathies, which constitutes an officially undocumented subcategory of APD.

Lykken [15] postulates that Sociopathy refers to individuals with normal temperament and in whom antisocial tendencies stem from the individuals' failure to acquire the basic attributes of socialization due to failure of the primary socializing agents, the parents, and especially due to weak parental bonding and control and averse parental example. Furthermore, sociopaths are believed to be involved in more criminal acts compared to psychopaths. On the other hand, antisocial tendencies in psychopathy are believed to stem from biological and temperamental differences, as well as qualitative differences in brain function, which make it difficult to socialize these individuals while they are growing up [9]. Finally, Lykken [15] conceptualizes sociopathy and psychopathy as conditions lying on the opposite ends of the same dimension, with maximized inadequate parenting being located at the sociopathic end and maximized difficult temperament being located at the psychopathic end.

Additionally, even thought psychopathy in general is believed to include features such as remorselessness, callousness, deceitfulness, egocentricity, failure to form close emotional bonds, low anxiety proneness, superficial charm, and externalization of blame, many theorists have argued that psychopaths can differ from one another substantially, both on a behavioral and on a categorical level [20]. Such conceptualizations led to the proposal of two different types of psychopathy, primary and secondary. These two subtypes are distinguished from one another based on anxiety proneness. Primary psychopathy refers to individuals who do not seem to experience anxiety or guilt due to low conscience; while secondary psychopathy refers to individuals with antisocial behavior who experience high levels of anxiety and neuroticism [20].

Nevertheless, neither sociopathy nor psychopathy have ever been clearly defined and are not even included in the contemporary official psychiatric nomenclature [15]. Thus, even though focus in research has been proportionally placed upon psychopathy, the majority of research has been mainly concerned with APD. APD is a chronic condition characterized by a pervasive pattern of disregard for, and violation of, the rights, wishes, or feelings of other people, which begins in childhood or the early teenage years and proceeds into adulthood [2]. This pattern of ignorance for the rights of others might be indicated by three or more of the following features: failure to conform to social norms, regarding lawful behavior, which is indicated in recurrent acts which can lead to arrest; deceitfulness and manipulative behavior, as evidenced in repeated lying, the use of aliases, conning, or malingering with an aim for personal profit or pleasure; impulsivity or failure to plan ahead, decisions taken on the spur of the moment without considerations about the consequences of one's behavior; irritability and aggressiveness, as evidenced by repeated physical fights or assaults, including spousal and child abuse; recklessness regarding one's own and others' safety, as indicated for example in speeding, driving while intoxicated, and substance abuse; irresponsibility, as evidenced in the person's inability to keep consistent work behavior, leading to recurrent job abandonments and prolonged unemployment periods, or the person's inability to meet financial obligations; and lack of remorse, as evidenced in behaviors of indifference or the use of rationalization for hurting or mistreating others. Moreover, for the diagnosis of APD to be applied the person must be at least 18 years old and there must be a history of Conduct Disorder (CD) before the age of 15 [2].

APD affects approximately 3% of males and 1% of females in community samples, whereas in clinical settings prevalence estimates range from 3 to 30%, with higher estimates being reported among substance abuse and prison settings [2]. Additionally, APD is closely associated with features traditionally attributed to psychopathy such as lack of empathy, callousness, cynical behavior, inflated or arrogant self-appraisal, superficial charm, and sexual exploitation [2]. Individuals with APD may also have a history of multiple sexual partners, and are more likely to be irresponsible parents, may fail to be self-supportive, and also have high probabilities of becoming impoverished and homeless, spend many years in penal institutions, or die prematurely by violent means, including suicide, accidents, and homicides [2]. Other associated

symptoms or disorders with APD include dysphoria, inability to tolerate boredom, anxiety disorders, depressive disorders, substance-related disorders, somatization disorder, and pathological gambling or other disorders related to impulse control, as well as features of other personality disorders, especially borderline, histrionic, and narcissistic personality disorders [2]. Finally, even though the condition is chronic, it is possible to become less evident as the person grows older, and especially around the age of 40 [2].

Overall, scientific research indicates that APD constitutes the developmental representation of CD in adult life, however, recent evidence also suggests that sociopathy can be acquired as a result of brain trauma or injury particularly in the right frontal region, including the orbitofrontal cortex (e.g., 8). Nonetheless, individuals with "acquired sociopathy" seem to be differentiated from individuals with developmental APD in that the former exhibit significant impairment in attributing mental states, such as fear, anger, and embarrassment, to others [6].

Relevance to Childhood Development

APD and associated disorders, including sociopathy and psychopathy, seem to be the consequences of CD, a behavioral disorder evident in childhood or early adolescence. CD is among the most common reasons that children and adolescents are referred to mental health professionals, affecting approximately 4–14% depending on age group, gender, and setting [8]. According to the diagnostic criteria of the DSM-IV-TR [2?A3B2 tlsb=-.012w?>] CD is characterized by a repetitive and persistent pattern of behavior by which the basic rights of others are violated or age-appropriate societal norms or rules are disobeyed. This must be manifested by the occurrence of at least three features from four categories of behavior for the past 12 months, and at least one criterion present for the past 6 months. The four categories of behavior include (a) aggression to people and animals, as manifested in bullying, threatening, or intimidating others, initiating physical fights, using a weapon that can cause serious physical harm to others, being physically cruel to people, being physically cruel to animals, stealing while confronting a victim (e.g., mugging, purse snatching, or armed robbery), or forcing someone into sexual activity; (b) destruction of property, as manifested in deliberately engaging in fire setting with the intention to cause serious damage, or deliberately destroying others' property; (c) deceitfulness of theft, evidenced in actions of breaking into someone else's house, building, or car, often lying in order to obtain goods or favors or to avoid obligations, or stealing items of nontrivial value without confronting a victim, such as shoplifting; and (d) serious violation of rules, as indicated by staying out at night despite parental prohibitions before the age of 13, running away from home overnight at least twice, or school truancy before the age of 13. These behaviors must cause clinically significant impairment in social and occupational functioning, and usually be present in a variety of settings, including home, school or the community [2].

Children with CD may be subcategorized on the basis of age of onset of the disorder. CD may have its onset in childhood, if at least one of the above criteria is present before the age of 10, or in adolescence, if none of the criteria are present before the age of 10. Children with childhood-onset CD are also characterized by more aggressive and impulsive behavior, and more cognitive and neurophysiological disturbances [11]. Additionally, childhood-onset CD combined with Attention-Deficit/Hyperactivity Disorder (ADHD), as well as child abuse or neglect, unstable or erratic parenting, and inconsistent parental discipline exacerbate the probability of developing APD in adulthood [2]. Conversely, children with adolescent-onset CD exhibit a severe and impairing pattern of antisocial behavior, which is particularly related to the process of individuation and independence and includes behaviors such as rejection of status hierarchies and religious rules [11].

In addition to the childhood versus adolescent onset classification, Frick et al. [10] classified CD subgroups in terms of the presence of callous-unemotional (CU) traits (e.g., lack of guilt, lack of empathy), an approach which is analogous to adult conceptualizations of psychopathy. The logic behind this classification system derives from studies revealing distinct correlates for the subsets of CD children who also show high levels of CU traits (*CD-high-CU*) compared to those who do not (*CD-low-CU*). *CD-high-CU* children, who are primarily characterized by proactive forms of aggression [16], have shown substantial evidence of deficits in emotion processing such as decreased orienting to affective stimuli [14], low fearful inhibition [12], reduced affective perspective-taking (not underlined by deficits in affective perspective-taking) [3], and reduced vicarious affective responsiveness [4] underlined by underactivity in the sympathetic autonomic nervous system [18]. All these findings may be suggestive of affective-specific deficits in *CD-high-CU* children. In *CD-low-CU* children, on the other hand, reactive rather than proactive patterns of aggression have been reported and their lack of impulse control has been related to a diverse set of interacting causal factors such as social information processing deficits, dysfunctional family background and verbal intelligence deficits [10].

Regarding the developmental course of CD, it is noteworthy that not all children with CD will develop APD in adulthood. Even though CD in childhood and adolescence is a strong predictor of antisocial behavior in adulthood, with studies indicating that children with high instances of antisocial behaviors have a 43% chance of meeting criteria for APD in adulthood and estimates being higher in institutionalized populations, not all youth with CD engage in antisocial acts in adulthood. Having a parent with APD seems to be a strong predictor of persistence of conduct difficulties from childhood into adolescence, and then into adulthood [21]. However, further research on the persistence of CD into adulthood indicated that persistence can be predicted mainly by genetic influences [7], as well as cognitive functioning and biological and social factors, and specific personality traits such as CU traits.

Etiology

Research has identified five clusters of environmental risk factors that can potentially lead to the development of CD in childhood and APD in adulthood. The clusters encompass (a) child, (b) family, (c) school, (d) peer, and (e) neighborhood factors [22]. Child factors include birth complications, difficult child temperament, impulsivity, substance use, aggression, early-onset disruptive behavior, and low intelligence. Family factors include parental antisocial and delinquent behavior, parental substance abuse, poor child-rearing practices, such as poor supervision [2, 22], physical punishment or inconsiderate discipline [2], poor communication [22], parental rejection and neglect [2], parental physical or sexual abuse, maternal depression, maternal smoking during pregnancy [2, 22], maternal malnutrition [5], single parenthood [22], large family size [2, 22], low socioeconomic status, unemployment, and poor education and familial history of APD, Substance Dependence or Abuse, and ADHD [2]. School factors include poor academic performance, low educational aspiration, and low school motivation [22]. Peer factors include peer rejection and being associated with deviant and delinquent peers [2, 22]. Finally, neighborhood factors include living in a disadvantaged, poor, or disorganized neighborhood and having easy access to weapons [2, 22].

Additionally, it is well documented that CD and APD are highly influenced by several neurophysiological and genetic factors. Neurophysiological models suggest the involvement of the Behavioral Inhibition System (BIS) and the Behavioral Activation System (BAS) proposed by Gray, in that the BIS, which is related to fear and anxiety and inhibits action in novel situations or in situations where punishment is involved, in children with CD appears to be underactive, whereas the BAS, which is related to reward-seeking and pleasurable behaviors, is overactive [22]. Moreover, other neurophysiological models refer to defects in the fight/flight (F/F) system, which is involved in defensive reactions in situations of frustration, punishment and pain, in that children with CD seem to have a reduced threshold for F/F [22].

Neurophysiological models also suggest that individuals with CD and APD demonstrate specific brain anomalies, especially in the prefrontal cortex, as well as neurotransmitter and hormonal defects, and particularly diminished noradrenalin, serotonin, and cortisol levels combined with excessive levels of testosterone [8].

From the genetic perspective, twin and adoption studies have revealed that there is high heritability among specific components of antisocial behavior, such as difficult temperament, sensitivity to alcohol, irritability, impulsivity, sensation seeking [5, 22], as well as risk-taking and CU traits [5]. In addition, specific genes related to aspects of antisocial behavior have been identified. These are predominantly specific 5-HT serotonergic genes, such as the HTR1B, the HTR2A, the HTR1DA, and the TDO2, and it is indicated that low levels of serotonin increase impulsivity and inhibit sensible behavior, thus increasing the likelihood for risky and antisocial behavior, such as drug abuse and gambling, and they are also associated with aggressive and violent behavior [5]. Moreover, the DRD2 dopamine receptor gene has been positively linked to impulsive, compulsive and addictive behavior [5].

Generally, twin and adoption studies have indicated that CD is significantly heritable, with estimates ranging from 27 to 78%. However, growing evidence suggests that both genetic and environmental influences, and particularly their interactions, are of utmost importance in our effort to explain individual differences in antisocial behavior, including differences in criminal behavior [5].

Management

The nature of antisocial behavior disorders, including sociopathy, psychopathy, APD, and CD, makes them particularly problematic for society [21] and understanding their origins is a crucial task for social scientists. To date, researchers have produced substantial evidence that the pathway to these disorders begins in childhood, with conduct problems, attention difficulties, high rates of aggressive behavior, and a persistent pattern of deviant and often illegal activity [7] that cause significant intra and interpersonal dysfunction across the lifespan. Thus reliable empirical identification of the variants of antisocial behavior shall improve our understanding of related disorders and enhance management and treatment efforts [20].

With respect to treatment, empirically supported interventions for children include psychoeducation, antisocial and pro-social behavior monitoring, behavioral parent training, family-based communication and problem-solving training, home-school liaison meetings and remedial tuition, child-based social problem solving skills training, parent counseling for managing personal and marital difficulties, treatment foster home placement when the family is extremely disorganized [8], contingency management, cognitive-behavioral intervention targeting social cognition deficits [13], community-based programs [22], and finally stimulant medication [13]. Research on effective interventions for adult populations indicated that psychodrama and personal construct therapy are potentially effective. A meta-analytic study, conducted by Salekin [19], indicated that psychoanalytic therapy has a success rate of 59%, cognitive-behavioral therapies have a success rate of 62%, whereas combined therapies have a success rate as high as 86%, suggesting that augmenting cognitive-behavioral with other psychotherapeutic techniques may be optimal for individuals with antisocial personality problems. Moreover, effectiveness, in this study, was also dependent on durations, with interventions lasting for more than 6 months being more effective than those which lasted for less than 6 months, and with intervention lasting for a year or longer having a success rates as high as 91% [19].

Somatic Sensory Cortex

Chad A. Noggle
SIU School of Medicine, Springfield, IL, USA

Synonyms

Postcentral gyrus; Primary somatosensory cortex

Definition

The somatic sensory cortex, also referred to as the primary somatosensory cortex, is localized to the postcentral gyrus of the parietal lobes, just posterior of the central sulcus, and is vested with the job of processing information being transmitted from the periphery.

Description

The somatic sensory cortex is more commonly referred to as the primary somatosensory cortex. Neuroanatomically, the primary somatosensory cortex is localized to the postcentral gyrus of the anterior portion of the parietal lobes. The essential function of the primary somatosensory cortex is processing peripheral sensation of the contralateral side [2]. Specifically, stimulation of sensory receptors, whether it be in the skin, joints, muscles and/or viscera on the right side of the body, will be processed by the primary somatosensory cortex in the left hemisphere. Vice versa, sensation on the left side of the body will be processed by the primary somatosensory cortex in the right hemisphere [1]. Beyond this basic contralateral organization, the somatosensory cortex and linked sensory pathways are topographically organized. This is to suggest that adjacent areas on the receptive surface are mapped to adjacent fibers in white matter pathways and to adjacent regions of the cortex [2]. Specifically, the adjacent representation of the foot to the leg, the tongue to the face, and/or the hand to the face peripherally is also found on the somatosensory cortex. Somatotopic representations of this arrangement commonly referred to as the sensory homunculus can be found throughout the literature. Essentially, beginning at the most superior point of the postcentral gyrus, that point at which it curves down into the longitudinal fissure, sensation from the genitals is processed. Next, by working inferiorly (i.e., up out of the longitudinal fissure and then down the side of the postcentral gyrus), comes the sensation processing points for the toes, feet, then legs, thighs, torso, neck, head, shoulders, arms, hands and fingers, face, teeth, tongue, pharynx and then abdomen [3, 4]. The site at which sensation from the tongue is processed sits on the cuff that is the sylvian fissure, which separates the parietal and temporal lobes.

In addition to the primary cortex there are secondary and tertiary somatosensory areas [5]. These regions lie posterior and/or inferior to the primary somatosensory cortex and serve as association points in which various incoming information may be integrated. In addition to it working in concert with secondary and tertiary zones, the primary somatosensory cortex is directly linked with motor areas of the brain in order to provide a reciprocal line of communication between one another such that feedback from the somatosensory system may be integrated into motoric processes thereby refining those actions [6].

Synonyms

Somatosensory system

Definition

The somatosensory area refers to the neuroanatomical region at which the various aspects of the somatosensory system converge.

Description

The somatosensory area may be perceived as a general term for the primary regions of the brain that act as a convergence point of the entire somatosensory system. While some may use somatosensory area interchangeably with primary somatosensory cortex, the latter is likely one aspect of the former. From a holistic perspective, the somatosensory area encompasses the postcentral gyrus, which houses the primary somatosensory cortex, as well as adjacent areas of the parietal lobes [4]. These regions receive neuronal input from specific nuclei of the thalamus that correspond with the handling of sensation along the lines of touch, pain, temperature and limb position [4]. This includes the ventral posterior lateral nucleus as well as the ventral posteromedial nucleus [2]. Somatosensory information is transmitted to these nuclei from the spinal cord and specific cranial nerves which then transmit this information on to the somatosensory area. Given their role in this process, both the ventral posterior lateral nucleus as well as the ventral posteromedial nucleus represent relay nuclei in which they receive inputs from various pathways and then project that information onto other areas of the cortex, in this case the somatosensory area [2]. By the time somatosensory information reaches the thalamic nuclei it has already passed through the pyramidal decussation within the medulla. This leads to the contralateral organization of the somatosensory areas. Specifically, somatosensory stimulation on right side of the body will be processed by the somatosensory areas in the left hemisphere whereas sensation on the left side of the body will be processed by the somatosensory areas in the right hemisphere [1]. Initial processes of the somatosensory area take place in the primary somatosensory cortex. The precise locality at which information is processed corresponds with the local area from which the stimulation originates. The somatosensory cortex and linked sensory pathways are topographically organized such that adjacent structures of the body correspond with adjacent structures on the primary somatosensory cortex [2]. Following this arrangement, somatosensory information originating at the genitals is processed at the most superior point of the postcentral gyrus; that point at which it curves down into the longitudinal fissure. Next, by working inferiorly (i.e., up out of the longitudinal fissure and then down the side of the postcentral gyrus), comes the sensation points for the toes, feet, then legs, thighs, torso, neck, head, shoulders, arms, hands and fingers, face, teeth, tongue, pharynx and then abdomen [3, 4]. Once this information is initially processed by the primary somatosensory cortex it is then transmitted on to the secondary and tertiary somatosensory areas as well as the motor areas of the frontal lobes [5]. It is at the point of the secondary and tertiary areas that somatosensory information is integrated with other sensory input and/or associated with various cognitive actions/processes. In terms of somatosensory areas transmitting information to the motor areas, this is done continuously, as refinement and coordination of the latter is largely dependent upon reciprocal feedback from the former [6].

Sotos Syndrome

Eric E. Pierson
Ball State University, Muncie, IN, USA

Synonyms

Cerebral giganticism; Nonverbal learning disability (NLD)

Definition

Sotos syndrome is a rare genetic disorder characterized by early rapid bone growth that has an unknown rate of prevalence that is typically diagnosed in early childhood. A high percentage of children and adolescents with Sotos syndrome exhibit global cognitive difficulties and borderline levels of cognitive functioning.

Description

Sotos syndrome is a rare genetic disorder with an unknown rate of prevalence. Estimates for its rate of prevalence within pediatric neurology referrals suggest that it occurs in 17% of persons referred with macrocephaly [5]. The syndrome was initially described in the early 1960s and was also known as cerebral giganticism. The initial descriptions focused on two main characteristics, early rapid bone growth and global cognitive impairments. In addition, it was observed that children with Sotos syndrome appeared to have similar facial features. Many, but not all, cases of Sotos syndrome can be linked to the NSD1 gene mutation.

While current literature appears to indicate that cognitive functioning for children with Sotos syndrome may not fall in the range of mental retardation, recent investigations do suggest that individuals with Sotos syndrome, on average, perform in the borderline range on standardized measures of cognitive functioning [1]. Borderline cognitive functioning falls in the range of 71–85 inclusive. Evidence that individuals with Sotos Syndrome have lower than average cognitive abilities is consistent with early descriptions of the presentation of the syndrome [2]. The view that all or most individuals with Sotos Syndrome have lower cognitive functioning has been challenged by several authors over the past 20 years, with Sarimski [4] and Rutter and Cole [3] being examples.

Because of the low prevalence rate of the disorder, much of the literature surrounding it is comprised of case studies and meta-analyses. As a result, there have been case study reports of psychosis and other psychiatric disorders that may be isolated incidents within a small pool of cases. Studies with larger samples do provide some evidence that children with Sotos syndrome may be more likely to exhibit symptoms of anxiety than other children with mild to moderate cognitive impairments [4].

Physically, individuals with Sotos syndrome may present with hand and skull growth that is above the 90th percentile prior to age 3. These individuals may have distinctive angular facial features as well. As individuals with Sotos syndrome enter older childhood and adolescence, height, hand, and skull growth slows causing the individual to have a less atypical appearance. Individuals with Sotos syndrome may retain the angular facial features that were present in early childhood.

Individuals with Sotos syndrome are often referred to neuropsychologists and related specialists because of concerns related to developmental delays, behavioral problems, and possible psychiatric concerns. Individuals with Sotos syndrome may exhibit difficulties in general cognitive ability, executive functioning, and specific fears. Individuals with limited cognitive abilities may have greater difficulty in using adaptive strategies for managing stressful events associated with specific phobias. As a result, those working with individuals with Sotos syndrome may have to develop strategies that allow for individuals to escape particularly stressful or anxiety invoking situations.

Interventions for individuals with Sotos syndrome need to focus on the following domains: academic, emotional, and when warranted, adaptive functioning. As a result of the variation in cognitive functioning in individuals with Sotos syndrome, evaluations of cognitive functioning, possible anxiety symptoms and its triggers, adaptive functioning, and academic skills are necessary.

Spanking

Tonya S. Watson, Steuart T. Watson
Miami University (OH), Oxford, OH, USA

Synonyms

Corporal (physical) punishment; Paddling; Smacking; Whipping

Definition

Spanking is a form of corporal punishment that usually refers to striking the buttocks with one's hand or other object (e.g., a wooden paddle, a switch, or ruler).

Description

Spanking as a form of discipline has likely been around for thousands of years. Currently, spanking by parents is illegal in 24 countries. In the United States, spanking by parents is permitted as long as excessive force is not used and it is not abusive in nature. Although some states prohibit spanking in schools, many states still allow corporal punishment by educators. It is estimated that as many as 1.5 million spankings occur each year in schools. Most professional organizations and international health organizations discourage spanking as a form of discipline and recommend less physical means of changing behavior.

Relevance for Childhood Development

Many American parents spank their children. They do so, primarily, because their children behave aggressively or fail to comply with their directions or commands. It is estimated that about 63% of parents spank their 1–2 year olds and 85% of adolescents have been spanked because of their behavior. Although infrequent, mild, controlled spankings are unlikely to have any lasting negative effects, children who are exposed to repeated, harsh spankings may experience many negative side effects. Some of these include increased aggression, decreased quality of the parent–child relationship, anger/ hostility toward the spanker, and an increased risk of abusing their own children or their spouse. Perhaps more troubling is that mothers who spank their children are three times more likely to engage in abusive behaviors including beating, kicking, hitting, burning, or shaking a child less than 2 years old. The likelihood of abuse increases as the frequency of spanking increases.

There is no question that spanking is effective for producing short-term compliance in children. That is, immediately following a spanking, children are much more likely to be compliant. However, spanking does not teach a new behavior (that is, what the child should be doing instead of the inappropriate behavior) nor does it produce long-term benefits. Also, spanking is not an intervention that one could use, or should even want to use, on more than an infrequent basis. There are other child behavior management techniques that are equally or more effective (e.g., time-out, response cost, overcorrection) that do not involve a physical punishment component. If parents insist upon spanking as a disciplinary technique, they should be encouraged to use the controlled spanking procedure that involves an open hand on the buttocks, leaving no marks or bruises, as a back-up technique for non-physical disciplinary measures, and used in conjunction with reasoning and within a loving family atmosphere.

Spatial Ability

►Spatial Intelligence

Spatial Intelligence

Jason Levi
Psychologist, Winston Salem, NC, USA

Synonyms

Gardner's theory of multiple intelligences; Spatial ability; Spatial reasoning; Visual-spatial reasoning

Definition

Spatial Intelligence is the capacity to envision, reason with, and recall nonverbal, symbolic information.

Description

Spatial intelligence involves the use of reasoning and memory skills with nonverbal, symbolic information. It has also been long thought of as an important component of general intelligence. Howard Gardner's popular theory of multiple intelligences defines it as the ability to perceive the visual-spatial world [3]. Others have further broken down spatial intelligence as comprising subcategories which typically include spatial perception, mental rotation, spatial visualization, and object location [2, 4].

As Linn and Peterson described in their meta-analysis, spatial perception involves examining spatial relationships in relation to their own orientation, such as having to place a rod vertically while looking through a tilted or rotated frame [4]. Mental rotation involves mentally rotating two and three dimensional objects, such as determining whether an object is identical to a rotated reference object. Spatial visualization involves the use of both spatial perception and mental rotation to solve more complicated mental manipulations where more than one solution may be possible, such as paper folding and block design tasks. Object location requires recall of object positions documented. As of yet, however, a well agreed upon categorization of spatial abilities does not exist [2], but most researchers do tend to agree that there is more than just one type of spatial ability [1].

There has also been debate over the existence and emergence of sex differences found on measures of spatial intelligence. The pendulum has, over the years, swung back and forth on whether observed sex differences are due to environmental factors, such as test development and stereotypes [1, 6], or to biological factors, such as neurophysiology and evolution [2]. Research has generally documented differences favoring males, with the most robust evidence on mental rotation tasks [4], while differences favoring females have been typically found on object location tasks. Men have also been found to rate their spatial abilities higher than women [5].

Relevance to Childhood Development

Researchers have also studied spatial intelligence in children. Over the years, researchers have debated about the emergence of the male advantage, with some contending for adolescence and others arguing for an earlier emergence [4]. Regardless, spatial abilities develop when children are given opportunities to manipulate and explore objects. It is reasonable to suggest that differential spatial abilities could be due to differential opportunities to explore the environment. Teachers are taught principles in differential teaching strategies that recognize that no student is alike in that some may have more developed skills (e.g., spatial intelligence) than others. Therefore, it is reasonable to suggest that children found to have less developed spatial skills should be given more opportunities to develop these skills.

Special Education

Christopher M. Oliva
City University of New York, Flushing, NY, USA

Synonyms

Exceptional education; Individualized education; Individuals with disabilities education act (IDEA); Special services

Definition

All children are entitled to an education. Children with disabilities, however, require special or extra adaptations and services to enable them to benefit from their educational program. According to the Individuals with Disabilities Education Improvement Act of 2004 (IDEIA), special education means specifically designed instruction, at no cost to the parents, to meet the unique needs of a child with a disability.

Special education services are the direct instructional activities or special learning experiences designed primarily for students identified as having exceptionalities in one or more aspects of their development, or as being underachievers in relation to their overall abilities. Categories of disability include: mental retardation, specific learning disabilities, serious emotional disturbances, speech or language impairments, vision loss, hearing loss, orthopedic impairments, other health impairments, deafness-blindness, multiple disabilities, autism, and traumatic brain injury. Programs for the gifted and talented are also included in some special education programs.

Description

The provision of special education services has a long and somewhat litigious history. Gaining power from the equal rights obtained in Brown vs. Board of Education (1954), special education enacted the Education for All Handicapped Children Act (Public Law 94–142) in 1975. PL 94–142 was the first Federal law to hold states responsible for educating school-age children with disabilities just as they had for children not labeled with a disability. Today, the Individuals with Disabilities Education Improvement Act of 2004 (IDEIA, also referred to as IDEA), which updated the Individuals with Disabilities Education Act (IDEA) of 1997, describes six principles that engender the framework of educational practices that are used to enable children with disabilities to learn. Without the procedural framework set out by law, the needs of many children with disabilities would likely not be met. These principles are: zero exclusion, nondiscriminatory evaluation, appropriate education, least restrictive environment (LRE), parent and student participation, and procedural due process.

Zero Exclusion

This principle requires a free appropriate public education to *all* children, regardless of type or level of disability. No child may be excluded from an education provided at the local educational agency's (LEA) expense. Zero exclusion acknowledges that all children are able to learn and benefit from an education, and therefore the public school system must educate them by meeting their unique needs and help prepare them for a meaningful and integrated life in the community.

Nondiscriminatory Evaluation

The nondiscriminatory evaluation (NDE) process is an essential starting point for planning an educational program for a child with a disability. The intent of NDE is twofold: to assess if a child has a disability, and then to identify the types of special education and related services the child should receive. NDE requires that the assessments, tests, and other measures of academic and developmental functioning must be objective and free from cultural and/or ethnic bias. IDEA also requires that assessment instruments be used for the purpose for which they were validated (e.g., an IQ test is not appropriate for curriculum planning), that a multidisciplinary assessment team considers information from multiple sources, and that assessments must be administered in the child's primary or native language.

The criteria for receiving special education and related services are twofold. First, the child must have a disability that is included in IDEA. Secondly, the child's disability must sufficiently interfere with learning so there is a need for special education and related services. These two factors make a child eligible for classification. Some children with disabilities who do not meet special education eligibility criteria can be supported through another federal program, Section 504 or the Americans with Disabilities Act, which provides for reasonable accommodation to enable them to access their education.

Appropriate Education

IDEA 2004 provides for a *free and appropriate public education* for each child classified as in need of special education and related services. It is free because it is provided at no cost to the parents and it is considered appropriate because it meets the individual needs of the child. Once a child aged 3–21 is classified as in need of special education and related services, a team of

professionals appropriate to that child's specific learning needs convenes to develop a written individualized educational program (IEP). For children birth to 2 years old, the plan is called an Individualized Family Service Plan (IFSP). Each individualized program is developed by professionals and the child's parents. The overall purpose of the plan is to design and deliver an IEP from which the child will benefit in accordance with IDEA.

Minimally, the child's IEP team must consist of a special education teacher, a general education teacher (if the child is participating or may be participating in the general education program), and a representative of the LEA who is knowledgeable about both the special needs of children with disabilities and about the general curriculum of the district. Additionally, the IEP team must include a professional who is qualified to interpret the results of the NDE. The IEP document provides for consistency in service delivery for the school district and a communication vehicle between parents and school personnel. The IEP must include: (a) present levels of educational performance; (b) measurable annual goals, including short-term objectives; (c) the special educational and related services and supplementary aids and services that will be provided to the student, and the program modifications or supports for school personnel that will be provided so that the student can make progress toward their annual goals, participate in the general curriculum and non-academic activities of the school, and be educated and participate with other students who do not have disabilities; (d) the extent, if any, to which the student will not participate with students who do not have a disabilities in general education and other non-academic activities; (e) any individual modifications in the administration of state-or district-wide assessments of student achievement so that the student can participate in those assessments, or if the IEP team determines that the student not participate why that decision was made and how the student will be assessed; (f) the projected date of beginning the services and program modifications and the anticipated frequency, location, an duration of each; (g) transition planning beginning at age 14; and (h) how the student's progress toward their annual goals will be measured and how the student's parents will be informed of progress toward annual goals, and the extent to which the student progress is sufficient to achieve the annual goals by the end of the school year.

According to IDEA, related services include, but are not limited to areas such as: transportation, speech-language pathology and audiology services, psychological services, physical and occupational therapy, recreation, social work services, counseling services, rehabilitation counseling, orientation and mobility services, and medical services (for the purpose of diagnosis and evaluation for special education).

Least Restrictive Environment

IDEA 2004 provides that children with special needs be educated to the maximum extent appropriate with children who do not have disabilities and that the removal of children with disabilities from the regular education environment occurs only when the nature or severity of the disability is such that education in regular classes, with the use of supplementary aids and services cannot be achieved satisfactorily. This component of IDEA is called the least restrictive environment (LRE). A continuum of placements is available, including: (a) general education classroom, (b) general education classroom with a special education teacher as a consultant to the general education teacher, (c) general education placement with resource room for specialized instruction, (d) special education class placement with some general education classes, (e) full-time special education class within a general education school, (f) separate special education school placement, and (g) home or hospital-school setting. The further away from a general education environment, the more restrictive the placement. The LRE appropriate for each child is determined by the IEP team which includes the child's parents. However, it is important to note that IDEA has a presumption in favor of inclusion. Thus, an LEA is supposed to provide for all the necessary adaptations, supplementary aids and supports, for the child in the LRE before a determination is made that a change in placement to a more restrictive setting is needed.

IDEA also provides for infants and toddlers (birth – 2) to receive services in *natural environments;* that is settings where children without disabilities are educated. These natural environments could include the infant or toddler's home, full-or part-time placement in public or private general pre-schools, or in special needs private schools.

Parent and Student Participation

The intent of IDEA is to have parents involved in all aspects of their child's education, especially regarding evaluation, IEP development and IEP team meetings. Parent participation is critical in the development of an appropriate education. Essentially, any time a decision is made that affects the free and appropriate education of their child, a parent must be notified and have the right to participate in decision-making. They have the right to see their child's evaluations and records, and school district general records about special education. Parent participation is also facilitated at the state level; for example,

parents are entitled to participate in statewide special education planning processes, must make up a majority of the membership of the statewide council on special education, and have the right to see the state's special education plan and receive public notice of hearings on the plan. Further, students themselves have a right to be members of their IEP team and are encouraged to do so, regardless of the level of their disabilities. Preparing students for meaningful participation on their IEP team can make students ready for constructive participation as adults in their community.

Procedural Due Process

IDEA provides a system of accountability and safeguards that must be followed to insure that a student with special needs receives a free and appropriate education; this system is called procedural due process. Parents have the right to be informed about possible changes in their child's free and appropriate public education including IEP, placement, and to consent or withhold consent from actions the school district wishes to take regarding their child. Parents must receive written notice of their due process rights at the initial referral of their child for evaluation, and upon notification of meetings regarding their child. Importantly, parents must also receive written notice of their right to file a complaint about the LEA's violation of their child's rights. All notices must be in a communication medium the parents understand. IDEA entitles parents to mediation services to resolve issues with the LEA and they have the right to a due process hearing before an impartial person. The losing party has the right to appeal to higher authorities.

Special Education Needs

►Special Needs

Special Needs

Jacqueline P. Parsons
St. Mary's University, San Antonio, TX, USA

Synonyms

Disability; Special education needs

Definition

The term "special needs" is an umbrella term referring to a variety of developmental disabilities. Special needs can include learning disabilities, visual impairment, hearing impairment, cerebral palsy, ADHD, physical limitations, asthma, Asperger's Syndrome, and Autism. Although the term includes gifted academic ability, people often limit the discussion to what the individual cannot do. In general, the term "special needs" is applied when a person needs services not usually provided to all citizens. For example, most school children are not provided physical therapy in the school. Therefore a child who does receive PT at school may be considered a special needs child.

Description

Government Programs

Most societies create mechanisms to help persons with special needs. There is a wide variation based on culture, economics, and type of government. These factors also determine the mix between government and non-government programs. In the US, there are numerous government organizations (GOs) which provide money and services to persons with special needs. Financial support is provided for persons with special needs by the social security administration (SSA). The SSA determines whether a person fits their definition of "disabled," and if so, provides financial assistance.

Health care is often provided by Medicare, which uses the same definition of "disabled." It is administered by the Centers for Medicare and Medicaid Services (CMS), a branch of the federal government. Another program which uses disability as a criterion is Medicaid. Medicaid is centrally overseen by the CMS, but administered and partially funded by the states. Medicaid coverage is primarily driven by income level. Because many disabled individuals have low incomes, they may qualify for Medicaid. Many states also have vocational and job facilitation programs, although there is a wide variation from state to state.

The two largest health care entities in the US fall under the Veterans Administration (VA) and Department of Defense (DoD). The VA provides healthcare as well as income to many disabled veterans. The VA uses different criteria for evaluating special needs, assessing percentages for various conditions. They also grant care only for conditions which arose during military service.

The DoD provides healthcare to active duty military, their families, and military retirees. Obviously the disabled veteran population and the military retiree population overlap. Special needs situations can arise in any segment of the military population. Military families can have special needs spouses and children, and the military has the Extended Care Health Option, a program which pays for special health care needs, as well as providing integrated services like case management.

Services for persons with special needs may also be provided by local government entities. Many US cities have special transportation services adult and child day care services, and meal programs.

Non-Governmental Programs

Persons with special needs can benefit from the efforts of non-governmental organizations (NGOs) which operate at many levels. International organizations such as the Gates Foundation, Lions Clubs, Rotary International, and numerous church groups can provide micro-level services to individuals and communities, or they may provide macro-level functions, such as funding medical research. There is a complex web of relationships between NGOs, other NGOs, and GOs, as they transfer money in the form of grants, and exchange information. In many cases NGOs are regulated by GOs through statute.

NGOs may also function at the national level. A good example of this is the March of Dimes, which focuses on the health of babies in the United States. Like the international NGOs, the March of Dimes performs research, provides services, educates, and advocates.

State and local-level NGOs also perform important functions. They may offer financial assistance, volunteer services such as babysitting, and educational and outreach services.

It can be difficult for a special needs family to negotiate the complex web of services and financial aid offered by this myriad of organizations. Regardless of whether the helping organization is governmental or non-governmental, or at what level it functions, a key component is informing and educating special needs families so they can best avail themselves of the services available.

Speech Therapy

Linda R. Sealey
Oklahoma State University, Stillwater, OK, USA

Synonyms

Articulation voice, or fluency therapy; Speech–language therapy

Definition

Speech therapy is the treatment of an individual for a disorder in one of three speech domains: articulation, voice, or fluency. Treatment is typically provided by a speech–language pathologist (SLP), often known as a speech therapist. Speech–language pathologists hold a master's degree and have advanced education in human communication, state license or certification, and are nationally certified by the American Speech-Language-Hearing Association (ASHA).

Description

Speech therapy is the treatment of an individual for remediation of a diagnosed speech disorder. After an in-depth diagnostic assessment has determined the presence of a speech disorder or delay, treatment is prescribed on an individual basis. Speech, a verbal means of communicating, includes articulation and phonology (the production and meaning basis of speech sounds), voice (the use and quality of the vocal folds, nasal resonance, and respiratory support) and fluency (the flow and rhythm of speech). A speech disorder may include a delay in development or disorder in any of these three areas to the point that a listener cannot understand, is distracted from what is said, or speech is painful or embarrassing to the speaker. Speech disorders are most commonly associated with articulation or phonological disorders. Articulation disorders are associated with a deficit in motor production aspects of speech. Phonological disorders are concerned with a deficit in producing appropriate speech sounds in context to demonstrate understanding and use of the phonological rules of a language. Voice disorders are associated with abnormal voicing during speech characterized by harsh, breathy, strained vocal quality, or lack of voice, nasality/resonance, or volume or pitch disturbances. These disturbances are often the result of misuse, abuse, overuse, or pathology of the vocal folds but may also be psychogenic in nature. Fluency disorders are typified by a disruption in the flow and rhythm of speech characterized by excessive production of repetitions, blocks, or prolongations and disturbances in the speed or rate of speech. Speech therapy is prescribed or sought for the remediation of these deficits in articulation, voice, and/or fluency [1].

Speech therapy is usually provided by a certified speech–language pathologist, and is typically guided by treatment goals determined during the diagnostic assessment and in conference with invested parties, such as the family, teachers, physicians, and client. Therapy is provided either in individual sessions, in which the client works one-on-one with the speech–language pathologist to address treatment goals, or in groups, wherein a number of clients attend joint treatment sessions to address treatment goals. To address treatment goals, a treatment approach or program is employed. Treatment approaches are built on theoretical paradigms and developmental, physiological, or normative data. The selection of a treatment program or treatment principles should be based on empirical evidence of effective treatment in clients with similar deficits and characteristics. Speech therapy generally includes the step-wise remediation of specific deficit skill-sets using behavioral treatment techniques. Therapy techniques may make use of mirrors, recordings, video feedback, self-evaluation, diaries, games, toys, pictures, tongue blades, and other materials or biofeedback [2].

Speech therapy is often needed in populations that present with hearing impairments, developmental delays, cleft palate or lip, oral muscle insufficiency, autism, traumatic brain injury, and respiration and motor planning deficits. Speech therapy may also be warranted in otherwise typically developing children who present with a delay or disorder in the development of speech, voice, and/or fluency skills. Young children who have difficulty being understood may experience frustration and withdraw from communicating. Early assessment and intervention by a speech–language pathologist will help to alleviate frustrations for both the speaker and the listener. In general, the earlier one begins therapy after the diagnosis or insult that propagated the disorder, the better the prognosis of correcting and mitigating effects of the deficit [3].

Language therapy differs from speech therapy although deficits in both language and speech may coexist and be treated simultaneously, concurrently, cyclically, or blended together in a therapy session [4].

Spelling Disabilities

Alpana Bhattacharya
The City University of New York, Flushing, NY, USA

Synonyms

Agraphia; Anorthography; Dysgraphia; Learning disability; Logagraphia

Definition

A neurologically-based impairment that affects an individual's knowledge of and memory for spoken and written language structure.

Concept of Spelling Disability

Individuals with spelling disability generally have difficulty analyzing and remembering sounds of the letters (e.g., j, v, s), syllables (e.g., pos, com, mem) and meaningful parts such as prefixes, roots, suffixes, and grammatical endings (e.g., pect, able, trans) of words in both spoken language and written language. Individuals with spelling disability have trouble remembering letters in words because they have trouble noticing, remembering, and recalling the features of language that those letters represent. Spelling disability is also identified as orthographic memory problem because of an individual's difficulty with memory for letters in written language [10].

Phases of Spelling Development

Since children's knowledge of the English spelling system follows a progressive pathway, spanning from novice to expert applications of letters, syllables, and meaningful parts of words [1], Ehri [4] classifies children's knowledge of the English spelling system into three distinct stages, semiphonetic, phonetic, and morphemic. Semiphonetic spellers generally rely on knowledge of letter names to generate spellings of words. Semiphonetic spellings therefore reflect an emphasis on boundary letter sounds (consonants) and an oversight of the medial sounds (vowels) because of reliance on sounds in letter names (e.g., WTR to spell *water)*. Phonetic stage spellers, unlike the semiphonetic stage spellers, tend to represent vowels and increased number of consonants in their spellings of English words. Advancement in their ability to connect letter names to their constituent sounds causes phonetic spellers to overemphasize letter sounds in spellings of individual words (e.g., BALAOSIS to spell *blouses*). Morphemic stage spellers move away from an exclusive reliance on letter-sound relations to use of word-based spelling patterns such as prefixes (e.g., in - *inadequate*), suffixes (e.g., able - *acceptable*), base words (e.g., *sign* – *signal*), consonant doubling (e.g., *flop* – *flopped*), and derivational relationships (e.g., *critic* – *criticize*).

The last three stages of Henderson's [8] spelling development model, within-word pattern, syllable juncture, and derivational constancy, are subsumed within the morphemic stage of Ehri's [4] spelling development model. Henderson's subdivisions of children's morphemic skills highlight transition of spelling development from an alphabetic base to a word-based and meaning-bearing subunit level. At the within-word pattern stage, spellers acquire knowledge of complex groups of letters, including vowel-consonant-silent e patterns (e.g., *rake*, *time*) and vowel digraphs (e.g., *train*, *bought*). Spellers acquire understanding of complex word-based patterns that support spelling of single-syllable words. Syllable juncture spellers, comparatively, learn use of consonant doubling (e.g., hop – *hopping*), prefixes (e.g., im – *immature*), and

suffixes (e.g., ance – *maintenance*) to spell multisyllabic words. The derivational constancy stage involves spelling of base and root words (e.g., bene – *beneficial*, *benevolent*, *benediction*).

From the preceding description of the phases of spelling development, it can be concluded that accurate spelling of words can take place when children learn to form consolidated connections between letter units (i.e., syllables) in written words and their sounds in pronunciations. Although good spellers can form complete connections between letter-sound units in words, which then facilitate accurate spelling of words, individuals with spelling disability often fail to establish full connections between letters-and-sounds in words which then constrain their ability to spell words accurately.

Research on Spelling Proficiencies

In recent years, researchers have compared spelling performances of individuals with and without spelling disability to determine similarities and differences in their ability to represent letter-sound relationships in spellings of different types of words. Manis et al. [9], for example, compared the phonological, orthographic, and spelling skills of children with and without dyslexia. Spelling processes were measured with a pseudoword spelling task (e.g., /vam/, /wifest/, and /flith/) and an irregular word spelling task (e.g., *people*, *enough*, and *business*). Orthographic processing was measured with two tasks, orthographic verification and homonym verification. The orthographic verification task required that on seeing spellings like, *woman*, *surprise,* and *library* (i.e., accurate spellings) or *streat, throte,* and *cumpleat* (i.e., inaccurate spellings) on a computer screen, children press "yes" or "no" to indicate whether the spellings were correct or wrong. The homonym verification task required that children identify a homonym as correct (e.g., "Monday is the first day of the week." – *week*) or incorrect (e.g., "The bear was hungry." – *bare*) after listening to a sentence read aloud by the experimenter and viewing display of a homonym. Phonological processing was measured with two tasks, phoneme deletion and pseudoword pronunciation. The phoneme deletion task asked children to repeat a pseudoword (e.g., *blif*) pronounced by the experimenter and to then pronounce the same pseudoword without one of the phonemes (e.g., *blif* without the /f/ - *bli*). The pseudoword pronunciation task asked children to pronounce pseudowords (e.g., *yaid*, *skoce*, *metion*). Data analyses indicated that the age-matched and reading-level matched children scored significantly higher than children with dyslexia on phonological, orthographic, and spelling tasks.

In an additional study focused on spelling development, Swanson and Ramalgia [13] compared the spelling performances of seventh, eighth, and ninth grade children with learning disabilities and reading-level-matched and spelling-level-matched younger elementary grade children without learning disabilities. Children were administered three graded word lists, one matched to their spelling level and two lower than their spelling level. Each graded list included 10 phonetic (i.e., regular word patterns) and 10 nonphonetic (i.e., irregular word patterns) words. Spellings of regular and irregular words were analyzed by classifying misspellings into three categories: semiphonetic errors – omission of medial and vowel sounds (e.g., *lidl* for *little*); phonetic errors – vowel substitutions (e.g., *fullist* for *fullest*), omission of silent letter (e.g., *new* for *knew*), and substitution of consonant grapheme for a phoneme (e.g., *wher* for *wear*); and morphemic errors – consonant doubling (e.g., *wadding* for *wading*), addition of an inaccurate marker letter (e.g., *ris* for *rice*), two vowel letters for long vowels (e.g., *tier* for *tire*). Analysis of regular and irregular word misspellings indicated that children with and without learning disabilities, who had lower scores on a standardized spelling test used to select and classify study participants, produced higher number of semiphonetic errors with an over reliance on boundary letters and slighting of the medial letters. Comparatively, children with and without learning disabilities, who had higher spelling score on the standardized test, produced misspellings that were phonetic in nature and exhibited overgeneralization of letter-sound relationships. Morphemic errors produced by children with and without learning disabilities were comparable.

Instruction for Spelling Development

Individuals with spelling disability generally do not use appropriate strategies to spell words and are not efficient at spelling words accurately without instruction [6]. Therefore, explicit spelling instruction is essential for developing poor spellers' ability to spell words accurately [3] and spelling instruction should emphasize knowledge of the language structure, specifically knowledge of sound-letter combinations and spelling patterns [7]. Furthermore, individualized instruction is recommended because successful learning of spelling patterns requires that teaching be adjusted to the cognitive abilities of the learner [2]. Consequently, teachers are advised to be mindful of the number of words selected for instruction of individuals with spelling disability. Careful selection of words is vital because individuals with spelling disability, compared to individuals without spelling disability, generally require more time to learn spellings of fewer words [12]. Morris,

Blanton, Blanton, and Perney [11] also suggest lowering of the difficulty level of spelling words to facilitate learning of an appropriate number of words matched with disabled spellers' knowledge of and memory for spelling patterns in words. In sum, improved spelling performance requires that individuals with spelling disability receive (a) sufficient time to learn word spellings, (b) feedback for correcting misspellings, and (c) spelling practice with minimum teacher supervision [5].

Sperm

Merry Sleigh
Winthrop University, Rock Hill, SC, USA

Synonyms

Male gamete; Male germ cell; Spermatozoa; Sperm cells

Definition

Male reproductive cells

Description

Human sperm are invisible to the naked eye and consist of three parts. The head of the sperm is called the acrosome and contains 23 chromosomes, the father's genetic contribution to the offspring. The chromosomes contained inside the sperm will determine whether the offspring is male or female. The head also holds enzymes that will help the sperm penetrate the outer layer of the egg. The short midsection of the sperm, or body, contains mitochondria to fuel the sperm's journey to the egg. The longest part of the sperm is the mobile tail, or flagellum, which propels the sperm forward.

Sperm production begins when testosterone, luteinizing hormone (LH), and follicle-stimulating hormone (FSH) activate the male testes during puberty. Spermatogenesis, or the creation of sperm, works best when the temperature of the testes is lower than that of the body. For this reason, the testes hang away from the body in the thin skin of the scrotum. Sperm maturation takes 72–74 days. Sperm will grow in the testes for several weeks, then move from the rear of each testicle to the epididymis, where growth continues for another 2–21 days. Mature sperm move through a small tube called the vas deferens into the seminal vesicle, where they are temporarily paralyzed by carbon dioxide. The seminal vesicle and prostate secrete fluids that will join with the sperm to become seminal fluid (or semen). At ejaculation, sperm and seminal fluid move through the vans deferens and to the urethra, a tube inside the penis, from which they are released. A typical ejaculation includes an average of 100–300 million sperm, with about 75% being motile and even fewer being healthy enough to fertilize an egg.

Sperm die quickly outside of the body, and only survive from 3 to 5 days in optimal conditions, which can be a challenge. Lubricants, saliva, and urine kill sperm. In the vagina, high acidity levels are detrimental to sperm, slowing their movement or killing them. During ovulation, a woman secretes cervical fluid that lowers the acidity of the vagina, assisting sperm in their journey. Similarly, the alkaline seminal fluid protects sperm against the acidic vagina and provides fructose to help fuel the sperm's journey.

Sperm must travel through the cervix and into the uterus, which is less acidic but contains white blood cells that can destroy the sperm. From the uterus, sperm enter one of the two fallopian tubes located on either side of the uterus. Chemical signals provide some information to sperm about where the egg is located, although many

sperm enter the wrong tube. Cilia within the fallopian tube move the egg toward the uterus, creating a current against which sperm must swim and a trap that sperm must avoid. In addition to these environmental hazards, if sperm from two different males are inside the reproductive tract simultaneously, the sperm will engage in a competition for fertilization. Ultimately, only a few hundred sperm reach the egg.

During this journey, sperm move an average of two to three mm per minute; however, there is individual variability. In addition, some sperm pause temporarily at the cervix or outside of a fallopian tube. Having sperm arrive at different times increases the chance that a sperm will be present during the short 24 h lifespan of an egg. Sperm containing a Y-chromosome, coding for a male offspring, are lighter and tend to travel faster; however, they also live for a shorter period of time. Sperm containing an X-chromosome, coding for a female offspring, are slower but hardier.

To enter the egg, sperm must cross the tough outer membrane of the egg called the zona pellucida. Enzymes in the acrosome break down this wall over a period of around 20 min. The sperm must then penetrate the inner part of the egg, gaining access to the egg's genetic material. The sperm's tail detaches and the head dismantles to allow fertilization, and the resulting cell is a zygote.

Sperm quality varies widely over the course of the day. Abnormal sperm are the most common cause of male infertility. Several factors can affect the quality, mobility, and number of sperm. For example, hormonal imbalance, environmental toxins, poor nutrition, illness, stress, and high testicular temperature have all been linked to spermatogenesis failure. Research has revealed that substances such as nicotine, cocaine, marijuana, steroids, and excessive amounts of alcohol reduce a man's sperm count and quality. Legal and illegal medications also can impact male fertility. These findings suggest that both mothers and fathers play a critical role in conception.

Spinal Cord

Edalmarys Santos[1], Chad A. Noggle[2]
[1]Middle Tennessee State University, Murfreesboro, TN, USA
[2]SIU School of Medicine, Springfield, IL, USA

Definition

The spinal cord is one of the two major divisions of the Central Nervous System (CNS), in addition to the brain, which connects rostrally to the inferior portion of the medulla and extends down the back serving as a primary highway in which signals are sent in between the CNS and Peripheral Nervous System (PNS).

Description

The spinal cord, in combination with the brain, constitutes the two primary structural divisions of the CNS which play different roles in carrying out functions. Structurally, the spinal cord has thirty segments divided amongst four divisions (Cervical, Thoracic, Lumbar, and Sacral divisions) and one additional Coccygeal segment. Each segment has a spinal nerve on both the right and left that are essential in the transmission of impulses to and from the CNS from and to the PNS (nerves outside of the CNS), musculature, and other body regions and structures [1]. In this way, the spinal cord may be viewed as the express communication highway providing a link between the body experiencing and receiving sensations and the

brain which perceives and interprets this information. This illustrates a bottom-up transmission however a top-down transmission occurs via the spinal cord as well. Specifically, neurological impulses regarding functions, such as movement, originate in the brain and are transmitted down through the spinal cord to the peripheral structures which will serve to carry out the movement. Given its role in both the reception of sensation and the transmission of motoric output, damage to the spinal cord may cause deficits within either domain [2]. For example, damage to the spinal cord can lead to complete or partial loss of sensation and/or movement in those systems and areas outside of the CNS. Furthermore, the nature of the impairment corresponds with the location and degree of insult. For example, complete damage of the spinal cord at the Cervical level (i.e., highest level) can lead to quadriplegia (i.e., loss of all movement and sensation below the neck) whereas partial damage may simply cause weakness in movement or a decrease in sensation perception. Furthermore, complete damage at a lower level may merely cause paraplegia (i.e., loss of all movement and sensation below the waist) whereas partial damage may again simply cause weakness in movement or sensation from the waist down.

Spinal Cord Contusion

►Spinal Cord Injury

Spinal Cord Injury

Brian P. Daly[1], Heather F. Russell[2]
[1]Temple University, Philadelphia, PA, USA
[2]Shriners Hospitals for Children, Philadelphia, PA, USA

Synonyms

Cord injuries; Post-traumatic myelopathy; Spinal cord contusion; Spinal cord laceration; Spinal cord transection; Spinal cord trauma; Spinal injuries

Definition

A spinal cord injury (SCI) may stem from traumatic damage to the spinal cord which results in a bruise (contusion), a partial tear, or a complete tear (transection) in the spinal cord. Non-traumatic SCI may be caused by an infarction (stroke), arthritis, cancer, blood vessel problems or bleeding, inflammation (transverse myelitis), infections (meningitis), disease, or degeneration of the disks and vertebrae in the neck (cervical spondylosis). The damage may cause a loss of sensation (feeling) and motor (muscular) control and may result in paralysis.

Description

Spinal cord injuries affect the whole body; however, impairments in sensation and/or motor ability typically occur below the site of the injury. For this reason, some persons have altered functioning in their legs and lower body only (paraplegic), while others have altered functioning involving all four limbs (tetraplegic). As such, SCI is classified according to the child's degree of loss of motor and/or sensory function.

Pairs of nerves are connected to the spinal cord in the space between two adjacent vertebrae. The nerves are named for the vertebrae where they exit the spinal cord. There are five sets of these nerves and they are defined as follows: (1) C1-8 nerves exit the spinal cord in the cervical region or in the neck; (2) T1-12 nerves exit the spinal cord in the thoracic region, or the chest; (3) L1-5 nerves exit the spinal cord in the lumbar region or the lower back; (4) S1-5 nerves exit the spinal cord in the sacral region or near the pelvis; and, (5) the coccygeal nerves exit the spinal cord near the coccyx, or tailbone [1].

Injury to the spinal cord may damage any one or more of these nerves. When nerves are damaged, functions such as urination, sexual function, sweating, blood pressure, etc., may be affected. Symptoms of spinal cord injuries may include muscle weakness, loss of voluntary muscle movement, breathing problems, loss of feeling, and loss of bowel and bladder function.

Diagnosis of SCI is made with a comprehensive physical examination, a study of symptoms, and diagnostic testing. Diagnostic tests may include X-rays, computed tomography scans (CT scans), and magnetic resonance imaging (MRI) scans of the spinal area.

Initial treatment for spinal cord injuries is immobilization. Steroid injections may be given to reduce inflammation and swelling. Currently, no treatments are available to make a spinal cord grow back to its pre-injury condition. However, some patients with SCI do recover at least a portion of their ability to move and/or feel below the level of injury. Rehabilitation focuses on

fostering independence and reintegration into the community by helping individuals with spinal cord injuries avoid complications and optimize those bodily functions they do control to aid in mobility and movement. Accurate predictions of prognosis for SCI, particularly in the acute phase, are very difficult. Current evidence suggests that recovery, if it occurs, typically transpires on a timeline that starts between a week and 6 months after injury. Impairment remaining after 12–24 months is likely to be permanent. However, there are case reports of small improvements occurring for up to two years or longer.

In the United States, approximately 10,000 individuals sustain a SCI each year. Approximately 3–5% of those injuries occur among children younger than 15 years of age and 20% are younger than 20 years. Motor vehicle accidents are the main cause of injury in pediatrics with medical/surgical complications, violence, falls, and sporting accidents also contributing [2].

Relevance to Childhood Development

The psychological challenges children face are different from those seen in adults with similar injuries. Children respond to their injury according to their developmental stage at the time, and this response continues to change as the child grows.

A major factor to consider in any child's mental health is the influence of the family members on the child's psychosocial adjustment process and vice-versa. In order to provide adequate emotional support, it is essential to pay attention to the unique and different challenges faced by each individual family member in addition to the ones the family faces as a whole.

The parents or caregivers of a child with SCI are often traumatized. They can experience feelings of anger, sadness, and guilt. They must learn a great deal of medical information about how to care for their child, while simultaneously providing emotional support. It is often the case that the caregivers have a difficult time parenting their child in the same way as before the injury. Specifically, parents frequently respond to the new situation by being overprotective and setting fewer limits or providing less discipline.

During the initial hospital stay and on an ongoing basis, the parent/caregiver must constantly ensure that the appropriate and necessary modifications are made at home, at school, and at any other location to where the child travels. In addition, the caregiver will likely face financial challenges secondary to possible employment changes and extensive medical, equipment, and therapy bills. Finally, after the initial learning and adjustment process has been conquered, the parents/caregivers need to support their child in creating future life goals and a plan to meet those goals. Even though it is common for parents/caregivers to have difficulty letting go of their child as she or he grows up and develops, that transition can be even more challenging when the child has a chronic physical disability.

Children with SCI experience unique challenges that can change depending on their age. When the child is injured at birth or in early childhood, he or she relies largely on the parents or caregivers for total support. At school age, the child is developing their sense of identity and can feel anxious or sad as a result of their physical limitations and having a perceived lack of control over their environment. The child is also learning how to socialize with peers. During adolescence, body image, sexuality, driving, and peer relationships become central issues. Emotions run high during this developmental stage in general and the teen with SCI is no exception. It is the job of adolescents to learn to separate from their parents/caregivers and to take on increased responsibility for their own medical care.

The transition to adulthood (including medical, social, emotional, financial, educational, vocational, and leisure aspects) is a process through which the young adult must navigate with support from her/his parents/caregivers and medical team.

The whole family of a child with SCI will likely go through some changes. It is important to take into consideration the way the family was functioning before the injury occurred, as this will affect their functioning moving forward. There may be a shift in the family dynamics, including marital, sibling, and parental relationships, as a result of the child's SCI. The increased amount of time it takes to care for a child with SCI takes away from leisure time. This decrease in "play time" occurs for the child, the siblings, and the parents/caregivers.

The overall goal in pediatric SCI is to return the child and the family as quickly and fully as possible back to their lives in their own communities with the appropriate support services in place. The child should be reintegrated back into school, social activities, sports, and chores or jobs as soon as medically possible. It is also important to monitor the child as they grow to ensure that they're keeping up with peers over time.

Hemispheric differences; Laterality

Definition

"Split Brain" is a term used to describe an early method of severing the corpus callosum and separating the two hemispheres of the brain. This was done to reduce the spread of seizures. Following this procedure differences were found between the left and right side of the brain; most of this research is attributed to Sperry [1].

Description

Split brain is a relatively rare situation which is usually the result of all other options being exhausted in attempting to control epilepsy and epileptic seizures. It involves the severing of a dense group of nerve fibers which connect the left and right hemispheres of the brain. Agenesis of the corpus callosum is often congenital and is secondary to a malformation that following surgical severing seems to provide clearer left-right differences. The result of having a split brain is typically the inability to name an object that is presented within the left visual field due to the information from the left visual field being only sent to the right side of the brain where speech is typically not localized.

There is some debate within the research over the idea of competing hemispheres or "two minds" which result from a split brain. Some patients have been seen after surgery to appear as though they have separate goals. For example, the left hand may reach for one object of clothing while the right reaches for a completely different article of clothing. Typically, these issues resolve themselves within a short period of time after surgery and patients report having a cohesive consciousness afterwards. Conclusions about the functioning of normal brains based upon those with epilepsy have been difficult to substantiate.

Standard Celeration Charting

Abigail B. Calkin
Private Practice, Gustavus, AK, USA

Synonyms

Celeration; Educational aims; Fluency; Frequency; Precision learning; Precision teaching; SCC; Timings

Definition

The Standard Celeration Chart (initially called the Standard Behavior Chart) is used to observe and improve human learning and interaction. The chart shows the frequency of performance and its celeration, i.e., growth of learning across time. Frequency, whose formula is F=Count/Time, tells what happened during a specific time. Celeration, whose formula is C=Count/Time/Time, or Frequency/Time, tells what happens across the longer period of time – weeks, months, years, or decades. All Standard Celeration Charts retain and present the original data in the form of frequency and celeration. The most common use is in special and regular education where the 1-min timing has resulted in research-developed frequency and celeration aims for academic behaviors. Data-based frequency aims are also emerging for inner behaviors.

Description

Pavlov used frequency, a standard unit in the measurement of scientific phenomena, to measure physiological responses in dogs. Skinner used frequency, free operant behavior, and the cumulative recorder to measure the behavior of rats and pigeons. Lindsley, with his background in engineering and experimental psychology, brought to psychology and education the most powerful and scientific use of measurement applied to human behavior. He became the first person to measure human behavior continuously. In 1953, he took lessons learned in Skinner's operant laboratories into his home and continuously recorded the toy-playing behavior of his infant daughter, Cathy. He also began to measure the behavior of schizophrenics at Metropolitan State Hospital in Waltham, Massachusetts, and coined and first published the term "Behavior Therapy," in the 1954 Boston telephone directory: Studies in Behavior Therapy. In 1965, he developed the standard behavior chart, now described as a family of Standard Celeration Charts – standard measurement charts for human behavior in daily, weekly, monthly, and yearly time periods. By 2000, the vast

majority of the million-plus charts came from education. The chart is not a teaching method; rather it is a system for monitoring the effectiveness of any method of teaching, learning, or changing human behavior.

Since 1967, educators and others have used the standard celeration chart to observe and improve human behavior. The people behaving have ranged from fetuses to students to those in their 80s.

Frequency and Celeration

Because of the design of standard celeration charts – the standard is the 34 degree angle of the doubling line from corner to opposite corner – all *ac*celerations and *de*celerations are *standard* no matter which chart. Using this graphic makes two critical elements apparent. First, behavior grows by *multiplying*, not by adding. Second, the chart makes one look at not only the *frequency* of a person's performance, but also at the *growth of learning across time*, i.e., the *celeration*. Frequency is performance: It tells what happened during one time period, but by itself it tells little about learning. The formula is F = C/T, or frequency equals count divided by time, e.g., a count of 77 behaviors in 1 min has a frequency of 77; a count of 192 in 10 min has a frequency of 19.2. To see whether performance accelerates or decelerates, we need to measure it across time. Since 1971, we have called this change in learning celeration, a word derived from the root word of acceleration and deceleration. Its formula is C=C/T/time, e.g., the growth of frequency *across* a week on a daily chart, or across a month on a weekly chart. Both frequency and celeration are standard measures of human behavior.

Different from most graphs, the standard celeration chart retains and presents the original data. Because of the SCC's design, the charter plots only frequency so the chart always displays performance within the time period.

Standard Celeration Charts

The *Daily Standard Celeration Chart* measures any human behavior that occurs on a daily basis. It goes from 0.00069, or one time per 24-h day, up to 1,000 per min. It has one behavior per day at the bottom, one behavior per minute in the middle, and 1,000 behaviors per minute at the top. Any line drawn parallel to the corner to corner line means learning has changed by ×2, an acceleration or improvement. From the top left to the bottom right the change is a ÷2, a deceleration, an improvement when errors, inappropriate behaviors, or negative inners are counted. Each Daily Chart has 140 days across it.

Three categories of daily behavior often monitored include: (1) academic learning – e.g., see say (read) words, see write quadratic equations, see say (memorize) musical notation or the Periodic Table, think say American government facts, see say parts of a microscope or skeleton; (2) other outer behaviors such as interrupts, greets people, sets goals, makes choices; or all-day charts of fetal movement; and (3) inner behaviors such as has thoughts of a former wife, feels jealous, pleasant and unpleasant feelings about oneself.

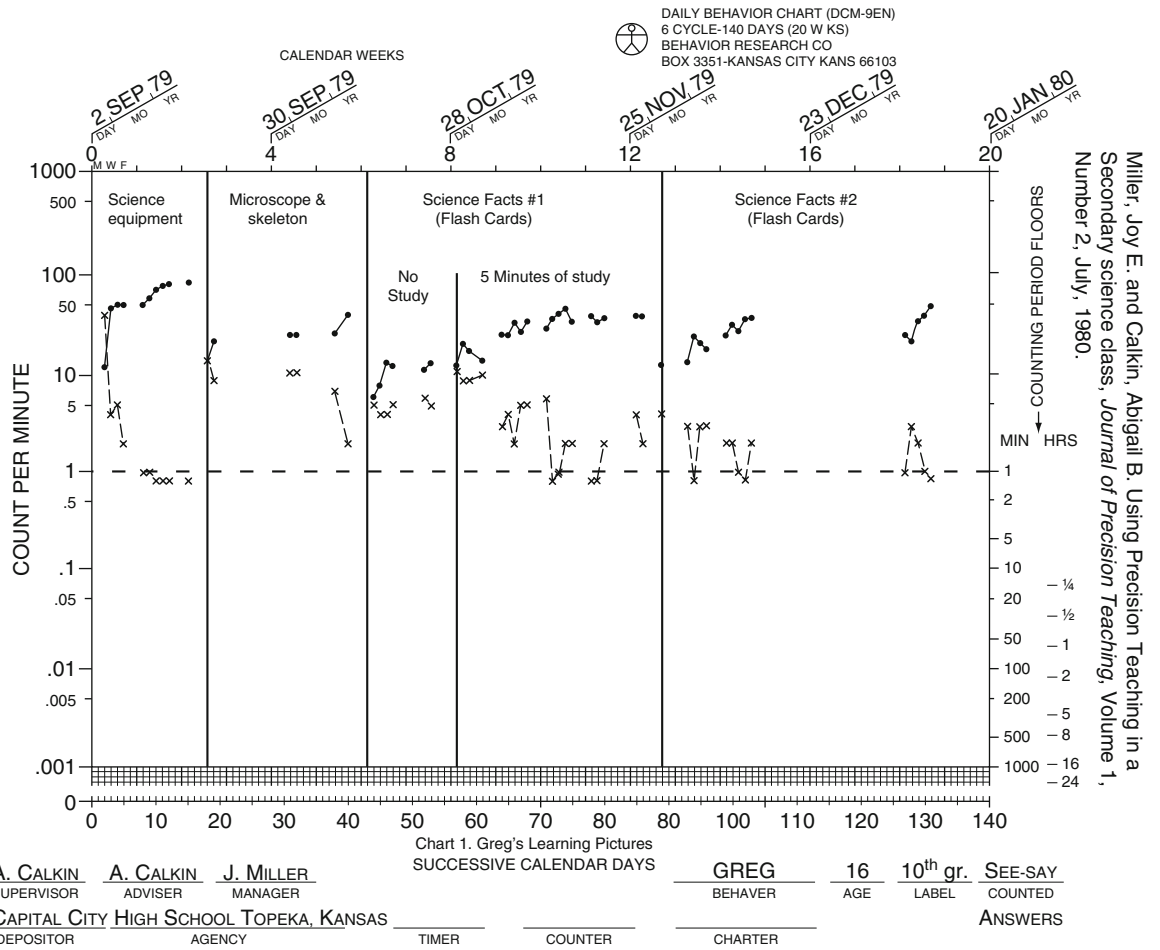
The daily chart in Fig. 1 shows Greg learning science facts by see say – he *sees* the object and *says* its name or he *sees* the front of the flashcard and *says* the information on the back.

In four of the five phases, the corrects go up (by ×1.8, or an 80%, increase per week) and the errors go down, most dramatically in the first phase by a ÷10 per week. In the third phase, Science Facts #1 (Flash Cards) No Study, the corrects and errors both increased. Seeing from the collection of charts that learning was not occurring well for about fifteen of her 19 students, the teacher made the decision to add 5 min of study time. The students' correct responses continued to accelerate and their errors stopped increasing and began to decelerate. Given that the chart is standard, the teacher could quickly see if each student learned and could tell whether she had made the correct teacher decision. Such is the analysis of learning behavior that the standard celeration chart offers.

Because the chart uses a standard scale to display change numerically, when looked at, each of these charts shows immediately whether the line went up, down, or stayed the same. The steepness of the line occurs not because of a differently graphed scale on the left or across the bottom but because the behavior changed.

The Uses of Standard Celeration Charting

In 1967, Lindsley formed the Behavior Bank to collect, analyze, summarize, and display facts about human behavior [1]. Banked projects include academic, personal management, and inner behaviors. *Handbook of Precise Behavior Facts* contains summaries of 11,947 standard celeration chart projects on people's learning. The banked information contains each pinpoint, the body part involved, the supervisors and contributors of the projects, the instructional technique, and the reward or punishment for each project as well as visual displays of the data summary for any pinpoint which had at least five charts banked; the highest, middle, and lowest frequency; and the most rapid (steepest), middle and the slowest (flattest) celeration. By 1973, the Behavior Bank contained 16,376 projects. Considering these data were sufficient to draw precise and inductively discovered conclusions about human behavior, Lindsley stated there were eight Laws of Human Behavior. The bank closed in 1974.



Standard Celeration Charting. Fig. 1. Daily behavior chart.

The 1-min timing is commonly used to implement change in precision teaching and in precision inner behavior. The first use of this important behavior change technique began in Ann Starlin's classroom in Eugene, Oregon in April 1968 to assist her students in their learning of geometric figure names; it is now widely used when helping students improve such academic areas as reading, math, social studies, and science skills, as well as improve the inner behaviors of pleasant thoughts and feelings. As early as 1970, Clay Starlin and Haughton had developed frequency aims for academic behaviors. Since then and as a result of hundreds of thousands more charts, academic and inner behavior frequency aims have been revised upwards and celeration aims also established.

In addition to helping students learn in regular and special education classrooms, learning centers, and universities, standard celeration charts have been used in many different fields – nursing, social work, psychology, inner behavior, business, analyses of historical and governmental events, administration, and geriatrics to name some. As well as in the United States, the standard celeration chart, also known as precision teaching for its dominant use in education, is also used in the Republic of Ireland, the United Kingdom, Norway, Australia, South Africa, and Canada.

Relevance to Childhood Development

Standard celeration charting is used in the measurement and monitoring of the behaviors of fetuses, infants, preschoolers, and kindergarteners.

Standard Scores

Robert Walrath
Rivier College, Nashua, NH, USA

Synonyms

Derived score; Deviation IQ; GRE/SAT Score; Normal Curve Equivalent (NCE); Normal Score; Norm-referenced scores; Sigma Score; Stanines; Sten Score; T Scores; Z Score

Definition

A score that is derived from an individual's raw score within a distribution of scores. The standard score describes the difference of the raw score from a sample mean, expressed in standard deviations. Standard scores preserve the absolute differences between scores. The standard score (Z) is computed with the following formula:

$$Z = X - M/SD$$

where X = the raw score, M = the mean, and SD = the standard deviation.

Description

The use of standard scores allows the set of raw scores to be "normalized" or statistically adjusted to fit the normal distribution or "bell shaped curve," allowing a more precise and meaningful comparison of scores across individuals in a sample. Standard scores in conjunction with standard deviations above and below the mean are often used to illustrate individual strengths and weaknesses on a measure, showing where an individual falls on the normal distribution [1]. They may also be used with some measures as a criterion score for classification purposes or as a descriptor of traits or symptoms on assessment measures.

Commonly used Standard Scores

Z score: Mean of 0, standard deviation of 1. Simplest and most common standard score, used to convert raw scores to other types of standard scores. For example, to covert a Z score to a T score (below), the following formula is used:

$$T = z(SD) + M$$

where SD is the standard deviation of the new standard score and M is the mean of the new standard score, in this case SD = 10 and M = 50.

T Score: Mean of 50, standard deviation of 10. Commonly used to express scores from psychological tests and behavior rating scales such as the MMPI-2 and the BASC-2.

Deviation IQ: Mean of 100, standard deviation of 15. Sometimes called the "Wechsler score," commonly used to report scores from most intelligence tests.

Stanine: Mean of 5, standard deviation of 2. Short for "standard nines," a range of scores from 1 to 9 that allows a gross classification of below average-average-above average scores across the normal distribution.

Sten: Mean of 5.5, standard deviation of 2. Short for "standardized ten," a range of scores from 1 to 10. Used in reporting of scores from the 16PF personality questionnaire, for example.

Normal Curve Equivalent (NCE): Mean of 50, standard deviation of 21.06. Based on percentile rank, the NCE creates equal interval percentile scores from 1 to 100.
SAT/GRE Score: Mean of 500, standard deviation of 100 [2].

Stanford-Binet Intelligence Scales

Stephen M. Wilson
Argosy University

Synonyms

Stanford Binet; SB5; Stanford-Binet intelligence scales, Fifth Edition

Definition

The Stanford-Binet Intelligence Scales is an individually administered measure of cognitive abilities. It was first developed in France in 1905 as the Binet–Simon scale, but adapted for use in the United States at Stanford University in 1916 where it obtained its current name. The instrument has undergone several revisions over the past century, and the Stanford Binet Intelligence Scales – Fifth Edition (SB5) is the most recent revision, which was published in 2003. Like previous editions, the SB5 is one of the most widely used psychometric instruments, and is often included in clinical, neuropsychological, and psychoeducational evaluations. The SB5 can be administered to individuals as young as 2 and over 85 years of age. The SB5 has a hierarchical structure in which overall intellectual ability (the Full Scale IQ score) is comprised of two Domains (Verbal and Nonverbal IQ) and five Factor Indexes (Fluid Reasoning, Knowledge, Quantitative Reasoning, Visual Spatial Reasoning, and Working Memory).

Description

The Binet–Simon Scale was developed over a century ago by Alfred Binet and Theodore Simon [1]. First published in 1905 and revised in 1908 and 1911, the Binet–Simon Scale was part of an effort to differentiate the intellectual abilities of Parisian school children and to classify levels of mental retardation.

Lewis Terman and his colleagues at Stanford University translated the Binet–Simon Scale into English, adapted it for use in the United States, and published the Stanford-Binet Intelligence Scale in 1916 [2]. Based on an age-scale format, the test performance of this standardization group was analyzed to determine which items were passed by the majority of test takers of a particular age. From these administrations, tables of "mental age scores" were derived, which allowed the performance of subsequent test takers to be compared with the standardization group. The 1916 edition was noteworthy for the use of the intelligence quotient, which represented the ratio of mental age to chronological age. A mental age score that was higher than the examinee's actual "chronological age" denoted above average performance; conversely, performance below the chronological age denoted below average performance. However, the distribution of scores was not constant across different ages; thus, scores by individuals at different ages were not directly comparable [3].

Revisions of the Stanford-Binet in 1937 and 1960 represented efforts to improve the standardization of the instrument and improve the representativeness of the sample on which the test was normed. The 1937 edition expanded the standardization group, created alternate versions of the test (Forms L and M) to facilitate readministration, and included more nonverbal items at younger ages. The 1972 revision combined the best items from the two versions of the 1937 edition and was dubbed the Stanford Binet Intelligence Scales, Form L-M. The standardization sample for this revision was the first to include African Americans and Latin Americans, as well as European Americans. Form L-M replaced the age-scale format that was introduced in the 1916 edition with a point-scale format, in which performance is based on scores that are converted into standard scores. Unlike ratio/mental age-based intelligence quotients, the mean and standard deviation of standard scores remain constant; thus, scores at different ages are comparable. These

early editions provided only one score, a measure of overall ability, and have been criticized for overemphasizing verbal abilities and rote memory while giving little consideration to other types of abilities that are hypothesized to underlie general intellectual ability (e.g., nonverbal abilities, visual perception, and spatial skills) [3].

The Stanford Binet Intelligence Scale, Fourth Edition (SB:IV), which was published in 1986 [4], was based on a four-factor hierarchical model. At the first level was a general intellectual factor ("g"), which was reported as the Test Composite Score. The four cognitive factors were Verbal Reasoning abilities, Abstract/Visual Reasoning abilities, Quantitative Reasoning, and Short Term Memory, which were reported as Standard Age Scores. The SB:IV was standardized on a group of over 5000 individuals (much larger than previous editions) that were similar to 1980 U.S. Census data in regard to gender, race, ethnicity, geographic region, community size, and socioeconomic status.

The SB5 was revised over a period of 7 years and published in 2003 [5]. The SB5 was normed on a sample of 4,800 subjects stratified to match variables from 2001 U.S. Census data vis-à-vis age, sex, ethnicity, geographic region, and education level. Data were also reported regarding community size and type of school attended. In addition, subjects from special groups were included in the sample: individuals with documented Learning Disabilities, Attention Deficit Hyperactivity Disorder, Mental Retardation, speech impairment, and hearing impairment.

The standardization sample of the SB5 was segmented into groups ranging from 2 years to above 80 (a segment that included individuals as old as 96 years). The inclusion of these age groups drastically increased the age groups to which the SB5 can be administered. The SB5 can be administered to individuals as young as 2 and over 85 years of age, whereas the 4th ed. was appropriate only for ages 2–23 years. A strength of the SB5 is that an individual's cognitive development could be monitored continuously via the same scale over a long period of years due to the wide age span of the test. However, due to a phenomenon known as the Flynn Effect [6, 7], which describes the trend for intellectual abilities in the general population to increase over time, it is necessary for tests to be revised periodically. Consequently, it is unlikely that any one individual would be monitored for more than approximately a 20-year span of time with the same version of any test. In addition to increasing the age range from previous editions, the SB5 increased the range of possible IQ scores. The SB5 is also theoretically linked to the Woodcock-Johnson III Tests of Achievement to facilitate the diagnosis of learning disabilities.

The SB5 Technical Manual [8] indicates that the test developers took extensive measures to assure that the instrument is culturally fair. Test items underwent "logical analysis" and were eliminated or altered if considered offensive or likely represent a construct differentially across demographic groups. Items also underwent empirical analysis of differential item functioning, item response theory, and construct-related studies of item fairness; items with poor demographic fairness were eliminated.

The SB5 has a hierarchical structure. At the first level is an overall measure of cognitive ability, the Full Scale IQ. At the second level are two domains (Verbal and Nonverbal) and five Factors (Fluid Reasoning, Knowledge, Quantitative Reasoning, Visual-Spatial Reasoning, and Working Memory). A third level consists of ten subtests, each simultaneously representing a domain and a factor (e.g., Verbal Fluid Reasoning). A fourth level consists of five or six testlets per subtest. Testlets are defined as sets of three to six items clustered into functional levels or levels of difficulty. The fifth level of the hierarchy consists of individual testlet items [9].

The ten subtests yield the Full Scale IQ score. Five of the subtests comprise the Verbal Domain and yield the Verbal IQ score, and five of the subtests comprise the Nonverbal Domain, yielding the Nonverbal IQ score. The Verbal subtests are presented with oral or printed directions and responses are largely verbal. In contrast, Nonverbal tasks have lower language demands, although they are not entirely nonverbal. They are presented with pictures, manipulatives, and brief oral directions, and responses involve gestures, manipulation and brief oral responses. Each Verbal subtest corresponds with a Nonverbal subtest and these pairs of Verbal and Nonverbal subtests comprise the five Factor Indexes. In addition, the SB5 provides an optional Abbreviated IQ score, which is based on scores from two subtests: Nonverbal Fluid Reasoning and Verbal Knowledge.

The SB5 is partially based on the Cattell–Horn–Carroll (CHC) theory of intelligence [10]. Briefly, CHC theory describes intelligence as composed of ten broad abilities: crystallized intelligence, fluid intelligence, quantitative knowledge, reading and writing, short-term memory, visual processing, auditory processing, long-term storage and retrieval, processing speed, decision speed/reaction time. The SB5 measures five of the factors described by CHC theory but prominently includes Verbal and Nonverbal Domains even though this dichotomy is not a part of the theory. It has been noted that it is not clear when test interpretations should be based on the two domains or the five factors [11].

In contrast with earlier editions of the Stanford Binet, IQ and Factor Index scores on the SB5 are reported as standard scores that have a mean of 100 and standard deviation of 15, which is a metric that is consistent with most other widely used ability tests. Subtest scores of the SB5 are reported as scaled scores, which have a mean of 10 and standard deviation of 3.

The SB5 utilizes a routing procedure in which the examinee's performance on a routing subtest determines starting level for other subtests within the same domain (i.e., Nonverbal or Verbal). The purpose of the routing procedure is to reduce testing time and examinee fatigue. The estimated time to administer all ten subtests is 45–75 min; however, shorter versions are sometimes appropriate. The SB5 generates an Abbreviated IQ score based on the examinee's scores on the two routing subtests. This abbreviated assessment is estimated to take 15–20 min. The Examiner's Manual also indicates that the examiner may chose to administer only the five subtests within a given domain in order to obtain a Nonverbal IQ score or a Verbal IQ score. For example, the Examiner's Manual specifies that the Nonverbal IQ score may be the most appropriate metric for examinees with communication disorders, hearing impairment, autism, or limited English language backgrounds. Conversely, the Verbal IQ score might be the most appropriate measure for examinees with orthopedic impairments or motor skills deficits [9].

Statistical reliability of the SB5 has been measured via multiple methods. Reliability of a test score refers to consistency across sets of items, time, and other conditions. The technical manual presents reliability coefficients for IQ scores and Factor Index scores, all of which were .90 or above (out of a maximum possible value of 1.0), which indicates a very high level of reliability. Test–retest reliability was assessed by retesting a group of subjects after a number of days (between 1 and 39 days). Stability coefficients were 0.89 and above for the IQ scores, and 0.81 and above for the Factor Indexes. Interscorer agreement refers to the correlation of item scores for the same examinee when rated by independent examiners. The median coefficient of interrater reliability was 0.90 [8].

Validity refers to the extent to which an instrument measures the trait that it purports to measure. Convergent validity measures the correlation between different instruments designed to measure the same traits. Studies of convergent validity indicated that the SB5 is highly correlated (median correlation $r = 0.83$) with the two editions of the Stanford Binet that preceded it, as well as the Wechsler Preschool and Primary Scale of Intelligence – Revised, the Wechsler Intelligence Scale for Children – 3rd ed., the Wechsler Adult Intelligence Scale – 3rd ed., the Wechsler Individual Achievement Test – end ed., and the Woodcock Johnson III Tests of Achievement [8].

Relevance to Childhood Development

According to the Technical Manual, "the SB5 was designed to measure developmental growth and life-span change" [8], (p. 103). The SB5 is appropriate for assessing the cognitive abilities of children at a variety of ages and developmental levels. Because it has been normed on children as young as 24 months, it is particularly useful for the early identification of developmental issues and other special needs. Indeed, the norming process for the SB5 included the following clinical and exceptional groups: intellectual giftedness, mental retardation, developmental delay, autism, learning disabilities, Attention Deficit Hyperactivity Disorder, severe emotional disturbances, speech/language disorders, and orthopedic or motor delays. The Technical Manual presents tables of scores for each group in an attempt to discern common profiles that, along with other corroborating sources of information, might aid in the identification of individuals with special needs. It was noted, for example, that children diagnosed with Attention Deficit Hyperactivity Disorder obtained significantly lower scores on the Working Memory Factor Index than other factor index scores.

Beyond simply identifying special needs, the test authors have provided recommendations for linking cognitive test results to strategies for teachers and parents for improving areas of weakness. These guidelines are clustered into five areas corresponding with the five Factor Indexes, and lead to recommendations for students who score one standard deviation below national norms on a factor index, or display a significant weakness within their own profile [12].

Stepfamilies

Michelle Cox
Azusa Pacific University, Azusa, CA, USA

Synonyms

Blended families; Remarried families; Stepparent households

Definition

Families of two adults in a formal or informal marriage where at least one of the adults has children from a previous relationship.

Description

Stepfamilies are described as families with at least one child living with a biological parent who has remarried or cohabits with a new partner. The other biological parent lives outside of the household and the child may or may not have contact with that parent through full or partial custody. The stepparent is one who has a

relationship, whether marital or not, with the child's biological parent and resides with the child on a full or part time basis. The stepfamily can also consist of stepsiblings, in which the stepparent has children from a previous relationship who reside within the stepfamily on a part time or full time basis. There may also be children created within the stepfamily between the stepparent and biological parent; which is considered a blended family.

Relevance to Childhood Development

Due to the increase of stepfamilies, it is important for stepchildren and stepparents to build positive and healthy relationships; however, if the relationship between the biological parent and stepparent is not intact, stepchildren may be reluctant to begin the process. Studies have suggested that the relationship between couples must be a priority to maintain the health of the family. After a child experiences a divorce with biological parents, the idea that another marriage may not be successful can create a sense of insecurity. Children who are entering a new stepfamily structure can develop feelings of separation.

Stereotype Threat

Janet Ward Schofield, Kira Alexander
University of Pittsburgh, Pittsburgh, PA, USA

Definition

Stereotype threat refers to being at risk of confirming as a personal characteristic an existing stereotype about a social category (gender, racial, or ethnic group, etc.) to which one belongs. Concern about possible confirmation of the stereotype commonly leads to performance decrements in domains related to that stereotype.

Description

Much of the early research on stereotype threat explored the idea that African-American students' intellectual performance might be undermined by stereotype threat, specifically by their concern that their performance might validate existing negative stereotypes about African Americans' intellectual abilities. For example, in the classic study that launched work on this topic, Steele and Aronson [4] demonstrated experimentally that African-American students who believed they were taking a test measuring their verbal reasoning ability performed less well than African-American students taking the same test who were led to believe that the test measured something else not related to racial stereotypes. However, stereotype threat appears to negatively impact the performance of individuals in many social categories when they believe their behavior might fulfill negative stereotypes about the social categories to which they belong. So, for example, Latinos in the U.S., who are also often stereotyped as less academically able than Whites, experience stereotype threat effects similar to those evidenced by African Americans. In addition, women, who are often stereotyped as poor in math compared to men, demonstrate stereotype threat effects when taking tests they believe measure their ability in math. Parallel negative effects have also been found on the performance of elderly individuals doing tasks they believe measure their memory and on the performance of low SES individuals undertaking activities they believe measure their verbal ability. Importantly, individuals belonging to groups that are not negatively stereotyped in specific domains do not generally show performance decrements related to whether or not the activity is described as measuring their abilities in those domains, supporting the contention that concern about the possibility that one's behavior will confirm a stereotype is the cause of the documented performance decrements. So, for example, men do not show performance decrements when an activity is said to test their math ability compared to when it is not. However, men have been shown to do more poorly on an emotion-processing task after being told that men are less good than women at such tasks than when they did not receive such potentially threatening information.

Stereotype threat not only appears to depress test scores in the short term. It can also lead to numerous other negative outcomes likely to undermine performance in the stereotype-relevant domain in the long run, including

the avoidance of challenging work in that domain, the rejection of critical feedback, and long-term lack of interest and engagement in the stereotype-relevant domain [1, 2].

Although the issue of how stereotype threat undermines performance is far from settled, research suggests a number of possibilities. Specifically, stereotype threat may create anxiety, which undermines performance. It can also lower individuals' expectations about their likely future performance and interfere with memory by leading individuals to devote some of their mental resources to processing and suppressing thoughts about being negatively stereotyped.

Numerous factors appear to influence whether stereotype threat is experienced [5]. For example, the likelihood of stereotype threat effects increases with increased task difficulty, increased levels of concern about performance in the domain in question, and increased identification with the stereotyped group. Also, individuals who themselves tend to believe stereotypes about their social category and those who expect to encounter prejudice and are more bothered by it than others are more affected by stereotype threat than are others, although personal belief in the validity of a stereotype is not necessary for stereotype threat effects to occur. There is some evidence that other personality predispositions, such as a high internal locus of control and a low tendency to self-monitor, are also related to increased stereotype threat effects.

Relatively little is dependably known about strategies that reduce or eliminate stereotype threat effects. However, some research suggests that individuals who are induced to believe that the stereotyped capability is malleable rather than being genetically determined are less prone to stereotype threat effects than are others. Also, educating individuals about the existence of stereotype threat and its potential to cause anxiety may be helpful. Importantly, both laboratory and school-based research suggests that leading individuals vulnerable to stereotype threat to self-affirm, i.e., to write about their most valued personal characteristic or about their values, can reduce stereotype threat effects, sometimes to a substantial extent [3]. Other strategies to reduce stereotype threat effects currently being proposed and investigated include emphasizing high standards and one's belief in the individual's potential, activating category memberships that are not linked to negative stereotypes, describing activities in non-threatening ways, and finding ways to make negatively stereotyped social categories less salient than they might otherwise be.

Relevance to Childhood Development

To the extent that negative stereotypes exist about the capabilities of children belonging to different social categories, stereotype threat can undermine children's development by reducing their performance and decreasing their interest in negatively stereotyped domains. Concern about this possibility is given weight by the fact that many children become aware of group stereotypes at a quite young age, certainly during if not before their school years. Furthermore, studies document stereotype threat effects in children as well as in older individuals. Stereotype threat can reasonably be considered one factor contributing to the substantial achievement gap between minority group students and their non-minority group peers, although it is clearly not the only one.

Stillbirths

Amy E. Zimmerman, Raymond S. Dean
Ball State University, Muncie, IN, USA

Synonyms

Fetal death; Intrauterine fetal death; Sudden Antenatal Death Syndrome (SADS)

Definition

A stillbirth is the death of a fetus prior to delivery or during its travel through the birth canal that occurs at 20 or more completed weeks of gestation. If gestational age is unknown, then the death of a fetus weighing 350 or more grams is considered a stillbirth [4].

Description

Stillbirths can be classified into three categories: early preterm, late preterm, and term. Early preterm is typically used for a fetal death occurring between 20 and 27 completed weeks of gestation. Late preterm refers to a fetal death occurring during 28–36 weeks of gestation. Term refers to a fetal at 37 weeks or more [4]. Miscarriage and stillbirth are not synonymous. A miscarriage is the death of the fetus before 20 weeks of gestation, whereas a stillbirth occurs at 20 or more weeks of gestation.

Male fetuses are more likely to be stillborn than female fetuses [6]. In the United States, approximately 26,000 stillbirths occurred in 2002 [5]. The stillbirth rate declined 52% between 1970 (14 per 1,000 births) and 1998 (6.7 per 1000 births) [1]. Although the cause of 25–60% of all fetal deaths cannot be determined, some causes of stillbirth have been identified, and include infection, lethal fetal anomalies, and fetal malnutrition [3]. Infection can lead to stillbirth through different mechanisms, such as placental damage, severe maternal illness, and development of a congenital anomaly in the fetus. The number of stillbirths caused by infection in developed countries, like the United States, ranges from 10 to 25%, but in developing countries, infection is a major contributing factor in stillbirths [4]. Another cause of stillbirth is the fetus being small for its gestational age or not growing at an appropriate rate. Abruption, in which the placenta prematurely separates from the uterine wall, has also been identified as a cause of stillbirth. Intrapartum asphyxia, impaired respiratory gas exchanged during labor, is another cause of stillbirth. The incidence of intrapartum asphyxia has decreased by 95% since the introduction of intrapartum monitoring [2, 3].

Researchers have identified several risk factors for stillbirth. Some of these risk factors are maternal obesity, low educational attainment, smoking, diabetes, hypertension, infection, thrombophilia, systemic lupus erthematousus (SLE), and multiple gestations. Infertility is a risk factor due to the use of advanced reproductive technologies, including in vitro fertilization (IVF) and ovarian stimulation [3]. The age of the mother is also a risk factor for stillbirth. Females who are under 20 or over 35 years old are more likely to have a stillbirth [1]. Another risk factor is race. Socioeconomic factors associated with race in relation to stillbirth include inadequate prenatal care as well as obstetric care early in the pregnancy [3]. However, African-American women are twice as likely to experience a stillbirth as their Caucasian counterparts even when evaluating only women who received adequate prenatal care [7]. There is also an interaction between race and maternal age. When over 35 years of age, an African American woman's risk of having a stillbirth is four to five times higher than the national average [5].

Stillbirth continues to be an important public health concern. Developing cost-effective prevention strategies is difficult due to limited information. Accurate reporting of stillbirths, including a proper investigation of the cause, can contribute to the development of both prevention and medical management strategies.

Stimulant Medications

Ramzi M. Hasson, Andy V. Pham, John S. Carlson
Michigan State University, East Lansing, MI, USA

Synonyms

Adderall; ADHD medication; Amphetamine salts; Concerta; Dexadrine; Dexamphetamine; Methylphenidate; Ritalin

Definition

Stimulant medications are psychoactive drugs that act on the central nervous system by inhibiting the reuptake of specific neurotransmitters including dopamine and norepinephrine, and consequently may elicit alertness, arousal, and in some cases euphoric feelings. Moreover, these medications may help attenuate symptoms of mild depression and narcolepsy, but are largely used to treat symptoms of Attention Deficit/Hyperactivity Disorder (ADHD). Popular stimulants in clinical use are largely prepared from methylphenidate, dextromethylphenidate, dextroamphetamine, or mixed amphetamine salts [3].

Description

Historical Context and the Modern Use of Stimulant Medications

The history of stimulant medication developed from the ancient use of stimulants, for largely recreational uses, by many cultures in different parts of the world. Stimulant use has been documented in multiple cultures across different continents. For instance, for the past 800 years people in East Africa and Lower Arabian Peninsula have chewed a stimulant leaf called Khat. Also, the early use of tea in ancient Chinese culture, the early tobacco use by Native Americans and how such stimulants are widely popular today around the world illustrates the pervasiveness of these stimulants. Additionally, the modern day proliferation of associated stimulants include Coca leaves and white powder Cocaine that began to be used in the early parts of the twentieth century for recreational as well as medicinal purposes [1].

Such historical recreational uses lead to the first synthesized stimulant, namely amphetamine in 1920. Amphetamine was produced for its effect as a mood-elevating drug and about the same time cocaine was medically prescribed for its stimulating effects [4]. The clinical use of stimulants for behavioral disturbances in children and adolescents first began in 1937 at the Emma Pendleton Bradley Home for Children in Rhode Island when Charles Bradley serendipitously discovered the positive effects of amphetamine on children's hyperactivity [6].

Another important development was the approval of methylphenidate for treatment of lethargy, mild depression, and narcolepsy by the Food and Drug Administration (FDA) in 1955. In the 1960s, methylphenidate acquired the trade name *Ritalin*, thus setting precedence of the popularity of stimulant medications [4].

In 1962, Bernard Weiss and Victor Laties extensively studied the effects of amphetamine (including methamphetamine). Before their detailed study there was "love/hate" affair with stimulant medications. The findings of Weiss and Laties portrayed amphetamines as "wonder drugs" that could greatly improve human cognitive abilities, as well as physical performance, but skepticism and worry about possible side effects still endured [4].

In the 1970s, there was increase in uproar about the possible negative consequences of giving Ritalin and other methylphenidate-based drugs to children. By the 1980s, with a new mental illness named to describe inattention in a small number of children as attention deficit disorder (ADD), the relationship between ADD and Ritalin and related drugs seemed clear cut and appropriate [4].

What suspicion there was in the 1970s was dissipated in the eighties and use and prescription among young children rose dramatically up until the late 1990s. Between 1987 and 1996, the use of stimulants among those younger than 18 increased up to sevenfold [10].

During the 1990s, the number of children and adults diagnosed with ADD rose from about 900,000 to almost 5 million. This figure was arrived at by the amount of medication prescribed for ADD. The sharp rise in ADD diagnosis is directly tied to another statistic: a 700% increase in the amount of Ritalin produced in the United States during the same time period. Furthermore, 77–87% of stimulant prescription from 1991–1997 was methylphenidate but a substantial increase of 7–14 fold in amphetamine prescription between 1996–1999 as observed by Medicaid and in health maintenance organizations [10, 11].

Although stimulant medications were used for several mental illnesses, today's use is largely for ADHD.

There is a plethora of stimulant medication options available. Ritalin was the icon of this class of medication, but today there are many more popular brands that are more flexible than previous stimulant medication amalgamations.

Commonly used stimulant medications for ADHD

Brand name	Generic name	Frequency	Duration of action
Dexedrine	D-Amphetamine	2 or 3 times per day	5 h
Adderall	Mixed amphetamine	2 or 3 times per day	5 h
Dexedrine Spansules	Dextroamphetamine	Once in a.m.	6–9 h
Adderall XR (extended release)	Extended release mixed amphetamine	Once in a.m.	9 h
Ritalin	Methylphenidate	3 times per day	2–4 h
Focalin	Dexmethylphendiate	2 times per day	2–5 h
Ritalin SR (slow release)	Slow release amphetamine	1 or 2 times per day	5 h
Metadate CD	Methylphenidate	Once in a.m.	8 h
Concerta	Methylphenidate	Once in a.m.	12 h

Benefits and Side effects of Stimulant Medications

In general, many studies show a significant improvement in ADHD core symptoms such as impulsiveness, aggressiveness and hyperactivity, with the use of stimulant medication. Placebo responses in children with ADHD are generally low ranging from 2–39% [3]. Furthermore, stimulant medications have been found to improve the quality of social interactions between children with ADHD and their parents, teachers, and peers [3].

The majority of psychiatrists and other mental health professionals recommend the use of stimulant medication intervention only after a great deal of consideration has been given to possible side effects and identifying comorbid issues such as learning disabilities or depression. Moreover, stimulant medications should only play a part in overall psychoeducational treatment plans that may include classroom accommodations, working memory training, parent education, and coaching [3].

Although there is generally a low rate of serious side effects, possible side effects include appetite suppression, sleep disruption, irritability, disruption in liver function, elevated heart pressure, elevated heart rate, moodiness, sad demeanor, abdominal pain, lethargy, weight loss, and headaches.

Relevance to Childhood Development

As has been discussed thus far, stimulant medications are largely used to treat ADHD symptoms. It also has been noted that stimulant medications have a controversial history, and currently there is debate about the administration of these drugs to children. Between 3 and 7% of school aged children are diagnosed as ADHD, and 77% of the initial referrals in schools for ADHD examination come from teachers who may play a significant role in the assessment. Other controversial issues center on whether ADHD is over- or under-diagnosed, and whether there is over- or under-prescription of stimulant medications.

Stimulants

Synonyms
Analeptics; Psychostimulants; Uppers

Definition
A class of psychoactive drugs that increases mood, feelings of well-being, alertness, and energy

Description
Stimulants are typically prescribed for treatment of attention-deficit/hyperactivity disorder (ADHD), narcolepsy, and short-term obesity. Stimulants have many short-term and long-term effects. The short-term effects are caused by an increase in the amount of norepinephrine and dopamine in the brain by inhibiting reuptake, which increases blood pressure, heart rate, blood glucose, breathing, and constricts blood vessels. The effects can be increased alertness, energy, attention, and euphoria. There are also harmful effects such as cardiovascular problems or seizures. Also, there are harmful long-term effects of continued stimulant use, such as addiction. Stimulant drugs are often abused and when taken in high dosages stimulants can cause paranoia, hostility, high body temperature, and an irregular heartbeat.

Types of Stimulants:

- Caffeine
- Nicotine
- Amphetamines
- Cocaine
- MDMA (Ecstasy)
- Norepinephrine reuptake inhibitor (NRIs) and Norepinephrine-dopamine reuptake inhibitors (NDRIs)
- Modafinil
- Ampakines
- Yohimbine

Relevance to Childhood Development
Stimulants may stunt children's growth. Also, abuse of prescribed stimulant medication has become increasingly common among adolescents and college students. Individuals who are prescribed stimulant medication for ADHD are selling their medication for recreational use. The medication is also being used to increase studying efficiency.

Storm and Stress Theory

Jackie Kibler
University of Montana, Missoula, MT, USA

Definition

Describes the period of adolescence as a time of difficulty and strife [2].

Description

G. Stanley Hall, father of the Child Study Movement, in his text titled *Adolescence* [4] discussed the "Storm and Stress theory" of adolescence. He defined this time as one characterized by behavioral difficulties and emotional storminess [4]. Albert Bandura challenged this claim of storm and stress with his 1964 study on the adolescent experience [1]. His research indicated that the majority of youth did not experience adolescence as a turbulent time [1]. Those who did indicate a stressful adolescent experience also indicated a stressful childhood experience, suggesting that the period of adolescence did not bring about the turbulence [1]. Contemporary research also challenges Hall's theory indicating that fewer than 10% of adolescents report experiencing extreme turmoil [3].

Strange Situation

Cynthia Field
William Alanson White Institute, New York, NY, USA

Synonyms

Ainsworth's procedure; Ambivalent attachment

Definition

The Strange situation is a standardized observational procedure involving short separations and reunions between an infant and his caregiver. Each successive phase of the procedure is designed to be increasingly stressful to the infant to induce attachment behaviors. The infant's behavior at departures and reunions are coded to assess the toddler's attachment style.

Description

The Strange situation was developed by Mary Ainsworth and her colleagues to assess the attachment between a mother and her infant. The procedure provides empirical support for attachment theory that she and her colleague John Bowlby developed (See Chapter Attachment Theory herein.). The structure of the observational technique is based upon Bowlby's concept of the protective function of attachments. When an infant is distressed, he turns to his attachment figure for comfort and to ensure his wellbeing. In addition, the structured technique is premised on Ainsworth's notion that infants use their mothers as a *secure base* from which they play and explore their environment. The physical arrangement of the laboratory facility is designed to resemble the sort of situations that a mother and her child encounter in their home, but with added stress so as to activate attachment behaviors.

Ainsworth and her colleagues developed a highly specified protocol for the Strange Situation. The procedure involves a sequence of eight episodes in which 12–18 month old infants are observed as they experience stress induced by separations from their mothers. The infant's responses to his mother at reunion is observed and used to classify the child into one of four attachment styles.

More specifically, in the first brief episode, the mother and infant are lead into the room by a stranger who asks the adult to sit quietly and place her child on the floor near some toys. In the next episode, the stranger leaves the room while the mother quietly reads a book. The mother has been told not to initiate any engagement with the child, but can respond appropriately if the infant initiates contact. Each successive episode is increasingly stressful to

the infant as he is separated from his primary attachment figure and is made anxious by the presence of a stranger.

Episode	Persons present	Duration	Action
1	Mother, infant, observer	30 s	Observer introduces mother and infant to room and gives instructions. Observer leaves.
2	Mother and infant	3 min	Mother sits in chair and reads while baby explores. Mother responds to infant but does not initiate.
3	Stranger, mother and infant	3 min	Stranger enters, silent (1 min.), talks to mother (1 min.), and approaches infant (1 min.).
4	Stranger and infant	3 min or less	First separation. Mother leaves room. Stranger comforts infant if needed, otherwise sits in chair.
5	Mother and infant	3 min or more	Stranger leaves. First reunion. Mother returns, greets and/or comforts infant, sits in chair and reads.
6	Infant alone	3 min or less	Second separation. Mother departs, leaving infant alone.
7	Stranger and infant	3 min or less	Continued separation from mother. Stranger enters, comforts infant if needed, otherwise sits in chair
8	Mother and infant	3 min	Second reunion. Mother returns. Stranger leaves.

The procedure is video recorded and scored by highly trained observers. These observers tabulate four 7-point scales that assess *proximity seeking, contact maintaining, avoidance of proximity and contact,* and *resistance to contact and comforting.* Although all of the infant's behaviors are closely noted, the observers pay special attention to the nature of the infant's reunion with his mother following separations.

Ainsworth and her colleagues grouped infants whose behaviors were alike in as many respects as possible. This analysis yielded three main groups of infants, designated as secure, avoidant and ambivalent, and subtypes of each of these styles. Subsequently, other researchers identified a fourth general pattern. Ainsworth hypothesized that differences in attachment were related to variations in the sensitivity and appropriateness of the mother's responses to her infant. The names assigned to the different styles refer to the infant's perception of his mother's response to him if he is in need of comfort or protection, and the manner in which he uses his caregiver to meet those needs.

Ainsworth identified a *secure* baby as one who protested when his mother left the room, greeted her pleasantly upon her return, and was able to resume play. When situated in the room with the mother close by, the infant would use her as a secure base from which he would explore the toys and other objects in the room. In contrast, an infant with an *avoidant attachment style* rarely cried when the mother departed from the laboratory room, and remained aloof on her return. He generally did not show his need for connection, although physiological studies showed that he has a physically measurable stress reaction. Thus, he does not express his attachment need to avoid risking rejection. Finally, an *ambivalent (or resistant)* infant is anxious before the mother leaves the room, and may become highly upset when she departs. When the mother returns, the infant engages with her in an ambivalent fashion: he seeks contact while resisting her by squirming away or kicking his mother. He has difficulty using his mother to obtain comfort and subsequently return to exploration. Later research revealed the *disorganized* attachment pattern. An infant who reflects this attachment style displays inconsistent or contradictory behaviors. For instance, the infant may happily approach the mother but turn away or shriek when she tries to pick him up. At other times the infant may evince extreme distress yet remain frozen and not seek contact with his mother. Those who displayed a disorganized attachment were found to have been abused or subjected to distressing experiences early on.

Relevance to Childhood Development

The strange situation is a powerful research tool that has been used in thousands of empirical studies to explore the influence of infant-caregiver attachment on child development. Longitudinal studies on attachment have shown its importance in personality growth and adjustment.

Stranger Anxiety

Maria-Eva Tsola, Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Synonyms

Fear of strangers; Stranger fear; Stranger wariness

Definition

An infant's anxiety response to someone other than the caregiver.

Description

Stranger anxiety is discomfort at the approach of an unfamiliar person. Infants differ considerably in both the way in which they demonstrate signs of discomfort and in the intensity of distress they experience once confronted with people that are unfamiliar. The manner in which an infant responds to a stranger has been found to be influenced by a variety of factors, namely, the infant's temperament and the security of the mother–infant relationship, aspects of the stranger such as gender and behavior toward the infant, and aspects of the situation, including the proximity and availability of an attachment figure or the infant's current mood [1–3]. Thus, infants may cry, cling and hide their faces, or merely become unresponsive and guarded [1].

Because researchers diverge in their views regarding behaviors that constitute evidence of stranger anxiety, the relevant literature does not denote a precise time period in which the phenomenon occurs. The majority of researchers agree, however, that by the time they are one year old most infants respond with some level of stranger anxiety [1, 4, 5].

The behavioral reactions characteristic of stranger anxiety have been viewed by attachment theorists as indicators of the infant's developing ability to discriminate between the attachment figure and other adults [6]. According to this explanation, labeled "the incongruity hypothesis" by Hebb in 1966 [2, 3], fear may result from discrepancies between the stranger's demeanor and that of the familiar caregiver. Because the emergence of the unexpected is incongruous and incompatible with infants' expectations, it produces anxiety and fear which is then manifested in avoidant behaviors. The emergence of stranger anxiety is thus viewed as a milestone of cognitive development: a behavioral demonstration of the infant's acquisition of the ability to represent persons mentally and to make a distinction among various persons in its environment, an important skill achieved in Piaget's fourth stage of sensorimotor development.

Strattera (Atomoxetine)

Amber R. Whited, Andrew S. Davis
Ball State University, Muncie, IN, USA

Synonyms

Atomoxetine

Definition

Strattera is a selective norepinephrine reuptake inhibitor (SNRI) commonly prescribed for treatment of Attention Deficit/Hyperactivity Disorder (ADHD).

Description

Strattera is manufactured by Eli Lilly and Company. It is administered as a capsule, which is taken whole. The medication is intended to reduce inattentiveness, motor hyperactivity, and impulsivity. Although effects may be observed as early as the first dose, signs of improvement may take 6–8 weeks to appear. Furthermore, improvement in symptoms may be more pronounced in female patients, as well as with patients who exhibit more severe symptoms prior to treatment or who exhibit predominantly inattentive type rather than hyperactive-impulsive type. Possible side effects for children and adolescents include digestive difficulties (i.e., upset stomach, reduce appetite, nausea), dizziness, drowsiness or fatigue, and mood swings. Digestive difficulties and drowsiness are reported most frequently. Adverse side effects are seen more commonly in young patients and patients who exhibit a high level of hyperactivity or impulsivity prior to treatment, while diagnosis of predominantly inattentive type has been linked with reduced frequency of reports of adverse side effects [2–4].

Strattera should not be taken by individuals who are sensitive to atomoxetine, who are taking a monoamine oxidase inhibitor (MAOI), or who have narrow angle glaucoma. Use in conjunction with Albuterol may increase heart rate and blood pressure. Due to the potential for increases in heart rate and blood pressure, caution is recommended in use of Strattera for patients with heart problems. Individuals with liver impairment may require a reduced dosage, typically being prescribed a 50% dosage for moderate liver damage and a 25% dosage for severe liver damage [3, 4].

Although Strattera has been approved by the Food and Drug Administration for treatment of ADHD, it may also be prescribed for treatment of depression. As with many antidepressants, Strattera carries a warning that use with children and adolescents may increase the risk of suicidal ideation. Patients should be monitored closely, particularly early in initial treatment with Strattera [3]. A meta-analysis conducted by Bangs et al. [1] noted suicide-related events were more common among patients given atomoxetine than individuals given a placebo, although the events occurred rarely. Suicide-related events usually involved increases in suicidal ideation, rather than attempted suicides.

Stress

Kristy M. Kelso
Western Carolina University, Cullowhee, NC, USA

Synonyms

Anxiety; Coping; Pressure; Tension

Definition

A condition in which an individual feels mental tension due to overwhelming circumstances – this mental tension can develop into depression once the individual feels hopeless or can be manifest as physical problems.

Description

The stress response occurs when the amount of stress exceeds what is typically tolerable, and tolerance levels tend to vary for each individual. No matter how the arousal is elicited (whether it be from a traumatic event, an exhilarating event, or anything in between) the stress response process remains the same. The autonomic nervous system is responsible for any stress-related processes, and is able to release hormones through two different neurological pathways. Both pathways are utilized, however they serve different functions and are activated by different hormones.

The Fast-Acting Pathway is activated when the hormone epinephrine is released, thereby preparing the body for the "fight or flight" response. During this process, epinephrine has two primary functions: preparing the body for an abrupt surge of activity and stimulating cell metabolism allowing the body to be ready for action. This survival mechanism only occurs when the mind perceives a critical or dangerous situation.

The Slow-Acting Pathway involves the hormone cortisol, a steroid released from the adrenal cortex. Cortisol results in the shutting down of any systems in the body that are not essential at the time of the stressful event. This allows the remaining energy in the body to be redirected in order to deal with the stressful event.

It is suggested that consistent exposure to or concentrated amounts of these stress hormones during prolonged stress and intense traumatic events may cause hippocampal damage. Such damage may increase one's vulnerability to stress-related disorders (Post-Traumatic Stress Disorder, Panic Disorders, Generalized Anxiety Disorder, and Acute Stress Disorder).

Relevance to Childhood Development

Although stress involves a significant biological component, it has an equally profound impact psychologically. Psychological beliefs are formed through the process of conditioning, whether it is through previous personal experiences or by observing the experiences of others. Thus, the events that happen during the developmental stages of children can have large implications on their lives as adults. Regardless of whether or not an event is negative or positive, it will ultimately influence an individual's beliefs, emotions, and reactions to all similar events in the future.

Developmentally, all children will experience stress. Large amounts of stress not only pose the risk of damage to the hippocampus, but the risk of abnormal social development as well. Depending upon the frequency and intensity of the stressor, the previously acquired coping skills, and the level of social support established, a range of outcomes can be possible for a child. The more positive coping skills a child possesses and the larger their social support system, the better they will be able to effectively manage the stressful situation. Children with fewer coping skills and/or smaller social support systems could be at greater risk for Post-Traumatic Stress Disorder, Panic Disorders, Generalized Anxiety Disorder, and Acute Stress Disorder. Theoretically, personality disorders could also be attributed to maladaptive coping strategies that may have been developed in response to growing up in stressful environments (examples would be the notoriously criminalistic behavior of Antisocial Personality Disorder or the manipulative behavior of Borderline Personality Disorder).

Ideally, levels of stress for children should be kept to a minimum as a more nourishing environment has been shown to correlate with better social skills and better overall mental health. The mental wellbeing and social skills of children are important throughout the developmental stages, however the benefits also extend to adulthood in regards to future career opportunities and personal relationships.

Striatum

Ioana Boie
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Neostriatum or striate nucleus

Definition

The striatum is a collection of subcortical anatomical brain structures named after their striped or striated appearance.

Description

The striatum includes the caudate and putamen, two of the three nuclei that make up the basal ganglia (the caudate, putamen, and globus pallidus). The striatum collects projected input from the sensory cortex and other cortical regions. These three nuclei work together to send their output to the motor areas of the cortex, through the globus pallidus and then the thalamus. The striatum is considered a motor region that has a role in planning and the initiation of voluntary movements, and it controls the proper timing, ordering and movement sequences.

The striatum's activity is disrupted in Parkinson's disease, which has symptoms such as resting tremors, a slow shuffling gait, and difficulty initiating voluntary movement. Huntington's disease also affects the caudate nucleus, and is characterized by puppetlike jerking and grimacing choreic movements.

With the help of neuroimaging techniques, other changes in the structures and chemistry of the striatum have been noticed in adults who used methamphetamines, specifically an enlargement of the striatum, while the effects of in utero exposure to methamphetamines have shown a decrease in the striatal structures.

Other studies have shown association between abnormalities in circuits involving the amygdala and striatum and bipolar disorder, as well as effects on mood regulation. Furthermore, other studies are investigating the links between the striatum and attention-deficit hyperactivity disorder.

Stroop Tasks

Audrey McKinlay
University of Canterbury, Christchurch, Canterbury, New Zealand

Synonyms

Color word task

Definition

The Stroop Test is designed to measure an individual's ability to inhibit automatic verbal responses.

Description

The Stroop Test refers to the phenomenon that if you try to name the color of the ink in which a word is written, the word itself can "interfere" with the process. The Stroop effect was first described by J.R. Stroop in 1935 [4] and is most obvious when the word, and color of the ink that the word is written in, don't match (i.e., they are incongruent). For example, the correct response for the three words below would be red, brown, and blue.

Blue
Green
Brown

However, in this situation it usually takes longer to name the color of the ink because of the need to inhibit the more automatic response of reading the word. On the other hand if the word does match its color (i.e., is congruent), it usually takes a shorter time to respond.

Administration

In the Stoop Test individuals are required to respond to three separate conditions. In the first condition, the participant is presented with a page that has rows of colored patches that they are required to name. In the second condition they are presented with rows of words that they are required to read. The third condition is the traditional "stroop effect" where the participant is presented with a page of words printed in incongruent ink colors. Participants are asked to name the color of the ink that the letters are printed in rather than reading the word. For example, the correct response for the first line of the text in the box below would be, red, brown, blue, and green [3].

Blue	Green	Brown	Red
Green	Brown	Red	Blue
Brown	ed	Blue	Green
Red	Blue	Green	Brown

Some test designers add a fourth condition. In the fourth condition participants are presented with a page with rows of words again printed in incongruent ink colors but in this condition some of the words are in boxes. The participant is required to name the color of the ink for the words that are not in boxes and read the word if the word is inside a box.

Scoring

In each condition individuals are required to name the colors or read the words as quickly as possible. A number of scores can be generated: (a) time taken to complete a condition, (b) number of uncorrected errors, (c) number of corrected errors. Normative data are available for most age groups [3].

Relevance to Childhood Development

The Stoop Test has become a well used measure of inhibitory control. Inhibitory control is an important aspect of development. As a general rule, children have a less developed ability to inhibit automatic responses. For example, a very young child may verbalize an inappropriate response (e.g., "look mommy that lady is fat") whereas a normal adult would be able to inhibit verbalizing "inappropriate" observations because of their more developed inhibitory control skills. For most children inhibitory control develops automatically as they mature. However, for some children this ability does not develop at the normal rate such as for children with Attention Deficit Hyperactivity Disorder [1]. In this situation the Stroop Test is a valuable tool in assessing the level of inhibitory control problems that these children are experiencing.

Because very young children are still developing their reading ability Stroop tasks have been developed that do not require this skill, such as color-object interference tasks where line drawings of well known objects (e.g., ducks, frogs) are used rather than words [2].

Structural Equation Modeling

Kristen M. Grabill
University of Florida, Gainesville, FL, USA

Synonyms

Analysis of covariance structures; Confirmatory factory analysis; Covariance structure analysis; Covariance structure modeling; Path analysis

Definition

Structural equation modeling (SEM) is a flexible and powerful set of statistical techniques which incorporates path analysis and confirmatory factor analysis.

Description

SEM represents an advantage over traditional general linear modeling in that it has flexible assumptions, the ability to test a complete model rather than individual coefficients, the ability to have more than one outcome variable, ease of modeling mediation, and ease of handling missing data.

SEM techniques include confirmatory factory analysis (CFA) and path analysis [1]. CFA is a process by which researchers use observed variables to measure unobserved, latent constructs. Factor loadings are calculated as a measure of the strength of the relationship between an observed variable and its latent factor. Path analysis in SEM tests relationships between observed variables or latent constructs in the form of paths or correlations. Path coefficients are calculated as a measure of the strength of association between a predictor and outcome variable. Models that contain both latent (unobserved) constructs and observed variables embedded in a path model require researchers to first test a measurement model using CFA, followed by testing a structural model using path analysis. However, SEM is an extremely flexible approach to statistical modeling, and although estimation of measurement and structural models are one frequent application of SEM, it is often used in other ways. For example, CFA may be used alone to validate the psychometric properties of a measure. Structural or path models may be used alone in cases when research does not involve latent constructs. SEM may also be applied to longitudinal data through use of latent growth curve modeling and analysis of time series data.

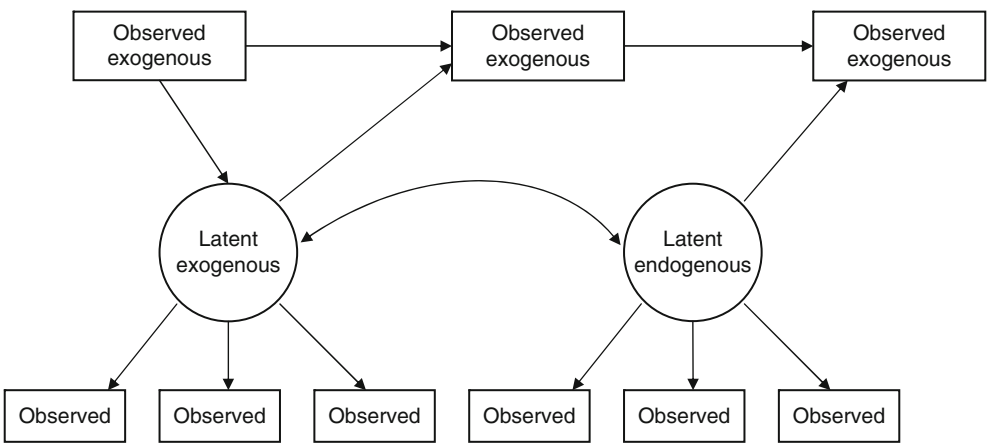
In general, models using SEM are not evaluated using significance levels, as with traditional GLM statistics. They are evaluated through assessment of various fit indices that are generated by the software program used to test the model. The software program may also calculate modification indices, which identify changes to the model meant to improve fit. However, modification indices are typically used sparingly, as SEM is a theory-driven statistical approach. LISREL, AMOS, Mplus, and EQS are popular software packages for SEM.

Interpretation of Path Diagrams in SEM (see Fig. 1)

An observed variable, represented graphically with a box, is one that has been directly measured by researchers. A latent variable, represented graphically by an oval, is one that is not directly measured, but is estimated by the model from observed variables. An exogenous variable is one that is not predicted by another variable in the model, but typically is a predictor of one or more other variables. An endogenous variable is one that is predicted by other variables in the model and may or may not also predict other variables. Each straight line with a single arrow represents a path, or hypothesized direct effect of one variable on another. Each curved line with two arrowheads represents a correlation between two variables.

Relevance to Childhood Development

SEM is a statistical application that is being used throughout research fields, including areas of child development and psychopathology. Recent applications include investigation of child social adjustment, impact of parental



Structural Equation Modeling. Fig. 1 Example path diagram used in structural equation modeling.

alcohol use on child outcomes, the relationship of parenting techniques to childhood aggression, development of parent–child relationships during adolescence, evaluation of family-based intervention for school success, and numerous others. Given the flexibility and utility of SEM, it will likely continue to increase in frequency as a statistical tool among child development researchers.

Structured English Immersion

Corey E. Ray-Subramanian
University of Wisconsin-Madison, Madison, WI, USA

Definition

An instructional approach designed for students with limited English proficiency todevelop proficiency in English and benefit from academic content instruction in English.

Description

Structured English immersion has as its goal sufficient English language acquisition for students to succeed in mainstream English-only classrooms. Instruction in these programs is in English and teachers use strategies such as visuals, graphic organizers, and gestures to help make the English content comprehensible [1]. Longitudinal research has demonstrated that students in Structured English immersion programs have similar academic skill and English language growth rates in the first few years of elementary school as compared to students in early-exit and late-exit ►transitional bilingual education programs; however students in late-exit transitional bilingual education programs tend to have accelerated academic skill and English language growth throughout the second half of elementary school as compared to students in Structured English immersion or early-exit bilingual education programs [2].

Study Skills

Carrie R. Ball
Ball State University, Muncie, IN, USA

Synonyms

Study strategies; Study tactics

Definition

Study Skills comprise an integrated repertoire of tactics and strategies, which facilitates acquisition, organization, retention, and application of new information.

Description

Study skills encompass a broad range of tactics and strategies that ultimately allow students to effectively learn, organize, and recall new information. Although children are often expected to develop study skills naturally, research indicates that many students exhibit study skill deficits and require explicit instruction to acquire and appropriately use study skills [5]. Additionally, the degree to which students are able to study effectively is a strong predictor of academic achievement [1].

An important distinction must be drawn between study tactics and study strategies, both of which are often used interchangeably with study skills. Study tactics, or the specific techniques involved in studying, form the building blocks for effective study skill development. Study tactics generally fall into one of three "clusters," each of which is characterized by its approach to learning new information [2]. *Repetition-based* tactics emphasize frequent rehearsal of material to encourage learning. Use of flashcards or spelling lists are common examples of repetition-based tactics, which are well-suited for the acquisition of rote facts or lists that require minimal information processing. *Procedural* tactics focus on developing steps or routines that enhance information processing. Note-taking, outlining, and SQ3R are some of the most common examples of procedural tactics, which are often beneficial for students in middle- to late-elementary school. Procedural skills allow children to practice a reliable method of acquiring and reviewing new information. Finally, *cognitive* tactics are often introduced during late elementary or middle school. Cognitive approaches, such as graphic organizers, question generation, and summarization, facilitate critical thinking and personal connections to new material.

In contrast to study tactics, study strategies refer to skills that are necessary to effectively select, integrate, and apply one or more study tactics in a way that facilitates learning. The development of study strategies typically occurs during middle school or later and is a key factor in meeting the increasing demands of secondary education. Study strategies are commonly referred to as ►metacognitive skills, and can include behaviors such as assessing the demands of a task, selecting and applying appropriate tactics, self-monitoring for comprehension and recall of information, and effectively managing the environment to facilitate learning. Students who struggle academically in high school almost always exhibit deficits with regard to effective study strategies [6].

Study skills, then, refers to an age-appropriate combination of both study tactics and study strategies. An appropriate balance between tactics and strategies varies depending upon the developmental level of the child. During early elementary school, for example, study skills may be considered appropriate if children can independently apply one or two study tactics. By late elementary and early middle school, students are typically expected to demonstrate competent use of multiple study tactics, in addition to a developing ability to select and apply a tactic appropriate for a particular task (i.e., apply a study strategy). Students in high school who demonstrate adequate study skills exhibit an extensive toolbox of study tactics, in addition to strategies that allow them to manage multiple courses and assignments, determine and use one or more tactics appropriate for each studying task, and self-monitor their study habits to ensure adequate comprehension and retention of material.

Relevance to Childhood Development

Study skills have a major impact on children's academic development. Children who struggle academically across a number of subject areas often exhibit significant study skills deficits. In young children, academic difficulty that results from inadequate study skills may be manifested through inattention, challenging behaviors, or low task completion across classroom settings. In middle and high schools, students with study skills deficits often have difficulty with low homework completion, poor test performance, and inappropriate organization and time management skills. Several resources are available for comprehensive assessment and intervention for children who demonstrate such deficits [3, 4].

It may also prove beneficial for parents and teachers to recognize two keys points regarding study skills. First, study skills develop along a continuum, from very basic rehearsal tactics to a complex array of techniques and strategies that are applied flexibly and intentionally to tasks. Helping children become competent at using age-appropriate tactics and strategies can contribute to long-range academic success. Second, study skills can be explicitly taught within an educational context. Incorporating study skills instruction into regular classroom activities allows students to receive modeling, feedback, and guided practice in the use of a variety of specific study tactics. This exposure and experience is likely to help students feel more independent in selecting and using study tactics independently.

Stuttering

Chandrabanu Shrivats, Kimberly Booker
Texas Woman's University, TX, USA

Synonyms

Falter; Stammer

Definition

To stutter is to speak with an involuntary disruption or blocking of speech (as by spasmodic repetition or prolongation of vocal sounds).

Description

Stuttering is a speech disorder in which the normal flow of speech is disrupted by frequent repetitions or prolongations of speech sounds, syllables or words, or by individual's inability to start a word. The speech disruptions may be accompanied by rapid eye-blinks, tremors of the lips and/or jaw, or other struggle behaviors of the face or upper body. Certain situations, such as speaking before a group of people or talking on the telephone, tend to make stuttering more severe. Other speaking situations, such as singing or speaking alone, often improves fluency. Diagnosis is usually based on the history of the disorder, including when it was first noticed and under what circumstances, as well as a complete evaluation of speech and language abilities. Stuttering may also be referred to as Stammering, especially in England and by the broader term of "dysfluent speech". Stuttering is different from two additional speech fluency disorders, *cluttering*, characterized by rapid, irregular speech and *spasmodic dysphonia*, a voice disorder. It is estimated that over three million Americans stutter. The precise mechanisms causing stuttering are not known.

Relevance to Childhood Development

Stuttering affects individuals of all ages but occurs most frequently in children who are developing language, typically between the ages of 2 and 6 years. Boys are three times more likely to stutter than girls. Most children, however, outgrow their stuttering, and it is estimated that less than 1% of adults stutter. Complications of stuttering in children may include social problems caused by fear of ridicule, which may make a child avoid speaking entirely.

The most common form of stuttering is thought to be developmental, that is, occurring in children who are in the process of developing speech and language. This relaxed type of stuttering is felt to occur when a child's speech and language abilities are unable to meet his or her verbal demands; that is, stuttering happens when the child searches for the correct word. Another form of stuttering is neurogenic, where the brain is unable to coordinate adequately the different components of the speech mechanisms. Neurogenic stuttering may also occur following a stroke or any other type of brain injury. Other forms of stuttering are classified as psychogenic, or originating in the mind or as a product of mental activity of the brain such as thought or reasoning. Psychogenic stuttering occasionally occurs in individuals who have some type of mental illness or have experienced severe mental stress or anguish.

There are a variety of treatments available for stuttering. Any of the methods may improve stuttering to some degree, but there is, at present, no absolute cure for stuttering. Developmental stuttering is often treated by educating parents about restructuring the child's speaking environment to reduce episodes of stuttering. Parents are urged to provide a relaxed home atmosphere with lots of opportunities to speak, and refrain from criticizing or reacting negatively to the child's dysfluencies.

Substantia Nigra

Ioana Boie
University of Texas at San Antonio, San Antonio, TX, USA

Definition

The substantia nigra is defined as a collection of neurons and nuclei that are part of the dopaminergic system, which are located in the midbrain or mesencephalon. The name of the structure is based on the dark color of the cells due to their high concentration of neuromelanin.

Description

The substantia nigra is involved in the function of basal ganglia through the dopaminergic nigro-striatal system, which connects the globus pallidus and the thalamus. This connection is believed to influence motor behavior.

There are two different parts of the substantia nigra, the *substantia nigra pars compacta* and the *substantia nigra pars reticulata. Substantia nigra pars compacta* is the upper, more dorsal part, in which the dopaminergic cells are distributed similar to a band stretching from the medial to the lateral area. *Substantia nigra pars reticulata* is located ventrally or below the *pars compacta*, and it consists of the dendrites of the dopaminergic neurons.

The degeneration of the substantia nigra and the deterioration of the dopaminergic pathways are the causes of Parkinson's disease, and the substantia nigra also is believed to play a role in learning.

Suicide

David N. Miller
University at Albany, SUNY Division of School Psychology, Albany, NY, USA

Synonyms

Self-annihilation; Self-destruction

Definition

Suicide refers to a fatal, self-inflicted act with the inferred or explicit intent to die.

Description

Suicide is the final and most serious form of suicidal behavior on a continuum that also includes suicide ideation and suicide attempts. Suicide continues to be a significant national problem; although it is the 11th leading cause of death among Americans overall, suicide is the third-leading cause of death among children and adolescents, trailing only accidents and homicide. The probability of suicide increases in both males and females as children grow older, with adolescents ages 15–19 being at higher risk than youth ages 10–14. Suicide does occur in children under the age of 10, although it is very rare.

In terms of race and ethnicity, in the U.S. Caucasian youth are at highest risk for suicide, followed by African American and Latino youth. Proportionally, however, the highest rates of youth suicide are among Native American youth. Possible reasons for this include a proportionally higher use of alcohol and firearms and a frequent lack of social integration in this group. Gender exerts a greater influence on youth suicide than does race and ethnicity. Although females report more suicide ideation than males and attempt suicide two to three times the rate of males, males complete suicide at a rate of five times that of females. Reasons for the higher youth suicide rate of males include the higher rates of significant risk factors among males as well as their being less likely than females to engage in a number of protective behaviors, such as seeking help. In terms of geography, youth suicide rates have consistently been highest in the Western states and Alaska and lowest in the Northeastern states. It has been frequently suggested that geographical differences in youth suicide rates may largely be attributed to differences in population density across various regions. Consistent with this hypothesis is the finding that suicide rates are typically higher in rural areas than in urban areas.

The majority of youth suicides occur in the afternoon or evening, and most often in the home, where the primary means for suicide (e.g., firearms) are typically available. The use of firearms is the most frequently used method of suicide completion among males ages 10–19. Although historically firearms were the most frequently used method of suicide completion among females in this age group as well, more recently females have been more likely to use hanging/suffocation rather than firearms. Although a number of studies have examined temporal variations in suicide completion, none to date have been specific to youth suicide. Among adults, research indicates that suicides occur most often between March and September, with the fewest recorded suicides occurring in December. Suicides appear to occur most often on Mondays and least often on weekends.

Although numerous risk factors for youth suicide have been identified, the most reliable and robust risk factor is the presence of psychopathology, particularly depression and related mood disorders. In addition to psychopathology, the other prominent risk factor for suicide is previous suicidal behavior, particularly previous suicide attempts. As opposed to risk factors, which are variables that may predispose an individual to suicidal behavior, warning signs are more dynamic and proximal factors that suggest the increased probability of a suicidal crisis. Some prominent warning signs for suicide may include hopelessness, increasing alcohol or drug use, acting recklessly or engaging in risky activities, feeling trapped, experiencing anxiety and/or agitation, withdrawing from family and friends, being unable to sleep or sleeping excessively, giving away prized possessions, and/or perceiving no reason for living or no sense of purpose in life.

There are many myths associated with youth suicide, including the erroneous beliefs that it is caused primarily by family and social stress rather than mental health problems, that individuals who threaten suicide are only doing

so to gain attention, and that once an individual decides to commit suicide there is little or nothing that can be done to prevent it. Perhaps the most significant and dangerous myth, however, is that asking questions or talking about suicide with children and adolescents will increase the probability of youth suicidal behavior. There is no evidence to support this belief, and research suggests that at risk youth who are able to openly discuss suicide with a trusted adult can lead to beneficial outcomes for them as well as their peers who may also be at risk. The direct questioning of youth suspected of being at risk for suicide is also an essential component of effective suicide risk assessment and prevention.

Suicide Ideation

David N. Miller
University at Albany, SUNY Division of School Psychology, Albany, NY, USA

Synonyms

Suicidal cognitions; Suicidal thoughts

Definition

Suicide ideation involves thoughts/cognitions about killing oneself as well as specific thoughts related to suicide.

Description

Suicide ideation may take a variety of forms, ranging from general thoughts about suicide, to wishes of being dead or never being born, to more serious thoughts of suicide involving specific plans to kill oneself, such as how, where, and when this might be accomplished. Suicide ideation is rare in children but highly prevalent among adolescents, with research suggesting that approximately 1 out of 6 high school students will seriously contemplate suicide in a given year. There are significant gender differences in regard to suicide ideation. Specifically, adolescent females report engaging in serious suicide ideation more often than males, although males have a much higher suicide completion rate.

Suicide ideation occurs at the beginning of the suicidal behavior continuum that also includes suicide attempts and suicide completion. The behaviors along this continuum vary and are not mutually exclusive, nor do all suicidal youth advance sequentially through them. Although suicide ideation typically is a necessary precursor to more serious forms of suicidal behavior (i.e., suicide attempts; completed suicide), most children and adolescents who engage in suicide ideation neither attempt nor complete suicide.

Sumner, Francis Cecil

Scott Graves
Bowling Green State University, Bowling Green, OH, USA

Life Dates

1895–1954

Introduction

Francis C. Sumner was the first African American awarded the Ph.D. in psychology from a U.S. institution in 1920. Graduating from Clark University under the tutelage of G. Stanely Hall, Sumner's dissertation was titled: Psychoanalysis of Freud and Adler.

Educational Information

Sumner received his elementary education through several school systems in Virginia, New Jersey, and the District of Columbia. Due to a lack of secondary education opportunities he did not graduate from high school. Even without a high school diploma, he performed well enough to enroll at Lincoln University in Pennsylvania during the 1911 school year at age 15. In 1915 he graduated magna cum laude with special honors in English, Modern Languages, Greek, Latin, and Philosophy. The prominent child psychologist G. Stanley Hall was the president of Clark University and he allowed Sumner to be admitted in 1915. In 1916 he was awarded a second B.A. in English from Clark University in Worcester Massachusetts. Upon completion of his Ph.D. in 1920 Sumner accepted a position as chair of the philosophy and psychology departments at West Virginia Collegiate Institute now known as West Virginia State University.

Accomplishments

Dr. Sumner established the first psychology department at Howard University in Washington D.C. He believed that in order to develop a strong program to train Black psychologists, psychology departments needed to be autonomous units. With the help of then Howard University's president, Mordecai Johnson, a separate department of psychology was permanently established and he was appointed full professor and head of the department in 1930.

Contributions

Because of his diligence while confronting the social and educational barriers of his time, Dr. Sumner is known as the pioneer for African American psychologists. Under Sumner's tutelage many of his students went on to become prominent psychologists. One such student was Kenneth Bancroft Clark whose psychological research on prejudice, discrimination and segregation in the developing child was used in the 1954 Supreme Court case Brown v. Board of Education. In addition, Sumner was an official abstractor for both the Journal of Social Psychology and the Psychological Bulletin, where he translated more than three thousand articles from German, French, and Spanish.

Superego

David Brandwein
Kean University, Union, NJ, USA

Synonyms

Uber-Ich (German)

Definition

According to Freud's structural model of the mind, as expressed in *The Ego and the Id* (1923), the superego is the part of the mind that is comprised of internalized moral standards and ideals learned both from parents and society–our sense of right and wrong. Freud believed the superego was the last component of the mind to develop, and begins to emerge at latency when the child "identifies" with the same-sex parent, thereby resolving the Oedipal Complex.

Description and Relevance to Childhood Development

The germination for the idea of the superego first appeared in Freud's writings, via his concept of the "ego-ideal" as elaborated in *On Narcissism: An Introduction* [2]. In this original conception of the ego ideal, the child projects an ideal image of himself or herself but is forced to abandon this image due to parental criticism. While this paper does not name the superego specifically, it does discuss a mechanism whereby the ego is watched and measured against the ego ideal. Seven years later, Freud [3] discusses how the ego-ideal can be shaped by others whom the person admires, while not necessarily specifying the role parental and authority figures play in superego development.

Building on his earlier ideas, Freud operationally defined the superego in *The Ego and the Id* (1923). The superego is composed of two parts: the *conscience* and the *ego ideal*. In a general sense, the conscience is a punitive, negative agent, and the ego ideal functions as an agent of reward.

The *conscience* is made up of prohibitions, and includes information about things that are viewed as bad by parents and society. These behaviors are often forbidden and lead to bad consequences, punishments, or feelings of guilt and remorse. Just as the parent has punished the child for his/her transgressions, so does the conscience punish the person with guilt, "accidentally" cutting one's finger, or intentionally self-destructive behavior [10].

Hall [6], among others, points out that an overdeveloped conscience can lead to the superego to adapt prohibitions even more severe than parental or societal prohibitions, leading to a "straight-jacket existence" (p. 46) or the development of thought patterns based on morals and ideals rather than reality.

The *ego ideal* includes the rules and standards for good behaviors. These behaviors include those approved of by parental and other authority figures. Obeying these rules leads to feelings of pride, value, and accomplishment. Just as the child has been rewarded for certain behavior by her parents (or parental figures), the child is rewarded by the ego ideal with increased self-esteem and pride. Freud [4] thought that the ego ideal was tied into childhood narcissism, which in adulthood can transform into the perfection of the ego ideal.

The superego acts in opposition to the id and the ego, and does not discriminate between what is real and what is imagined. It rewards, punishes, and makes demands, and its goal is to eliminate the pleasure principle and the reality principle. The superego does not only keep watch over behavior, it oversees cognition, namely those of the ego, as thinking is just as bad as doing. Freud, in his later writings, described the superego as representing the "cultural past" [5, p. 206] and felt that the superego helped maintain social order by restraining sexual and aggressive behavior that, if unrestrained, could de-stabilize society.

Other psychoanalytic theorists have examined Freud's conception and definition of superego. Klein [8] (Melanie Klein (1882–1960)), though agreeing with Freud's conception of the superego, disagreed with its formation at latency. She instead proposed that the superego is formed early in life by the first object-introject, namely the mother's breast. Similarly, she also disagreed with Freud's idea that boys developed a stronger superego than girls because they have a penis and girls do not. She posited that girls are better adjusted psychosocially than boys, because boys have to separate from their mother, while girls are extensions of their mother and thus do not need to separate. Erikson [1] acknowledges the need for superego development for socially acceptable behavior, but views its development as a loss because it often blunts imagination and initiative. Lacan [9] proposes that superego "has nothing to do with moral conscience as far as its most obligatory demands are concerned" (p. 310). He felt that superego is not the ethical agency of the mind, but in fact, is the anti-ethical agency. He felt that the betrayal of desire is what leads to guilt, and that the ego ideal compels us to give up on our desires and live according to the demands of the social order.

Psychoanalytic theorists, most prominently the object-relations psychologist Otto Kernberg, have traced character pathology to issues with superego development. In his book, *Object Relations Theory and Clinical Psychoanalysis* [7], he theorized that since older children and most adults show some form of ego and superego conflicts, most people show some degree of "splitting" of their psyches that stems from infancy. Kernberg and many others have argued that when the developmental history of splitting is examined, it is found to begin shortly after birth and eventually develops into adult forms of "ego" versus "superego." An excessive form of splitting is traced to Borderline Personality Disorder, while Narcissistic Personality Disorder and Anti-Social Personality Disorder have etiology in deterioration and/or destruction of the superego.

Swallowing Reflex

Cheryl L. Giddens
Oklahoma State University, Stillwater, OK, USA

Synonyms

Involuntary swallow; Pharyngeal response mechanism; Pharyngeal swallow response; Swallowing response

Definition

Automatic physiological mechanism that results in breath hold secondary to vocal fold adduction, laryngeal and hyoid anterior and superior movement, velopharyngeal closure, and epiglottal posterior movement to cover the trachea during bolus movement through the hypopharynx and the upper esophageal sphincter.

Description

The swallowing reflex is one phase of the swallow which is under reflexive or involuntary control. This stage of the swallow begins after food which has been masticated has been gathered together in the mouth and formed into a bolus which is passed from the posterior tongue through the faucial arches. As the bolus begins its descent from the posterior tongue through the hypopharynx to the upper esophageal sphincter, the swallow becomes reflexive. Breathing stops at this time as the epiglottis covers the airway entrance, the vocal folds adduct or close to further protect the upper airway, the larynx moves upward and forward, the velopharyngeal port closes to prevent nasal regurgitation, and the upper esophageal sphincter opens [4]. This process occurs in less than 2 sec [3] and is essential to protection of the airway during feeding, drinking, and when managing saliva. When impaired, a condition referred to as dysphagia, food, drink, and/or saliva can penetrate the upper airway to the level of the vocal folds, or become aspirated below the vocal folds. Aspiration pneumonia is a potentially deadly condition manifested by a sudden spike in core body temperature and acute onset of upper respiratory infection.

Both normal and pathological conditions can affect the swallowing reflex. Normal aging results in psychomotor slowing, muscle atrophy, and reduced peristaltic muscle action. Slowing and degradation of the swallowing reflex is no exception. An aging swallow reflex commonly results in increased incidence of laryngeal penetration during the swallow in normally aging individuals [1]. In addition to the observable peripheral effects of aging upon the swallow reflex, central nervous system changes have been identified. Older individuals have been found to activate more cortical sites during swallow than do their younger counterparts, possibly indicating a change in the neurophysiology of the swallowing reflex over time [2].

A primitive swallowing reflex has been observed in those with neurological immaturity and/or neuropathology. This reflexive response is normally observed in infants only. The primitive swallowing reflex can be elicited by a puff of air to the maxillary-mandibular and maxillary-ophthalmic regions of the face and there is speculation that the primitive reflex could be exploited to improve swallow safety in those with neuropathology and/or immature nervous systems [5]. Other static and progressive neuropathologies which commonly affect swallow include cerebrovascular accident (CVA) or stroke, amyotrophic lateral sclerosis (commonly referred to as Lou Gehrig's disease), Parkinson disease, cerebral palsy, and traumatic brain injury.

Anatomical defects can result in an impaired swallow reflex as well. Supraglottal laryngectomy may result in the surgical removal of the epiglottis, the ventricular vocal folds, and/or other tissue above the level of the true vocal folds. Partial laryngectomy may result in the loss of a portion or an entire true vocal fold. The loss of these airway protective mechanisms puts an individual at risk for aspiration. In addition, irradiation of the pharynx for

treatment of tumors commonly results in an impaired swallow reflex and dysphagia due to reduced peristaltic movement of irradiated muscles.

Dysphagia is most commonly diagnosed and treated by a speech-language pathologist. The swallowing reflex is commonly screened informally by a speech pathologist. When the reflex appears delayed, weak, or otherwise disordered, the speech pathologist will often recommend that a modified barium swallow study (MBSS) be performed in fluoroscopy in conjunction with a radiologist. The speech pathologist and the radiologist can determine which consistencies of food and drink are best to maintain a safe swallow, as well as any postural or behavioral modifications necessary to improve swallow safety. In addition, the speech pathologist may target elicitation of the swallowing reflex through various sensory methods in an attempt to reduce or eradicate dysphagia. Persons who cannot or do not respond to postural, behavioral, and/or food consistency modifications and who remain at risk for aspiration may demonstrate the need for alternative feeding methods including temporary placement of a nasogastric feeding tube, or placement of a more permanent gastronomy tube.

Swallowing Response

►Swallowing Reflex

Switch-Hitter

►Bisexual

Swyer Syndrome

Synonyms

XY gonadal dysgenesis

Definition

A type of hypogonadism in which there is a uterus and fallopian tubes, but no functional gonads present to induce puberty in an individual with XY chromosomes (male chromosomes) but an external female appearance. These individuals instead have clumps of tissue called streak gonads, which may become cancerous later in life and need to be removed.

Description

Sywer syndrome is a fairly rare syndrome, occurring in approximately 1 in 30,000 people. It is most commonly caused by a SRY mutation that prevents the production of the sex-determining region on the Y protein (usually male) or produces a nonfunctioning protein. Since, the male determining protein is faulty individuals with Sywer syndrome will by default develop female sex organs. This syndrome is typically not genetically linked but can be passed on by a father who has a mosaic SRY mutation (in some cells but not others) or in rare cases has the SRY mutation but is not affected by it. In cases where the SRY mutation is inherited, the syndrome is said to be a Y-linked inheritance syndrome. The syndrome can also be caused by a NR5A1 mutation; similar to a SRY mutation, a NR5A1 mutation can be spontaneous or inherited. Another mutation that can cause Swyer syndrome is the DHH gene mutation, which is inherited in an autosomal recessive pattern (both parents are carriers). A mutation in the NR0B1 gene can also cause Swyer syndrome and is usually a X-linked inheritance.

Individuals with Swyer syndrome are usually raised as females and typically identify with the female gender. Hormone replacement therapy is a viable option, and can be started during adolescences to induce menstruation cycles and develop secondary sex organs. Also, hormone replacement therapy helps to prevent reduced bone density, which can be an issue for individuals with Sywer syndrome. However, due to lack of gonads these individuals cannot produce eggs, but may become pregnant through a donated egg or in vitro fertilization.

Symbolic Thought

Anne Fierro Vanderlaan
Saybrook University, Meridian, ID, USA

Synonyms

Internal symbols; Pretending actions; Thinking symbolically

Definition

For young children to engage in making up or imagination by acting as if things are real when they are not real. Symbolic thinking is a cognitive stage of development in young preschool age children.

Description

Symbolic thought is common for children to engage in through the process of pretend or make believe. Young children express symbolic thoughts by reenacting actions of parents or care givers by using various objects that represent what they pretend them to be. An example is children playing in the dirt to make food. The children imagine themselves to be other people or animals also using drawing, writing, singing and talking [1].

Relevance to Childhood Development

Caregivers and parents can help in their children's development by understanding mirroring plays an important role in the development of symbolic thought. Language develops by symbolic functions. The child is able to imagine behaviors of adults observed in the past and to reconstruct the behaviors by make-believe. Having available dress-up clothing, paper, crayons, empty boxes and containers help in this development. Various cultures have items representing different foods, dress, and tools that caregivers can include when caring for children [2].

Synaptic Pruning

Edalmarys Santos[1], Chad A. Noggle[2]
[1]Middle Tennessee State University, Murfreesboro, TN, USA
[2]SIU School of Medicine, Springfield, IL, USA

Definition

Synaptic pruning refers to the process by which extra neurons and synaptic connections are eliminated in order to increase the efficiency of neuronal transmissions.

Description

Beginning in the earliest embryonic stage and lasting until approximately 2 years of age, new neurons and synapses

are formed at an amazing rate, at times reaching 40,000 new synapses formed per second [2]. By the end of this process individuals are left with far more neurons and synapses than are functionally needed and/or preferred. Synaptic pruning is the process by which these extra synapses are eliminated thereby increasing the efficiency of the neural network. The entire process continues up until approximately 10 years of age by which time nearly 50% of the synapses present at 2 years of age have been eliminated [2]. The pattern and timeline pruning follows varies based on brain region. Again the process is intended to increase the efficiency of the neurological system. In this way, synaptic pruning is not random [3]. Rather, synaptic connections that have been frequently used and thus strengthened through sensory and cognitive input as well as motor and cognitive outputs are spared [3]. Those connections that have been weakly reinforced and are no longer functional or those that are redundant with connections of adequate strength are "pruned" away [1].

The idea that pruning continues up to 10 years of age ties in with the concept of brain plasticity in early age. Specifically, early in life with pruning not yet complete young children still have extra synaptic connections in place. If an insult occurs to the brain, impeding the functionality of conditioned (i.e., strengthened) synaptic connections, extra and/or redundant connections which have yet to be pruned may then be utilized in place of the damaged pathways thus preserving the function itself.

Syntax

Tony Wu
Walden University, Diamond Bar, CA, USA

Synonyms

Grammar; Lexical configuration; Morphology; Sentence structure

Definition

The rules and structures that govern the construction of phrases or sentences.

Description

Brown [1] suggested that researchers have long been investigating the order in which children develop and understand the various components of grammar and syntax. It is generally believed that children are able to acquire language proficiency across environments and understand the language structures through the notion that mastery of syntax is based on innate and biological structures that exist among individuals. In this biological framework, any differences among individuals are highly correlated with differences in their genetic predisposition to language differences [7].

According to this genetic explanation, languages activate children's capacity to establish the parameters of languages within appropriate syntactical structures [6]. In that regard, for children with specific language disabilities, they often exhibit high syntax errors in conversation which often lead to communication difficulties [4] resulting in major social and interpersonal problems [2]. Research has also suggested that children with specific language disabilities have phonological and lexical impediment. For example, these children have difficulties with reiterating nonsense syllables and listing words which might be attributed to inadequate phonological representation, storage, and short-term memory in phonology. Research also found that lexical representations become complex in children's later years [3]. As children's receptive and expressive language ability mature, their phonological and syntactical representations are refined and enhanced [5]. It is thought that effective access and retrieval of languages often depend on successful encoding and decoding of phonological information [8].

Systems Theory

Lee A. Wilkinson
Nova Southeastern University, Fort Lauderdale, FL, USA

Synonyms

Cybernetics; Ecological systems theory; Family systems theory; General system theory; Systems thinking

Definition

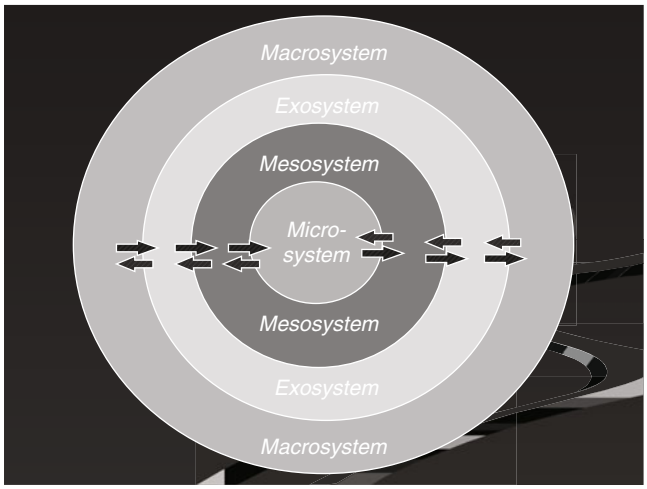
Systems theory is a conceptual framework based on the principle that the component parts of a system can best be understood in the context of the relationships with each other and with other systems, rather than in isolation.

Description

Systems theory was first introduced in the 1940s by biologist Ludwig von Bertalanffy [13] and furthered by W. Ross Ashby [1] and George Bateson [2]. Bertalanffy initially argued for open systems as opposed to the more closed systems associated with classical science. Open systems refer to systems that interact with other systems or the environment outside of the systems, whereas closed systems do not. Open systems usually include biological and social systems, whereas closed systems are mostly mechanical systems. The boundaries of open systems are more flexible than those of closed systems, which are rigid and, for the most part, impenetrable. There are various types of systems. For example, there are biological systems, mechanical systems, human/mechanical systems, ecological systems, and social systems. Systems also range from simple to complex. Complex systems, such as social systems, are comprised of numerous subsystems, each with its own boundaries. Complex systems usually interact with their environments and are, thus, open systems. Because of the interdependence between systems (or subsystems), systems rarely exist in isolation.

The principles of systems theory have been applied across fields and disciplines, including the natural sciences, social sciences, mathematics, business, and technology. Systems theory is not a single unified theory but rather a way of conceptualizing the structure and properties of an organization in terms of the relationships and interdependence among its components. Most scientists and researchers use a systems thinking approach. That is, they think in terms of systems and apply this concept to the study of systems in a variety of fields (e.g., families, biology, communication, mental health, social sciences, and technology). Thus, there are different systems theories depending on the context. For example, family systems theory is derived from the work of Minuchin [7] and Bowen [3] who applied the concepts of systems theory to families and other social systems. Family systems theory views the family as an emotional unit and uses systems thinking to describe the complex interactions within the family unit. Consistent with systems theory, a change in one person's functioning is predictably followed by reciprocal changes in the functioning of others [3].

Systems theory has also been applied to organizational development and management theory as a framework for conceptualizing organizations as multifaceted and dynamic entities comprised of smaller, interactive subsystems [6, 8, 9]. Most theorists and researchers recognize that traditional organizational theory fails to take into account many of the environmental influences that affect the efficiency of an organization and now view organizations from an open-systems perspective.



Systems Theory. Fig. 1 Ecological Systems Model. *Source*: From [11]. Reprinted with permission.

Relevance to Childhood Development

Systems theory has important applications to child development and the diagnosis and treatment of childhood disorders. A key assumption of systems theory is that an individual's problems are symptomatic of structural and interactional difficulties in a larger system [7]. The child's family or school is considered to be a dynamic open system, each component contributing to the maintenance of the whole system. The parts of the system are interconnected and what occurs in one system affects the other systems as well. Consequently, problems are not viewed as within the child, but rather as a function of the interaction of the child with systems to which he or she belong [10]. In other words, problems are conceptualized as systems-centered rather than individual-centered.

The work of Uri Bronfenbrenner [4, 5] provides an example of how systems theory has influenced the way psychologists and others approach the study of child development. Regarded as one of the world's leading scholars in the field of developmental psychology, Bronfenbrenner's ecological systems theory views the child as an inseparable part of a social system. This conceptual framework emphasizes the importance of the interrelations and linkages among a child's primary environments and the reciprocal influences of systems on a child's behavior and learning [11, 12]. Relationships among systems impact the child in two directions, toward and away from the child. Bronfenbrenner called these bi-directional influences. According to ecological systems theory, child development occurs in the context of four layers or interrelated systems. Each system contains roles, norms and rules that can effectively shape development. Bronfenbrenner called these layers the (a) microsystem (such as the family or classroom); (b) the mesosystem (which is two microsystems in interaction, e.g., home-school); (c) the exosystem (external environments which indirectly influence development, e.g., parental workplace); and (d) the macrosystem (the larger socio-cultural context). Figure 1 depicts the interrelated systems of the ecological systems model. At the microsystem level, bi-directional influences are the strongest and have the greatest impact on the child. Structures in the microsystem (e.g., family, school, or childcare environments) interact with the child and affect how he or she develops; the more nurturing these relationships, the more opportunity the child has to develop and mature normally. If the relationships in the immediate microsystem are disconnected, the child cannot explore other parts of the environment, resulting in instability and negatively affecting normal development. It is this concept of interacting systems in a child's life and the importance of shared problem-solving within and between these systems that provide a potentially powerful model for developing and delivering interventions in clinical and educational contexts [10, 11].

Tabula Rasa

Robert Walrath
Rivier College, Nashua, NH, USA

Synonyms

Blank slate

Definition

Tabula Rasa (Latin: Blank Slate) refers to the concept that humans are born with no native abilities, knowledge or mental capacity, and that our entire set of knowledge and skills at a given time are a product of our sensory perception and experiences up to that point in time. In the nature versus nurture controversy, proponents of the nurture position generally promote the concept of tabula rasa.

Tactile Stimulation

Matthew J. Hertenstein
DePauw University, Greencastle, IN, USA

Synonyms

Contact; Touch

Definition

Touch has been described as the most fundamental means of contact with the world, and the simplest and most straightforward of all sensory systems. Tactile stimulation is vital in several domains of the infant's and child's life, including social, cognitive, and physical development.

Description

Touch has been described as the most fundamental means of contact with the world [2], and the simplest and most straightforward of all sensory systems [7]. Touch is vital in several domains of the infant's and child's life, including social, cognitive, and physical development (e.g., (5)). In fact, touch is the first sense to develop in utero and by 14 weeks after gestation, the surface of the fetus is almost entirely sensitive to tactile stimulation. Touch continues to play a central role in adulthood when flirting, expressing power, soothing, playing, and maintaining proximity between child and caretaker [4]. By adulthood, the skin constitutes the largest organ of the body, covering 1.8 m^2 of the average person. As with humans, touch serves many functions in non-human primates as well. Different species groom to reconcile following aggressive encounters, to initiate sexual encounters, to reward cooperative acts of food-sharing, to maintain proximity with caretakers, and to sooth conspecifics in stress [3].

The Physiological Underpinnings of Touch

As mentioned, the skin is the largest organ of the human body and weighs between six and ten pounds [11]. The skin is a multilayered structure containing several receptors, each of which sends unique signals to the brain through neurons via the spinal cord. Information from the spinal cord enters the thalamus – the "relay station" of the brain – which then sends this input to a strip of the brain called the somatosensory cortex located on the parietal cortex. The more area on the somatosensory cortex that is dedicated to a given area of skin on the body, the more sensitive that area of skin is to tactile stimulation. Thus, areas of the body such as the fingers and lips – two of the most sensitive areas of the body to tactile stimulation – are well represented on the somatosensory cortex compared to less sensitive areas of the skin such as the back.

Learning About the World Via Touch

Throughout life, we actively explore the world with our hands to learn about objects in the world – a process known as haptic perception [10]. Haptic perception, in conjunction with vision, is particularly important for infants to learn about the world. Research indicates that by 3 months of age infants can distinguish objects by size and shape (e.g., a cube from a hollow square), by 6 months of age they can distinguish objects by hardness and texture, by 9 months of age they can distinguish objects by weight, and by 15 months of age they can distinguish between shapes that are similar in features but differ in spatial arrangement.

Effects of Touch on Biology

Touch plays an instrumental role in brain development and growth, especially in early life [5]. Without adequate tactile stimulation early in life, the brain does not grow to a normal size and the synapses between neurons do not develop properly. In addition, adequate tactile stimulation early in life can buffer the effects of tactile deprivation later in life. Thus, exposure to adequate amounts of touch early in life seems to form a foundation for later nervous system development.

The importance of touch does not wane later in life. Research indicates that when nonhuman animals are provided extra tactile stimulation later in life, their brains increase in size and the synapses between neurons increase. Moreover, tactile stimulation can help stimulate neuronal growth due to brain lesions and infarcts in the brain later in life. In addition to studying the effects of touch on the brain, researchers have investigated the effects of touch on premature infants' growth. In one study a group of premature infants received a 10-day protocol of massage therapy comprised of tactile/kinesthetic stimulation while a control group did not receive the massage therapy protocol [6]. Compared to the control group, the treatment group gained 47% more weight, was more active and alert, and spent six fewer days in the hospital.

Effects of Touch on Cognition, Emotion, and Social Interaction

Tactile stimulation has a significant impact on cognitive development [8]. A wide body of literature suggests that cognitive development is intimately tied to brain development in the childhood years and, as mentioned, touch plays a pivotal role in neuronal development in the early years of life. Parental aversions to touch as well as harsh touch have been implicated as factors in the development of language and learning disorders. In addition, research suggests that parents who use touch to stimulate the central nervous system regularly and appropriately have children that are more likely to develop an accurate and sophisticated body image. These parents provide a variety of forms of tactile stimulation to a number of areas on the body.

Touch plays an integral role in the caregiver-child relationship from the beginning of life. In one U.S. sample, infants were touched for 33–61% of the time during brief interactions with their mothers. The frequency of contact is much higher in some cultures such as the !Kung and the Efe tribe of Zaire where mothers spend approximately 75% of the time in contact with their infants [8].

In infancy, caregivers' touch is thought to serve a variety of communicative functions while they are in contact with their infants [8]. Two of the most important are the communication of emotions, as well as the communication of security. A number of studies indicates that touch is capable of communicating and eliciting positive and negative emotions. One powerful demonstration of the power of touch to elicit positive emotions has been shown when researchers use the "still-face paradigm" to study infant emotionality. The still-face paradigm is comprised of a period of interaction when the caregiver assumes a still-face, thereby not responding to the infant's actions. During this period, infants typically react negatively because this is an unusual event in most infants' lives. Several studies indicate that if caregivers touch their infants during the still-face period, their infants' emotional displays are significantly less negative and more positive compared to infants who are not touched during the still-face period.

The quality of caregiver-infant touch is a central feature of the responsive and available caregiving environment that is necessary to foster an infant's sense of security. Several studies suggest that touch between the caregiver and infant is the "ultimate signal" of security of the infant. In one experimental study, researchers compared how infants were attached to their caregivers when they carried their infants ventrally in soft infant carriers versus those who were carried in harder infant seats [1]. The researchers found that infants carried in the soft infant carriers were significantly more likely to be securely attached to their caregivers than infants who were carried in the infant seats. This study and others strongly suggest that touch plays a key role in the communication of security to children.

Touch continues to play an integral role in social communication in adulthood [9]. For example, touch communicates power and emotions to others, as well as aids in persuading others to comply with our requests. In addition, touch increases verbal interaction among people, gains attention from others, and communicates our attraction toward others.

Temper Tantrums

Theodora Koulenti,
Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Synonyms

Aggressive behavior problems; Behaviorally disorganized children; Children of high emotionality; Difficult children; Inflexible-explosive children [3]

Definition

Temper tantrums are defined as "disruptive or undesirable behavior of emotional outbursts displayed in response to unmet needs or desires, or an inability to control emotions stemming from frustration or difficulty expressing the particular need or desire" [8].

Description

Temper tantrums are among the most common behavioral problems of young children reported by parents, specifically between the ages of 18 months to 4 years. Tantrums are often expressed with crying and in less-common cases with attention-getting events such as breath holding and head banging. Parents often talk about their children grunting and growling while other children make sounds similar to animal cries. Because of screaming too loudly and for so long there are cases in which children's cheek capillaries burst and their eyes become bloodshot. In extreme cases, children yell until they vomit or become inflexible and rigid [5]. During temper tantrums children may also engage in actions such as limb-flailing or foot-stomping, and if language is more developed, abusive and blasphemous words may be screamed in a violent flow of anger. During these moments children are described as demanding, unrestrained, infuriated, egocentric and omnipotent and resist any form of control [3].

Researchers underline the importance of distinguishing between disruptive behavior and normative misbehavior in preschool children. "Normative misbehaviors," such as aggression and tantrums, are exhibited by 75% of children by age 2. However, in many cases, noncompliance, temper loss and aggression are signs of disruptive behavior disorders. In order for this differentiation between normative and non-normative misbehavior to be successful, direct assessment observation is needed, either in clinical laboratories or in natural settings [7].

Temper tantrums usually develop in stages: during the first stage the tantrums start with early warnings about possible problems, afterwards the actual tantrum takes place and lasts for some minutes and finally there is a period of "hangover," when the child returns to a stable condition, after feeling tired [8]. Additionally, during tantrums, angry behaviors and shouting occur first, while sobbing occurs later on [5].

Research findings have revealed that healthy children usually demonstrate less violent, self-injurious, destructive and orally aggressive tantrum behaviors than children who meet the diagnostic criteria for mood and disruptive disorders. Furthermore, healthy children's tantrums are shorter and less severe and require less recovery time. However, researchers argue that these results cannot in any case cover the importance of individual differences in emotional development [1].

Additionally, 5 high risk tantrum styles are identified which may form the basis for determining typical versus atypical tantrum behaviors and therefore help us decide whether mental health evaluation is needed. According to the first tantrum style, consistent aggression against

caregivers or objects is displayed. In the second style, which should be considered extremely serious and is not common, children engage in self-injurious behavior during tantrums. Children falling in the range of the third tantrum style, meaning that they display 10–20 tantrum episodes in a 30-day period or have more than 5 tantrums per day, are at risk for having a serious clinical problem. In the fourth style, tantrums have a long duration, lasting 25 min or longer on average. Finally, in the fifth style, children are unable to calm themselves, regardless of the length, intensity, context and the severity of the temper tantrum. It is important to note that tantrums related to unmet typical needs, such as sleep, hunger or illness, should not cause distress [1].

Many researchers tried to answer the question whether children who demonstrate temper tantrums are at risk for becoming ill-tempered adults. One of the biggest demands that the society poses on the developing child is the need to control impulses and regulate emotional expression. However, this achievement often depends on the child's ability for ego control. Research evidence indeed verified the hypothesis that ill-tempered children develop into ill-tempered adults. Longitudinal studies have revealed that children with a stable pattern of temper tantrums in early childhood usually face difficulties in many life tasks as adults. Both sexes were facing problems at the domain of work, in their marriages, in their roles as parents, in educational and military settings and they were more at a risk for divorce or conflict in their marriages [2].

Causes

People often raise the question why some children demonstrate tantrums while others seem immune to such expressions. Researchers have identified that factors such as temperament, defenses and coping competence for dealing with risks, danger, affect stimulation and tension/frustration are factors that are possibly related to the manifestation of temper tantrums [3]. They assert that they occur in early childhood as a result of a still immature ego but research findings also reveal that temper tantrums can sometimes prove to be signs of externalizing psychopathology in childhood and a predictor for antisocial behavior in older children. However, recent surveys have revealed that certain psychosocial factors, such as maternal depression, corporal punishment, low social class, minor illness and other behavior problems could be associated with extreme temper tantrums [4].

Intervention

Temper tantrums may often have a strong impact on parents. Specifically, in cases in which parents have to deal with tantrum behaviors which are repeated and prolonged, and in cases where object-destruction or acts of serious aggression are involved, parents are more probable to become irritated, frightened by their child's behavior or even anxious about their own feelings. That could be a possible explanation for why children with temper tantrums are more at risk for abuse. It could be helpful for parents to have an idea about the duration of their child's tantrums and how long a particular one might last because in many cases the parents simply have to wait for the tantrum to end, without interfering, and these moments can be extremely frustrating or anxiety-provoking [5]. Moreover, the role of parent training is emphasized as a successful intervention for children's explosive behavior. Research findings reveal the important causal role of parenting in antisocial behavior and delinquency. Observations and parent reports demonstrate that cases of unskilled parental discipline measures are linked to high tantrums in later childhood [6].

Temporal Discounting

Derek D. Reed[1], James K. Luiselli[2]
[1]University of Kansas, Lawrence, KS, USA
[2]The May Institute, Inc., Randolph, MA, USA

Synonyms

Impulsivity; Self-control; Time-delay discounting

Definition

The phenomenon in which the value of a reward decreases as the time delay until its receipt increases.

Description

Temporal discounting refers to the phenomenon in which the subjective value of some reward loses its magnitude when the given reward is delayed (see [2]). Similar to the notion of "delayed gratification," relatively high degrees of discounting are synonymous with impulsivity. On the contrary, when individuals demonstrate a sustained interest and motivation in a delayed reward, they are said to have less discounting, and thereby more self-control. Temporal discounting may be measured via two assessment methods: (1) hypothetical choice trials or (2) choices with deliverable outcomes. During hypothetical choice trials, individuals are presented with the option between a hypothetical smaller sooner reward (e.g., $5 now) and some larger delayed alternative (e.g., $10 in a week). These hypothetical choices are then titrated to find the amount in which the delay is no longer tolerable and the smaller reward becomes more preferred. While offering an actual delivery of the chosen reward alternative would be a seemingly more valid indicator of discounting, many procedural limitations exist precluding its utility. For one, hypothetical rewards do not compound across multiple choice trials, as actual rewards would become cumulative and confound the direct relationship between a delay duration and reward magnitude.

Relevance to Childhood Development

As a behavioral indicator of self-control and impulsivity, temporal discounting has been found to serve a discriminant function in adolescents in identifying students with attention deficit hyperactivity disorder and oppositional defiant disorder [1]. That is, students with these disabilities scored as more impulsive on discounting assessments. In addition, children with better self-control on discounting measures have been found to have greater verbal intelligence quotients on norm-referenced standardized tests [6]. Moreover, numerous discounting studies have suggested that this phenomenon generally improves – relative impulsivity improves – across the developmental lifespan (e.g., [4]). Examining discounting at an early age may be beneficial, as adults with high discounting scores often exhibit numerous undesirable behaviors such as compulsive gambling (e.g., [3]) and dangerous drug habits (e.g., [5]).

Temporal Lobe Seizure

▶Psychomotor Seizures

Temporal Lobes

Chad A. Noggle
SIU School of Medicine, Springfield, IL, USA

Definition

The temporal lobes represent the lower lateral lobes of the cerebral cortex that play a vital role in auditory processing, receptive language, and memory.

Description

The temporal lobes represent the lower lateral lobes of the cerebral cortex that are bordered anteriorly and superiorly

by the sylvian fissure and posteriorly by the lower portion of the occipital lobe [4]. While the sylvian fissure provides a distinctive separation of the temporal lobes from the frontal and parietal lobes, such a clear separation is not seen between the temporal lobe and the occipital lobe. Rather an imaginary line that extends between the preoccipital notch and the transverse occipital sulcus known as the parieto-occipital sulcus separates these two areas [2]. Functionally the temporal lobes play a vital role in auditory processing, receptive language, and memory.

First, the temporal lobes' role in auditory processing is directly related to it housing the primary auditory cortex. This area is housed on what is referred to as Heschl's gyrus, which lies at the most superior portion of the lobe slightly inside the sylvian fissure [5]. It works in combination with the planum temporale, which lies posterior to Heschl's gyrus, also within the temporal lobe [5]. In comparison to one another Heschl's gyrus is believed to play a more prominent role in non-speech aspects of language and musical processing whereas the planum temporale is believed to play a greater role in actual speech comprehension [5].

In terms of the temporal lobes' role in receptive language, this is by way of it housing Wernicke's area, which lies just posterior to the primary auditory cortex [2]. Upon auditory stimuli being received and processed by the primary and secondary auditory centers, the information is transmitted posteriorly to Wernicke's area to assist in comprehension [3]. However, Wernicke's area can also play a role in reading and writing [3].

Finally, the temporal lobes play a vital role in memory. This is largely related to the functioning of the medial temporal lobes and the hippocampus [5], which are vital structures and regions in the consolidation of information into long-term memory. In this way the temporal lobes are important to new learning and memory. This is best exemplified by presentations that are related to impairment of new learning and memory, such as Alzheimer's disease. In this presentation the aforementioned areas of the temporal lobes represent the sites of primary affliction and thus the disease manifests largely as impairment in new learning and memory [1]. This is not to say that the temporal lobes represent the site of a memory center, rather, once information to be remembered is processed by the aforementioned structures/areas that information is sent back to various cortical areas for storage.

Terminal Illness

Brenda Moretta Guerrero
Our Lady of the Lake University, San Antonio, TX, USA

Synonyms

End-stage disease; Fatal illness

Definition

Terminal illness refers to an illness or disease process that is not responsive to curative medical treatment and which will worsen and eventually cause death.

Description

A person who suffers from a terminal illness is said to be terminally ill, and although it is difficult to predict exactly how long a terminally ill person will live it is often assumed that a terminal illness will result in death in 6 months or less. This timeframe is most applicable to illnesses with somewhat predicable trajectories, such as cancer. In contrast, some other common conditions such as Alzheimer's disease, organ system failure, lung disease, and AIDS, for example, may exhibit much less predictable disease trajectories and may not result in death for many months or even years. Consequently, the predictability of when an illness has reached the terminal stage can vary significantly [9].

Medical Treatments Utilized During the Course of Terminal Illness

In general, as the course of an illness progresses to the terminal stage, curative treatment options become increasingly limited. However, in search of remission or

cure, some terminally ill patients continue to pursue aggressive treatment regimens, such as chemotherapy, until the time of their death. Other terminally ill patients combine traditional western medicine with complementary treatments, and still others elect to forgo all traditional treatment approaches in favor of trying untested or alternative approaches to manage symptoms or achieve a cure [6, 14].

Regardless of which treatment approaches are utilized throughout the course of a patient's disease process, by the time an illness is terminal it is generally not responsive to curative medical interventions. When the chance of cure becomes remote and the negative side effects of aggressive treatment outweigh the benefits, some terminally ill patients discontinue curative treatment in favor of palliative care or hospice.

Palliative care is a medical specialty that aims to enhance the quality of life of patients and their families and to alleviate patient suffering associated with distressing disease symptoms or aversive side effects of medical treatments [16]. Although palliative care can be provided from the time a patient is initially diagnosed with a chronic or terminal illness, many do not receive palliative care until they are terminally ill and even then only a relatively small number of patients receive palliative care at any point during the course of their disease. The number of physicians who are trained in palliative medicine and the number of facilities which offer palliative care programs are limited. Additionally, patients are often unaware of the benefits of palliative care or only associate palliative care with hospice [8, 16].

Palliative care and hospice care share many commonalities, and in fact all hospice patients receive palliative care. However, it is hospice that is typically considered to be the gold-standard model for end-of-life care. The goal of hospice is to offer comfort, state-of-the-art pain control, symptom management, and sensitive care in an effort to reduce suffering and enhance the quality of life of terminally ill patients until their death. An interdisciplinary team of health care professionals provides daily, around-the-clock care and support throughout the course of the dying process, often at the patient's home. Like palliative care, hospice offers holistic medical care to meet the physical, social, psychological, and spiritual needs of the patient as well as the patient's family and bereavement support is also offered to families following the patient's death [3].

Regardless of which treatment approaches are pursued, dying patients and their families generally agree that preventing and managing pain and other distressing symptoms, ensuring continuity of care, supporting patient and family emotional and spiritual well-being, making informed decisions, and increasing survival time are priorities related to terminal care. Unfortunately, many families, patients, and medical professionals believe that with the exceptions of hospice and palliative care, these health care priorities for end-of-life care have yet to be satisfactorily addressed in the American health care system [8].

General Quality of Terminal Care in the United States

In 1997, the International Work Group in Death, Dying, and Bereavement published *Assumptions and Principles Underlying Standards for Terminal Care* [13]. At that time, the work group noted that medical patients routinely suffered from inept terminal care. More recently, in 2003, a report on end of life care titled: *Means to a Better End: A Report on Dying in America Today* was released by Last Acts, the nation's largest coalition advocating for improved end-of-life patient care [8]. The report graded all 50 states and the District of Columbia on the availability and use of eight key elements of end-of-life care. Unfortunately, most states earned grades of Cs or below on the eight terminal-care measures. It is not surprising then that the Institute of Medicine has identified end-of-life care as a priority for improving the quality of health care in the United States and health care providers such as Ira Byock, a nationally-recognized authority on terminal illness and hospice, has testified before Congress and argued that end-of-life care in the United States has reached a state of crisis. Finally, at the same time that Last Acts published their findings on the quality of each state's terminal care, they also released the results of a national survey showing that 93% of Americans, including those who have recently lost a loved one, are dissatisfied with end-of-life care and believe that terminal care needs to be improved.

Relevance to Childhood Development

The majority of terminal illnesses occur during adulthood. However, each year in the United States approximately 500,000 children struggle with life-limiting, serious illnesses and 30,000 pediatric deaths occur [7]. Of those 30,000 deaths the majority is accident related, but cancer accounts for 1,500 deaths and is the leading cause of disease-related death in children [1]. Caring for children with potentially fatal cancer or any other terminal illness poses unique personal and professional challenges and is quite different from caring for terminally ill adults [7]. At a very basic level the suffering and impending death of a child seems inherently unfair. It challenges an adult's

understanding of the natural order of death and triggers a profound sense of helplessness at being unable to protect the sick child.

As noted previously, the quality of care for terminally ill adults is poor and unfortunately it has been reported that terminally ill children also suffer needlessly and receive inadequate physical and psychosocial support [11]. Although hospice care would seem to best meet the multifaceted needs of terminally ill children and their families, many hospice programs lack significant experience in caring for terminally ill children. Additionally, receiving hospice care is contingent upon the cessation of all curative treatment efforts and choosing to discontinue any further life-extending treatments for a child can be an excruciating decision for both parents and physicians [1, 11].

In addition to bearing witness to the suffering of terminally ill children and struggling to find the best quality medical care for them, another challenging issue related to caring for those children is whether or not to openly share information regarding their condition and impending death. This issue has been studied and contested in the literature for over 50 years [5, 10, 12] and relates to the quality of psychosocial support offered during the course of pediatric terminal care.

The Dying Child's Understanding and Emotional Response to Their Death

Until the late 1960s, researchers reported that although terminally ill teenagers could understand their own mortality, terminally ill children under the age of ten did not possess the capacity to understand their fatal prognosis as evidenced by their lack of questions about their death. Consequently, information regarding their illness and prognosis was generally withheld from critically ill children in an effort to shield them from distress. In the early 1970s, however, several researchers discovered that terminally ill children could, in fact, express an awareness of their impending death even when no one had discussed their prognosis with them [12]. Several years later, in a seminal article, Maria Bluebond-Langner reported that fatally-ill children came to understand the seriousness of their illness through a series of five stages and fully understood the terminal nature of their illness [2]. Initially the children learned that they had a serious illness. They then proceeded to learn the names and side-effects of drugs used to treat their illness, followed by the purposes of medical procedures and treatments. As their disease progressed, they learned that they would experience a series of relapses and remissions and then ultimately understood that they would die as a result of their disease.

Since the publication of Bluebond-Langer's article and numerous corroborating reports which followed, it has become generally accepted that a child's personal experience with serious illness and medical treatment can accelerate an understanding of their prognosis such that even young children can understand the seriousness of their condition. Consequently, an essential component of providing psychosocial support for terminally ill children would seem to include encouraging open communication and answering questions in a developmentally appropriate manner [15].

In addition to providing needed information, allowing for and supporting open communication with dying children also provides essential emotional support. In spite of their ability to understand the seriousness of their health status, terminally ill children still lack emotional maturity and need the presence of caring adults to support them in their efforts to adapt to their circumstances. Unfortunately, parents and other close loved ones who would normally help the child cope with emotionally challenging situations are deeply, personally affected by the child's illness and impending death and may lack the ability to provide emotional support. Health care providers may also be unavailable to provide support because they sometimes emotionally withdraw from seriously ill children when they too are deeply affected by the child's condition [4].

Although providing end-of-life care for terminally ill children and adults is inherently challenging, it is essential that both groups receive high quality, holistic support that strives to meet their physical, emotional, social, and spiritual needs. The goal is to not simply add days, weeks, or months to a terminally ill person's life, but to add quality to their life.

Test Anxiety

Kristin D. Sawka-Miller
Siena College, Loudonville, NY, USA

Synonyms

Evaluation anxiety; Performance anxiety

Definition

Test anxiety refers to the subjective experience of intense physiological, cognitive, and/or behavioral symptoms of anxiety before or during test-taking situations that interferes with test performance.

Description

Test anxiety is a specific type of performance anxiety that occurs when a person is being evaluated formally or informally. Children most often experience test anxiety in response to taking exams, delivering presentations, and participating in class [1]. Fear of being negatively evaluated (e.g., "My teacher will think I'm stupid") is a common fear reported by children with test anxiety. Symptoms of test anxiety can be physiological (e.g., rapid heart rate, muscle tension, flushing of the skin, sleeping problems, headaches), cognitive (e.g., memory difficulties, attention problems, concentration problems, worry, problem-solving difficulties, cognitive distortions) and/or behavioral (e.g., task avoidance, withdrawal, rapid speech, fidgeting, failure to complete tasks) [2].

Test anxiety is a common occurrence that affects approximately 50% of school-aged students. It generally peaks during the elementary years and again in early adolescence, with an interim decline [1]. Symptoms related to test anxiety typically impair performance, and studies have demonstrated that children with test anxiety score significantly lower on academic achievement test when compared with other children. Children with test anxiety are also more likely to experience lower self-esteem, lower self-perceived social and cognitive competence, and more non-test anxiety. The comorbidity rate of test anxiety and generalized anxiety disorder, characterized by apprehension about many events on most days in the absence of conditions that would normally provoke such a reaction, is 50% [2].

Relevance to Childhood Development

Test anxiety is typically treated using behavioral and/or cognitive-behavioral methods. Behavioral interventions include relaxation training and systematic desensitization. In systematic desensitization, children are gradually exposed to items on a hierarchy of anxiety-provoking situations while relaxation is achieved at each step. Cognitive-behavioral strategies focus on changing irrational and/or faulty thinking patterns. For example, a child might be taught to replace their automatic thought of "I'm going to do terrible on this test" with "I am well prepared and will take one question at a time" [3].

Given the high prevalence of text anxiety among school-aged children, there has been a recent emphasis on preventative strategies. While the research on the use of these strategies for preventing test anxiety is still emerging, practices such as educating teachers about performance anxiety, altering assessment methods to make the evaluation process less threatening, and teaching students study and test-taking skills are all recommended as promising approaches [1].

Test of Memory and Learning

David Ritchie, Barry Nierenberg
Nova Southeastern University, Fort Lauderdale, FL, USA

Synonyms

TOMAL-2

Definition

The Test of Memory and Learning – second edition (TOMAL-2) is an assessment of immediate verbal and nonverbal memory with a delay recall component for verbal memory.

Description

The TOMAL-2 was published in 2007 and is an individually administered assessment of memory and learning indicated for children and adults from ages 5 years 0 months through 59 years 11 months. For older adults who need a shorter battery, the assessment developers created a truncated battery to use for adults aged 55 years 0 months through 89 years 11 months [3].

Structure

Scores from the TOMAL-2 subtests provide four core index scores: Verbal Memory Index (VMI), Nonverbal Memory Index (NMI), Composite Memory Index (CMI) and Verbal Delayed Recall Index (VDRI). The indexes are derived from eight core subtests, separated into verbal and nonverbal categories. Tables 1 and 2 provide a comprehensive look at the subtests and which subtests are organized into each domain. These eight subtests will assess a wide range of memory functioning including: concrete and abstract memory functions, learning processes, and immediate and delayed recall [1].

Test of Memory and Learning. Table 1 Core and supplementary subtests of the TOMAL-2 which have a mean score of 10 and a standard deviation of 3

Core subtests	Supplementary subtests
Verbal	Verbal
Memory for stories	Letters forward
Word selective reminding	Letters backward
Object recall	Digits forward
Paired recall	Digits backward
Nonverbal	Nonverbal
Facial memory	Visual selective reminding
Abstract visual memory	Manual imitation
Visual sequential memory	
Memory for location	

Test of Memory and Learning. Table 2 Core and supplementary indexes for the TOMAL-2 which have a mean of 100 and a standard deviation of 15

Core indexes	Supplementary indexes
Verbal memory index (VMI)	Sequential recall index (SRI)
Nonverbal memory index (NMI)	Free recall index (FRI)
Composite memory index (CMI)	Associative recall index (ARI)
Verbal delayed recall index (VDRI)	Learning index (LI)
	Attention/concentration index (ACI)

The VMI assesses memory for information presented verbally and reproduced in a sequential manner. This task is especially important in diagnosing learning disabilities with primary deficits in speech and language issues in children and adults and assessing adults with occupations which rely heavily on verbal communication. This index is comprised of Memory for Stories, Word Selective Reminding, Object Recall and Paired Recall [1].

The NMI assesses memory for information that is presented nonverbally and reproduced nonverbally. This index taps into deficits in the right hemisphere, and is particularly useful in diagnosing learning disabilities with primary deficits in perceptual-motor or related nonverbal functions or in brain injured individuals with nonverbal deficits. This index is comprised of Facial Memory, Abstract Visual Memory, Visual Sequential Memory and Memory for Location [1].

The CMI assesses the overall combination of the patient's verbal and nonverbal memory by combining the scaled scores on the previous two measures. It is the most reliable measure of the patient's general memory abilities and should be interpreted first before looking at the other indexes. This index is most useful when compared to the VMI and NMI to assess for specific deficits compared to global deficits [1].

The VDRI assesses memory for information presented verbally for recall after a delayed period with distraction in between [1]. This area of memory is particularly important when assessing a patient for a traumatic brain injury, as delayed recall is typically more affected than immediate recall. Additionally, dementias or progressively deteriorating mental conditions, also are often impaired more on delayed versus immediate recall which can be crucial information in the differential diagnosis.

The goal of the TOMAL-2 is to give the examiner an idea of the memory and learning functioning of the patient. Within the subtests, the patient is asked to store and then reproduce stimuli after an intermittent time delay. On certain subtests the patient is also offered corrective feedback through reminding which allows the scoring and interpretation of learning or acquisition curves.

Learning Curves

Word Selective Reminding, Object Recall, Paired Recall and Visual Selective Reminding can be combined to calculate a learning curve across the trials. Within these subtests the examiner reminds the patient of items that were performed incorrectly and there is a high repetition component built in with these subtests. This index allows the examiner to compare learning to memory in order to shed light on differentiation between memory and other factors which could impair daily functioning [1].

Standardization

Reynolds and Voress standardized the TOMAL-2 using 1,921 individuals from a population-proportionate stratified random sampling of the United States and drawn to mimic the 2002 US Bureau of Census statistics on the basis of geographic region, race, family income, educational attainment and exceptionality status. These individuals' scores were used to derive the standard scores and norms found in the test manual. For further information on the standardization sample, see Reynolds and Voress [3].

Relevance to Childhood Development

The TOMAL-2 as an assessment to quantify deficits in memory and learning has a wide array of applications for the clinician. Primarily the test is used for diagnosing learning disabilities, traumatic brain injuries, attention deficit/hyperactivity disorder (ADHD), affective disorders and dementia and neurological/neurodevelopmental disorders [1–3]. For the pediatric population it is particularly useful in psychoeducational evaluations to diagnose learning disabilities or exceptionalities for the purpose of proper recommendations and providing appropriate accommodations [2].

Thalamus

Chad A. Noggle
SIU School of Medicine, Springfield, IL, USA

Definition

The thalamus is one structure of the diencephalon that serves as the primary relay station for sensory information, while also sharing connections with the limbic system, cerebellum, and basal ganglia as well as a number of other systems.

Description

The thalamus represents one structure of the diencephalon, which is an aspect of the forebrain. Functionally, the thalamus is most often conceptualized as the main sensory and motor relay station in the brain [3]. The thalamus exerts its influence along these lines by way of its projections to and/or from the spinal cord and cranial nerves, visual and auditory sensory receptors, and the cerebellum and basal ganglia [1, 3, 4]. However, in addition to its role in relaying sensory and motor information the thalamus also presents with projections to the limbic system as well as a number of other areas of the cerebral cortex [6].

While the thalamus, as a whole, is linked with a number of systems, structures, and functions, many of the nuclei included as part of this entity present with topographical projections that are function or system specialized [5]. The thalamus is the summation of a number of nuclei that fall into one of three functional categories: relay, intralaminar, or reticular. These categories correspond with the general role the nucleus plays. Relay nuclei are so termed as they receive incoming information from various pathways and then pass this information on to relevant areas/systems throughout the cortex [2]. The vast majority of thalamic nuclei are relay nuclei. These include the ventral posterior lateral nucleus (relays somatosensory spinal inputs to the cortex), ventral posteromedial nucleus (relays somatosensory cranial nerve inputs and taste to the cortex), lateral geniculate nucleus (relays visual inputs to the cortex), medial geniculate nucleus (relays auditory inputs to the cortex), ventral lateral nucleus, ventral anterior nucleus, and lateral dorsal nucleus (all relay basal ganglian and cerebellar inputs to the cortex), pulvinar nucleus and the lateral posterior nucleus (relays signals concerning behavioral orientation toward visual and other stimuli), ventral medial nucleus (relays signals concerning alertness and consciousness relays), mediodorsal nucleus (relay to and from the limbic system and frontal lobes), and the anterior nucleus and midline thalamic nuclei (relay to and from the limbic system) [2]. In comparison to the relay nuclei, the intralaminar nuclei are similar functionally in that they receive and then project information; however, they are differentiated in that they are housed within the internal medullary lamina and their projections primarily involve transmission to and from the basal ganglia as well as aspects of the brainstem, in lieu of projecting to the cortex like the relay nuclei do [2]. The intralaminar nuclei include the central medial nucleus, paracentral nucleus, central lateral nucleus, centromedian nucleus and parafascicular nucleus [2]. Finally, the reticular nucleus stands alone and is distinguished from the other nuclei in that it does not project to the cortex nor to the basal ganglia and/or brainstem, but instead only receives input from the cortex as well as the multitude of other thalamic nuclei that it projects back to the thalamus [2].

Thematic Apperception Test

Robert Walrath
Rivier College, Nashua, NH, USA

Synonyms

TAT

Definition

A performance based, projective story-telling technique consisting of 31 cards that portray people in differing situations, nature scenes and 1 blank card. Subjects are

asked to make up a story about each of 20 cards chosen for administration based on gender and other variables, and are encouraged to elaborate through queries about what characters are thinking, what led up to and follows the story described, how it might end, is there a moral to the story, and so on. Subjects are encouraged to use their imagination in responding. Content and structural aspects of each story are analyzed to identify personality characteristics and emotional states of mind.

Description

The TAT, developed by Murray [4], was the result of his early studying individual differences in the measurement of personality variables. The term "apperception" reflects the test's focus on subjects' interpretation of what they see in the cards, and the meaning they attach to these perceptions [6]. Murray developed the concept of "needs" or motivational influences, together with "presses" or environmental factors working in concert to determine personality and presented case studies showing the use of the TAT to uncover these individual characteristics. He is considered the primary proponent of the *idiographic* method of personality assessment.

The TAT is one of the more widely used projective personality measures with dozens of formal scoring systems [3] but it has critics who voice concerns about poor reliability and validity, difficulty with use in certain populations, a lack of standardization, and outdated and "dark" stimulus cards [6]. These criticisms have spawned similar, alternative apperception tests including the Children's Apperception Test and the Senior Apperception Test [1], The Roberts Apperception Test for Children (Roberts-2; [5]) and the Tell-Me-A-Story-Test (TEMAS; [2]).

Thomas and Chess Classification of Infant

Temi Bidjerano
Furman University, Greenville, SC, USA

Synonyms

Behavioral style; Temperament

Definition

A system for classifying a constellation of behavioral characteristics that is present at birth and relatively stable over childhood and adolescence.

Description

In the late 1950s, the child psychiatrists Alexander Thomas (1914–2003) and Stella Chess (1914–2007) launched a 30-year longitudinal study, known as the New York Longitudinal Study of Child Temperament (NYLS). The impetus for the study was the clinicians' increasing disenchantment with the prevailing, at that time, environmental views of children's behavioral problems as a consequence of unfit, poor parenting. In their clinical practice, they observed numerous instances of children raised in caring families, who nevertheless displayed some sort of psychopathology, as well as cases of lack of behavioral problems in the context of dysfunctional parenting. It became clear that the existing theories regarding parenting as the only source of influence provided unsatisfactory and insufficient explanations for such inconsistencies.

One of the major goals of the study was to explore the origin, nature and dynamics of behavioral disorders in children. The longitudinal project evolved into a study of children's temperament, defined as a behavioral style explaining the *way* in which an individual behaves. Unlike ability and motivation, which refer to the *what*, *how well* and *why* of behavior, temperament, according to the authors, represents the *how* of behavior [3].

The initial sample, gathered over the course of 6 years, consisted of 141 children coming from 87 families, the majority of whom were Jewish (78%) and of middle and upper-middle class backgrounds. The data collection occurred in several stages: when the children were 2–3 months old, every 3 months before the infants turned 18 months, every 6 months until 5 years of age, at 7, 8, 16, 18, and 22 years of age, and finally when the subjects were in their middle and late twenties [1].

In infancy, the primary source of information was parental report of children's behavior. Data were gathered through open-ended interview questions, in which the parents were asked to provide detailed descriptions of their offspring's routine daily activities, reactions to ordinary and unusual events, special incidences, and trauma. To guard against possible parental biases in reporting, data were gathered systematically and objectively through detailed interview protocols. Parents were encouraged to describe their children's behavior in precise terms, provide specific details and refrain from subjective interpretations of their children's psychological states and motives [3]. As children grew older, additional data were gathered through teacher interviews, direct observations in the school setting by trained research personnel, examination of school records, psychometric testing, and parent and youth interviews [1].

Following the initial wave of data collection, 22 parent interviews were analyzed by the means of inductive content analysis through which nine broad dimensions of children's temperament emerged. The nine broad temperamental categories were later found to be relatively stable throughout childhood and present in children from Puerto Rican descent. These categories included: (1) *Activity Level* (i.e., the child's motor activity and the diurnal proportion of active and inactive periods); (2) *Rhythmicity/Regularity* (i.e., the extent to which bodily functions such as sleeping, feeding and elimination patterns follow a predictable vs. unpredictable schedule); (3) *Approach or Withdrawal* (i.e., the nature of the child's initial response to a novel stimulus such as a new person, event, toys, and situation. Approach is manifested in behaviors such as smiling, positive vocalization, actively reaching for the new object; whereas withdrawal is demonstrated through negative states and behaviors such as crying, fussing, grimacing, moving away, and rejecting the object); (4) *Adaptability* (i.e., the ease with which the child adjusts to changes and transitions); (5) *Threshold of Responsiveness* (i.e., the intensity of stimulation necessary to evoke a positive or negative response to sensory stimulus, objects and social contacts); (6) *Intensity of Reaction* (i.e., the energy level of the response, regardless of its duration and whether it is positive or negative in nature); (7) *Quality of Mood* (i.e., the amount of positive and negative affect and behavior); (8) *Distractibility* (i.e., the extent to which a child could be diverted from an ongoing activity or behavior through an extraneous stimulation); (9) *Attention Span and Persistence* (i.e., the duration of a particular activity pursued by the child as well as the child's inclination to continue his/her engagement in an activity when faced with obstacles and distractions).

Qualitative analysis and subsequent factor analysis of the dimensions of nine temperamental categories resulted in the

delineation of three significant temperamental constellations. Although the majority of the children in the NYLS sample were categorized using the established three temperamental constellations, the behavioral styles of approximately 35% of the children were unaccounted by the suggested classification. The researchers established substantial variability within each of the three types of temperaments.

- The first temperamental constellation was labeled "*The Easy Child*"; it was characterized by rhythmicity (regularity), positive approach, adaptability, and a predominantly positive quality of mood. The easy children, comprising approximately 40% of the NYLS sample, tend to develop quickly predictable schedules and routines, have moderate levels of motor activity, approach rather than withdraw from new experiences, adapt to new situations easily, and experience positive emotions.
- The second behavioral style was termed "*Difficult child*" and was found to be present in 10% of the NYLS sample. The constellation was characterized by irregularity in bodily functions, withdrawal from new stimuli, lack of or slow adaptability to change, and negative affectivity. The difficult child tends to establish irregular sleeping and eating patterns, be irritable, require more time to adjust to new people, situations and routines, cry frequently, have tantrums, and have inability to be soothed.
- The third temperamental constellation, evident in about 15% of the original sample, was labeled "*Slow-to-warm-up*"; it included a combination of low activity level, mild negative responses, moderate negative affectivity, slow adjustment to change, and withdrawal from new situations. These infants were shy and likely to withdraw from unfamiliar stimuli, however with repeated exposure, they tended to adapt successfully to change and transitions.

In addition, Thomas and Chess emphasized the interaction between children's temperamental profile and the environment. Temperament is that special characteristic that might predispose a child to a behavioral problem, regardless of the demands of the environment and the stress present in it. The child's individual behavioral style could not only affect the manner in which he/she responds to specific events and child-rearing practices, but it can also elicit particular favorable or unfavorable parental attitudes and behaviors. To recognize the bidirectional nature of influences, Thomas and Chess coined the term "goodness of fit," which refers to the consonance between the child's individual temperament and the demands and expectations of the environment. They maintained that there should be a good fit between a child's temperament and his/her environment in order for optimal healthy development to occur. In contrast, observed deviations from the course of normal development, manifested in a variety of indices of maladjustment, could be attributed to a poor fit or dissonance between a child's initial biological predispositions and excessive stress and environmental demands [2, 3].

The Thomas and Chess classification of children had a profound influence on subsequent conceptualizations of temperament and led to proliferation of research on the role of individual predispositions. In addition, several intervention models based on their work have emerged and have been successfully utilized both in clinical practice and work with parents [2].

Thorazine®

Anna L. Lopez
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Chlorpromazine; Major tranquilizer; Neuroleptic

Definition

Thorazine® is a typical antipsychotic medication, brand name for chlorpromazine. This medication is FDA approved for the treatment of schizophrenia in patients above the age of 18 as well as for children over the age of 1 for treatment of disruptive and aggressive behavior disorders.

Description

Thorazine® is a dopamine receptor antagonist. It was the first medication introduced for the treatment of hallucinations and delusions. Although it is one of the oldest antipsychotics, Thorazine® is not as commonly used as other antipsychotics. It is considered low potency, meaning that a higher dosage of Thorazine® is needed in order for it to

have the same effect as a high potency antipsychotic such as Haldol®, Prolixin®, or Navane®. Because a higher dosage of Thorazine® is necessary, this agent is more sedating than high potency antipsychotic medications.

Thorazine® is available in tablets (10, 25, 50, 100, and 200), capsules (30, 75, 150, 200, and 300 mg), liquid solution (10 mg/5 mL, 30 mg/mL, 100 mg/mL), intramuscular injections (25 mg/mL), and rectal suppositories (25 mg and 100 mg).

Relevance to Childhood Development

Thorazine® may be used for the treatment of aggressiveness, impulse control, extreme irritability, hostility, and agitation. However, use of antipsychotic agents to control children's disruptive behavior has been described as controversial. It is recommended that if antipsychotics are used with children, the high-potency and less sedating antipsychotic agents are utilized instead of the more sedating low-potency drugs.

Thorndike, Edward Lee

Angela Mounger
University of Tennessee, Knoxville, TN, USA

Life Dates

1874–1949

Educational Information

Edward Lee Thorndike was born in Williamsburg, Massachusetts. He was raised in a strict environment and his early years were characterized by frequent moves due to his father's work as a Methodist minister. Throughout his school career Thorndike excelled academically and in 1891 selected the Methodist church supported Wesleyan University in Connecticut for his undergraduate education. During his junior year at Wesleyan, Thorndike became interested in the emerging field of psychology and began reading works by William James. He graduated from Wesleyan in 1895 with Phi Beta Kappa Honors and the ambition of becoming a secondary English teacher. Following his graduation from Wesleyan, Thorndike enrolled at Harvard University. While at Harvard he enrolled in psychology courses taught by William James. After completion of these courses, Thorndike decided to pursue a career in psychology. Also during his time at Harvard he developed an interest in animal intelligence and began a series of experiments on learning in chickens. In 1897 he left Harvard for personal reasons and enrolled at Columbia University [1].

At Columbia Thorndike was given permission to continue the animal learning experiments he began at Harvard. He began working with cats in puzzle boxes in order to test his theories regarding learning in animals. These experiments led to Thorndike's formulation of the Law of Effect. Thorndike earned his Ph.D. degree from Columbia in 1898 with the dissertation *Animal Intelligence: An Experimental Study of the Associative Processes in Animals.*

Accomplishments

The Law of Effect, developed while Thorndike was a doctoral student at Columbia, was formalized in 1905. This theory had far reaching implications for the fields of psychology and education. The Law of Effect examines the relationship between a stimulus and an organism's response to the stimulus. Responses that are paired with satisfaction or reinforcement increase the likelihood of the response reoccurring, whereas responses that are paired with dissatisfaction or discomfort decrease the likelihood of the response occurring.

Thorndike contributed heavily to the field of education during his 43 year tenure as a professor at Columbia Teacher's College. He desired to make teaching a science and published numerous books and articles on how to improve the quality of teaching in schools. Notable publications include: *Educational Psychology* (1903), *Introduction to the Theory of Mental and Social Measurements* (1904), *Principles of Teaching* (1906), *The Teacher's Word Book* (1921), *The Measurement of Intelligence* (1927), and the *Fundamentals of Learning* (1927) [2]. Many of Thorndike's books were widely read and his suggestions helped inform practice in classroom settings in the United

States and abroad. Two of the most prominent examples were the *Thorndike Arithmetics* which was adopted as the state textbook for California and Indiana with over a half million copies sold in the first year of publication, and the *Thorndike – Century Junior and Senior Dictionaries* which were also widely published and distributed [2].

In addition to his numerous publications, Thorndike was also involved in the construction of psychological assessments. He constructed the CAVD Examination in 1925 which measured four components of intelligence: sentence completion, arithmetic, vocabulary, and following directions. The CAVD test was used to assess the ability of students at Columbia and other universities. Another test developed by Thorndike to measure reasoning in the area of reading was the Thorndike-McCall Reading Tests developed in 1921.

Thorndike maintained a lifelong interest in assessment and was a founding member of the Psychological Corporation. Thorndike was elected as President of the American Psychological Association in 1912. In a 1921 poll conducted by American Men of Science, Thorndike was the top-ranked psychologist in the United States. Additionally, he served as president of the American Association for the Advancement of Science in 1933.

Contributions

Thorndike had a significant impact on two generations of professionals in the field of education. Throughout his life he was a prolific writer of both articles and books. Additionally, his Law of Effect was influential in the study of behavior, notably how rewards and punishment impact learning. Among his other contributions, Thorndike served on a committee of nine psychologists who were appointed to study how psychology could benefit the war effort during World War I.

Thrombophilic Disorders

Madeline Gross
Fordham University, Mount Vernon, NY, USA

Synonyms

Clotting disorders; Hypercoagulability; Thrombophilia

Definition

Thrombophilic Disorder is a broad term for disorders and conditions in which the blood forms clots easily or excessively, also known as thrombophilia. These disorders may result in an increased risk of blood clot formation in the veins and arteries, which can contribute to complications resulting in severe injury or death. Thrombophilic disorders can be due to either hereditary or acquired factors.

Description

Blood clotting is a natural and normal process in which the blood cells and proteins group together to form a clump, or clot, to slow or inhibit bleeding after a blood vessel has been injured. Most blood clots tend to dissolve naturally through cellular activity. Some people, however,

may experience thrombophilia, where blood clots form without the presence of injury at increased rates. These blood clots can travel through the blood stream to other locations, resulting in a thrombosis, or a blood clot that obstructs the flow of blood through the circulatory system. The resulting blockage is referred to as a venous thromboembolism. A venous thromboembolism can have serious, even fatal, implications. These blood clots can block the circulation of blood to the heart or brain, resulting in a heart attack or stroke, respectively. Clots may also obstruct the blood flow to the extremities, which left untreated, could result in tissue death (necrosis) or infection (gangrene). These clots may also lodge within the veins of the lungs, leading to potentially fatal condition known as a pulmonary embolism. Thrombophilic disorders are characterized by the increased risk of thrombosis formation, and are often diagnosed after a thrombosis or thromboembolism event has occurred.

Symptoms

The thrombophilic disorder does not usually present with its own symptoms, and is primarily only discovered after an abnormal clotting event has occurred. A thrombosis formed within the veins of the upper and lower extremities (legs, and more rarely, arms), also known as deep vein thrombosis (DVT), may cause swelling, redness, and discomfort of the area. Left untreated, the DVT can cause tissue damage or tissue death. These clots are most often diagnosed with ultrasound or other imaging tests, and are generally treated with blood-thinning drugs [2]. DVT may also occur within veins of major organ systems, such as the liver, kidney, and abdomen, and can form within the placenta or umbilical cord during pregnancy.

Causes

Thrombophilic disorders may be due to congenital/hereditary factors and/or acquired conditions. Heritable causes of thrombophilia include genetic mutations of the genes encoding the natural anticoagulants and clotting factors of the body. Acquired conditions such as Lupus, some cancers, limited mobility, and previous vein or arterial damage can promote thrombosis formation. Pregnancy, tobacco usage, prolonged periods of immobility, long periods of airplane travel, and oral contraceptives can also greatly increase the occurrence of a thrombosis, especially when paired with a preexisting heritable condition [1].

Management and Treatment

Some patients with a present thrombophilic state or increased risk for thrombophilia may require behavioral or medical intervention. Some behavioral changes, such as increased mobilization (especially during long air flights or prolonged periods of sitting), increased hydration, cessation of tobacco usage, and the use of compression stockings or mechanical compression devices during periods of immobility and injury, may be helpful. Women with an increased risk for thrombophilic disorders may be advised to limit or stop oral contraceptives and/or hormone treatment, and use blood thinners during pregnancy [1]. Some doctors may also advise daily doses of Aspirin or other blood thinners as a method of prophylaxis in some patients diagnosed with thrombophilia but with no previous thromboembolic event.

Patients who have had a thrombotic episode may be treated with a combination of blood thinners and anticoagulants. Oral anticoagulation may need to be continued on a long term basis if the thrombophilic state persists. This decision should be discussed and monitored in conjunction with input from local hematology specialists [3].

Tics

Kristen M. Grabill
University of Florida, Gainesville, FL, USA

Synonyms

Habit; Spasm; Tourette's disorder; Twitch

Definition

A tic is a sudden and repetitive movement or vocalization.

Description

Motor tics are characterized by rapid and involuntary repetitive or jerking movements, while vocal tics are characterized by sounds or words that are repetitive and serve no function [1]. Tics can range from simple (e.g., head jerking or throat clearing) to complex (e.g., words or more complex movements). Many individuals with tics report having a "premonitory urge," or unpleasant sensation prior to ticcing that is relieved after the tic is performed. When individuals have both motor and vocal tics for at least one year, they are often diagnosed with Tourette's disorder. In the general population, the estimated prevalence of Tourette's Disorder and other tic disorders ranges from 1 to 4.8% [2], with boys being four times more likely than girls to have a tic disorder [3]. Tourette's disorder occurs in diverse racial and ethnic groups. Factors contributing to tics and tic disorders are largely considered to be biological, although behavioral factors are sometimes thought to maintain the presence of tics. Vulnerability to Tourette's disorder appears to be genetic. Tics and Tourette's disorder are first diagnosed in childhood, with age of tic onset as young as two and usually developing during childhood or early adolescence [1]. Although some people with tics have them throughout life, many experience a reduction in symptoms in late adolescence or early adulthood. Individuals with tic disorders experience impairment in a variety of domains, and the current treatment of choice for tics is pharmacotherapy (Riddle & Carson, 2001; Kurlan, 1997), although recent research has shown that behavioral therapy may also be helpful.

Relevance to Childhood Development

Tics and tic disorders are considered a diagnosis that is first made in childhood [1]. As such, they are associated with social, familial, and academic impairment in the lives of children during critical periods of learning and development. Physically, tics can result in pain, discomfort, cuts, burns, and bruises. Psychosocially children with tic disorders report disruptions in family functioning, high levels of family conflict, and occupational difficulties as they reach adulthood. They also report having low self-esteem, while their peers describe them as less socially acceptable than other children without tics. In addition to impairment caused directly by tics, having tics is associated with high comorbidity of other psychological disorders, such as attention deficit hyperactivity disorder (ADHD), obsessive-compulsive disorder (OCD), trichotillomania, and other anxiety and depressive disorders. Those disorders are also associated with impairment across multiple domains. Currently, treatment options for children with tic disorders are limited due to lack of efficacious and safe pharmacological treatment options. While behavioral treatments such as habit reversal training (HRT) demonstrate promise, few rigorous studies have been completed and those treatments have yet to be disseminated to community providers.

Time-Delay Discounting

►Temporal Discounting

Timeouts

Gregory E. Everett, Brooke Ferrero-Baker
Southern Illinois University, Edwardsville, IL, USA

Synonyms

Behavior management; Negative reinforcement; Parent training; Punishment

Definition

A timeout (TO) is a behavior management procedure through which a person is separated from access to positive reinforcement following the display of inappropriate behavior, therefore, making reinforcement unavailable for some length of time.

Description

As a child behavior-management procedure, TOs have been effectively employed with children of varied functioning levels (e.g., developmentally delayed, normal intelligence) and ages (e.g., preschoolers, adolescents), in a wide variety of settings (e.g., schools, homes, inpatient settings), for the treatment of a range of externalizing problem behaviors (e.g., noncompliance, tantrumming, aggression, self-injurious behavior; [6]). Although used

extensively by parents, teachers, and others responsible for child behavior management over the past four decades, TO should not be conceptualized as a singular intervention to be employed in the same manner for all forms of child misbehavior. Rather, appropriate TO usage involves considerations of the differing forms of TO as well as the varied effects on child behavior that the technique may produce. In addition, the numerous procedural variables involved in TO implementation (i.e., the actual steps of TO usage) represent a series of options that users of the intervention may select.

Types of TO. Regarding differing TO types, Harris [7] outlined five forms arranged along a continuum of restrictiveness specific to the degree of change to a less reinforcing environment. Essentially, the varied forms of TO involve consideration of the magnitude of difference between the amount of reinforcement available to the child in the natural environment (called the time-in [TI] environment) versus the amount of reinforcement available while in TO. In order for TO to be effective, the child must perceive a noticeable difference between the positive consequences available to them in the TI environment and the lack of such positive consequences while in TO [12, 14]. It is in this way that each TO type moves along the continuum from those forms most closely resembling the reinforcement opportunities available in the TI environment to those forms conceptualized as far more restrictive.

Nonexclusion TO, the least restrictive TO type, involves removing the child from direct access to reinforcement, while permitting them to remain in the same general space to observe others [7]. For example, a child placed in TO for hitting their brother would be moved away from their brother, but remain in the same room so as to observe their brother's continued appropriate behavior and reinforcement. In addition to classification as a broad category, three specific subtypes of nonexclusion TO labeled ignoring, removal of reinforcing stimulus conditions, and contingent observation also exist [3]. Although all may not immediately seem synonymous with TO, each fits coherently with the previous definition. Ignoring simply involves turning away from the child so as to deny them access to attention for a period of time (i.e., access to adult attention is widely viewed as a primary motivating factor for child behavior). Removal of reinforcing stimulus conditions is the actual removal of some tangible object from the child's space (e.g., taking away a preferred toy for a period of time). Finally, contingent observation requires the child to observe the ongoing behavior of others, although they are not allowed to directly participate in the ongoing activity (e.g., the broad nonexclusion example outlined previously represents contingent observation TO).

Progressing along the continuum of restrictiveness are the other two broad forms of TO, labeled exclusion and isolation TO [7]. Exclusion TO also involves the removal of the child from access to reinforcement (as in nonexclusion forms), but also prohibits observation of ongoing activities, thereby, increasing the restrictiveness. Common means through which exclusion TOs are effected include facing a child to a corner or placing the child behind some visual impediment (e.g., a screen). Isolation TO, the most restrictive all of TO forms, involves complete child removal from the TI environment. Generally speaking, such procedures involve removing the child from the space in which the misbehavior occurred and placing them in a different room until TO completion. Although clear in terms of differing reinforcement contingencies between the TI and TO environments, a decision to use isolation TO should not be made hastily. Rather, issues of child safety and missed opportunities with respect to ongoing activities in the TI environment (e.g., classroom instructional time) should be given the utmost consideration. As such, some have proposed that the use of isolation TO should include a predetermined length of time for the removal, adequate supervision throughout alternative room placement, and protection of the rights of the removed child [1, 9].

Behavioral effects of TO. Regarding the differing effects that TO may have on childhood behavior, diverging possibilities exist, one commonly considered (and simple to understand) and one commonly overlooked (and more difficult to understand). First, TO is most often viewed as a behavior reduction procedure and, therefore, a punishment intervention employed to decrease the frequency of problematic behavior [12]. This relationship is simple to understand, in that TOs applied as a consequence for bad behavior lead to less such bad behavior in the future. For example, placing a child in TO for hitting their brother (as previously outlined) leads to less hitting in the future. Conversely, TO may also function to increase the behavior that it follows and, therefore, may be classified as a negative reinforcement procedure [5, 13]. Such behavioral relationships occur when placement in TO allows the child to escape completion of some aversive task or event. For example, sending a child to TO for failure to complete a math assignment may actually make the child less likely to complete math work in the future because by placing them in TO they are able to escape (i.e., get out of) math work completion. Given such divergent behavioral consequences, TO is commonly recommended as a consequence for

behaviors maintained by positive reinforcement and advised against with behaviors maintained by negative reinforcement. Although this proscription makes intuitive sense, recent research (i.e., [5]) has begun to shed new light on the possibilities of using TO with escape-type behaviors. Through the inclusion of specific TO implementation variables, the procedure may yet demonstrate applicability with such behaviors.

TO implementation variables. Procedurally, a number of TO variables are available for parents, teachers, and other adults to select from when employing a TO intervention. Although a multitude of implementation options do exist, there continues to be no agreed upon standard TO protocol. Rather, differing researchers and practitioners use different combinations of procedural variables when using TO. As such, the following presents a brief summary of some of the most common TO implementation variables.

Two initial variables to be considered are verbalized reasons and verbalized warnings. Although closely related in that both involve verbal statements from the adult to the child prior to TO placement, each is a separate variable in that the foci of the verbalizations are distinct. Specifically, verbalized reasons are stated explanations prior to TO indicating why it was initiated and verbalized warnings are statements that specify TO as the consequence for continued misbehavior. To contrast further, consider the following examples using the previously introduced illustration involving a child sent to TO for hitting their brother: (a) reason – "You hit your brother, TO." (b) warning – "If you hit your brother again you will go to TO." As can be seen from these statements obvious implementation differences exist between the use of verbalized reasons and warnings. Although little empirical study has been conducted on the individual effectiveness of either reasons or warnings, basic understanding of behavioral principles seems to indicate that if verbal interactions are to precede TO placement, they should be kept as short as possible so as to not reinforce inappropriate child behavior via access to adult verbal attention [14]. In addition, specific to the use of warnings, such verbal interaction may actually prolong the duration of inappropriate behavior as the warning essentially allows for one more occurrence of bad behavior before the adult takes corrective action.

Following the use or exclusion of verbal procedures as introduced, determinations regarding both the duration and location of TO should be made. Meaning simply the length of time a child must remain in TO prior to release, many variations of TO duration have appeared in the literature. Ranging from as short as a few seconds to several hours or more [15], TO duration is one of the most frequently reported implementation parameters across TO investigations. Although often directly outlined by researchers, individual investigations regarding the relative effectiveness of one duration versus another are scarce. Some have indicated that shorter TO durations (e.g., 1 min) are effective although longer durations (e.g., 4 min) may produce greater behavioral changes [8], although such conclusions are far from definitive. A more well established conclusion is that of a sequencing effect indicating that shorter durations are as effective as longer durations only if the shorter one precedes the longer [7]. Regarding TO location, implementation decisions often relate to the type of TO to be employed, as in those options outlined by Harris. Specifically, the choice of a nonexclusion, exclusion, or isolation TO procedure brings with it known location criteria. For example, the use of a nonexclusion TO dictates that the child remain in the natural environment, so that environment would be the TO location.

Similar to the ways in which both verbalized reasons and verbalized warnings are related yet distinct, two other TO implementation variables share similar relational aspects. More specifically, although TO escape contingencies and release procedures both involve children leaving TO, definitive procedural differences exist. Escape contingencies are methods used following a child's leaving TO prior to dismissal in an attempt to prevent such behavior from occurring again, while release procedures are the ways in which children are actually dismissed from TO by the overseeing adult. Common TO escape contingencies include (a) repeated returns – repeatedly guiding the child back to TO, (b) spanking – hitting the child on buttocks with an open hand, (c) holding – physically restraining the child in TO, and (d) barrier – use of a physical impediment to block TO escape [14]. Although past research indicates treatment efficacy of both spanking and barrier procedures [10, 11], research of repeated return procedures (which may be less aversive to children) has yet to be conducted. Regarding TO release procedures, determinations usually involve one of the following options: (a) time-based – dismissal occurs following passage of a given time duration, (b) behavior-based – dismissal occurs when specific behavioral contingencies are met (e.g., sitting quietly without protesting TO placement) absent any time requirement, (c) contingent delay – dismissal occurs when both time and behavioral requirements are met with TO extended for inappropriate behavior, and (d) child release – child makes individual determination regarding cessation of TO. Although empirical support for contingent delay release is the strongest [2, 4], results again are far from conclusive.

In sum, TO has been and continues to be an effective intervention for the treatment of a wide variety of childhood problem behaviors across multiple developmental levels, ages, and settings. Although often conceptualized as a simple procedure to be used in the same manner for all children, effective TOs require a deeper understanding of distinctive TO types, differing effects on child behavior, and interrelated implementation variables. Although briefly introduced, the previous discussion does not outline all implementation variables that influence TO effectiveness. Other variables include distinctions such as whether children are verbally instructed versus physically placed in TO, the use of some signaling device to indicate that TO has commenced, and the use of a debriefing procedure following TO dismissal among several others [15].

Titchener, Edward Bradford

Daniel Patanella
New York City Department of Education, New York, NY, USA

Life Dates

1867–1927

Educational Information

Titchener studied at Oxford University, and then earned his doctorate in psychology under Wilhelm Wundt (1832–1920) at Leipzig.

Accomplishments

Titchener spent his entire academic career at Cornell University, where he developed what was then the United States' largest doctoral program in psychology. He was the primary proponent of a theory he named Structuralism. Titchener's Structuralism attempted to distinguish, isolate, and

This work represents the scholarship of the author and does not imply any official position of the New York City Department of Education.

catalogue mental elements such as sensations, images, and affections through the use of a trained method of reporting called introspection. As such, while Titchener was aware of and personally supported research in such areas as child, animal, social, and abnormal psychology, he did not regard such areas as the proper domain for experimental psychology. As is common with his mentor Wundt and many other German psychologists of the era, there were strong overtones of psychophysical methodology and concerns within Titchener's conceptualization of experimental psychology.

Titchener was an early member of the American Psychological Association and founded his own society, called the Experimentalists, in 1904. He published multiple research articles and mentored 56 doctoral students, and wrote a four-volume series of books entitled *Experimental Psychology* between 1901 and 1905. These books, informally referred to as "Titchener's Manuals," were written for both the psychology student and instructor, and their meticulous detail combined with an approachable writing style to provide a wider audience with a taste of the rigor Titchener's students experienced in his laboratory [4, 5].

Among Titchener's more illustrious students were Margaret Floy Washburn (1871–1939) who would be elected president of the American Psychological Association in 1921, and Edwin Boring (1886-1968) who would author the well-known text *A History of Experimental Psychology* in 1950 [1].

Contribution

While Titchener was not the only Wundtian student with a successful and influential career in the United States, he is usually portrayed as a Wundt loyalist and Structuralism is described as being nearly identical to the Wundtian system of psychology. A portion of this reputation is due to Titchener's authoritative translations of several of Wundt's major works, and another part undoubtedly stems from the manner in which Titchener's former student Boring wrote about his mentor. Boring's strong personal bond with his mentor, as described by Samelson [4], led him not only to dedicate his *A History of Experimental Psychology* to Titchener, but to place Titchener's Structuralism within the same chapters on German psychology rather than within later chapters on American psychology. In a crucial re-evaluation of Titchener's philosophy and methodology, Leahey [3] successfully argued that there are huge differences between Wundt's and Titchener's systems and that Structuralism was best described as a type of descriptive, correlational psychology. Regardless, recent research indicates that the misconception of Titchener as a sort of "mirror image" of Wundt still persists in textbooks to the present [7].

Titchener's true legacy lies neither with Structuralism nor in the misrepresentation of him as a Wundt loyalist but in his strong commitment to psychology as an experimental, rather than an applied, science. Titchener's scientific conservatism, which Leahey [3] found analogous to Skinner's radical behaviorism, provided a strong positivistic counterpoint to the applied direction of American psychology during World War I. Titchener's stress on the importance of rigorously testing consciousness theory using respected methodology within the laboratory also stood in contrast to early classical conditioning, which he regarded as a technology due to its perceived atheoretical focus. Thus, Titchener deserves credit for not only helping to establish the laboratory's primacy in psychological research but also for promoting the role of empirically-based theory-testing as the goal of psychological science, and reiterating the importance of consciousness within psychology.

Token Economies

James K. Luiselli
The May Institute, Inc., Randolph, MA, USA

Synonyms

Conditioned reinforcement; Motivational system; Secondary reinforcement

Definition

Token economies are based on learning principles derived from operant psychology, specifically secondary positive reinforcement, and have the objective of increasing and supporting desirable child behaviors.

Description

A token is any inanimate object such as a coin, mark on a piece of paper, ticket, or sticker. By themselves, tokens do not have intrinsic value. However, when paired (conditioned) with pleasurable consequences, tokens acquire reinforcing properties. For example, parents might give their 10-year-old son poker chips each time he completes assigned household chores. By allowing the child to exchange his earned poker chips for favorite objects and activities (e.g., watching television, purchasing a toy), the poker chips will function as positive reinforcement. Positive reinforcement is defined as a consequence following behavior which increases the future probability of that behavior.

Token economies are established first by selecting one or more "target" behaviors. These behaviors represent desirable and adaptive skills that benefit children and their quality of life. Next, the type of token and method of delivery must be selected. Grades or ratings on a report card, for example, are token stimuli experienced by virtually every school-age child.

Subsequent steps in designing token economies include choosing so called "back up" reinforcers and deciding how a child can acquire them through token exchange. Using the previously cited report card illustration, parents could have their child earn a special night out when she/he receives a certain number of "good" and "excellent" grades. The grades in this depiction are the tokens and the special night out is the "back up" reinforcer.

The effectiveness of token economies depends on the correct pairing of tokens with "back up" reinforcers and consistently presenting tokens when "target" behaviors are demonstrated. The essential procedures comprising token economies can be varied further, for example, by adding additional "target" behaviors, requiring more tokens to be accumulated before exchanging them, and changing token value. Much like our real-world economy, these manipulations can enhance motivation within an incentive-focused system.

Token economies have several advantages for improving child behavior. First, tokens bridge the gap between responding and pleasurable consequences that are provided at a later time. Second, virtually any behavior can be reinforced with tokens. Third, a token economy can be implemented in multiple settings, be they school, home, or the community. And fourth, tokens allow for the selection of idiosyncratic child preferences and delayed activities (e.g., going to the movies, having a party) as positive reinforcement.

Relevance to Childhood Development

The importance of behavior consequences in child development has long been recognized. Learning is facilitated when children experience positive effects from their behavior. As infants, the behavior-consequence contingency is dominated by adult bonding and the fulfillment of basic needs. Typical child development is then characterized by learning that is supported by social consequences such as praise, approval, and recognition. As behavior becomes more sophisticated, it is less dependent on immediate and tangible consequences but instead, is maintained by delayed and secondary sources of pleasure, often mediated "symbolically" in a manner consistent with token economies.

Tourette Syndrome

Jeremy R. Sullivan
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Gilles de la Tourette's syndrome; Tourette's disorder

Definition

Tourette Syndrome (TS) is classified as a Tic Disorder in the *Diagnostic and Statistical Manual of Mental Disorders* [1]. TS includes four diagnostic criteria: (a) the presence of both multiple motor tics and at least one vocal tic; (b) occurrence of tics on a frequent and consistent basis for more than 1 year; (c) onset before 18 years of age; and (d) tics are not accounted for by substance use or a general medical condition such as Huntington's disease or multiple sclerosis [1].

Description

The *DSM-IV-TR* defines a "tic" as "a sudden, rapid, recurrent, nonrhythmic, stereotyped motor movement or vocalization" [1]. Motor tics include eye blinking, nose twitching, neck jerking, touching, smelling, head shaking, jumping, grooming behaviors, copropraxia (i.e., making obscene gestures), and echopraxia (i.e., imitating gestures used by others). Vocal tics include grunting, barking, sniffing, throat clearing, echolalia (i.e., repeating sounds or words used by others), and coprolalia (i.e., uttering obscene words) [1, 3]. Although coprolalia tics receive much attention in the popular media, these behaviors are relatively rare, occurring in less than 10% of people diagnosed with TS [1]. The diagnosis of TS requires the presence of multiple motor tics in addition to at least one vocal tic, frequent and consistent occurrence of tics for more than 1 year, onset before 18 years of age, and lack of other explanations for the tics (e.g., substance use, other medical conditions).

The prevalence of TS is estimated at approximately 5–30 children per 10,000 [1], although other estimates are closer to 1% of children and adolescents [8] and epidemiologic studies have presented widely varying prevalence estimates [11]. TS is diagnosed between three and five times more frequently in males than in females in clinical settings, but only about two times more frequently in males in some community samples [1]. Research suggests that TS has been found across all countries, cultures, and ethnic groups [10].

The mean age at onset of TS is between 6 and 9 years, and diagnosis usually occurs by early adolescence [1, 8]. Severity of tics can range from very mild to very severe, resulting in varying levels of distress and social stigmatization [1]. The course of TS is quite variable, but tics are typically the worst between 8 and 12 years of age, followed by a gradual decline in tic severity into young adulthood [12]. Thus, some symptoms may last into adulthood, but short- and long-term periods of remission may occur, and the severity and frequency of symptoms usually decrease in adolescence and adulthood [1]. It is estimated that about 20% of children with TS experience at least a moderate level of impairment by young adulthood, and those who continue to experience TS symptoms as adults are more likely to experience more severe symptoms such as self-injurious tics and coprolalia [5, 12]. Tics may get worse when the child is under stress or during times of excitement or fatigue, and may become less severe or frequent when the child is expending their energy concentrating on physical or mental tasks [3].

Children diagnosed with TS often demonstrate additional behavioral symptoms such as obsessions, compulsions, inattention, hyperactivity, and impulsivity, and many may experience embarrassment, depression, and peer rejection due to their tics [1]. TS also has been associated with deficits in multiple areas of neuropsychological

functioning, including intelligence, language, perceptual-motor skills, memory and learning, academic achievement, and executive function, although research with many of these areas has produced inconsistent findings [9]. Common comorbid diagnoses include Attention Deficit Hyperactivity Disorder (ADHD), Obsessive-Compulsive Disorder (OCD), and Learning Disabilities (LD) [1, 8], in addition to anxiety disorders, mood disorders, sleep disturbances, self-injurious behaviors, difficulty controlling temper, and oppositional-defiant disorder [3, 10]. ADHD co-occurs in greater than 50% of children with TS in many clinical and epidemiological studies, OCD co-occurs in about 35–50% of children with TS, and LD co-occurs in about 10–25% of children with TS; at the same time, most children who are diagnosed with ADHD, OCD, or LD do not meet criteria for TS [9].

The combination of TS and comorbid diagnoses is often associated with more severe behavioral and psychological impairment than TS alone, and research suggests that many difficulties are accounted for by comorbid conditions rather than related to TS alone [3, 10]. Thus, it appears that the likelihood of significant impairment increases as does the number of comorbid conditions or symptoms. Further, the neuropsychological, emotional-behavioral, and family functioning profile may be quite different when TS is combined with other diagnoses, which will have implications for prognosis and treatment [9].

With regard to etiology, TS is considered a genetic neurodevelopmental disorder due to strong evidence for genetic influences [1, 2]. The specific genes that contribute to TS are under investigation and numerous models for inheritance have been proposed, but the genetics of TS are not yet fully understood [10, 12], although available research suggests that TS is caused by multiple genes rather than by a single predictable gene. From a neurological perspective, TS is believed to be related to abnormal neurotransmitter activity causing disinhibition of cortico-striatal-thalamic-cortical circuitry, or circuits that link regions of the frontal lobes with subcortical structures [3]. Decreased motor inhibition due to impaired modulation of neuronal activity in the basal ganglia and thalamus has been implicated, which likely involves the circuit from the prefrontal cortex to the caudate, then to the globus pallidus and substantia nigra, then to the thalamus, and finally back to the cortex [7]. Numerous abnormalities in neural functional connectivity and specific structures have been observed among children and adolescents with TS (see [9], for a review). Specific neurotransmitter systems identified as potential causal factors in TS include dopamine, serotonin, acetylcholine, GABA amino acids, and others [10]. Environmental influences related to TS and tic severity include prenatal and perinatal insults such as maternal stress during pregnancy, maternal use of stimulant medications and smoking during pregnancy, low birth weight, and birth complications, but a lack of controlled studies prevents definitive conclusions about these variables [4, 10]. Environmental factors may interact with genetic and neurobiological factors to determine whether children with the genetic predisposition for TS will actually develop the disorder.

Evidence-based interventions for TS include pharmacological and psychosocial approaches. Currently there is greater empirical support for pharmacological approaches (e.g., typical and atypical antipsychotics, alpha-adrenergic agents, selective serotonin reuptake inhibitors) as these appear to be the most commonly used interventions for TS, although evidence is starting to accumulate for psychosocial interventions such as habit reversal training and response prevention [9]. Children with TS undergoing stimulant medication treatment for comorbid ADHD should be closely monitored for worsening tics, as stimulant medications may exacerbate tics among some children with TS [10].

Relevance to Childhood Development

Children with TS are likely to receive special education services under the Other Health Impaired category of IDEA, although they may be classified into other categories (e.g., Emotional Disturbance, Learning Disability) depending on the unique nature of their symptom presentation, comorbidity, and specific emotional, behavioral, and academic difficulties. Common academic consequences of tics include interference with reading and handwriting due to motor tics, and avoidance of reading aloud and asking questions in class due to interfering vocal tics and related embarrassment [6]. As a result, many students with TS (especially those with comorbid conditions) receive classroom accommodations or instructional modifications to address their behavioral and academic needs.

Tower Tasks

Audrey McKinlay
University of Canterbury, Christchurch, Canterbury, New Zealand

Synonyms

Stockings of Cambridge; Tower; Tower of Colorado; Tower of Hanoi; Tower of London; Tower of London-Drexel

Definition

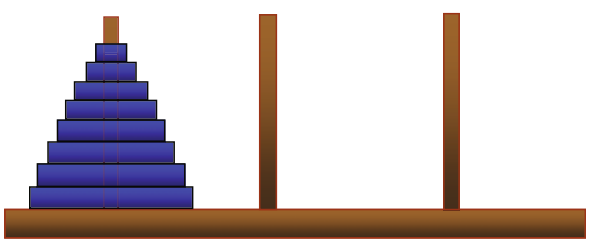
The tower tasks are puzzles most commonly used to measure planning ability. They require the individual to solve a specified problem using the least number of moves to arrive at the solution.

Description

There are multiple versions of the tower tasks [10]. The over riding feature of each is the requirement that the individual solve a problem by moving the pieces and arriving at goal position in the least number of moves. Tower tasks are most commonly used to measure planning ability. Planning refers to the ability to look ahead through a series of possible steps, some of which may be counter-intuitive, to reach a desired goal. The ability to plan is an essential part of daily living, and difficulties with this skill may impact on an individual's autonomy.

Tower of Hanoi

The Tower of Hanoi (TOH) was invented by Edouard Lucas, a French mathematician. Originally the task consisted of eight disks of increasing size that were stacked on one of three pegs (see below in Fig. 1). The goal of the



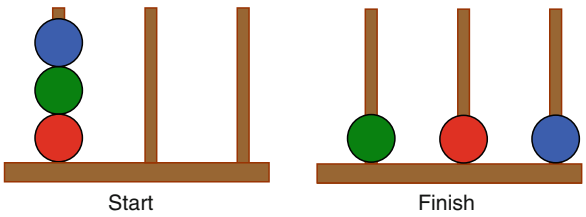
Tower Tasks. Fig. 1 An eight disk Tower of Hanoi task.

task was to move all the disks from the left peg to the right one following rules: (1) move only one disk at a time, (2) never place a larger disk on top of a smaller disk. The problem required a recursive shuffling of the disks until the problem is solved in the minimum number of moves.

Various adaptation of the TOH have been devised, one of the more recent ones appears in the Delis-Kaplan Executive Function System (D-KEFS). In this version the tower test consists of five disks which vary in size from large to small. For each of the nine problems, the participant is presented with a visual example of the tower to be built and two to five disks on the board in a predetermined starting position, depending on the level of difficulty of the tower [5]. They are then required to make the disks on the board match the ones presented in pictorial form. The rules remained the same as in the original TOH: participants were asked to plan their moves prior to starting while observing two rules, never place a larger disk on top of a smaller disk and only move one disk at a time.

Tower of London

The Tower of London was first devised by Shallice [14] to assess problem solving skills associated in patients with frontal lobe deficits [14]. Shallice suggested that although the TOH met some of the pre-requisites required for planning the task was difficult to use experimentally because of difficulties grading the levels of complexity for the different problems. Therefore, he adapted the TOH to a task that he named the Tower of London (TOL) task. In the original TOL task there are two configurations of three balls placed on three pegs (see Fig. 2). One configuration is the start point and the other the finish point. The rules for this task were that only one ball could be moved at a time. Once again the object of the task was to solve the problem in the least number of moves. Different start and finish points could increase or decrease the level of complexity of the problem. Shallice's original TOL used 12 problems of increasing difficulty. Individuals were instructed to plan all their moves prior to beginning. The problems required the formulation and execution of a series of sub-goals to complete.



Tower Tasks. Fig. 2 Tower of London task.

As with the TOH various versions of the TOL have been devised. Most of these variations manipulate the difficulty of the task by increasing the number of balls and pegs as in the Tower of Toronto task or the five disk TOL task suggested by Ward and Allport [2, 3, 15]. However, a unique variation of the TOL task was devised by the Cambridge group and is called the Stockings of Cambridge, which is computerized. In this task the participants are shown two displays of three colored balls, one in the top half of the screen and the other in the bottom half of the screen [13]. The balls are held in pockets or stockings, suspended from a line. Each pocket is a different size, one could hold only one ball, another a maximum of two balls and the third held a maximum of three balls. The participant is required to rearrange the balls in the bottom half of the screen to match the arrangement of the colored balls in the top half of the screen. A touch sensitive screen enabled the balls to be moved by the participant who selected the desired ball by touching the image of the ball on the screen and then touching an empty pocket space where they wanted to place the ball.

One difficulty with the popularization of the tower tasks is that the different variations of the TOL and TOH have been used interchangeably with patient groups, despite the fact that there is currently no evidence regarding their relative sensitivity. Another area of difficulty relates to the complexity of different tower problems. In the literature little attention has been paid to the selection of problem sets. However, recent research has placed particular importance on the selection of tower problems as it has been suggested that different aspects of individual problems may increase or decrease the level of task complexity [7, 12]. For example, subtle aspects of the TOL task may impact performance. These aspects include:

1. Sub-goals required
2. Search depth
3. Sub optimal alternatives
4. Counter intuitive moves
5. Start position
6. Goal position
7. Nested problems

At the most basic level, the number of moves can be considered an indicator of problem difficulty. However, two problems may have the same number of moves but differ with respect to the number of alternative moves available. This was outlined in the recent work by Berg and Byrd [10] in their description of the "problem space" associated with the TOL task.

The problem space defined by Berg and Byrd [10] is the graphic representation of the moves possible under the

rules of the task in which there are six permutations. As pointed out in the work of Berg and Byrd [10], for each permutation there are six possible ball positions. Each of the permutations are the same in that they have an identical six possible ball positions, but differ in the arrangements of the ball colors [1]. There are 210 spatially unique problems for each permutation in the type of TOL task ranging from 1 to 8 moves problems, giving a total of 1,260 possible unique problem sets (see [1] for a complete discussion regarding the problem space). It is easy to see that the difficulty of a particular problem may be influenced by more than just the number of moves required for its solution. For example, problems with the same number of moves may have a different "search depth" or sub-goal pattern. A sub-goal refers to moves that are essential to the solution of a given problem, but do not place a ball into its goal position [16]. The search depth is defined as the number of sub-goal moves before the first ball can be moved into a goal space. A longer search depth is considered to increase the difficulty of the problem as it requires more moves to be held in mind prior to being able to place the first ball in its goal position. Not only may a problem vary according to the number of paths available for achieving an optimal solution, but there may also be "sub-optimal alternatives." Sub-optimal alternatives refer to problems with one or more paths which take more than the minimum number of moves, but allow the first ball to be placed into its goal position within a number of moves equal to the optimal solution.

Further, the presence and number of "counter-intuitive moves" increases complexity. Counter-intuitive moves are moves that do not lead directly to the end goal and in some cases may require a ball to first be removed from its goal state in order to perform the optimal solution. Start position and finish positions may affect the individuals' performance. For example, in the flat start position, where there is one ball on each peg, there is no obvious first move. In contrast, a tower start position where all three balls on the tallest peg, the ordering of moves to obtain the finish position is more obvious [1]. Further, the latter has only two possible start moves while the former has four [1]. Moreover, a flat finish position provides an unclear final sequence, whereas a tower end gives a clear ordering for the sequence of final moves.

The importance of the finish position or "goal hierarchy" has been discussed in some depth by Kaller et al. [8]. These authors suggest that a tower end position can be considered "unambiguous" in relation to the final moves required, whereas a flat goal position can be considered "totally ambiguous." A goal position in between these two extremes may be considered "partially ambiguous." Finally, problems may be "nested," referring to the situation where the optimal path for the first problem is contained entirely in the second. The second problem differs only with regard to the additional moves at the start or finish.

Relevance to Childhood Development

The ability to perform frontal tasks such as the TOL and TOH systematically develops with age [11]. For example, younger children, 4–5 year olds, perform worse than 7–8 year olds who perform worse than adults [11]. Further, older adults (80s) perform worse than younger adults (20s) [4]. This age related ability to perform on the tower tasks is thought to reflect the development of the frontal lobes [6]. Because the ability to perform planning tasks such as the TOL and the TOH systematically develops in normally functioning children, they are able to be used in clinical contexts with children who have difficulties, including developmental delays or medical conditions and brain injury [8]. For example, children with closed head injury are likely to have more difficulty solving problems. Studies on children with traumatic brain injury indicate that severity of injury and age at testing are strongly correlated with performance on tower tasks [9].

Trail Making Test

Audrey McKinlay
University of Canterbury, Christchurch, Canterbury, New Zealand

Synonyms

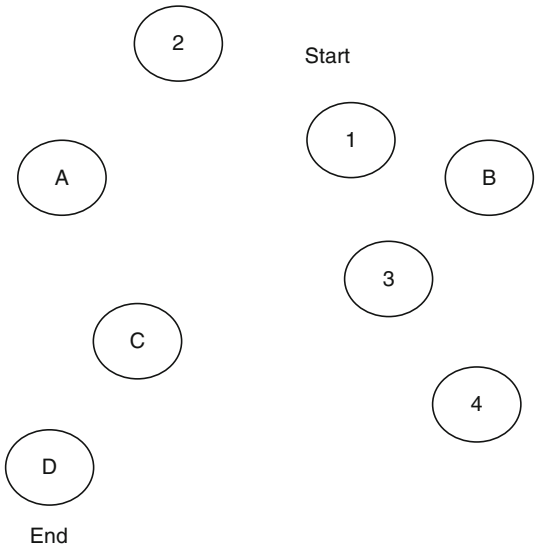
Complex trail making test; Trails

Definition

The trail making test is a neuropsychological test that assesses motor speed, speed of mental processing and mental flexibility. This test is considered to be highly vulnerable to the effects of brain injury.

Description

The original trail making test was a paper a pencil test with two parts. In part A the individual was asked to draw lines between 25 consecutively numbered circles spread randomly across a sheet of paper. Part B (sample shown below) is more difficult, the participant is asked to draw lines alternating between numbers and letters in sequence. For example, 1 → A → 2 → B, etc. They are asked to complete the task as quickly as possible without lifting the pencil from the paper. The test takes a maximum of 5–10 min to complete. The time taken to complete the task is recorded and this is used to assess the individual's performance. Norms are available to interpret the scores [6]. Performance is affected by age with older individuals taking longer to complete the task [1].



Interpretation

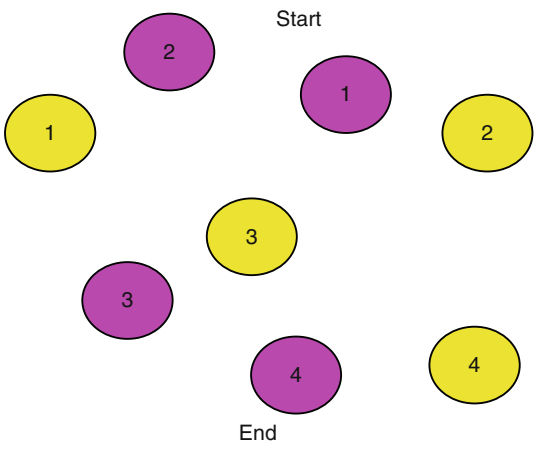
The Trail Making Test, particularly Trails B, is a good predictor of brain impairment and is useful for identifying frontal lobe damage [3, 4]. However, care must be taken in interpretation of the scores. For example, while slow performance on either part A and/or part B may suggest brain damage it could also be caused by motor slowing, lack of coordination, visual scanning difficulties and poor motivation. Other difficulties associated with this test are that it is inconsistent at differentiating individuals with brain injury from individuals with other psychiatric difficulties such as depression. So while this test has clinical utility for the identification of neuropsychological difficulties it is not a diagnostic tool.

The Trail Making Test has been included in the Delis Kaplan Executive Function System (D-KEFS) using an extended form which has five parts (visual scanning,

number sequencing, letter sequencing, number-letter switching and motor speed) [2]. This expanded form allows for a much more comprehensive assessment of performance and overcomes a number of the difficulties in the original Trail Making Test by enabling different aspects of performance to be assessed separately.

Relevance to Childhood Development

The Trail Making Test was originally designed for use with adults. However, it has been updated to include a child version. This test is only useful for children between 9 and 14 years of age. In response to the need for non culturally biased testing a Color Trails has also been developed for use with children [7] and has been successfully used with children 5 years and older. In this version Part A requires the child to correctly sequence numbers from 1 to 15. All odd numbers are embedded in circles that have pink background while all even numbers are embedded in a yellow background.



Part 2 contains numbers 1–15 in yellow and a duplicate set of numbers 1–15 in pink. For this part the child must again connect the circles in ascending order but this time must alternate between pink and yellow e.g., Pink 1, Yellow 2, Pink 3, Yellow 4, etc. [7] (see sample above).

Despite efforts to ensure that the test is culturally sensitive recent research indicates that both the Trails Test and The Children's Color Trails Test are influenced by language background and intelligence [5]. Therefore, some caution should be exercised when using the test with groups for whom English is not their first language.

Transitional Bilingual Education

Corey E. Ray-Subramanian
University of Wisconsin-Madison, Madison, WI, USA

Definition

An educational approach in the United States for students with limited English proficiency in which the students are instructed in their primary language for a limited time until they have reached sufficient proficiency in English and are then transitioned to English-only instruction.

Description

Transitional bilingual education programs are referred to as *early-exit* programs if students receive bilingual instruction (i.e., at least some instruction in primary language in addition to instruction in English) for 2 years or less and *late-exit* if students receive bilingual instruction for most or all of their elementary school years (typically around 40% of instruction in primary language until sixth grade) [1]. Language proficiency and academic achievement in English is the central long-term goal of such programs. Longitudinal research has demonstrated that late-exit bilingual education programs are associated with faster growth rates in academic achievement and similar growth rates in English language proficiency as compared to early-exit transitional bilingual education [2].

Traumatic Brain Injury

MaryBeth Bailar-Heath
Nova Southeastern University, Fort Lauderdale, FL, USA

Synonyms

Brain disorders; Brain injury; Closed head injury; Closed head trauma; Head injury; Head trauma; Open head injury; Open head trauma; TBI

Definition

A traumatic brain injury (TBI) is an acquired injury to the brain caused by an external force to the head. The term "TBI" is *not* applied to individuals who have developmental brain disorders, such as attention deficit disorder, a cognitive disability, or a learning disability, nor is it the result of a tumor, infection, stroke, or loss of oxygen to the brain. A TBI may be classified as mild, moderate, or severe.

Description

Epidemiology, Morbidity and Mortality

According to the Centers for Disease Control (CDC), approximately 475,000 children ages birth to 14 years sustain a TBI in the United States each year. These brain injuries in children account for 37,000 hospitalizations and 435,000 emergency department visits annually, as well as approximately 2,700 deaths [8]. In fact, TBI is a leading cause of death among youth and represents a major public health concern [11]. As many as half of the deaths resulting from trauma are associated with brain injuries [7]. Virtually all of those who survive a TBI encounter adverse outcomes, which may range from a persistent vegetative state, severe disability, moderate disability, and minimal neurobehavioral impairment.

Classification of TBI

Traumatic brain injuries are classified by their level of severity. The most commonly used measure of injury severity is the Glasgow Coma Scale (GCS [9]), which can be used to assess individuals age four and over. An individual's best response in the following domains is recorded: eye opening, motor response, and verbal response. An adaptation of the GCS is shown below.

Eye opening	*Score*
Open spontaneously	4
Open to verbal command	3
Open to pain	2
No response	1
Best motor response	*Score*
Obeys verbal command	6
Localizes pain in response to painful stimulus	5
Flexion-withdrawal in response to painful stimulus	4
Abnormal flexion in response to painful stimulus	3
Extension in response to painful stimulus	2
No response	1
Best verbal response	*Score*
Oriented and converses	5
Disoriented and converses	4
Inappropriate words	3
Incomprehensible sounds	2
No response	1
Glasgow coma scale total	*3–15*

The Children's Coma Scale (CCS [5]) is a modified form of the Glasgow Coma Scale, and is recommended to assess the severity of TBI in children ages three years and younger. The CCS assesses functioning in the same three domains as those in the Glasgow Coma Scale, for a total score ranging from 3–15. A summary of the Children's Coma Scale is shown below.

Eye opening	*Score*
Spontaneous	4
Reaction to speech	3
Reaction to pain	2
No response	1
Best motor response	*Score*
Spontaneous (obeys verbal command)	6
Localizes in response to painful stimulus	5
Withdraws in response to painful stimulus	4
Abnormal flexion in response to painful stimulus	3
Abnormal extension in response to painful stimulus	2
No response	1
Best verbal response	*Score*
Smiles, oriented to sound, follows objects, interacts	5
Crying is consolable; interaction is inappropriate	4
Crying is inconsistently consolable; moaning may be present	3
Inconsolable; irritable and restless	2
No response	1
Children's coma scale total	*3–15*

A head injury is considered mild if the individual receives a GCS or CCS score between 13 and 15. Scores between 9 and 12 usually represent moderate injuries, and scores of 8 or less are indicative of severe injuries. The vast majority (85%) of traumatic brain injuries that require medical treatment are mild; 8–10% are moderate, while 6–13% are severe [11].

In addition to the depth of coma (i.e., GCS or CCS score), injury severity may also be determined by characteristics such as the duration of impaired consciousness (i.e., time period during which the child does not follow motor commands) and the length of post traumatic amnesia (PTA; i.e., time during which the child is not fully oriented and does not display intact memory for daily events) [11]. A mild traumatic brain injury may be indicated by a brief or no loss of consciousness and PTA lasting less than 24 hours. If a child is in a coma for less than 24 hours and demonstrates PTA for 1–7 days, the TBI is usually considered moderate. Severe TBI is suggested by a coma lasting more than 24 hours and PTA lasting more than 7 days.

Causes of Injury

Causes of brain injury vary significantly with age. The leading cause of TBI in infants and young children is falls, which account for about 39% of all child traumatic brain injuries [8]. Older children are more likely to sustain a TBI as a result of sports and recreational accidents and pedestrian or bicycle collisions with motor vehicles. Motor vehicle accidents cause the majority of brain injuries in the adolescent population [7].

Types of Head Injuries

A TBI is often referred to as either an "open head injury" or a "closed head injury." In an open head injury, the skull and brain are penetrated by an external object, such as a bullet from a gun. In a closed head injury, the skull and brain are not penetrated; a closed head injury may result from a fall or car accident.

The pathophysiology of a brain injury occurs at the time of impact, but continues over a period of time, possibly as long as weeks or months. The various injuries that result from a TBI may be classified as primary injuries or secondary injuries. Primary injuries are observable injuries resulting from the trauma itself. These may include skull fractures (in an open head injury), intracranial contusions and hemorrhage (i.e., bleeding within the brain), and/or mechanical injuries from nerve fibers and blood vessels. Secondary injuries result indirectly from the trauma. Brain swelling, hypoxia, hypotension, and increased intracranial pressure are all examples of secondary injuries. Secondary injuries may also include a multitude of neurochemical events. One common chain of neurochemical events includes the production of free radicals and excitatory amino acids along with the disruption of normal calcium homeostasis. These events act to exacerbate the hypoxic-ischemic insult that is a common secondary injury. Finally, secondary injuries include a variety of late effects. One is posttraumatic seizures. Approximately 3–9% of children with head injuries experience these seizures, with most of these children experiencing their first seizure within 2 years following their head trauma. Posttraumatic seizures appear to occur more commonly in younger children as well as those who sustained a penetrating injury or depressed skull fracture. Other possible but less common late effects of head injury include white matter degeneration, cerebral atrophy, enlarged ventricles, and hydrocephalus [11].

Neurobehavioral Consequences

A TBI may result in a variety of neurobehavioral consequences, depending on the specific location of the trauma in the brain, and the type (i.e., closed versus open head injury, primary versus secondary injuries) and severity of the injury. While no specific, all-inclusive list of symptoms and sequelae can be generated to describe the outcomes of every pediatric TBI, there are areas where impairments frequently occur. These domains include intellectual/cognitive, speech/language (including memory), academic, sensorimotor, and behavioral or emotional functioning [2, 4].

Intellectual and Cognitive Functioning. Impaired performance on intelligence tests is frequently seen after a child has sustained a TBI, particularly on nonverbal measures, such as the Perceptual Reasoning and Processing Speed indices on the Wechsler Intelligence Scale for Children, Fourth Edition (WISC-IV). It is thought that individuals with TBI have more trouble with fluid problem-solving skills and speeded motor output, while they may do better with previously acquired knowledge. Though a child's IQ scores may significantly improve in the one to two years following a TBI, scores often remain depressed relative to pre-injury levels. This is particularly true among children with severe head injuries [11].

Memory difficulties are another common and persistent consequence of a TBI [3]. Additionally, complaints regarding attention problems very often follow childhood head injuries [11]. Finally, executive functions, such as concept formation, integrating, organizing and generalizing information, problem solving, and judgment, also tend to be negatively impacted by pediatric TBI [2].

Functional limitations associated with these commonly occurring cognitive impairments often include poor initiation of tasks and poor task orientation [3]. Unfortunately, significant cognitive weaknesses can be overlooked following TBI, as children may appear intact due to the relatively rapid recovery of mobility, self-care skills, and basic language functioning [4].

Speech and Language Functioning. Children with TBI often display pronounced difficulties with the pragmatic aspects of language [11]. Deficits have been demonstrated in a variety of skills, such as language comprehension, abstraction, making inferences, organization of verbal or written material, expression of complex ideas, and word fluency [4]. It has been suggested that receptive language improves at the same rate as cognitive and perceptual functioning. Studies further show that expressive language (speech) correlates with improvements in motor function [3].

Academic Performance. Given the cognitive deficits described above, it is not surprising that pediatric TBI is often associated with reported declines in academic functioning. Deficits in basic cognitive processes resulting from brain injury almost always cause impairment in academic performance. In some cases, this impairment may not be apparent for a year or more following the injury. As a result, when the deficits are identified, they may not be attributed to the injury. Even if correctly attributed to the TBI, however, improvements in academic achievement are often slow [2].

Research has shown that a child's premorbid academic ability is a strong predictor of reading and spelling achievement two years following a brain injury. It is suggested that the higher a child's ability prior to an injury, the higher his or her reading and spelling achievement is likely to be at 2 years post-injury. Interestingly, research does not indicate a similar effect for mathematics achievement [1].

Sensorimotor Functioning. In terms of sensory functions, some studies have shown that up to 25% of children with severe injuries display deficits on tests of stereognosis (i.e., the ability to perceive the form of an

object by using sense of touch), finger localization, and graphesthesia (i.e., the ability to recognize writing on the skin only using sense of touch) [11]. Some children report hemianopsia (i.e., blindness to one side of the visual field), diplopia (i.e., double vision), blurred vision, and even cortical blindness (i.e., loss of the ability to interpret visual information). Hearing loss occurs in approximately 35% of TBI patients. Inner ear problems are reported as much as 6 months following the injury in 50% of children with TBI. Lastly, nearly all children require extra time to process sensory information following a severe brain injury [4].

Up to 33% of children with TBI evidence some motor control sequelae, and children with these impairments may show improvement for up to 7 years post-injury [3]. Motor problems may include impairments in gait and coordination, complex psychomotor tasks, and fine motor skills [2, 11]. Children with TBI may perform better on motor tasks when speed is not a requirement. Many children regain motor abilities faster than in any other domain of functioning. Unfortunately, adults may unknowingly interpret the regaining of these abilities as a total recovery on the child's part, since the child now looks and acts "normal."

Behavioral Functioning and Emotional Disturbances. Of all the aspects of adaptive behavior, social problems with peers and family members tend to be the most unrelenting [4]. Families tend to rate behavioral disturbances and personality change as the most troublesome and persistent problem following pediatric TBI. Problems in social behavior are often associated with impaired executive functioning and prefrontal brain injury. Common behavioral sequelae from brain injury include increased aggression, poor anger control, and hyperactivity [2].

Adaptive deficits and behavioral disturbances can be related to severity of injury as well as the child's premorbid functioning [11]. Interestingly, behavioral functioning following pediatric TBI does not appear to be correlated with cognitive outcomes; thus cognitive and behavioral outcomes may be somewhat independent following the injury, and their determinants may vary significantly. Research suggests that cognitive outcomes may be related more strongly to injury-related variables, while behavioral outcomes appear to be related more strongly to measures of preinjury family functioning [12].

After a brain injury, a child might also experience depression for a variety of reasons. The child may realize, for example, that he or she has a disability and is different from classmates or peers. Additionally, the child may have enough insight to understand that he or she is no longer performing at his or her preinjury level. The child may even mourn the loss of the person he or she once was prior to the injury. It is important to note that symptoms of childhood depression often differ from those demonstrated in adulthood. Whereas depressed adults often appear sad and withdrawn, children may appear irritable and easily agitated. Thus, irritability, agitation, and anger could be a result of the brain injury itself, or could be the child's psychological reaction to the injury's effect on his or her life.

Prediction of Outcomes

Several factors appear to contribute to the outcome of a child's TBI. The severity of the injury is one of these factors, though it must be noted that there is a wide variation in outcomes even in individuals in one particular range of severity. In addition to injury severity, a child's preinjury characteristics (i.e., age, developmental level, academic achievement), family functioning, and behavioral adjustment interact with the brain injury itself to determine the child's initial presentation and long-term outcome [1, 6].

Though the clinical picture of TBI can differ from one injury or individual to another, children who survive brain injuries generally demonstrate a rather predictable sequence of recovery, moving from coma to a period of agitation and disorientation, then to more purposeful and age-appropriate behaviors. It is the duration of time in which this sequence of recovery occurs that differs according to injury severity, the child's preinjury characteristics, and his or her environment. The most rapid recovery generally takes place in the first 6–12 months after the injury, though continued gradual improvements can be observed for several years following the TBI [4].

It is a common misconception that the earlier a child sustains a head injury, the more likely he or she will be to recover, because the brain is malleable and can compensate for the deficits. In reality, however, the sequelae of the injury will often be worse the younger the child is at the time of injury. Unlike adults with TBI, children are in the midst of rapid developmental changes in all domains of functioning, including physical, cognitive, and behavioral [4]. Since developmental milestones must synchronically be met before proper development can occur, a child's neurological impairments resulting from a TBI can hinder future learning and cognitive development [10]. Recent studies suggest that children demonstrate less damage than adults early in recovery, but deficits often emerge later as the child matures [3].

Trichotillomania

Michael P. Twohig, Katherine A. Crowell
Utah State University, Logan, UT, USA

Synonyms

Chronic hair pulling; Hair pulling

Definition

Trichotillomania is a psychological disorder that involves the pulling out of one's own hair that leads to physical damage and/or difficulties in social, occupational, or other types of functioning. In many, but not all, cases the hair pulling is preceded by a feeling of tension or arousal that is reduced or negated by the pulling. The pulling may occur from many sites but the scalp is the most common pulling area. The pulling is commonly done with one's fingers but devices such as tweezers are also used. Finally, the pulled hair is often manipulated, and in a small percentage of people it is ingested.

Description

Trichotillomania (TTM) is defined as recurrent or chronic hair pulling that (a) is preceded by an immediate increase in tension due to the pulling itself or by attempts to resist pulling; (b) results in feelings of gratification, pleasure or relief; (c) is not accounted for by another disorder; and (d) results in significant impairment or distress in important areas of functioning [1]. Due to the developmental and cognitive differences observed children and adolescents (referred to as *children* from here on), criteria (a) (preceding tension) and (b) (feeling of gratification) may not be necessary for a diagnosis of TTM in children. Similarly, hair pulling in children younger than 2 years of age may be better accounted for as a habit disorder rather than TTM.

Pulling Types and Methods

Hair pulling is generally separated into two categories: "focused" and "automatic." Focused pulling is deliberate and often done to regulate internal experiences (e.g., decrease boredom or tension). Automatic pulling occurs

habitually and without the person's immediate awareness. Focused pulling often occurs in bathrooms and in front of mirrors, whereas automatic pulling often occurs while reading or watching television. To date, three studies have examined the rates of focused versus automatic pulling [2, 3, 7]. Even though different methods were used to collect these data, it was found that between 15 and 34% of adults reported pulling that was largely focused and between 5 and 47% reported pulling that was mainly automatic. It is commonly believed that most individuals present with both types of pulling or fall on a continuum between focused and automatic pulling. Recent research shows that these constructs also capture childhood TTM [8].

The scalp is the most common pulling site in children, followed by eyelashes and eyebrows [14]. As children mature and develop hair in other areas of the body, those areas might also become pulling sites. It is estimated that 23% of children pull from a minimum of two sites [18]. Individuals with TTM often report pulling hairs that have a distinct quality such as thicker, coarser, curly, broken, or a different color than other hairs. People will often pull hairs in the hope that they can find ones that have a large follicle or a follicle that is a certain color (e.g., red from blood). Pulling is commonly done with one's fingers, but utensils such as tweezers are often used in the pulling.

After pulling, the hair may be examined and manipulated, discarded or collected, or mouthed and/or ingested. Post-pulling oral behaviors occur in approximately 48–77% of individuals with TTM [3]. Additionally, 5–18% of individuals with TTM ingest parts or entire hairs (trichophagy) which can lead to serious medical consequences [3, 4]. The development of internal hairballs (trichobezoars) can cause serious illness and in the most severe cases death [19].

Quality of Life Issues

Individuals with TTM typically pull for one or greater hours per day. Recent research examining quality of life issues in adults indicates most individuals with TTM have social impairments (e.g., decreased contact with friends, avoidance of dating, and work related distress) and negative affect as a result of their disorder. Additionally, the majority of individuals with TTM report grooming related problems, issues with physical health, and frequently avoided recreational activities [6]. Although quality of life issues have not been as extensively studied in children with TTM, specific issues include: avoidance or reluctance to attend school due to a fear of being teased by peers, habitual tardiness resulting from a loss track of time while pulling hair, difficulties with attention and concentration caused by frequent pulling in class, and criticism or punishment by teachers because of hair pulling.

Etiology and Maintenance

The most commonly espoused models for the development of TTM are neurological, animal, and behavioral. Neurological differences have been detected in individuals with TTM as compared to control participants [13, 15, 16]. In general, these findings point to a possible role within the dopamine and serotonin systems in TTM. Comparisons have been made between human hair pulling and self-injurious licking exhibited by cats and dogs. Similarly, birds sometimes pick out their own feathers for no apparent reason. Finally, mice that have mutations on the Hoxb8 gene will show excessive grooming behaviors [9]. Behavioral models generally focus on the immediate effects of the pulling in the maintenance of the disorder. Pulling serves a reinforcing function for many individuals whether it is the reduction in stress or tension or the pleasure of pulling itself.

Prevalence and Onset

Prevalence estimates for TTM vary from approximately 1–3.4% [14]. The mean age of onset for TTM is between 10.7 and 13 years of age with standard deviations of 6.3 and 8 years [3, 5]. It is generally believed that TTM is more common in adult females but that may be because females show a greater willingness to seek treatment for TTM. The gender distribution is more equal in children [12].

Comorbidity

Co-occurring disorders are common in adults with TTM, with mood, anxiety, substance use, and personality disorders being the most common. Approximately one third to two thirds of children with TTM meet criteria for a second diagnosis. Anxiety disorders and internalizing disorders are the most common.

Assessment

Validated Assessments

The *Trichotillomania Scale for Children* (TSC; [17]) specifically examines hair pulling behaviors in children by assessing severity, distress and impairment. *The Milwaukee Inventory for Styles of Trichotillomania-Child Version* (MIST-C; [8]) is helpful to determine the degree to which children with TTM have focused or automatic pulling.

Self-Monitoring/Alopecia Ratings

Treatment progress is frequently assessed using self-monitoring methods. Clients collect or count the number

of hairs pulled over a given period of time (e.g., per day or per week) which are then entered into a computer and plotted on a chart. This can serve to increase motivation for treatment because children can see their pulling decrease on the chart. Alopecia ratings are collected by taking photographs of pulling sites prior to and over the course of treatment. The photographs then allow both the client and the clinician to monitor hair growth throughout treatment.

Treatment

The first step in the treatment of TTM is a medical evaluation to rule-out a medical reason for the hair loss or pulling (e.g., ringworm, dry skin). If medical or pharmacological treatment is not warranted psychosocial interventions are the first lines of treatment. The most supported treatment for children with TTM is simplified habit reversal [11]. Simplified habit reversal involves three steps: awareness training, competing response training, and social support. Awareness training involves teaching the client to recognize the movements involved in pulling or the urges that precede pulling. These movements and the urges are labeled "warning signs." Contingent on these warning signs the client practices the competing response for 1 min. The competing response generally involves doing something else with one's hands such as making fists. Finally, a family member is taught to reinforce the correct use of the competing response. It is presumed that habit reversal is more effective with automatic pulling.

Procedures to target focused pulling have been added to the treatment of TTM such as cognitive therapy procedures [10] or procedures from acceptance and commitment therapy [20]. In addition, pharmacological interventions have been successful in treating TTM including Fluoxetine, Chlomipramine, Haloperidol, Imipramine, & Trimipramine with Chlordiazepoxide [14].

Trileptal®

Anisa Fornoff
Drake University, Ankeny, IA, USA

Synonyms

Oxcarbazepine

Definition

A prescription medication FDA approved for the treatment (monotherapy or adjunctive therapy) of partial seizures in adults and children ages 4 or older with epilepsy. Also, it is approved as adjunctive therapy in the treatment of partial seizures in children two or older with epilepsy.

Description

Exactly how this medication works is not known. It is available in a tablet or as an oral suspension.

The recommended starting dose for this medication is based on weight for children and adolescents and is typically taken twice a day. Maximum suggested dose is 600 mg a day or depending on weight. The recommended starting dose for adults is 300 mg taken twice a day with the recommended daily dose being 2400 mg. The dose of this medication should be slowly increased to prevent side effects and should only be taken as directed by a doctor.

Some side effects are listed here: dizziness, tiredness, headache, upset stomach, tremor, abnormal gait, vision problems, joint pain, and weakness.

Relevance to Childhood Development

Trileptal® is FDA approved for children 2 years of age or older.

Trust Versus Mistrust

Jennifer L. Stapel-Wax
Argosy University, Atlanta, GA, USA

Definition

Trust versus mistrust is the first stage in Erik Erikson's psychodynamic theory of psychosocial development.

Description

Erikson postulates a theory of psychosocial development that spans the lifespan and emphasizes an interaction between biological needs and the environment. According to Erikson, there are stages in development in which a child's unfolding biological needs and abilities engage the child with significant adults, resulting in interactions that help or hinder the child in meeting healthy psychosocial milestones. The patterns that emerge can be described as involving (1) key areas of the physical body, (2) the types of activity that the child is engaged in mastering at that level of development, and (3) the types of social interactions that result as the growing child relates to others with their new abilities [1]. Additionally, the resulting experiences from each stage lay the foundation for transition through the subsequent developmental stages.

Trust versus mistrust is conceptualized to coincide with infancy, defined as birth to 18 months of age. This stage is the first conflict described in Erikson's theory and coincides with the oral-sensory stages I and II in which "incorporation" [1, 3] is the most crucial action for the

infant. During this time, the infant seeks to meet their basic needs (food and physical comfort) and establish regulation (feeding, sleeping and elimination) through "incorporation" [1, 3] of input from the world. In the first part of this stage, the child learns to get what they need from the environment. In the second portion of the stage, the child learns to take a more active role in meeting their needs through burgeoning skills such as biting, grasping and discerning specific stimuli [3, 4].

The stage of trust versus mistrust is characterized by the child getting practice with trusting their caregivers to meet their needs and also with trusting themselves to cope [3]. While this experience is initially associated with biological needs, the child learns about themselves through interactions with the environment and significant others. Optimally, this period in infancy is characterized by smooth and mutually regulated interactions with the mother that comfortably satisfy the infant's needs. This interaction between mother and infant results in the infant developing trust in the mother and world that she represents. Accordingly, as this trust develops, the child can begin to accept the absence of the mother without experiencing undue anxiety. Essentially, the infant develops confidence that she will return and their environment will remain stable and predictable. This inner representation of trusted people and the formation of a qualitatively rich relationship is a cornerstone in the foundation of ego identity development. At the successful conclusion of this stage, the child emerges with a sense of trust in their caregiver, their environment and in themselves. Accordingly, if this stage is marked by unpredictable, inadequate or inconsistent care, then the child may develop a lasting sense of mistrust in the world and in themselves [3].

Relevance to Childhood Development

The Eriksonian stage of trust versus mistrust is significant to child development as it coincides with and lays the foundation for similar theories of infant development. Additionally, Erikson's ideas about the mechanism of learning to trust one's environment versus experiencing mistrust that their needs will be met converges with attachment theory and possibilities for the origins of maladaptive behaviors and psychopathology [1, 2].

Trust Versus Mistrust (Erikson's Infant Stages)

Lacy Allen
Floride Institute of Technology, Melbourne, FL, USA

Definition

Erik Erickson's Trust versus Mistrust stage is the first of eight stages in his psychosocial life-span development model.

Description

Erik Erickson accepted the basic ideas of Freudian theory; however, he expanded on it by developing a life-span psychosocial dimension to Freud's theory of psychosexual development. In other words, Erickson believed that an individual is influenced by parental figures and the environment. Unlike Freud, he also believed that the personality continues to develop after the age of 5 [1].

According to Erickson's psychosocial model of development, an individual's personality becomes increasingly differentiated and hierarchically organized as it unfolds in, and is shaped by a particular environment. There are eight stages in Erickson's psychosocial model that involve a crisis or conflict. Each stage builds on successful completion of an earlier stage. If the crisis is successfully resolved then the result is adjustment, if not, then the result is maladjustment and will likely pose as a problem in the future [2].

The first stage in Erickson's psychosocial model of life-span development is called *Basic Trust versus Basic Mistrust* and is the stage that generally takes place between birth to 1 year of age. The main task in the first stage is to acquire a favorable ratio of trust to mistrust that most likely develops from the mother or primary caregiver. Trust is the foundation that gives the child a good chance of coping with later crises [5].

Caregivers are the most important figure in the child's life during the trust stage, as the infant depends on the mother or father to feed them when they are hungry and to comfort them when they are afraid or in pain. The child will ultimately tolerate having their mother out of sight because they are confident that she will return. Infants also

develop trust in themselves from the feeling that others accept them and from increased familiarity with their bodily urges. If the child's environment is trustworthy, the virtues of hope and confidence are instilled [4].

It is during this stage that the infant also learns what to fear and what not to fear. In fact, some mistrust is critical in order to allow detection of impending danger or discomfort and to discriminate between honest and dishonest people. However, if more mistrust is developed than trust, the child may be frustrated, hopeless, withdrawn, suspicious and lacking in self confidence.

Turner Syndrome

Cheryl Twaragowski
Niagara University, Niagara, NY, USA

Synonyms

Genetic disorder; Monosomy X; Ullrich–Turner syndrome

Definition

Turner Syndrome (TS) is a chromosomal abnormality that only occurs in females. This genetic disorder leads to a variety of physical, medical, psychosocial, behavioral, and academic challenges, affecting approximately 1 out of every 2,000–3,000 live births. Prevalence is similar across all races and ethnicities [7].

Description

Several different types of TS exist, with the most common form of TS referred to as "pure TS", a diagnosis that occurs in about 50% of diagnosed females [7]. Females with this type of TS have 45, X0, and demonstrate an absence of one of the X chromosomes that the fetus should have received from either parent [7]. Individuals with this karyotype have more pronounced features of TS and are often diagnosed at a younger age. Another form of TS that occurs in about 30–40% of diagnosed females is "mosaicism." In mosaicism, the cell division that replicates the chromosomes fails to replicate the genetic material completely and some cells contain a different set of chromosomal material [7]. Diagnosis of this karyotype is often challenging given that females with this form of TS demonstrate fewer syndromic features. Other forms of TS occurring infrequently in the population feature partial deletion of one arm of the X chromosome, or a duplication of one arm of the X chromosome with the loss of the other arm [7].

Several common physical abnormalities have been found among females diagnosed with TS. These physical characteristics include short stature (somewhere between 4 feet 6 inches and 4 feet 10 inches tall), lack of spontaneous development of secondary sexual characteristics due to gonadal dysgenesis, a webbed neck, broad chest, skeletal and facial abnormalities, high-arched palate, hypoplastic or underdeveloped nails, low posterior hairline, and low-rotated ears [7]. Short stature is the most common and apparent physical abnormality in females diagnosed with TS, resulting from the loss of the SHOX (short stature homeobox-containing) gene on the X-chromosome which is important for long bone growth [7]. On average, affected females are approximately 20 cm shorter than their suspected height, and they tend to grow disproportionately and have a stocky appearance with a wide body and large hands and feet [2]. In order to attain a normal height as quickly as possible and progress through puberty at a normal age, growth hormone treatment is recommended for girls with TS [2].

Diagnosis of TS typically occurs when a female reaches late adolescence. Hearing loss is also common among females with TS. About 50% of females with TS have mild hearing loss, 60% have sensory neural hearing loss, and 25% have conductive hearing loss [6]. Hearing loss may be the result of recurrent otitis media and chronic middle ear infections [6]. Given the prevalence of hearing loss in females with TS, it is important to regularly assess hearing and middle ear function. Females with TS may evidence congenital cardiovascular defects including bicuspid aortic valve and coarctation of the aorta [9]. Approximately 3–8% of girls with TS have aortic root dilatation which can lead to aneurysms, aortic rupture, and even death [9]. Therefore, it is important for all girls who have been diagnosed with TS to regularly receive a cardiac evaluation along with a complete physical examination.

Relevance to Childhood Development

Research has demonstrated that females born with TS have Verbal IQ scores that are similar to the general population, while typically attaining lower Performance IQ scores in comparison to peers their same age [7]. Females born with TS tend to have difficulties with tasks that are largely nonverbal in nature including visual-spatial processing, visual memory, visual constructional skills, arithmetic, and executive functioning. It has been suggested that the cause of these difficulties stems from right-hemispheric dysfunction [7]. The left hemisphere is unaffected in females who have TS, therefore, difficulties with language and symbolic operations are not often observed. The most frequently occurring academic challenge affecting school age children with TS involves mathematics [7]. Most mathematic difficulties appear to involve conceptual and factual domains, which require memory ability to facilitate problem solving. Girls with a mosaic form of TS typically evidence fewer cognitive and visual-spatial difficulties than girls with the pure form of TS [7].

Females with TS tend to have lower self-esteem, difficulty forming strong peer relationships, and are more socially isolated compared to other children [7]. Such isolation often results from physical differences and abnormalities that are readily apparent to others. Children are often teased about their height and physical abnormalities in school and may be treated according to the age they appear to be rather than their actual age, contributing to lower self-esteem and social immaturity [7]. Those children who have deficits in visual-spatial processing also have a difficult time discerning various social cues and facial expressions of others [7], while evidencing difficulty reading nonverbal communication such as tone of voice and body language [7]. Females with TS frequently demonstrate behavioral problems resulting from the aforementioned social immaturity, including poor peer relationships, hyperactivity, and attention problems [7].

Growth hormone treatment has been shown to be relatively effective in assisting those with TS reach final adult stature, can be effective as early as 9 months of age, and is FDA approved at a dose of 0.375 mg/kg per week [2]. However, despite reports of early efficacy, growth hormone therapy is not typically started until the child's height falls below the 5th percentile for healthy girls of the same age [9]. Girls may increase their height as much as 8 to 10 cm on growth hormone therapy [9]. Over 90% of females with TS experience gonadal failure, therefore, estrogen therapy is used as a way to initiate pubertal development [2]. If menses does not occur by the age of 15 years old, girls with TS are treated with estrogen therapy in order to induce breast development and other features of puberty, maintain their secondary sexual development, and protect their bones from osteoporosis [9]. Puberty should commence at a physically appropriate age in females to optimize self-esteem, social adjustment, and initiation of sexual activity [3]. Estrogen therapy should only be used in girls for feminization and should be initiated only after the child has reached her final height potential and when her bone age is 12 years or more [9]. Growth hormone therapy and estrogen treatment can lead to positive changes for females with TS, including higher self-esteem, improved social and physical functioning; however, treatment should be continuously monitored by a physician [1].

Upon diagnosis, females with TS must face several psychosocial challenges. For many children, diagnosis of TS incites change in self-concept stemming from the need to accept that they are chromosomally and physically different from others their age. Some females with TS have various physical problems that may interfere with their lifestyle and quality of life, including issues related to infertility [7]. Therefore, in treating females who are diagnosed with TS it is important to receive the most accurate medical, psychological, and developmental information and intervention. When the child is of school age it is also important for parents of children with TS to collaborate with the school in order to ensure appropriate school based intervention [7]. Overall, females diagnosed with TS function well and independently in their day-to-day lives. The most challenging issue that females with TS are confronted with is dealing with premature ovarian failure and loss of fertility [2]. Under-diagnosis or delayed diagnosis has been a problem among this population, however, early detection can help to prevent medical complications [2]. A comprehensive medical and psychological evaluation should be conducted on a regular basis in order to ensure well-being and psychological adjustment.

Umbilical Cord

Jill A. Anderson
University of Texas Health Science Center - Houston, Houston, TX, USA

Synonyms

Birth cord [4]

Definition

The umbilical cord is the soft tube containing blood vessels that connects the placenta to the developing fetus [1, 2, 4–6].

Description

The umbilical cord serves as a conduit through which oxygen, nutrients, and waste products are transported between the *placenta* and the *fetus* [1–6]. The umbilical cord is formed by the fifth week of fetal development and replaces the *yolk sac* as the source of nutrients for the *fetus* [1, 2, 4]. It contains one vein, which transports oxygenated, nutrient-rich blood from the placenta to the fetus, and two arteries that transport deoxygenated, nutrient-depleted blood from the fetus to the placenta [2–4]. By full term, the umbilical cord is usually 20–22 inches (50–56 cm) long and about 0.75 inches (2 cm) [1, 2, 4–6] in diameter.

Relevance to Childhood Development

After birth, the cord is clamped and cut, and its remaining tip forms the umbilicus, which is also known as the navel or belly button [1–6]. Cord blood is a rich source of *stem cells* [2–4]. Because of this, many parents choose to save the cord blood in private cord blood banks in case future medical use becomes necessary. The cord blood cells can be used for bone marrow transplant [1–6].

Underachievement

Alandra Weller-Clarke
Benedictine University, Lisle, IL, USA

Definition

Underachievement occurs when a child's academic performance is below what is expected based on the child's ability, aptitude or intelligence.

Description

Academic underachievement is often measured by significant discrepancies between IQ scores and grades, or between IQ and achievement test scores. It may also become apparent as a result of unexplained decreases in any or all of these measures. For example, a child who scores in the 90th percentile range on standardized tests can be expected to excel in school, to be earning As and perhaps some Bs. A child with high potential who earns less than Bs is said to be underachieving.

Characteristics of Underachieving Students

Underachievers are not a uniform group, and they may exhibit a variety of characteristics. Since no single comprehensive model exists that can organize educators' understanding of underachievement, checklists of characteristics can be especially useful. Montgomery [3] suggests that the presence of five or more of the following indicators should lead teachers to suspect that a student is underachieving:

- Inconsistent pattern of achievement in schoolwork subjects
- Inconsistent pattern of achievements within a subject area
- Discrepancy between ability and achievement, with ability much higher
- Lack of concentration
- Daydreaming
- Clowning and other work avoidance strategies
- Poor study skills
- Poor study habits
- Noncompletion or avoidance of assignments
- Refusal to write anything down
- Overactivity and restlessness
- Overassertive and aggressive or oversubmissive and timid social behavior
- Inability to form and maintain social relationships with peers
- Inability to deal with failures
- Avoidance of success
- Lack of insight about self and others
- Poor literacy skills
- Endless talking

Factors to Consider

McClelland et al. [2] suggest that there are two main sets of factors affecting the performance of able underachievers. These are *emotional and motivational factors*, and *factors concerned with strategies for learning*. McClelland et al. believe that when factors from the two sets are combined and interact they seem to have the powerful consequence of preventing able students from becoming high achievers.

These *emotional and motivational factors* include the possibility that students:

- May be unaware of their own potential: they may lack insight about themselves and others [1]
- May have low, limited, or narrow expectations [3]; Butler-Por [1] suggests that this factor can manifest itself as a lack of clear personal goals and values
- May have a sense of inadequacy and low self-esteem – indeed, they may be vulnerable to disparagement by others [1]
- May have experienced emotional difficulties and/or be prone to depression and anxiety [1]
- May be unmotivated to achieve in school, despite a high self-concept [3]
- May have a fear of failure [3]
- May have a fear of success [3]
- May have a habit of blaming others [3]

Butler-Por [1] points out that some emotional and motivational factors can stem from the influence of family and/or family background. These may include hostility in family relations; rejection of the value of that member of the family; excessive parental expectations; lack of support for emotional and social development and stability; and finally, lack of interest in the child.

Some *factors connected with the quality of learning* mentioned by McClelland et al. [2] include that students:

- May not perform well in test situations
- May achieve below expectation in one or all of the basic skill areas: reading, language arts, mathematics

- May submit work that is often unfinished or poorly done
- May avoid trying new activities
- May show tendencies to perfectionism and self-criticism
- May have difficulty functioning in a group (of any size)
- May set goals unrealistically, either too high or too low
- May dislike practice or drill work, memorization and mastery
- May find it hard to focus attention and concentrate on tasks
- May have difficulty in making and maintaining peer relationships and friendships.

Assessment

Children's levels of ability, achievement and motivation, their social/emotional functioning and other factors should be assessed using objective, subjective, and projective procedures. By including as many different types of assessment, true potential is less likely to be overlooked. These may include the following:

- Individually administered measures of intelligence;
- Comprehensive out-of-level academic placement testing;
- Projective psychological assessment;
- Gross neurological screening;
- Parent and teacher questionnaires;
- Behavioral observations and clinical interviews;
- Assessment of creative portfolios, as needed; and
- Vocational interest testing (for teens and adults), as needed.

Relevance to Childhood Development

Understanding and remediating underachievement is not just a matter of improving school performance or of addressing students' problems with learning strategies. There is also a vital psychological aspect, as those who underachieve often have problems with motivation, socialization and/or self-image. Support should be the joint responsibility of the school as a whole, subject departments, individual teachers, other supporting adults, and students' parents and families.

UNICEF

Purvita A. Patel
Argosy University, Atlanta, GA, USA

Synonyms

United Nations Children's Fund (UNICEF)

Definition

An organization created by the United Nations General Assembly in December 1946, with the primary objective of providing emergency relief in the form of food and healthcare to mothers and children in developing countries [1, 6].

Description

UNICEF was created in 1946 as an organization that aimed to provide emergency food and healthcare for countries that had been adversely impacted during World War II. In 1953, the organization permanently became a part of the United Nations. It was also at this point that the name of the organization was modified from its original name, United Nations International Children's Emergency Fund, to its present name, The United Nations Children's Fund. UNICEF's headquarters are currently based in New York City and the general purpose of the organization remains to provide humanitarian assistance to mothers and children in developing countries. A major focus of services provided by UNICEF is to help children reach adequate development. In this regard, the organization focuses its services in the following areas: child survival and development (by providing preventative and curative healthcare, immunization, nutrition services, and basic and safe sanitary living conditions); child protection from abuse, exploitation, and violence [3]; access to education as a right of every child and gender equality in education; positively impacting children affected by HIV/AIDS by prevention of HIV transmission from mother to child and from adolescent to adolescent (by providing treatment to children infected with HIV and, by protecting and supporting children affected by HIV and AIDS in their families and communities); and policy analysis, advocacy and building partnerships for children's rights [7].

Relevance to Childhood Development

Through its humanitarian efforts in developing countries, UNICEF strives to mitigate the environmental impediments to optimal child development. For example, due to the adverse effects vitamin deficiencies have on development, UNICEF called for the mitigation of such deficiencies in developing countries. The organization put into effect deadlines for the reduction or elimination of the deficiency in multiple nutrients necessary for optimal growth and development. These include Vitamin A, iodine, and iron [2, 5]. Additionally, by taking action against violence in communities, exploitation of children, and child abuse, UNICEF strives to reduce some of the factors that adversely impact a child's development [3, 4]. Through the reduction of these factors, UNICEF enhances the chances that children in adverse environments will achieve adequate development.

Uninvolved Parenting Style

►Indifferent Parenting Style

Uninvolved Parents

Theodora Koulenti, Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Synonyms

Indifferent parents; Neglecting parents; Rejecting parents; Rejecting/neglecting parents

Definition

Uninvolved parents are described as cold and uninterested in their child's needs. They keep their child at a distance by

minimizing time-sharing and interaction. They have a low degree of commitment to their role as parents [9].

Description

Parenting Styles

Parenting styles are described as the set of parental attitudes, practices and non-verbal expressions that characterize parent-child interactions across various situations [9]. A number of different studies reveal that the quality of parenting practices has a strong effect on children's development. Various forms of psychopathology and key emotional and behavioral problems have been associated with a range of family risk factors, such as poor parenting, lack of a warm positive relationship between children and parents, insecure attachment, and inadequate involvement with children [10].

Three prototypes of parenting style are most frequently cited: authoritarian, authoritative, and permissive [6]. This distinction was based on the assessment of a number of different dimensions, such as acceptance, control, demandingness, disciplinary practices and encouragement of autonomy [1]. However, the term "neglectful parenting," or "uninvolved parenting," was later introduced in order to be distinguished from the term "indulgent parenting," both of which were under the label of "permissive parenting" [7].

Uninvolved Parents

Permissive parents can be either warm or uninvolved with their children. However, this parenting style often reflects parents' inattention and indifference towards the child, instead of commitment [7].

As far as uninvolved parents are concerned, they demonstrate low levels of warmth-responsiveness, thereby limiting actions that are supportive and consistent with the needs and demands of the children. They provide little structure and appear indifferent and self-centered. Moreover, uninvolved parents exhibit low levels of demandingness in relevance to behavioral expectations and disciplinary practices [4]. They are often preoccupied with their own problems and they are so disengaged from parental responsibilities that they do not monitor their child's behavior or support their interests [5]. In extreme cases, this parenting style might encompass both rejecting and neglecting.

Relevance to Childhood Development

Research findings on parental management of adolescent peer relationships reveal that uninvolved parents do not generally engage in guiding their children, however they may increase guidance whenever they realize that their children have been involved in actions such as drug use. Conversely, because of the lack of parent-child relationships, the children often do not comply even when their parents are involved in their guidance. In the cases of uninvolved parents, monitoring is not sufficient enough to recompense for the problems associated with the uninvolved parenting style [8].

Moreover, children raised with the uninvolved parenting style, because of the absence of clear messages from the parents in relevance to the acceptable range of peer relationships, are at risk for selecting friends who face problems, such as drug use [8]. Likewise, neglectful parenting is often related to extremely delinquent and aggressive behaviors of children [2]. Furthermore, children brought up by uninvolved parents are at risk of exhibiting lack of frustration tolerance, emotional control, interest in schoolwork and long term goals for the future [9]. This parenting style is also linked to poor maturity, self-reliance, social responsibility and competence, independence and cognitive competence [3]. During adolescence they are often engaged in antisocial behavior, such as excessive drinking and delinquency [9]. Research findings also reveal that, among all types of parenting styles, children of uninvolved parents are the most disadvantaged and these deleterious effects accumulate over time [5].

Unipolar Depression

Maria Stylianou, Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Synonyms

Major depression; Major depressive disorder or clinical depression

Definition

Unipolar depression consists of one or more episodes of moderate to severe depression with persistent depressed mood and other symptoms of depression including suicidal ideation, suicide attempts, inability to experience pleasure when doing normally pleasurable activities, impaired concentration, change in appetite, change in weight, difficulty sleeping, and/or increased sleep. These major depressive episodes cannot be due to a medical condition, medication, abused substance, or Psychosis. If Manic, Mixed, or Hypomanic Episodes develop, the diagnosis is changed to Bipolar Disorder [1].

Description

Epidemiology

Unipolar Depression (and related suicide attempts) is a major cause of death worldwide. Prevalence varies widely, from 3% in Japan, 11% in Britain to 17% in the US. In most countries the number of people who would suffer from unipolar depression during their lives falls within an 8–12% range [8]. Population studies have consistently shown unipolar depression to be about twice as common in women as in men, although it is unclear why this is so [8].

People are most likely to suffer their first depressive episode between the ages of 30 and 40. The risk of major depression is increased with neurological conditions such as stroke, Parkinson's disease, or multiple sclerosis. It is also more common after cardiovascular illnesses. According to the World Health Organization, in the year 2030, it is predicted to be the second leading cause of disease burden worldwide after HIV [9].

Comorbidity

Alcoholism and illicit drug abuse dramatically worsen the course of this illness, and are frequently associated with it. Dysthymic Disorder often precedes the onset of this disorder for 10–25% of individuals. Unipolar depression also increases risk of having Panic Disorder, Obsessive-Compulsive Disorder, Anorexia Nervosa, Bulimia Nervosa, and Borderline Personality Disorder [2].

Etiology

Unfortunately, it is not fully known what exactly causes unipolar depression. There are numerous theories about the causes of this disorder, including biological factors, genetic factors, environmental influences, and childhood or developmental events. However, it is generally believed that unipolar depression is most often caused by the influence of more than just one or two of these factors.

The biopsychosocial model proposes that biological, psychological, and environmental factors all play a role to varying degrees in causing depression. The diathesis-stress model argues that depression results when a pre-existing vulnerability is activated by stressful life events. The pre-existing vulnerability can be either genetic [3, 7], or resulting from views of the world learned in childhood. These interactive models have gained empirical support.

Biological Theories of Depression

Monoamine Dysregulation Theories

Most antidepressants increase synaptic levels of serotonin, one of a group of neurotransmitters known as monoamines. Serotonin is hypothesized to help regulate other neurotransmitter systems and decreased serotonin activity may cause these systems to act in unusual and erratic ways. According to this "permissive hypothesis," depression arises when low serotonin levels promote low levels of norepinephrine, another monoamine neurotransmitter. Some antidepressants increase the levels of norepinephrine directly, whereas others raise the levels of dopamine, a third monoamine neurotransmitter. These observations gave rise to the monoamine hypothesis of depression. The monoamine hypothesis posits that a deficiency of certain neurotransmitters is responsible for the features of depression. Norepinephrine is said to be related to alertness and energy as well as anxiety, attention, and interest in life; a lack of serotonin to anxiety, obsessions, and compulsions; and dopamine to attention, motivation, pleasure, and reward, as well as interest in life.

In the past two decades, research has revealed multiple limitations of the monoamine hypothesis, and its explanatory inadequacy has been criticized within the psychiatric

community. Intensive investigation has shown antidepressant medications do not work for everyone. Experiments with pharmacological agents that cause depletion of monoamines have shown that this depletion does not cause depression in healthy people nor does it worsen symptoms in depressed patients – although an intact monoamine system is necessary for antidepressants to achieve therapeutic effectiveness. If there were a direct causal link between the level of a neurotransmitter in the brain and depression, then we would expect a much higher rate of success with medication.

Endocrine Dysregulation Theories

Another area of research in determining the causes of unipolar depression is focused on the endocrine system. This system works with the brain to control numerous activities within the body. The endocrine system is made up of small glands within the body, which create hormones and release them into the blood. The hormones that are released into the body by the glands regulate processes such as reaction to stress and sexual development. It has been found that a great number of people who are depressed have abnormal levels of some hormones in their blood despite having healthy glands.

The hormone estrogen has been implicated in depressive disorders due to the increase in risk of depressive episodes after puberty, the antenatal period, and reduced rates after menopause [4]. The use of estrogen has been under-researched, and although some small trials show promise in its use to prevent or treat depression, the evidence for its effectiveness is not strong [4].

Additionally, of those individuals who are clinically depressed, about one-half will have an excess of the hormone cortisol. Unipolar depression may therefore also be caused in part by an overactive hypothalamic-pituitary-adrenal (HPA) axis that is similar to the neuro-endocrine response to stress. Investigations reveal increased levels of the hormone cortisol and enlarged pituitary and adrenal glands, suggesting disturbances of the endocrine system may play a role in some psychiatric disorders, including unipolar depression. Oversecretion of corticotrophin-releasing hormone from the hypothalamus is thought to drive this, and is implicated in the cognitive and arousal symptoms.

Immune System Dysfunction Theories

Various theorists have also argued that there is a link between the functioning of the immune system and the occurrence of depression. A growing body of evidence, largely based in studies of adults, shoes that exposure to chronic stress or acute loss leads to both impaired immune system functioning and depression. Impaired immune system functioning increases susceptibility to infection and consequent illness; which in turn may maintain or exacerbate depression.

Genetic Theories

At least five reports on the basis of twin studies, describing 11 subject samples, have been published demonstrating that the etiology of unipolar depression has a significant heritable component [6]. A meta-analysis of these studies estimated that the degree of heritability for unipolar depression was 0.33 (with a 95% confidence interval of 0.26–0.39). Heritability was greater in women with unipolar depression than in men, and was also most likely to cause phenotypic expression among individuals who lived in environments that provided diverse types of experience, particularly when such environments included highly stressful life events. Expression of unipolar depression's heritability is also influenced by the family environment; thus, parental coldness was found to be associated with a 38% increased risk for developing this disorder [6]. Familial dysfunction and genetic predisposition could interact to promote unipolar depression in several ways; for example, an errant gene affecting brain function might – as proposed below – make the individual more vulnerable to environmental stresses, or by impairing the child's temperament, might make life in the family intrinsically more stressful. However, just because a person inherits a gene that predisposes him or her to a depressive illness, does not mean that he or she is destined to develop unipolar depression. It is believed that a genetic influence is only partially responsible for causing depression.

Other Biological Theories

There may also be a link between depression and neurogenesis of the hippocampus, a center for both mood and memory. Loss of hippocampal neurons is found in some depressed individuals and correlates with impaired memory and dysthymic mood. Drugs may increase serotonin levels in the brain, stimulating neurogenesis and thus increasing the total mass of the hippocampus. This increase may help to restore mood and memory. Similar relationships have been observed between depression and an area of the anterior cingulate cortex implicated in the modulation of emotional behavior.

Additionally, depression may also be related to abnormalities in the circadian rhythm, or biological clock. For example, the REM stage of sleep, the one in which dreaming occurs, may be quick to arrive, and intense, in depressed people. REM sleep depends on decreased serotonin levels in the brain stem, and is impaired

by compounds, such as antidepressants, that increase serotonergic tone in brain stem structures. Overall, the serotonergic system is least active during sleep and most active during wakefulness. Prolonged wakefulness due to sleep deprivation activates serotonergic neurons, leading to processes similar to the therapeutic effect of antidepressants, such as the selective serotonin reuptake inhibitors (SSRIs). Depressed individuals can exhibit a significant lift in mood after a night of sleep deprivation. SSRIs may directly depend on the increase of central serotonergic neurotransmission for their therapeutic effect, the same system that impacts cycles of sleep and wakefulness.

Furthermore, research on the effects of light therapy on treating seasonal affective disorder suggests that light deprivation is related to decreased activity in the serotonergic system and to abnormalities in the sleep cycle, particularly insomnia. Exposure to light also targets the serotonergic system, providing more support for the important role this system may play in depression. Sleep deprivation and light therapy both target the same brain neurotransmitter system and brain areas as antidepressant drugs, and are now used clinically to treat depression.

Psychological Theories of Depression

Various aspects of personality and its development appear to be integral to the occurrence and persistence of depression. Although depressive episodes are strongly correlated with adverse events, a person's characteristic style of coping may be correlated with their resilience. Additionally, low self-esteem and self-defeating or distorted thinking are related to depression.

American psychiatrist Aaron T. Beck developed a cognitive model of depression where he proposed that three concepts underlie depression: a triad of negative thoughts comprising cognitive errors about oneself, one's world, and one's future; recurrent patterns of depressive thinking and distorted information processing. From these principles, he developed the structured technique of cognitive behavioral therapy (CBT).

Depressed individuals often blame themselves for negative events. In a study of hospitalized adolescents with self-reported depression, those who felt responsible for negative events did not take credit for positive outcomes. This tendency is characteristic of a depressive attributional, or pessimistic explanatory style. According to Albert Bandura, a Canadian social psychologist associated with social cognitive theory, depressed individuals have negative beliefs about themselves, based on experiences of failure, observing the failure of social models, a lack of social persuasion that they can succeed, and their own somatic and emotional states including tension and stress. These influences may result in a negative self-concept and a perceived lack of self-efficacy; that is, they do not believe they can influence events or achieve personal goals.

Environmental Causes

Environmental events are those things that happen in the course of our everyday lives. These may include situations such as prolonged stress at home or work, coping with the loss of a loved one, or traumatic events.

It has long been understood that experiences we have in our lives can affect our state of mind. The relationships we have with others, how we are brought up, losses we have, and crises we encounter all may affect our thoughts, emotions, and behaviors. How we react to these environmental events may influence the development of unipolar depression. An examination of depression in women indicates that vulnerability factors – such as early maternal loss, lack of a confiding relationship, responsibility for the care of several young children at home, and unemployment – can interact with life stressors to increase the risk of depression. For older adults, the factors are often health problems, changes in relationships with a spouse or adult children due to the transition to a care-giving or care-needing role, the death of a significant other, or a change in the availability or quality of social relationships with older friends because of their own health-related life changes. Child abuse (physical, emotional, sexual, or neglect) is also associated with increased risk of developing depressive disorders later in life. In adulthood, stressful life events are strongly associated with the onset of unipolar depressive episodes; a first episode is more likely to be immediately preceded by stressful life events than are recurrent ones. Adverse conditions at work, particularly demanding jobs with little scope for decision-making, are associated with depression, although confounding factors make it difficult to confirm that the relationship is causal.

Features

Unipolar depression is a serious illness that affects a person's family, work or school life, sleeping, eating habits, and general health. A person suffering a unipolar depressive usually exhibits a very low mood pervading all aspects of life and an inability to experience pleasure in previously enjoyable activities. Depressed people may be preoccupied with, or ruminate over, thoughts and feelings of worthlessness, inappropriate guilt or regret, helplessness, hopelessness, and self hatred [1]. Other symptoms include poor concentration and memory, withdrawal from social

situations and activities, reduced sex drive, and thoughts of death or suicide. Insomnia is common: in the typical pattern, a person wakes very early and is unable to get back to sleep [1]. Hypersomnia, or oversleeping, is less common [1]. Appetite often decreases, with resulting weight loss, although increased appetite and weight gain occasionally occur [1]. The person may report multiple physical symptoms such as fatigue, headaches, or digestive problems; physical complaints are the most common presenting problem in developing countries according to the World Health Organization's criteria of depression [6]. Family and friends may notice that the person's behavior is either agitated or lethargic [1]. Older depressed persons may have cognitive symptoms of recent onset, such as forgetfulness, and a more noticeable slowing of movements. In severe cases, depressed people may have symptoms of psychosis such as delusions or, less commonly, hallucinations, usually of an unpleasant nature [1]. Among children, symptoms of depression may be expressed as irritable mood.

Treatment

The three most common treatments for depression are psychotherapy, medication, and electroconvulsive therapy. Psychotherapy is the treatment of choice for people under 18, while electroconvulsive therapy is only used as a last resort. Some studies have shown that antidepressant drug therapy combined with psychotherapy appears to have better results than either therapy alone.

Psychotherapy

The most studied form of psychotherapy for depression is CBT, thought to work by teaching clients to learn a set of useful cognitive and behavioral skills. Earlier research suggested that CBT was not as effective as antidepressant medication; however, more current research suggests that it can perform as well as antidepressants in patients with moderate to severe depression. Overall, evidence shows CBT to be effective in depressed adolescents [10], although one systematic review noted there was insufficient evidence for severe episodes.

There is also evidence for the effective treatment of unipolar depression using interpersonal psychotherapy (IPT). This form of therapy focuses on the social and interpersonal triggers that may cause depression. The therapy takes a structured course with a set number of weekly sessions (often 12), and the focus is on relationships with others. Therapy can be used to help a person develop or improve interpersonal skills to allow him or her to communicate more effectively and reduce stress.

Furthermore, psychoanalysis is used to treat clients presenting with unipolar depression. However, a more widely practiced, eclectic technique, called psychodynamic psychotherapy, is loosely based on psychoanalysis and has an additional social and interpersonal focus. In a meta-analysis of three controlled trials of Short Psychodynamic Supportive Psychotherapy, this modification was found to be as effective as medication for mild to moderate unipolar depression.

Medication

There are several types of antidepressant medications used to treat unipolar depression. To find the most effective antidepressant medication with tolerable or fewest side effects, the dosages can be adjusted, and, if necessary, combinations of different classes of antidepressants can be tried. Response rates to the first antidepressant administered range from 50 to 75%, and it can take at least 6–8 weeks from the start of medication to remission [5]. Antidepressant medication treatment is usually continued for 16–20 weeks after remission, to minimize the chance of recurrence [12]. People with chronic depression may need to take medication indefinitely to avoid relapse.

Selective SSRIs, such as sertraline, escitalopram, fluoxetine, paroxetine, and citalopram are the primary medications prescribed owing to their effectiveness, relatively mild side effects, and because they are less toxic in overdose than other antidepressants [5]. Patients who do not respond to one SSRI can be switched to another and this results in improvement in almost 50% of cases. Another option is to switch to the atypical antidepressant bupropion [14].

Tricyclic antidepressants have more side effects than SSRIs and are usually reserved for the treatment of inpatients, for whom the tricyclic antidepressant amitriptyline, in particular, appears to be more effective.

Monoamine oxidase inhibitors, an older class of antidepressants, have been plagued by potentially life-threatening dietary and drug interactions. They are still used only rarely, although newer and better tolerated agents of this class have been developed.

Electroconvulsive Therapy

Electroconvulsive Therapy is a treatment that causes a seizure by means of an electrical current. Hospital psychiatrists may recommend electroconvulsive therapy for cases of severe major depression which have not responded to antidepressant medication or, less often, psychotherapy or supportive interventions. Electroconvulsive therapy can have a quicker effect than antidepressant therapy and thus may be the treatment of choice in emergencies such as catatonic depression where the patient has stopped

eating and drinking, or where a patient is severely suicidal. Electroconvulsive therapy is probably more effective than pharmacotherapy for depression in the immediate short-term, although a landmark community-based study found much lower remission rates in routine practice.

Prognosis

Major depressive episodes often resolve over time whether or not they are treated. Outpatients on a waiting list show a 10–15% reduction in symptoms within a few months, with approximately 20% no longer meeting the full criteria for a depressive disorder [11]. General population studies indicate around half those who have a unipolar depressive episode (whether treated or not) recover and remain well, while 35% will have at least one more, and around 15% experience chronic recurrence. Recurrence is more likely if symptoms have not fully resolved with treatment. Current guidelines recommend continuing antidepressants for 4–6 months after remission to prevent relapse. Evidence from many randomized controlled trials indicates continuing antidepressant medications after recovery and can reduce the chance of relapse by 70% (41% on placebo vs. 18% on antidepressant). The preventive effect probably lasts for at least the first 36 months of use.

Relevance to Childhood Development

Twenty years ago depression in children was almost unknown. Now the fastest rate of increase in depression is among young people. Recent studies show that the diagnosis of the prevalence at 1–2% in children aged 6–12 years and 2–5% in those aged 13–18 [13]. Pediatric depression is marked by low mood, anhedonia, disagreeability/defiance, pessimism, morbid thoughts and somatic symptoms, such as stomach upsets and headaches. There are evident sex-differences in susceptibility with an almost equal gender ratio pre-puberty switching to a female preponderance in adolescence. The clinical picture is somewhat similar to adult-onset depression although differing neurobiological markers and responses to treatment suggest that the etiology underlying the two may not be the same.

Features

Episodes of depression in children appear to last 6–9 months on average but in some children they may last for years at a time. The symptoms of depression in young children may vary from that in adults in severity and duration but are much the same as those of adults. They may also display an irritable rather than a depressed mood and show varying symptoms depending on age and situation. Most exhibit a loss of interest in school and a decline in academic performance. They may be described as clingy, demanding, dependent, or insecure. Diagnosis may be delayed or missed when symptoms are interpreted as normal moodiness.

Treatment

There are two main groups of treatments for the depressed child with demonstrated evidence of efficacy: psychotherapy and pharmacotherapy. Recent guidelines advise that the first-line treatment for children and adolescents presenting with moderate to severe depression is 4–6 sessions of psychological therapy. The two specific psychotherapies which show efficacy in children and/or adolescents are CBT and IPT. If they fail to respond to such therapy then they should be prescribed antidepressants in conjunction with psychological therapy. At present fluoxetine is the only antidepressant recommended for patients under the age of 18 years.

Universal Nonverbal Intelligence Test

Brett R. Nelson, Andrea Morillas-Brown, Grace Boyd
California State University, San Bernardino,
San Bernardino, CA, USA

Synonyms

Intelligence testing without verbal communication

Definition

The Universal Test of Nonverbal Intelligence (UNIT) is a test designed for children and adolescents (ages 5:0 to 17:11). This cognitive measure is a useful alternative to traditional measures that involve verbal and language material. The UNIT provides a comprehensive assessment of nonverbal intelligence.

Description

The following information is taken from the UNIT Examiner's Manual [1].

Organization of the UNIT

The UNIT is made up of six subtests. These subtests include: Symbolic Memory, Spatial Memory, Object Memory, Cube Design, Analogic Reasoning, and Mazes.

During the Symbolic Memory subtest, the examinee is shown a sequence of universal symbols (baby, girl, boy, woman, man in either green or black) for 5 s. After the 5 s, the stimulus is removed and the examinee uses the symbolic memory response cards to re-create the stimulus. This subtest measures short-term visual memory and complex sequential memory.

The Spatial Memory subtest displays patterns of green, black, or green and black dots on a grid for 5 s. The examinee then recreates the pattern with chips after the stimulus is removed. This subtest measures short-term visual memory for abstract material.

In the Object Memory subtest the examinee is shown a random pictorial selection of common items for 5 s. Once the stimulus is removed, the examinee is shown a second stimulus with the same objects and additional items. The examinee is asked to identify the objects from the first stimulus by placing a chip on the recognized items. This subtest measures short-term recognition and recall of significant symbolic material.

During the Cube Design subtest, the examinee is shown and asked to construct abstract, geometric designs using cubes with two colors. This subtest measures visual-spatial reasoning.

The Analogic Reasoning subtest requires the examinee to point to the missing component out of four possible responses in a matrix design. The matrices are composed of common objects and novel geometric figures. This subtest measures symbolic reasoning.

In the Mazes subtest, the examinee must complete a maze by making a route from the beginning of the maze to the appropriate endpoint without making any mistakes. The mazes become increasingly difficult. This test measures reasoning and planning skills.

Administration of the UNIT

There are three different administration options when using these subtests. The Abbreviated Battery consists of the Symbolic Memory and Cube Design subtests. It is mostly used as a screening measure of cognitive ability. Next, the Standard Battery is the most commonly used administration. It consists of the Symbolic Memory, Cube Design, Spatial Memory, and Analogic Reasoning subtests. Last, the Extended Battery includes the Standard Battery plus the Object Memory and Mazes subtests. It is beneficial for providing more detailed diagnostic information.

The administration of the UNIT requires unique hand and body gestures to convey the direction of the test in a nonverbal manner. Some of these gestures include: Head nodding to depict "yes," open-handed shrugging to convey "what is the answer?", and hand waving to explain that the examinee should choose from a series of answers. These hand and body gestures should be explained and demonstrated to the examinee prior to beginning the test.

Description of the UNIT Scales

The UNIT has four Quotient scales: Memory Quotient (MQ), Symbolic Quotient (SQ), Reasoning Quotient (RQ), and Nonsymbolic Quotient (NSQ). The scores of

the Quotient scales make up the Full Scale Intelligence Quotient (FSIQ).

The Memory Quotient (MQ) measures complex memory functioning. More specifically, this Quotient measures short-term recall and recognition of common and conceptual items. The Symbolic Quotient (SQ) assesses an individual's problem solving skills with common information in which the answers involve the processes of labeling, organizing, and categorizing information. The Reasoning Quotient (RQ) measures an individual's thinking and problem solving skills with known and unknown situations. In particular, the RQ explores an individual's ability to plan and comprehend relationships among abstract patterns. The Nonsymbolic Quotient (NSQ) assesses problem solving skills with conceptual non-meaningful information. The Full Scale Intelligence Quotient (FSIQ) provides an overall measure of nonverbal cognitive ability.

Relevance to Childhood Development

The UNIT is standardized on 2,100 children and adolescents between the ages of 5 years of age to 17 years and 11 months. The national standardization sample is representative of the variety of ethnicities in the United States including: White, African-American, Asian/Pacific Islander, Native American, Hispanic, and Other. The UNIT is also normed on typical children in General Education and several Special Education populations including children with Learning Disabilities, Speech and Language Impairments, Emotional Disturbance, Mental Retardation, Giftedness, and English as a second language.

During the development of the UNIT, various studies were conducted to determine the reliability and validity of test scores. Subscale scores ranged from a reliability of 0.87 for the Symbolic Quotient, 0.91 for the Nonsymbolic Quotient, and 0.93 for the Full Scale scores [3]. Internal validity of the UNIT was determined through intercorrelations of the four scales having consistent coefficients of 0.90 or above [1]. External validity was also noted through correlational studies that found both adequate concurrent and predictive validity for this test [3].

In an effort to ensure that the UNIT continues to be a reliable and valid measure, various aspects of this test should continue to be researched. In particular, the research should examine the predictive validity with varied populations [2].

U-shape curve; U-shape development; U-shape framework; U-shaped behavioral growth

Definition

U-shape learning is a framework of development displayed by the appearance of a behavior or skill, the disappearance of the behavior or skill, and the reappearance of the behavior or skill.

Description

Early theories of child development viewed development as a linear progression of abilities that increase in complexity with age. A linear view of development is reflected in Jean Piaget's stages of cognitive development, behaviorist Burrhus Fredrick Skinner's view of learning as the accumulation of knowledge shaped by experience, and in the cultural-contextual view of Lev Vygotsky. However, a linear view of development provided a limited explanation of regressions and changes that occur in children's learning [2]. The theory of u-shaped learning was devised as a response to the limitations of stage-linked perspectives of cognitive development.

According to a u-shape framework, changes in behavior and learning are exhibited through three phases [13]. Children demonstrate the accurate use of a behavior or skill during Phase 1. Children exhibit a decline in the correct use of a behavior or skill during Phase 2. However, children display a resurgence of the accurate use of a behavior or skill during Phase 3. Data are collected at each time point. The data are graphed according to the percentage of accurate responses on one axis in relation to the participants' age along the other axis. Studying development using a u-shape framework provides the opportunity to investigate the underlying processes, the relationships, and the interactions between each phase and learning.

In the 1960s and the 1970s researchers investigated alternatives to the linear developmental perspectives to explain the changes in children's thinking. Interest into the u-shape curve peaked in 1978 with the workshop "U-Shape Behavioral Growth" hosted by Tel-Aviv University in coordination with the Massachusetts Institute of Technology and held in Tel-Aviv, Israel. The conference explored u-shaped learning in the domains of scientific reasoning, language acquisition, creativity, facial perception, and social cognition. In 1982, the book *U-shaped Behavioral Growth* edited by Sidney Strauss with Ruth Stavy, was published. The book presented the outcomes from the Tel-Aviv conference.

As indicated from the outcomes of the conference, the u-shape curve was used as a framework to support theories of representational reorganization to describe patterns of learning and behavior. Studies applied the u-shape curve to describe short-term and long-term changes in knowledge. Strauss [13] described short-term term changes in learning and behavior as bursts of performance instability. The fluctuation in performance occurred as knowledge transitioned between domains. Task accuracy resumed and performance stabilized once the new representation system was formed.

Stavy et al. [12] used the u-shape curve to portray the integration of intuitive knowledge with the application of rules to complete a task. Children were found to apply rules from one representational system to another. Also, children unraveled and selected the necessary rules needed

to solve the problem accurately. The initial phase of learning was gained through experience and reflected an intuitive understanding of the task. Often children completed tasks accurately without understanding the conceptual underpinnings. During the second phase, children acquired the rules to complete the task. However, children's performance declined as they applied new rules. By the third phase, children were able to sort the rules according to their functions. Accuracy in task performance resumed as the children selected the appropriate rules from their repertoire to complete the task. This suggested that children resolved conflicts between intuitive knowledge and new information as part of the learning process.

Studies were conducted to determine if a u-shape curve was a result of conflicts between representational systems. This viewpoint suggested that the rise and fall of performance occurred through process to determine the appropriate over-riding system. Accurate performance resumed once the appropriate system gained dominance [13].

Also, a nativist perspective of development used the u-shape curve framework to investigate changes in learning. The nativist stance suggested that development moves from a general domain of knowledge to specific representations. Learning is acquired through the confirmation or the rejecting of a hypothesis. The transitions from general to specific forms of knowledge lead to errors in skills. Awareness of the transitional states would provide insight into optimal periods for learning [7, 13].

Early critics suggested that a u-shape curve did not contribute new information to studies into child development. Richards and Siegler [10] suggested that findings within a u-shape curve reflected children's interactions with the demands of a task rather than fluctuations in cognitive development. Klar [5] provided a similar criticism indicating that a u-shape pattern in development was an artifact of the task or measure.

Interest into u-shape learning declined in the 1980s. Researchers investigating children's language acquisition continued to apply a u-shape curve. The curve was useful in explaining children's acquisition of regular and irregular verb tenses [9, 11].

Developmental psychologists showed renewed interest into the u-shape behavioral curve in the mid 1990s. In 2004, the *Journal of Cognition and Development* dedicated an entire issue to u-shaped development. The three studies presented in the issue applied the u-shape curve to investigate the general underlying processes that affected changes in learning and behavior. Overall, the studies suggested that the rise and fall of performance reflected improvements in domain-general processes [1, 11]. Each of the studies published in the issue presented different perspectives as to how the changes occurred.

Gershkoff-Stowe and Thelen [3] investigated changes in infant stepping, reaching, and in early object naming. The authors concluded that changes in learning and behavior are comprised of multiple internal and external factors that are reconfigured and shape learning. Greshkoff-Stowe and Thelen indicated that the use of a u-shape framework provided opportunities to explore the basis of the processes of development.

Cashon and Cohen [1] explored the processing of upright and inverted faces by infants between 3 and 7 months of age. The study utilized an information processing perspective within the u-shape framework. The results from the study indicated that changes in the processing of facial features occur between the ages of 3–7 months. The findings suggested that the processing of upright faces followed an n-shape function. However, the infants' recognition of inverted faces followed an inverted u-shape curve. Infants at 3 months of age processed the individual features of a face. The authors suggested that infants approximately 4 months of age begin to integrate the features of upright and inverted faces. Yet, infants approximately 6 months of age revert to processing the individual features of a face. Infants 7 months of age appear to have resumed the skills to integrate the features of upright and inverted faces. The authors suggested that the changes in processing facial features were indicative of improvements in general-domain processes. Though changes in facial processing were discussed in relation to a u-shape curve, Cashon and Cohen [1] indicated that use of a u-shaped or an n-shaped function might create confusion rather than aid in the explanation of development.

Namy et al. [8] conducted a study that investigated the use of iconic and arbitrary gestures to support symbol learning and symbol-to-referent mapping in children 18 months, 26 months, and 4 years of age. The results indicated that children 18 months of age were able to use both arbitrary and iconic gestures to support symbolic learning. However, children at 26 months declined in ability to map unrelated gestures to a referent in order to support symbolic learning. Children by 4 years of age exhibited a resurgence of the skills to map iconic and arbitrary gestures to support symbolic learning. The authors proposed that the decline in linking arbitrary gestures in 26 month-olds was due to an increase in awareness of connections between iconic gestures to a referent in order to learn new information. The ability of using arbitrary and iconic gestures to support symbolic learning returned at 4 years of age

and possibly reflected an increase in linguistic skills. Namy et al. suggested that the use of a u-shape behavioral curve to display arbitrary gesture gave insight into the shift of children's understanding of symbols.

As in the 1980s, researchers continued to question the methodology of the u-shape framework. For example, Karmiloff-Smith [4] suggested that u-shape development focuses on the mastery of a behavior. The focus on performance outcomes provided a narrow perspective regarding the multiple factors that influence learning. Marcus [6] proposed that a u-shape behavioral curve might reflect measurement error. Marcus suggested that the display of a u-shape curve would need to be considered as an independent event. According to Marcus, empirical studies that can be replicated need to occur to investigate the soundness of a u-shaped development framework.

The u-shape developmental framework provided an alternative to a traditional linear view of child development. As indicated by Strauss [13], "U-curves can be used as a springboard for considering epistemological issues" that are relevant to understanding behavior, learning, and development.

Uterus

Pamelyn M. MacDonald
Emporia State University, Emporia, KS, USA

Synonyms

Womb

Definition

The uterus is the major female reproductive organ. The medical term uterus is the Latin word for *womb*.

Description

The uterus is a pear-shaped, muscular organ that is divided anatomically into four segments: The *fundus*, *corpus*, *internal os* and the *cervix* [1]. At the top of the uterus are the *fallopian tubes* and *ovaries*. Together with the *vagina*, *ovaries* and *fallopian tubes*, the uterus is a part of the *female reproductive system* [1]. When a woman is pregnant, the *fetus* is nourished by and grows inside the uterus until it is born [3].

Relevance to Childhood Development

In prenatal development, once an egg is released by the ovary, it passes into the fallopian tube, where fertilization may occur within the first 3 days following *ovulation* [1]. If fertilization occurs, the fertilized egg, or *zygote*, travels down the remainder of the fallopian tube while undergoing cell divisions. Once the zygote reaches the uterus (about 1 week following conception), it contains multiple layers of cells that are beginning to differentiate, called a *blastocyst*. The blastocyst implants itself into the *endometrium*, or lining of the uterine wall. The inner layer of the blastocyst becomes the *embryo*. The outer layer of the blastocyst

develops into the *placenta*, *umbilical cord* and *amniotic sac*. The uterus continues to house and nourish the embryo, and later the fetus, until the birth of the baby [2].

If the egg is not fertilized, the endometrium and the unfertilized egg are discharged from the uterus through the vagina in a process called *menstruation* [2].

Validity

Jeremy R. Sullivan
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Accuracy; Appropriateness; Fidelity

Definition

Historically, validity has referred to evidence that a psychological or educational test measures what it purports to measure. A more contemporary perspective holds that validity refers to sources of evidence that support the appropriateness and accuracy of uses, interpretations, and decisions that are based on test results. There are several different methods of establishing validity with evidence gathered through a gradual accumulation of research and clinical findings.

Description

Just as reliability is a characteristic of scores rather than a characteristic of tests, validity describes the uses, interpretations, and decisions made on the basis of test results, rather than describing an absolute property of the test itself [2]. The use and interpretation of a test and its results may be more appropriate and valid for some purposes than others. For example, using scores on a norm-referenced intelligence test may be highly valid for predicting educational achievement but of very limited validity for predicting social functioning.

Validation is the result of a gradual accumulation of evidence that suggests whether or not test scores can be used as meaningful indices of the construct of interest, and to make decisions or predictions on behalf of the test-taker. For published tests, preliminary evidence for validity should be provided in the test manual, but additional evidence is accumulated over time with additional research. Rather than dividing validity into separate types, the current conceptualization of validity considers three interrelated aspects of validity. Each of these aspects contributes to test users' understanding of whether a test score will tell them what they really want to know about the test-taker.

The first aspect of validity is content-related evidence (historically referred to as "content validity"). This source of evidence is typically considered and evaluated during the development of the test or assessment procedure, and reflects the extent to which test items address relevant content or skills. The underlying assumption of this aspect of validity is that the sample of test items should represent the purpose of the instrument and the construct or behavioral domain that the test purports to measure. Further, the test items should emphasize the most important and most relevant content, and should constitute a "representative sample" of all possible items that could be used to assess the domain of interest.

Evidence that demonstrates content-related validity is often established through the test specification method. This method involves developing a table of specifications (or test blueprint) in order to precisely identify the objectives of the test and relevant content. These objectives then determine the specific items of the test based on the content and skills that need to be assessed. Another method commonly used to establish validity evidence is expert review, which involves consulting with experts in the construct of interest. These experts might examine the test items and provide the test developers with feedback regarding the adequacy of items. This feedback may lead the test developers to generate additional items (if the initial items do not constitute an adequate sample), revise items to improve relevance or wording, or eliminate items to reduce redundancy. When expert review is used, the test manual typically describes how many experts were consulted, how they were selected, and the basis for their expertise.

The second aspect of validity is construct-related evidence (historically referred to as "construct validity").

Sam Goldstein & Jack A. Naglieri (eds.), *Encyclopedia of Child Behavior and Development*, DOI 10.1007/978-0-387-79061-9,

This aspect of validity involves providing evidence that performance on the test can be interpreted as a meaningful measure of the construct of interest (as opposed to other constructs). Because most of the constructs of interest in psychology and education are not directly observable (e.g., intelligence, self-esteem, attitudes), we must infer these characteristics on the basis of test scores or performances.

Two of the most commonly used methods of establishing evidence for construct-related validity are convergent and discriminant studies. Convergent studies involve correlating scores on different measures of the *same* construct with one another. For example, if a researcher was developing a depression scale, she would administer her new scale and an established depression measure to the same group of people, and correlate the scores on these two scales. In this case, the researcher would desire high correlation coefficients, which would indicate performance on her new scale is strongly related to performance on the established measure (i.e., the inference is that both tests are assessing the same construct: depression). At the same time, we would not expect extremely high coefficients or perfect relationships, as these would negate the need for the new test (unless it is shorter or easier to administer than established tests).

Discriminant studies, on the other hand, involve correlating scores on different measures of *different* constructs. Continuing with the previous example, the researcher would now administer her new depression scale and a measure of a different construct, such as anxiety, to the same group of people and then correlate the scores on these two scales. In this case, the researcher would want to see lower correlation coefficients, which would indicate a weak relationship between scores on these tests (i.e., the inference is that the new test is measuring something other than anxiety). In psychology and education, constructs are often correlated with one another to some extent (e.g., depression and anxiety, intelligence and academic achievement), so this researcher would not expect a coefficient of 0.0 between depression scores and anxiety scores; rather, she would look for a pattern in which convergent correlations are higher than discriminant correlations.

In sum, in order to provide evidence of construct-related validity, test developers attempt to show that test scores are highly correlated with scores on similar tests and weakly correlated with scores on dissimilar tests. Exploratory and confirmatory factor analytic methods also are sometimes used to establish construct-related validity evidence. These analyses help to understand the relationships among the items on a test in order to facilitate the creation of subscales and to determine whether items group together in a manner consistent with theory, logic, or prior hypotheses.

The third aspect of validity covered here is criterion-related evidence (sometimes referred to as "diagnostic validity" or "clinical validity"). This aspect of validity is concerned with the extent to which performance on the test is related to some pertinent external variable or outcome (called a "criterion variable"). Thus, gathering criterion-related evidence involves correlating scores on the test or procedure with performance on the criterion measure. This sort of evidence is often gained through concurrent and predictive studies.

Concurrent validity studies examine how well performance on a test or procedure estimates *current* performance on a criterion variable; scores on the test and criterion variable are therefore obtained at approximately the same time. For example, a test developer might correlate scores on a newly developed math reasoning test with current grades in math. A high correlation coefficient would suggest that the math reasoning test is a good indicator of current math achievement.

Predictive validity studies examine how well performance on a test or procedure predicts *future* performance on a criterion variable; scores on the criterion variable are therefore obtained at some later time. For example, predictive validity of scores on scholastic aptitude tests such as the SAT and ACT (which are designed to predict performance in college) might be examined by correlating test scores with criterion variables obtained later, such as GPA at the end of the freshman year or upon college completion. High correlation coefficients would indicate that these test scores are related to important outcome variables, thereby supporting the use of these tests in college admissions.

By considering these methods of concurrent and predictive validation, it becomes apparent that criterion-related validity evidence is directly related to the decisions practitioners and researchers make on the basis of test scores (these decisions are often categorized into true positives, true negatives, false positives, and false negatives, based on whether the test scores contribute to accurate descriptions or predictions). For example, if test performance will be used as part of clinical or educational decision making (e.g., diagnosis, placement in special education), the test user should have evidence that test scores are related to these criterion variables of interest (i.e., concurrent validity evidence). Similarly, if test performance will be used to make predictions about outcomes such as psychological functioning, educational achievement, or occupational success, the test user should have evidence that test scores are actually related to these outcomes (i.e., predictive validity evidence).

The three broad aspects of validity discussed here are influenced by numerous factors, which may be seen as forces that limit the validity of test results and the decisions made on the basis of those results. A few of these factors include: inappropriate vocabulary (e.g., unfamiliar or unnecessarily complex terms, which may limit examinees' ability to respond to the items), unclear or ambiguous directions (e.g., directions that are confusing and do not clearly indicate how the examinee should respond to the task or items), too few items (e.g., the items do not provide a representative sample of the domain of interest, which confines the interpretations users can make from the results), and changes to standardized administration procedures (e.g., with norm-referenced tests, any departure from standardized procedures reduces the validity of the results).

The framework presented here, which includes the three traditional aspects of validity, captures most of the sources of validity evidence proposed by the seminal *Standards for Educational and Psychological Testing* (prepared jointly by the American Educational Research Association, American Psychological Association, & National Council on Measurement in Education [1]), including evidence based on test content (content-related validity evidence), internal structure (construct-related validity evidence), and relations to other variables (construct-related and criterion-related validity evidence). An additional source of evidence proposed by the *Standards* is evidence based on response processes. This source of evidence is often considered by investigating examinees' item responses and asking them what kinds of strategies or processes they used as they approached the tasks, or by observing examinees as they complete testing procedures. This information can provide test developers with evidence that the tasks are related to the constructs or processes they are trying to measure (and unrelated to irrelevant constructs or processes) and can provide support for anticipated interpretations of test performance. As an example, researchers who are interested in developing a test of mathematics achievement for children might observe examinees as they complete the different sections and then question the strategies they used as they approached the items. Through these observations and interviews, the researchers may discover that children struggled with some of the word problems because they were not familiar with some of the terms used. Thus, performance on certain sections of the math achievement test was influenced by vocabulary and reading comprehension variables rather than math achievement, leading the researchers to revise the vocabulary used in the word problems.

See Wright [3] for discussion of how test bias and fairness are related to validity, including how statistical procedures such as cross-validation and differential item functioning can be used to examine bias. A test or procedure that produces biased or unfair results likely will not lead to valid interpretations or decisions.

Relevance to Childhood Development

Standardized psychological and educational tests or procedures are often used for clinical decision making, instructional decision making, educational placement, and research purposes. In order to have confidence that the results of these procedures will lead to accurate predictions and appropriate interpretations, there should be adequate evidence of validity. Each aspect of validity (i.e., content-related, construct-related, criterion-related) can provide test users with distinct pieces of information that can either support or not support the use and interpretation of a particular test score. The more aspects of validity that have been examined, either in test manuals or in the research literature, the more confidence users have that the test results will help them reach accurate decisions and predictions.

Valium

Tony Wu
Walden University, Diamond Bar, CA, USA

Synonyms

Anti-anxiety medications; Benzodiazepines; Diazepam

Definition

An anxiolytic medication that is used to treat anxiety disorders.

Description

Valium or Diazepam has become one of the most prescribed anxiolytic medications since its introduction [1].

Valium is one of the benzodiazepine medications that has been shown to be effective when compared to other types of sedative-hypnotics in the treatment of anxiety-related disorders [4]. Valium exerts its therapeutic effect at the neurotransmitter receptor sites by changing biochemistry of gamma-aminobutyric acid (GABA) through prolonging chloride channel-opening, which increases the GABA-induced inhibition [3].

Because of its calming effects, Goldberg [2] noted that Valium is used frequently for both long-term management of anxiety-related disorders as well as treatment of sudden onset of panic and anxious symptoms. Other symptoms that are treated with this medication include acute alcohol withdrawal, skeletal muscle spasm, cerebral palsy spasticity, and disorders of convulsion. Studies have found that the most frequent side effects of Valium include drowsiness, dizziness, and unsteadiness. It should be noted that the use of alcohol may depress the central nervous system (CNS); therefore, alcohol should be avoided while a patient is on Valium. Furthermore, psychotropic medications, anticonvulsants, and antihistamines may yield additive CNS depressive effects to the patient [5].

Because Valium is absorbed quickly via oral ingestion and travels to the brain promptly, anxiety symptoms are alleviated immediately [5]. Valium should not be discontinued suddenly without consulting with the prescribing physician. Withdrawal symptoms such as convulsions, tremor, and muscle cramps are commonly reported after abrupt withdrawal of the medication [2]. Withdrawal symptoms often occur when large quantities or long-term used of Valium are indicated. Additionally, dependency on Valium increases with age, level of anxiety disorders, dosage, and patterns of drug uses [8]. Finally, a person's functional skills, such as driving and operating equipment, might be affected; this is a potentially deadly benzodiazepine-related side effect [7]. In general, individuals without history of substance or alcohol abuse are able to take Valium as prescribed without any difficulties [6].

Regarding dosage of Valium, the management of anxiety-related disorders, skeletal muscle spasm, and convulsive disorders typically require a dose of 2–10 mg, taken two to four times a day. The generic versions of Valium tablets are available in different formats and various sizes depending on the drug company.

Values

William E. Herman
The State University of New York at Potsdam, Potsdam, NY, USA

Definition

Values are normally thought of as prized beliefs which form one of the key motivational elements most often employed to explain human actions, emotions, and thoughts. The formation of values begins during the earliest periods of life and the adaptive potential for maintaining existing values, adopting new values, and modifying existing values is theoretically present throughout the human lifespan. It is possible to think of values developing at a personal (individual or micro) level or at a cultural (societal or macro) level. Debate continues in two major areas: which values to teach and how to teach values.

Rokeach [7] defined a "value" as "an enduring belief that a specific mode of conduct or end-state of existence is personally or socially preferable to an opposite or converse mode of conduct or end-state of existence" (p. 5). This author offered a line of research that provided an operational definition for values and values systems in the form of a survey measurement instrument and data analyses to understand the political change process.

Numerous other research attempts have been made to scientifically study values.

Description

Values at the personal level are often inferred from behaviors and become part of one's personal identity. For example, if a child hoards pencils given out by the teacher in school and others might also need such pencils, many people are likely to think of such a student as a greedy child. What others say and believe about us often becomes incorporated into how we view ourselves. Of course, it is possible that such a child could employ defense mechanisms and reject this label of greediness and think of himself/herself as a kind, generous, and giving person. It is also possible to misinterpret values in that the child hoarding pencils might actually plan to save these items and offer them to classmates who need them in the future. The values that an individual subjectively perceives about self could be contrary to how others might characterize a person in value-laden terms. The ability to consistently act upon one's chosen or professed values is also a major challenge due to competing value and reward systems, speed with which decisions might have to be made, and social influences.

Much of the current research, theorizing, and applications regarding values and ▶moral development can be traced back to the work of the educational philosopher Dewey [1]. He highlighted the importance of the "hidden curriculum" in schools where classroom rules, student interaction, teacher actions, and school policies transmitted important attitudes regarding acceptable or unacceptable behaviors such as persistence, helping others, stealing, and cheating.

During the 1970s, an approach called "values clarification" became very popular with educators where situation-based dilemmas were used to help students better understand how values were involved in the decision making process (see [8]). Some values lend themselves best to personal choices such as musical tastes and clothing styles, while other circumstances might involve more difficult choices where harm could come to another person as a result of a specific decision. Therefore, some values involve moral issues while other values might not involve moral and ethical decisions. A values clarification approach can be useful in both situations because it is not the content of values that is being taught, but rather the process of values development based upon knowledge of options and rational decision making. Moral dilemmas ideally are best resolved if a person examines the roles process and end product could play in the decision making process. Kohlberg [6] offered a developmental stage theory of moral reasoning (6 stages) where cognitive maturity and social interaction could lead to advanced moral thinking and ideally higher level moral actions. While Kohlberg primarily focused upon justice themes in moral development, Gilligan [2] has added the importance of caring and concern themes in moral development. Kirschenbaum [5] offered a later attempt to merge values clarification and the focus upon character education into a more comprehensive approach to values education.

Two sequences (Stage 1: transmission of values and Stage 2: development of values) that incorporate the theories of Freud, Erikson, Kohlberg, and Gilligan have more recently been identified to describe values acquisition (see [3, 4]). Values can be directly transmitted to an individual from external sources such as societal institutions (schools, governmental laws/rules, religious organizations, clubs, etc.); parents; teachers; mass media; and peers through a reward/punishment system. The transmission approach uses socialization to impart values when human beings as children are young and inexperienced, yearn for acceptance, and are most vulnerable to social pressure. This implies that the same transmission medium as a process could promote healthy and unhealthy or socially acceptable and socially unacceptable values. The psychoanalytic theorists (Sigmund Freud and Neo-Freudians like Erik Erikson) refer to these lessons of childhood as identifications in order to highlight the fact that these values could be learned at both the conscious and unconscious levels.

The development of human values begins to crystallize around adolescence, but the antecedents of a person's personal set of lifetime adult values obviously begin in childhood. During late childhood, adolescence, and early adulthood a person has a chance to re-invent himself/herself by a thoughtful examination of values accumulated through the transmission approach in the form of childhood identifications and observational lessons. In other words, the socialization process has the initial powerful influence upon one's personality through the transmission approach, but as a person matures and leaves the confines of childhood a more personal and developmental process of values acquisition can come into play. This developmental process allows for the personalization of values needed for identity formation (see this entry for more details) and adaptation to a lifetime likely to be filled with dramatic scientific, technological, societal, and personal change. Values in the form of cultural traditions are therefore fairly resistant to changes by societal whims, trends, and fads, while at the same time malleable for longer-term adaptive and survival purposes. It seems

crucial to point out that some human beings never fully discover the possibility or importance of making conscious decisions regarding which childhood values to keep, modify, or discard. It is possible that some adults are living their lives based upon values transmitted to them in childhood without this critical review process. For most people it is inevitable that some personal crisis in life will challenge such a person to more carefully examine the strengths and weaknesses of transmitted values.

At the broader cultural level, values are often shared or rejected by members of groups and society as a whole. Values implied through behaviors are frequently employed as a condition of membership in order to distinguish members from non-members and are encouraged through rewards. Group membership normally implies that individuals share at least some values. Values tend to be more obscure than norms that are clearly stated and more measureable. Conflicting values as perceived within a group setting might be tolerable or may be the basis for dismissal, rejection, or persecution.

Relevance to Childhood Development

Many people would claim that the values established in childhood form the cornerstone of a healthy/unhealthy and productive/non-productive adult life. What is crucial to understand is that the values transmitted during childhood not only have a powerful influence upon the behaviors of adolescents and adults, but also that childhood is better thought of as a staging ground for the further development and refinement of values during adolescence and adulthood. The content of values is also critical, since it is possible for a person to be very devoted to and enthusiastic about values such as racial, ethnic, or religious hatred.

The topic of values is of great interest to politicians, business leaders, school personnel, religious leaders, parents, and others because changing values in cohort groups or across society means a potential re-directing of emphasis in society that could threaten established institutions and traditional belief systems. For example, the values promoted by the mass media in the form of entertainment or advertising or the Internet could quickly change the values of a society for better or worse and perhaps toward some of both outcomes. The renewed interest in character education and moral development has encouraged the further exploration of how values can contribute to the development of moral character in children and on into adulthood.

Vanderbilt ADHD Diagnostic Parent Rating Scale

►Vanderbilt Parent Assessment Scales

Vanderbilt Attention-Deficit/Hyperactivity Disorder Diagnostic Teacher Rating Scale (VADTRS)

►Vanderbilt Teacher Assessment Scale

Vanderbilt Parent Assessment Scales

Katherine E. Kiker
University of Florida, Gainesvile, FL, USA

Synonyms

VADPRS; Vanderbilt ADHD diagnostic parent rating scale; Vanderbilt parent rating scales

Definition

The VADPRS is a parent-completed rating scale that assesses symptoms of ►attention-deficit/hyperactivity disorder (ADHD) and common comorbid conditions in children.

Description

The VADPRS is a parent-completed rating scale that assesses symptoms of ADHD as well as related performance

in children between ages 6 and 12. The scale contains 55 items, takes approximately 10 min to complete, and has a third grade reading level. The scale contains all 18 criteria for ADHD from the *Diagnostic and Statistical Manual of Mental Disorders* (4th ed.) (DSM-IV [1]), which includes nine symptoms of inattention, six symptoms of hyperactivity, and three symptoms of impulsivity. The VADPRS also contains 8 items measuring symptoms of ►oppositional defiant disorder, 12 items measuring symptoms of ►conduct disorder, and seven items that screen for anxiety and depression [2].

Parents rate the frequency of the symptoms on a four point scale, from "never" to "very often." A diagnosis of ADHD is given if enough scores of 2 or 3 are checked, based on the DSM-IV criteria for ADHD (1).

The VADPRS also contains an eight-item performance section, with 4 items examining academic performance (reading, mathematics, written expression, and overall academic performance), and four items examining relationships (peers, siblings, parents, and participation in organized activities). Parents rate each item on the performance section on a 5-point scale, from "problematic" to "above average [2]."

Relevance to Childhood Development

The VADPRS is used to facilitate the identification of some of the most common disorders of childhood. Psychometric evaluation of the VADPRS suggests that it has acceptable internal consistency and factor structure. The developers of the VADPRS suggest that it is a useful clinical tool to help evaluate ADHD in children, screen for common comorbid conditions, and assess school and relationship performance. Additionally, they suggest that the scale can be used as a time-efficient and cost-efficient research tool [2].

Vanderbilt Teacher Assessment Scale

Julia A. Ogg, Sarah A. Fefer
University of South Florida, Tampa, FL, USA

Synonyms

NICHQ Vanderbilt assessment scale-TEACHER informant; Vanderbilt Attention-Deficit/ Hyperactivity Disorder Diagnostic Teacher Rating Scale (VADTRS); Vanderbilt teacher behavior evaluation scale; Vanderbilt teacher rating scale

Definition

The Vanderbilt Teacher Assessment Scale is a teacher-completed rating scale that can be used to assess the core and peripheral features of Attention-Deficit/Hyperactivity Disorder (ADHD) as outlined in the *Diagnostic and Statistical Manual of Mental Disorders* (4th ed.; DSM-IV; [2]).

Description

The Vanderbilt Attention-Deficit Hyperactivity Disorder Diagnostic Teacher Rating Scale (VADTRS; [3]) is a 43 item rating scale that is designed to obtain data from a child's teacher to assist in the diagnosis and treatment of ADHD. The scale is designed for use with children between the ages of 6 and 12. The VADTRS is available on the internet at no cost and is currently available in English and Spanish. The scale allows teachers to report the presence and severity of inattention, hyperactivity, and impulsivity displayed by a child in the school setting. The VADTRS items directly correspond to the DSM-IV [2] ADHD diagnostic criteria. The instructions provided on the scale direct the teacher to consider each rating in the context of age-appropriate behaviors for the student. There are nine items that assess Inattention and nine items assessing Hyperactive/Impulsive symptoms. The VADTRS also includes items that can be used to screen for coexisting conditions. There are 17 items that address oppositional/conduct and anxious/depressive behaviors. ADHD and comorbid symptoms are rated from Never (0) to Very Often (3). Symptoms are considered present, in regard to DSM-IV criteria, if they are rated as a 2 ("often") or 3 ("very often"). The teacher also rates 8 performance items on the VADTRS that relate to functional impairment in the academic and classroom behavior domains. The performance measures are rated

from Problematic (1) to Above Average (5). A rating of a 1 or 2 on one or more items in the performance section is considered to be indicative of impairment. The directions for the VADTRS indicate that a child must score a 2 or 3 on six or more items on the Inattentive scale and/or six or more items on the Hyperactive/Impulsive scale, as well as a 1 or 2 on one or more functional impairment items to meet the symptoms and impairment criteria for ADHD in the school setting. Three or more items scored as present for either the oppositional/conduct or the anxiety/depression scale indicate a positive screen for comorbid behavioral or emotional concerns. There is also a related follow-up scale that includes only ADHD and performance items to assist in evaluating treatment effects (NICHQ Vanderbilt Assessment Follow-up – TEACHER Informant).

The VADTRS and the Vanderbilt Attention-Deficit Hyperactivity Disorder Diagnostic Parent Rating Scale (VADPRS; [6]) are included in the *Caring for Children with ADHD: A Resource Toolkit for Clinicians*, a toolkit developed for pediatric health care providers by the American Academy of Pediatrics (AAP) and the National Initiative for Children's Healthcare Quality based on the AAP clinical practice guidelines for diagnosis and evaluation [1]. These guidelines include basing diagnoses on the criteria outlined in the DSM-IV [2], obtaining parent and teacher reports of ADHD-specific behaviors (via rating scales, interviews etc.), and screening for potential comorbidities.

Psychometric data for the VADTRS are available [3]. The original study examing the psychometric properties of the VADTRS included elementary-age children in Tennessee. The internal consistency reported for the Inattention (coefficient alpha=0.92), Hyperactivity/Impulsivity (coefficient alpha=0.90), Oppositional-Defiant/Conduct (coefficient alpha=0.87), Anxiety/Depression (coefficient alpha=0.80), Classroom Behavior Performance (coefficient alpha=0.94), and Academic Performance (coefficient alpha=0.95) scales appear adequate. In a multinational study, internal consistencies for Inattention ranged from 0.95 to 0.96, while the internal consistencies for Hyperactivity and Impulsivity items were calculated separately and ranged from 0.87 to 0.93 [4]. Wolraich et al. [3] used both exploratory and confirmatory factor analysis with two sets of data and suggested that both supported their proposed latent variable structure. In a second study, using confirmatory factor analysis, Wolraich, Lambert, Baumgaertel, Garcia-Tornel, Feurer, Bickman et al. [4] compared a one factor model (Inattention and Hyperactivity/Impulsivity together), a two factor model (Inattention and Hyperactivity/Impulsivity separately), and a three factor model (Inattention, Hyperactivity, and Impulsivity separately) across multinational samples. When all aspects were considered, data most strongly supported the two factor solution (Inattention and Hyperactivity/Impulsivity separately), suggesting that the author's proposed structure was appropriate. No test–retest reliability data have been reported for this instrument.

Relevance to Childhood Development

Rating scales are recommended as one tool that can be used in the assessment of ADHD for physicians, who most commonly diagnose this disorder [1]. These scales are an efficient and reliable way to obtain data from a child's teacher and have demonstrated a high level of consistency with other assessment methods, such as structured diagnostic interviews [5]. The VADTRS can assist clinicians in evaluating the *DSM-IV* criteria for ADHD, which requires the presence of symptoms in two settings, a set threshold of symptoms, and demonstrated functional impairment.

Variables, in Experimental Developmental Research

Daniel Patanella
New York City Department of Education,
New York, NY, USA

Synonyms

Dependent variables; Independent variables; Latent variables; Mediators; Moderators; Outcome variables; Predictor variables

Definition

Anything that is observed or measured in a scientific study can be considered a variable.

Description

A key component in all research designs, variables can be broadly conceptualized as being in two different classes: predictor, or independent, variables (often represented as *X*) and criterion, or dependent, variables (often represented as *Y*). Independent variables are what researchers either control or use to categorize their subjects, and dependent variables are the measurements taken to determine the effect the independent variable or variables had on the subjects in the study. It is important to note that variables represent different values or qualities of a property of the research subject.

Within this broad distinction, there are numerous ways to classify subcategories of variables. Some researchers, for example, prefer to distinguish between independent variables that can be truly manipulated or assigned and those which cannot (such as age or ethnicity), which are then often termed "subject variables." Modern psychometricians specializing in multivariate analyzes refer to any predictor variables which are indirectly measured as "latent variables." While some psychologists from a radical behaviorist standpoint often argue against the validity of such variables, latent or indirectly observed variables have a long history within psychological research; intelligence, for example, cannot be directly measured and can only be inferred through intelligence tests. Regardless, the key distinction between independent and dependent variables still stands.

Beyond the research perspective of independent vs. dependent variables, scientists also distinguish between discrete and continuous variables. Discrete variables have only a limited number of possible, mutually exclusive values whereas continuous variables have a large number (theoretically an infinite number) of values between the two extreme scores of a particular scale. The use of discrete and continuous variables influences the researchers' choice of statistical analysis in completing the research study. The number of variables also impacts the choice of inferential statistics, with simple one-variable designs requiring univariate statistics and more complex multiple-variable designs requiring multivariate statistics.

The relationships among different independent variables are also of practical and theoretical importance to researchers. Modern psychological research draws a distinction between "mediating" and "moderating" variables. Mediating variables are variables that intervene between the independent and dependent variables being studied, and moderating variables are variables that change the direction of or affect the strength of the relationship between the independent and dependent variables of interest. The differences between mediation and moderation may be subtle, and the proper identification of variables as mediating or moderating requires specialized statistical testing. The benefits of such identification include refinement of theory development and the testing of additional hypotheses on a more granular level.

Variables of primary interest to developmental researchers include age, gender, ethnic and racial backgrounds, birth order, intelligence, cognitive maturity, response latency, emotional functioning, behavior, and many others.

Verbal Intelligence

Kristine Augustyniak
Niagara University Academic Complex, Niagara, NY, USA

Synonyms

Crystallized intelligence; Language-based reasoning; Verbal ability; Verbal aptitude; Verbal comprehension; Verbal IQ

Definition

Intelligence in the use and comprehension of language, including the ability to understand and profit from experience with language [40].

Description

In his theory of Multiple Intelligences, Howard Gardner identified Verbal-Linguistic intelligence as one of eight core intelligences along with logical-mathematical, spatial, bodily-kinesthetic, musical, interpersonal intrapersonal, and naturalistic intelligence. Gardner described Verbal-Linguistic intelligence as an individual's sensitivity to and facility with spoken and written language. High verbal-linguistic intelligence is associated with lexical knowledge, verbal memory, ability to understand and manipulate syntax and the capacity to utilize symbolic and abstract language. Linguistic ability is observed in an individual's ease in learning primary and secondary languages and capacity to use language effectively to accomplish certain goals such as expressing oneself rhetorically or in prose, learning via literacy skills, analyzing syntactic information, and persuading or instructing others [12, 13]. Gardner's assertion that multiple intelligences exist independently, rather than as subsets of general intellectual ability (aka "*g*") has been criticized based on the lack of validating studies [23, 34]. However, examination of the content of a variety of instruments which measure verbal abilities provides empirical support for the greater part of Gardner's definition of Verbal-Linguistic intelligence. Therefore, even if the conceptualization of Multiple Intelligences is rebuffed, one may find Gardner's definition useful as a pragmatic framework from which to view the functional expression of verbal intelligence.

The construct of verbal intelligence has indeed been widely supported in psychometric research. Verbal intelligence is typically evaluated as part of a broader assessment of cognitive abilities/IQ, although it may also be

evaluated through brief intelligence tests and specific language assessments. The reliability and validity of measures of verbal intelligence are typically supported by psychometric analyzes including normative statistics, reliability analysis (coefficient alpha, test–retest, alternate forms, etc.), correlational methods examining convergent/divergent/predictive validity, and confirmatory/exploratory factor analytic methods to support construct and criterion validation. When compared with other measured dimensions of human intelligence such as nonverbal reasoning, speed of information processing, and memory, scales representing verbal intelligence tend to be the most psychometrically robust in regard to reliability (e.g., standard error of measurement) and contribution to general intelligence (i.e., amount of variance in "*g*" accounted for by verbal intelligence) [21].

The Cattell-Horn-Carroll (CHC) theory of cognitive abilities [21] is an empirically grounded, psychometric theory of intelligence. Many psychologists believe that CHC theory, which combines Cattell and Horn's Gf-Gc theory (i.e., general fluid and general crystallized intelligence) [5, 15] and Carroll's [4] three-stratum theory, provides the most comprehensive framework available for understanding the structure of human cognitive abilities [20]. The apex, Stratum III, represents the general level: general intellectual ability or "*g*". Stratum II, the broad level, is comprised of eight factors including fluid intelligence, crystallized intelligence, general memory and learning, broad visual perception, broad auditory perception, broad retrieval ability, broad cognitive speediness, and processing speed. The broad cognitive abilities subsume approximately 70 narrow cognitive abilities represented by Stratum I. Crystallized intelligence, which is associated with verbal intelligence, refers to knowledge and skills that are primarily influenced by environmental and sociocultural factors and is generally assessed through verbal skills [16]. For example, on the Woodcock Johnson-III Tests of Cognitive Abilities [39] the CHC cognitive factor (*Gc*) is entitled Comprehension-Knowledge and is comprised of two subtests: Verbal Comprehension which requires naming pictured objects, providing synonyms or antonyms, and solving verbal analogies, and General Information which requires answering questions presented orally. Together the subtests assess an individual's breadth and depth of knowledge of a culture, ability to communicate knowledge, and ability to reason using previously learned knowledge.

The Wechsler scales are commonly used for the assessment of general intellectual ability [35, 37]. The Wechsler Adult Intelligence Scale and Wechsler Intelligence Scale for Children reflect a four factor model of intelligence, where verbal intelligence is represented by the Verbal Comprehension Index (VCI). Although the Wechsler scales were not based on the CHC premise, the content of scales measuring verbal intelligence is consistent with the theoretical framework Crystallized intelligence (*Gc*). The VCI is a measure of general verbal skills, such as verbal fluency, ability to understand and use verbal reasoning, and verbal knowledge.

There are numerous instruments designed to assess multiple dimensions of verbal intelligence, many with similar content to the Woodcock Johnson-III Tests of Cognitive Abilities and Wechsler scales. These include the Stanford-Binet Intelligence Scales-fifth edition [29], the Differential Ability Scales – second edition (DAS-II, [11]), and the Kaufman Assessment Battery for Children, second edition (KABC-II, [17]). Yet, there are many children whose true verbal abilities may be under-represented by traditional assessments. These include children for whom an adequate assessment has not been standardized in their primary language, children who have limited experience with the dominant culture, those who are deaf, or those who suffer from a hearing impairment, speech and language disorders, neurological disorders, traumatic brain injury, language-related learning disabilities, autism, selective mutism or other neurological or mental disorders. In such cases, psychologists may choose to administer non-verbal assessments that provide insight into symbolic representation, a particular area of crystallized/verbal intelligence. Symbolic representation has been long recognized as the basis for human communication, with aural/oral language exchange being only one manifestation [10]. Tasks involving symbolic memory, learning, and reasoning skills draw upon an individual's cognitive skills in internal verbal mediation. Some nonverbal assessments, such as the (CTONI, [14]) and the Universal Nonverbal Intelligence Test (UNIT, [3]) allow for specific assessment of symbolic abilities and provide a standardized administration with no expressive or receptive language requirements on the part of the examinee. Based on the PASS (Planning, Attention, Simultaneous, Successive) Theory of Cognitive Processing [9], the Cognitive Assessment System [24], provides a unique purview into an individual's ability to process successive verbal information. On the CAS, Successive processing is defined as the means by which an individual "integrates stimuli in a specific order that forms a chain like progression" (p. 5) and is associated with the syntactic nature of language and the ability of one to derive meaning from it. The findings from such instruments can provide valuable but circumscribed information about discrete domains of verbal intelligence.

Relevance to Childhood Development

Perhaps the most important contribution of developmental psychologist Lev Vygotsky [33] was his theory on the relationship between language and thought. Vygotsky asserted that cognitive development potentiates from a dialectical process whereby a child learns through experiences with others and where language is the primary form of interaction. Language begins as an external, "interpsychological" tool for social exchange and becomes an "intrapsychological" tool which the child utilizes to makes sense of his/her world. This can be observed in a child's utilization of "private speech," a repetition of comments by others, which is often first expressed aloud and later becomes internalized/silent self-talk. As learning progresses, the child's own language comes to serve as her primary tool of intellectual adaptation, concept formation, and self-awareness. Eventually, children can use internal language to direct and regulate their own behavior, thoughts and emotions. Contemporary developmental theories have also supported the role of linguistic abilities in enriching development of interpersonal skills, emotional regulation, and executive cognitive functioning [1, 30, 32].

With the caveat that both are influenced by background, previous education, and cultural experiences, verbal ability is a good predictor of achievement orientation. Assessment of verbal abilities using psychometrically sound instruments can be a valuable tool in identifying preschoolers at-risk for academic and cognitive delays [19, 22]. In older children, lexical knowledge [8, 18], syntactic awareness [2, 7] and verbal working memory [6, 31] have been found to be related to basic literacy and spelling skills. Aggregate measures of verbal intelligence (i.e., Verbal IQ) have also been positively correlated with reading comprehension skills [25, 26]. Moreover, measured verbal intelligence has been found to be more strongly related to academic achievement measures of reading, mathematics, and written language than non-verbal measures [27, 28, 37].

Verbal IQ

►Verbal Intelligence

Verbal Memory

Definition

Memory for words and other verbal information

Description

Evidence supports that most people process verbal information with the left side of their brain, and damage to this region of the brain can impair verbal processing and memory, as well as, speech. Further, some individuals are thought to have better verbal processing and memory skills, while other individuals may have better spatial skills. More specifically women tend to have superior verbal memory skills to men.

When assessing verbal memory it is important to compare it with spatial memory, in order to target more specific deficits or strengths and also detect damaged brain regions. Verbal memory can be assessed through neuropsychological testing; these tests include variations of remembering a long list of words or a short story. One of the most predominantly used neuropsychological tests for verbal memory is the California Verbal Learning Test (CVLT).

Verbal Rehearsal and Self-Statements

►Self-Talk

Verbal Skills

Synonyms

Communication skills; Expressive language; Language; Oral skills; Speaking; Speech; Spoken language; Verbal communication

Definition

The skills used to communicate one's knowledge orally.

Description

Effective use of verbal skills involves using intentional communication, comprised of several components and/or characteristics including vocalizations, vocabulary, grammar, syntax, fluency, word retrieval, and responsiveness to cues from the environment, to convey information and ideas to others.

Verbal skills are acquired through both environmental experience (e.g., modeling speech production of the primary caregiver and others in the immediate environment) and formal education. Measurement of verbal skills generally involves assessing an individual's ability to produce single word utterances, phrases, and sentences in responses to queries and prompts using oral and/or visual stimuli.

Very Low Birth Weight

Anna Mazur-Mosiewicz, Raymond S. Dean
Ball State University, Muncie, IN, USA

Synonyms

At risk infants; VLBW

Definition

Very low birth weight (VLBW) is defined as a birth weight of 1500 g or less in a liveborn infant.

Description

The primary causes of VLBW are premature birth (infants born before 37th week of gestation and often before the 30th week) and intrauterine growth restriction, which is usually due to problems with placenta, maternal health, or to birth defects. VLBW places the infants at higher risk of mortality and morbidity. Risk factors for VLBW are largely preventable. They include poor maternal nutrition, adolescent pregnancy, use of alcohol and drugs, smoking, multiple births, and sexually transmitted diseases. Families from lower socioeconomic backgrounds are at the greatest risk of these factors [1, 2].

The national percentage of the VLBW infants oscillate around 1.2 and 1.4. The rate of VLBW babies is increasing, due mainly to the increase in prematurely-born multiple gestations, which is in part associated with introduction of modern reproductive techniques. The percentage of VLBW infants is greater in minority groups, particularly African-Americans. According to statistics, the percentage of African-American babies born with very low weight was three times that of Caucasian-American babies. Reasons for these demographic differences are complex and generally relate to socioeconomic status and biological differences between the two groups. For example, pregnant African-American females are more likely to receive poor prenatal care, face more psychosocial stress, and are at higher risk of teenage pregnancy. Other factors include biological differences in gestational length.

Relevance to Childhood Development

Children born with VLBW are at high risk of neonatal complications, which are negatively correlated with the weight of infants. Clinical problems associated with VLBW include hypothermia; hypoglycemia; aphnea; metabolic acidosis; hypoglycemia; perinatal asphyxia; respiratory problems, particularly the Respiratory Distress Syndrome and aphnea of prematurely; fluid and electrolyte imbalances, which increase risk of dehydration, fluid overload, hypernatremia, hyponatremia, hyperkalemia, hypocalcemia, hypermagnedemia; hyperbilirubinemia; anemia; impaired nutrition; infections; neurological problems, including intraventicular hemorrage, periventricular leukomalacia, and increased risks for cerebral palsy, developmental delay; ophthalmologic complications; hearing deficits; and sudden infant death syndrome [2, 4, 5].

VLBW is associated with higher than normal risk for long-term developmental and neurocognitive disorders and delays. VLBW infants are at higher risk for cerebral palsy, developmental delays, mental retardation, visual problems (including blindness), hearing impairments, other neurosensory disorders, and chronic lung disease. Moreover, these children are at higher risk of learning disabilities (particularly in math), psychosocial maladjustment, and academic difficulties. Children with VLBW often present impairments in the areas of visual-motor performance and visual-motor abilities, overall cognitive performance, and attention. Additionally, when attending school, children who were identified with VLBW are often reported to develop low self-perception of competency, struggle with learning, and present behavioral problems. Other life-long problems often include adult-onset diabetes, coronary heart disease, and high blood pressure [3, 5].

Video Games

Steuart T. Watson, Darrell Davis
Miami University (OH), Oxford, OH, USA

Synonyms

Console games; PC games

Definition

An electronic game with video feedback where user input has consequences that affect the game environment.

Description

Video games were first introduced in 1972. The term video game has become synonymous with a wide range of electronic devices, software, and gaming experiences. The term is used as a reference for both hardware, for example, console games, and software, for example, individual game titles. Although the term video games is used to describe both objects and activities, the key characteristics are the electronic nature of the games and the presence of visual and auditory feedback.

The electronic components in video games introduce a wide array of possibilities when determining how the player interacts with a game. Electronic input devices accept player inputs which are then used to alter the game environment. Input devices range from simple gamepad controllers and keyboards to more specialized inputs like joysticks and steering wheels. The interaction among the player, the game interface, and the game environment, results in an overall gaming experience.

There are many characteristics associated with video games, but these characteristics are neither required nor do they fully define a video game. Characteristics like the presence of rules, generation of points, or competition are present in many video games but they are not all required. For most video games, however, competition is a significant portion of the experience. Competition may be in the form of other players as is the case in online games, or it may be in the form of predetermined standards like a score to attain or a time to beat. In these cases, winning is an important goal, but incremental progress is also very important in maintaining the behaviors associated with gaming. The attainments of sub-goals, or the steady increase in the mastery of requisite skills, are very reinforcing aspects of playing video games.

Improvements in technology have led to an increase in video game complexity and realism. In addition to delivering entertainment, modern video games are being used for specialized purposes. For example, the military has paired the teaching potential of video games and the increased realism afforded by modern technology to produce video games that are both recruitment and training tools. Recruitment and training tools like America's Army challenge the previous notion that video games are just for children [1].

Relevance to Childhood Development

Video games are quite pervasive in our culture as 92% of children ages 2–17 play them, with little more than two times more males than females playing. A third of these children have the games in their bedrooms. The amount of time that children spend playing video games ranges from about 20 to over 60 min per day. Generally, as children age, the amount of time spent playing increases with children ages 8–13 reporting the most playing time.

As video games, particularly violent video games, become more pervasive in the culture, they also become the focus of controversy. Researchers are currently examining the effects of violent video games on subsequent behavior of the game player. Despite what one may hear in the popular media, there are no data to suggest that playing violent video games causes aggressive or violent behavior in the game player. Although a number of studies suggest a link between playing violent video games and increased physical and verbal aggression, there is no definitive level of causality between the two. That is, one can not say that playing violent video games "causes" aggressive behavior [2, 3, 4].

There are many positive features of video games, particularly those whose aim is to teach academic skills, problem-solving skills, decision-making, and visual-motor coordination. In addition, playing video games is often a child's first introduction to computer literacy and may enhance their facility with computer-based technology. Some studies have found that playing video games improves spatial visualization and visual attention skills.

Perhaps the most serious consequence of playing video games is the time devoted to playing them. Approximately 25% of children admit that playing video games occasionally interferes with homework and other academic performance. When playing video games interferes with social interaction with friends, with school and other activities, and with family time, no matter what type of game is being played, then the negatives most likely outweigh the positive effects.

Vineland Adaptive Behavior Scale

Audrey McKinlay
University of Canterbury, Christchurch, Canterbury, New Zealand

Synonyms

Adaptive Behaviour Scales

Definition

The Vineland Adaptive Behavior Scales (VABS) are an objective measure of adaptive behavior. Adaptive behavior refers to the individual's ability to undertake daily activities appropriate for their age group.

Description

The VABS are a revision of the Vineland Social Maturity Scale, which was developed in 1935 and revised in 1967 [2, 3]. The Vineland Social Maturity Scale was designed to provide an objective measure of adaptive behavior for use in evaluating individuals with mental retardation [2, 3]. Adaptive behavior was defined as "performance of the daily activities required for personal and social sufficiency" [5]. Three principles were associated with the definition: (1) adaptive behavior is age related, (2) adaptive behavior is defined by expectations or standards of other people, (3) adaptive behaviors are defined by typical performance not ability [5]. Levels of adaptive behavior and intelligence are compared when determining whether or not an individual should be classified as having mental retardation.

Published in 1984, the VABS is used to assess personal and social sufficiency for individuals from birth to adulthood, and may be used to asses an individual's daily functioning in a variety of clinical, educational and research settings [5]. The VABS may be used to prepare individual education and treatment programs, monitor progress, and evaluate the success of a program. The scales are also applicable for individuals with or without disability [5] and are valuable in determining the degree to which specific disabilities may affect daily functioning in individuals [5].

A major advantage of the scale is that it allows assessment of individuals who will not or cannot perform on command, such as infants and individuals with severe retardation, emotional, or physical disability. The VABS does not require the direct administration of tasks to an individual; rather it requires a respondent who is familiar with the individual's behavior. There are three versions of the VABS; each version is designed to measure adaptive functioning in the following four domains.

1. Communication which has three sub-domains; receptive, expressive, and written communications.
2. Daily living skills which has three sub-domains; personal, domestic, and community.
3. Socialization which has three sub-domains; interpersonal play, relationship play, and leisure time.
4. Motor skills which has two sub-domains; gross motor skills and fine motor skills.

These four domains and their sub-components are considered to accurately categorize the daily activities of most individuals [5]. There is an optional set of items which covers maladaptive behaviors; however, these questions can only be used with individuals 5 years and older. The motor skills domain is only administered to children without disability of 6 years or younger unless a motor skills deficit is suspected. The educational form is administered as a questionnaire and is completed by the teacher [5].

Forms

1. The survey form, which includes 297 items, is used to provide a general assessment of adaptive behavior and to give and indication of areas of strength and weakness. It may be used with individuals from birth to 18 years 11 months or for low functioning adults. The expanded form includes an additional 280 items which are presented to the primary caregiver of the individual in a semi-structured interview format (administration time = 20–60 min).
2. The expanded form, containing 577 items, 297 of which are from the survey form. This is a more comprehensive assessment of adaptive behavior and may be used to prepare an individual educational or treatment plan (administration time = 60–90 min).
3. The classroom edition: This form has 244 items taken from the other two forms, but which are related to basic academic functioning. This form is for use with students between the ages of 3 and 12 years 11 months (administration time = 20 min).

Administration

The VABS are designed to measure what the individual usually does, not what they are optimally able to do. Not all questions need to be administered as an approximate starting point for individuals without disability is indicated in the record booklet for each domain. Lower starting points may be necessary for individuals with suspected deficits and are based on the best estimate of mental or social age, and are derived from previous data or information from the primary caregiver. By this means, not all items are required to be administered as basal points are established for each domain.

Scoring

Each item can receive a score of 2, 1, or 0. A score of 2 indicates yes or usually, 1 sometimes or partially and 0 indicates no or never. No opportunity and don't know can be given as a response and are counted as a 1. An adaptive behavior composite score is generated with a mean of 100 and standard deviation (SD) of 15. Percentile ranks, stanines, adaptive levels and age equivalents can be calculated from tables in the manual. In addition, for each of the sub-domains an adaptive level and age equivalent may be determined. With the survey and expanded form, a percentile rank may be obtained for adaptive behavior composite and for the domains which indicate how the individual with a disability rates relative to other individuals with a similar disability. The scores may be plotted in a standard score profile.

The maladaptive domain on the survey and expanded form indicates whether the level of maladaptive behavior is significant or non significant compared with individuals of the same age or with the same disability.

Relevance to Childhood Development

Mental retardation is considered to be a disorder first diagnosed in childhood [1] and can be caused by a diverse range of factors including Down syndrome, heredity factors or traumatic brain injury [1]. Approximately 1% of the population are affected by mental retardation and these individuals are vulnerable to exploitation and abuse (i.e., physical or sexual) [1]. To ensure the best outcomes for individuals with mental retardation requires optimal environmental inputs. But to target these interventions requires a reliable method of identification. Prior to 1960 a diagnosis of mental retardation only required a score one or more SD below the mean on a test of intellectual ability. However, this cut off was found to be too inclusive and disadvantaged minority group members. Later a cut off of two SD was used but this still tended to included a disproportionate number of minority group members [4]. Therefore, deficits in adaptive behavior as well as deficits in intellectual functioning are now required for a diagnosis of intellectual retardation. The current diagnostic criteria in the DSM-IV-TR [1] states that the individual must have a significantly sub average intellectual functioning (i.e., <70) and concurrent deficits in adaptive functioning (as measured by scales such as the VABS) with onset prior to age 18 years.

Visual Area

Chad A. Noggle
SIU School of Medicine, Springfield, IL, USA

Synonyms

Primary visual cortex

Definition

The visual area of the brain, also known as the primary visual cortex, is a portion of the occipital lobe and is the site at which visual information is processed.

Description

The visual area of the brain is housed within the occipital lobe of the brain, which is the smallest and most posterior lobe of the cerebral hemispheres. More commonly referred to as the primary visual cortex, the visual area of the brain represents the region of the cortex where visual information is initially processed prior to being transmitted anteriorly for additional processing [3]. While all visual information is eventually received here, it is first transmitted through specific nuclei of the thalamus. Specifically, the lateral geniculate, pulvinar, and lateral posterior nuclei of the thalamus initially receive different forms visual information and then relay it onto the visual area [1]. Upon being received, the nature of the visual information determines how it is processed by the visual area. All information is received by the two areas that largely make-up the primary visual cortex, sometimes labeled as V1 and V2 for visual area 1 and visual area 2. Beyond this, information is sorted by whether the information is related to object recognition or visual action [2]. That information related to object recognition is sent via the ventral stream for further processing and that information corresponding to visual action is sent via the dorsal stream for further processing [2]. Again, while areas V1 and V2 enact influence on both streams, the remaining areas do not necessarily do the same. Area V3 is the only other area that has feeds to both the ventral and dorsal streams. In regards to the prior, V3 assists in the processing of elements of dynamic form while for the latter it assists in the processing of elements related to more general form processing [2]. In comparison, V4 solely operates within the ventral stream and serves to assist in recognition of color form whereas V5 operates almost exclusively within the dorsal stream assisting the processing of motion [2].

Visual Scanning

Benjamin K. Barton, Paul Jorritsma
University of Idaho, Moscow, ID, USA

Synonyms

Visual attention; Visual search

Definition

The pattern of eye movements used to examine a given person, image, or object.

Description

Visual scanning refers to the pattern of fixations and saccades while an individual is examining visual stimuli. Scanning is first rather disorganized in infants, then becomes more exploratory but fairly limited, and finally develops into controlled, goal-directed behavior. In older children and adults, scanning emerges as more sophisticated visual search skills and is part of a larger set of selective attention abilities.

Relevance to Childhood Development

Visual scanning rapidly develops during infancy. Eyesight is less developed at birth in comparison to other senses, such as hearing. Scanning patterns are somewhat disorganized at birth, but by approximately 1 month, infants attend to the outer edges of a visual stimulus, such as a pattern or face, but do not explore the inner areas of the stimulus until several weeks later [9, 16]. Infants as old as 12 weeks still tend to fixate on a specific region along the periphery, a corner for example, and do not vary their search over multiple aspects of the pattern [12]. As scanning ability develops, infants expand their examination and explore different features of visual stimuli [2]. Visual scanning finally matures as a controlled, goal-directed behavior [3].

Visual scanning is not entirely dependent on physical or cognitive development. Characteristics of visual stimuli also affect infants' scanning behaviors. Brightness, familiarity with an object, texture, and motion all partially

determine the attractiveness of an object and the ensuing visual scanning behaviors (e.g., [4]). Motion in particular seems to attract infants' attention. Due to the attractive qualities of certain objects, we can see a link between visual skills and other areas of development. Infants' first words often refer to important objects (i.e., mother or father) or other objects they have seen in motion [14].

Visual scanning is important for establishing human social interaction. Infants tend to gaze at their parent's face, exploring facial features and learning the synchronization of features, sounds, and expressions. The parent's mouth and eyes are perhaps most interesting to the infant [11]. While an infant scans, the parent speaks to the infant and engages in physical contact providing warmth and security. Through this close interaction with the parent, the foundations for speech and attachment are laid.

As children grow past infancy, visual scanning becomes integrated into the sophisticated ability to selectively attend to visual stimuli comprising multiple subskills, one of which is visual searching [6]. Visual searching results from the combination of orienting attention and filtering irrelevant information [15]. Some evidence suggests the basic perceptual processes that form the foundation of visual search are invariant from infancy into adulthood [8].

Developmental differences in visual search are clearly present after infancy. Visual search ability becomes faster and more accurate with age [13]. However, visual search abilities are taxed to a much greater degree in children than adults, even by small amounts of interference [10]. For example, children ages 5 and 6 require more time in visual search tasks than older children [18]. The presence of multiple moving stimuli also challenges children's visual search abilities. Younger children (6–8) have more difficulty than older children (10–12) when identifying and tracking a moving target surrounded by distracters, and experience even greater difficultly accurately tracking multiple moving targets [19].

Visual attention mediates the roles of experience and environment on brain maturation [5]. An example of this mediation is seen in the development of motor skills in young children; for example, walking. Learning to walk requires environmental affordances and development of brain structures responsible for motor skills. However, affordances and innate structures in the child are not sufficient. Environmental affordances must be visually perceived, then acted upon by the child (e.g., [17]). The ability to visually scan the environment supports the developing comprehension of shapes, textures, and depth cues. Experience with visual scanning also supports growth within the brain structures responsible for continued motor development.

Visual scanning abilities remain important after infancy, but the use of visual skills changes with development. Infants use visual scanning to learn about their environment, form social bonds, and develop motor skills. In childhood, visual skills are important in different domains. Academic and athletic activities, for example, rely heavily on visual skills (e.g., [7]). Certain forms of child injury also depend heavily on visual skill development [1]. Among adults, visual skills are employed each time an automobile is driven or a busy airport concourse is navigated. In short, our use of visual scanning persists across the lifespan.

Visual-Spatial Intelligence

Amy E. Zimmerman, Raymond S. Dean
Ball State University, Muncie, IN, USA

Synonyms

Non-verbal intelligence; Visuo-spatial intelligence

Definition

The capacity to perceive the visual world accurately, and/or perform transformations and modifications on perceptions, construct mental representations of visual information, and use the representations to perform activities is often considered visual-spatial intelligence [2, 3, 5].

Description

Some professionals have erroneously designated visual-spatial intelligence as one of Gardner's original seven multiple intelligences. These individuals are in fact referring to spatial intelligence. Gardner himself readily admits there is often a visual component to spatial intelligence. However, he differentiates between visual-spatial and spatial intelligence as he indicates other senses can be involved in spatial intelligence aside from sight. For instance, a blind individual, who has no access to the visual world, can develop spatial intelligence by utilizing the tactile modality of their perceptual system [3, 4]. Therefore, in relation to Gardner's theory on multiple intelligences, visual-spatial intelligence is a subcomponent of spatial intelligence.

Visual-spatial intelligence encompasses several abilities, including but not limited to, visual discrimination, recognition, projection, mental imagery, spatial reasoning, image manipulation, and the duplication of inner or external imagery [1]. This intelligence also involves the ability to think in three-dimensions [9], including constructing three-dimensional forms out of two-dimensional information [10]. Any or all of these visual-spatial abilities may be expressed by a single individual. Consequently, persons with well-developed visual-spatial intelligence do not all exhibit the same skills. Carpentry, architecture, engineering, interior design, mathematics, surgery, and aviation are some examples of careers involving visual-spatial abilities [1].

There are no standardized assessments designed to specifically measure visual-spatial intelligence per se. However, there are standardized assessments which measure cognitive abilities associated with visual-spatial intelligence. For instance, the *Woodcock-Johnson Tests of Cognitive Abilities*, Third Edition (WJ-III-COG) has factors based on the Cattell-Horn-Carroll theory of cognitive abilities, and one of these factors is visual-spatial thinking. Visual-spatial thinking is the ability to perceive, analyze, synthesize, and process visual patterns as well as the ability to store and recall visual information [8]. It is considered a broad ability, and can be broken down into four narrow abilities: visualization, spatial relations, visual memory, and spatial scanning [6]. The *Stanford-Binet*, Fifth Edition (SB-V) also evaluates visual-spatial abilities. Visual-spatial processing, one of the five factors on the SB-V, measures an individual's ability to perceive patterns, relationships, spatial orientations, or the gestalt whole among pieces in a visual display [7].

Development Implications

It is important to help children develop and/or hone their visual-spatial abilities because visual-spatial thinking is a basic avenue of obtaining, processing, and representing information [1]. Not to mention, abilities related to visual-spatial intelligence support academic pursuits in the areas of geography, biology, chemistry, mathematics, geometry, physics, and art [10]. There are techniques and

tools available for teachers to utilize in the classroom in order to stimulate the visual-spatial intelligences of their students. A list of technological visual-spatial tools for the classroom includes slides, overhead transparencies, film strips, movies, interactive videodisc (IVD), compact disc-read only memory (CD-ROM), compact disc interactive (CDI), and graphics programs [1].

Vygotsky's Cognitive Development Theory

Melisa Moore
Argosy University/Atlanta, Atlanta, GA, USA

Synonyms

Vygotsky's social development theory; Vygotsky's socio-cultural theory

Definition

Vygotsky's Cognitive Development Theory postulates that social interaction is fundamental to cognitive development. Vygotsky's theory is comprised of concepts such as culture-specific tools, language and thought interdependence, and the Zone of Proximal Development. Furthermore, the theoretical concepts presented herein provide part of the foundation for constructivism and have contributed greatly to the restructuring of formal educational systems [1, 3].

Description

Vygotsky's Cognitive Development Theory argues that cognitive abilities are socially guided and constructed.

As such, culture serves as a mediator for the formation and development of specific abilities, such as learning, memory, attention, and problem solving. It is proposed that culture-specific tools play an integral role in the way children organize and think about the world. These tools may include various social artifacts, ranging from books and computers to cultural traditions [1].

Additionally, it is said that signs (or systems) mediate cognitive development. The most prominently referenced of these signs are language, writing and counting. Learning involves the internalization of these signs. Moreover, when discussing language, Vygotsky's theory of cognitive development emphasizes the interdependence of language and thought. A key component of this interdependence is evidenced through an early childhood behavior termed private speech. Private speech is a verbal dialogue that young children use for guidance and modification during the completion of a task or exploration of a new situation or concept. This dialogue is not socially communicative, and it may not be perceived as cohesive or well developed by observing adults. However, it aids in the organization of new information and directs development toward a higher-order processing. Private speech eventually becomes silent, transitioning into internal speech and then, ultimately, verbal thinking [2, 4].

It also is argued that learning occurs as external activity and awareness become internalized. Initially, behavior is exhibited without true intent; however, as the behavior becomes socially mediated it is internalized as meaningful and then purposefully demonstrated. For instance, Vygotsky offered the example of an infant reaching for an object just beyond reach. As the infant reaches, an adult caregiver socially responds to the nonverbal gesture and that gesture is then transformed into the intentional and socially-driven behavior of pointing [2, 3].

Another predominant aspect of Vygotsky's theory of cognitive development is the Zone of Proximal Development. According to this concept, there is a disparity between what a child can perform independently and the potential learning that can occur with the assistance of an adult or through collaboration with peers. Thus, a child's potential cognitive abilities are greater than the actual, measurable ability. Facilitated by adults or peers with more expertise, learning occurs in the Zone of Proximal Development [2, 3].

Although not specifically mentioned by Vygotsky, scaffolding has become closely associated with the Zone of Proximal Development. It is a technique that is used to maximize learning and requires that an adult or more more-skilled peer aid a child's acquisition of new knowledge and skills. This aid is slowly tapered off as the child becomes more versed in the particular skill [1].

Relevance to Childhood Development

The true impact of Vygotsky's Cognitive Development Theory was not realized during Lev Vygotsky's lifetime. However, this theory of cognitive development greatly influenced the understanding of child development. The primary concepts associated with this theory have engendered inherent changes in the way in which Western educational institutions approach learning. Specifically, many educational systems now integrate the concept of Zone of Proximal Development into a foundational framework. As such, practices such as scaffolding, in which a child's learning is aided by the assistance of teachers, has become an integral part of education [2, 3]. In addition, Vygotsky's theory of cognitive development provided an alternate way to view quantifiable concepts, such as intelligence.

Washburn, Margaret Floy

Kelli Vaughn-Blount
York University, Toronto, Canada

Life Dates

1871–1939

Educational Information

Washburn was born in Harlem, New York in 1871 and graduated from high school at the age of 15. In 1886, Washburn entered Vassar at the age of 16 with the intent to study chemistry and French. By the time Margaret Washburn graduated in 1891 her interests had grown to include both psychology and philosophy. Washburn pursued her graduate studies in experimental psychology with minors in philosophy and ethics at Cornell University as the first graduate student of E.B. Titchener, only 4 years her senior. Cornell was her second choice, as she had originally spent a year at Columbia University under James McKeen Cattell, who had recently established a psychology laboratory. However, Columbia's androcentric policies, like many at the time, would not recognize women as students (although Dr. Cattell agreed to allow her to sit in on his classes and to work in the laboratory). Cornell offered the opportunity for Washburn to receive an official degree unlike her contemporaries (see Christine Ladd-Franklin, Mary Whiton Calkins, and Lillien Jane Martin) at other U.S. and German Universities. In 1894, Margaret Washburn became the first woman to receive a university recognized Ph.D. in psychology and one of the first elected to membership in the newly formed American Psychological Association (APA). Her mentor–mentee relationship with Titchener deteriorated and finally ended as Washburn began to move away from Titchener's school of structuralism. In a 1927 letter to Christine Ladd-Franklin, Washburn stated her feelings towards her former advisor as someone that she felt less close to than any other human being in the world and whom she had not spoken to in over 20 years.

Accomplishments

Although living in a society that disregarded women's professional capabilities, Washburn was free from many gender restrictions and her obstacles were alleviated in part due to her social circumstances and personal choices, in comparison to other female psychologists (e.g., Margaret Morse Nice, Millicent Shinn). In addition to familial encouragement and economic support (a family trust), a fundamental contributor to her success was her maintenance of early contacts that she made while learning from and working with significant contributors in the field (such as Cattell) as well as professional relationships with leaders of systems and organizations (e.g., Robert M. Yerkes and Cornell University), regardless of their conceptual ideas. These characteristics, along with her active participation in specialized organizations and many editorial responsibilities, contributed to her full participation in the psychological sciences. That is not to say that Washburn had an easy time of it. Before proving herself to be an extensively capable researcher in the field, she faced constant rejections in the social system. She was aware of the social stigma of being a female professional, especially one who consciously chose to pursue a career without marriage. Marriage was not an asset for most professionally ambitious early women psychologists. In fact, female psychologists who chose to marry while employed often found themselves either unemployable, relegated to part time, or on the losing end of resource acquisitions. At times frustrated, Washburn nevertheless was forthright in defending herself and her work and was able to achieve prestige as a woman at a woman's college. Analogous to Calkins' position at Wellesley, women with PhDs were typically limited to hold positions at women's colleges or find jobs in applied settings outside of universities, as most educational institutions were unwilling to

Sam Goldstein & Jack A. Naglieri (eds.), *Encyclopedia of Child Behavior and Development*, DOI 10.1007/978-0-387-79061-9,

hire women as faculty. Even professional organizations such as the APA suppressed women professionals as women did not generally occupy top-level positions in the APA "in proportion to their numbers and qualifications" [9]. Washburn would be fortunate to see the first two female APA presidents during her lifetime; the first being Mary Whiton Calkins, 1905, and the second herself in 1921. It would be 51 years until APA would see its next female president, Anne Anastasi, in 1972. A similar occurrence was seen following Washburn's election to Titchener's Experimentalists Society. Washburn and June Etta Downey were the first female psychologists elected to the society in 1929; the next female member to be elected was Eleanor Gibson in 1958. She was also the first woman psychologist (and second female) elected to the National Academy of Sciences in 1932.

Washburn's research covered many areas but she is primarily known for her work in animal psychology (i.e., comparative) and mental motor processes (affective). Margaret Washburn's doctoral dissertation on the effect of visual imagery on judgments of tactual distance and direction [15] was published in Wilhelm Wundt's journal *Philosophische Studien*. This was a rare honor and her study became the first foreign study to appear in this European journal [10]. She had short term appointments elsewhere (Cornell, Cincinnati) but in 1903 Washburn became an Associate Professor of Philosophy at Vassar College where she would remain for the next 36 years. Under her direction, a department of psychology and active experimental psychology program were established within 5 years. Equipped with her own laboratory, Washburn pursued her many research interests (including, but not limited to, emotion, memory, and animal psychology). Due to the nature of female colleges of the period, Washburn's department would never include graduate training during her lifetime. Even though the women of her department would go on to publish 66 articles under her guidance, the fact that they would have gone on to study under others for graduate training means that her legacy would be diminished. In early psychology a scientific legacy was normally established through students who went on to be professionally successful and included their mentor in their academic legacy. Because Washburn's students would have trained elsewhere they would have counted their graduate mentors in their primary academic legacy and would most likely have excluded Washburn's influence from their historical records. Dallenbach (1940) states that Dr. Washburn's students went on to study at such institutions as Columbia, Cornell, Harvard, Ohio, Yale, and Michigan.

Margaret Washburn also held a prominent role in the history of psychological publishing. Her most prominent and lasting was that of editor for the *American Journal of Psychology* from 1903 to 1925. In addition, Washburn served in various editorial capacities for *Psychological Bulletin*, *Journal of Animal Behavior*, *Psychological Review*, and the *Journal of Comparative Psychology*.

Washburn was one of several influential women included in the first edition of the *American Men of Science*, which was published in 1906 by Dr. James McKeen Cattell. This project was a comprehensive directory of individuals in North America who had completed work that advanced the natural and exact sciences. Washburn's inclusion, along with other notable women, demonstrated the impact that women psychologists had on the field, despite the gender bias present in the professional and academic realms at the time.

Contributions

Washburn's love of animals inspired her lifelong foray into animal psychology. The former when combined with a growing interest in the study of consciousness resulted in the publication of *The Animal Mind* published in English in 1908 and in Japanese in 1918. A precursor to behaviorism, this publication was the first textbook in animal psychology to present the results of previous studies in a logical and coherent manner; although there had been earlier texts on animal intelligence by others such as George J. Romanes and Edward L. Thorndike. It was and is accepted as a classic and became the required textbook for certain courses at a number of universities such as Harvard and Berkeley. The text went out of favor only with the mainstream adoption of behaviorism. This was due in part to Washburn's refusal to remove the text's inclusion of mental phenomena/consciousness components. She would publish the fourth and final edition of *The Animal Mind* in 1936. The theories of consciousness had quickly fallen out of favor in the 1920s and 1930s.

In spite of Cattell's early functionalist teachings, Washburn accepted and maintained Titchener's structural approach to psychology throughout the 1890s. By 1903 however, her growing reservations about several principles of structuralism led her to develop her motor theory of consciousness, which emphasized the importance of motor processes on conscious processes. She presented and developed this theory through the publication of her second book *Movement and Mental Imagery* in 1916. This evolution of Margaret Washburn's motor process theory is best reflected in modern theoretical

constructions of behavior as part of cognition better known as the dynamic systems approach. Margaret Washburn continues to be the most frequently cited of the early female psychologists.

Washburn suffered a stroke in 1937, which led to her eventual death in 1939.

Watson, John Broadus

Steuart T. Watson, Amber L. Kokol
Miami University (OH), Oxford, OH, USA

Life Dates

1878–1958

Introduction

John B. Watson is best known as the founder of behaviorism. He is also known for his role in initiating moving the field of psychology from a philosophical-based, mentalistic profession to a scientific, research-based profession in the early 1900s. Labeled as a radical by some of his colleagues and embraced by others, Watson enjoyed a tumultuous academic and personal life until his departure from Johns Hopkins University [1]. After leaving academia, he experienced great success in the advertising industry, rising to Vice-President first at the J. Walter Thompson Agency and then at the William Esty Agency. He remained in advertising from 1920 until his retirement in 1945. Insight into Watson's life and resolution of conflicting information is sometimes difficult as he burned all of his personal papers, correspondence, and manuscripts just prior to his death.

Educational Information

Watson began attending Furman University in 1894 at age 16 and graduated with a Master's degree in psychology in 1899. He went on to attend the University of Chicago, where he worked with the likes of John Dewey, Jacques Loeb, James Rowland Angell, and Henry Donaldson. While at the University of Chicago, he became interested in an objective, descriptive approach to psychology which was greatly at odds with the traditional mentalist approach en vogue at the time. Watson graduated with a doctorate in psychology in 1903.

Accomplishments

One of Watson's earliest accomplishments occurred in 1913 when he outlined the parameters of his new approach to psychology called "behaviorism." Often referred to as the "Behaviorist Manifesto" the article titled "Psychology as the Behaviorist Views It" noted that the goals of psychology should be prediction and control and that introspection had little relevance for a science of behavior. In 1914, Watson published a textbook, *Behavior: An Introduction to Comparative Psychology.* He hoped that

the textbook would introduce behavioral methodology to a wide audience and actually addressed a number of socially important topics of the era [1, 3].

Watson is most well known for his "Little Albert" experiments in 1920 in which he conditioned a fear response to a white rat in a 9-month-old infant while working with his assistant, Rosalie Rayner, who would later become his wife. In what may be one of Watson's most infamous misattributions, he is often quoted as saying, "Give me a dozen healthy infants, well-formed, and my own specified world to bring them up in and I'll guarantee to take any one at random and train him to become any type of specialist I might select – doctor, lawyer, artist, merchant-chief and, yes, even beggar-man and thief, regardless of his talents, penchants, tendencies, abilities, vocations, and race of his ancestors." Indeed, this is an accurate quote, but this last sentence is often omitted to retain some semblance of valid criticism of Watson's behaviorism: "I am going beyond my facts and I admit it, but so have the advocates of the contrary and they have been doing it for many thousands of years." When looking at the totality of this quote, Watson was merely suggesting that traditional psychology was, and had been, going far beyond its data in its description of the human experience and that psychology needed to pursue answers to its questions using the scientific method [2].

Contributions

After getting his doctoral degree in 1903, Watson went on to work at Johns Hopkins University as a professor and researcher. Along with Robert Yerkes, they founded the *Journal of Animal Behavior* in 1910 in an attempt to connect psychology to the scientific fields of physiology and anatomy. Watson and Yerkes can be credited with laying the foundation of the behavioral approach to psychology and significantly impacting the current practice of psychology and psychological research, particularly with luminaries such as B. F. Skinner [2]. Watson published a textbook titled *Psychology from the Standpoint of a Behaviorist* in 1919 that elaborated on many themes from his "manifesto" [3]. Watson achieved monumental success before leaving Hopkins in 1920 in the midst of considerable controversy because of his affair with his graduate student Rayner. Watson, in his naivete and perhaps arrogance, thought himself and his actions were impervious to scrutiny because of the international status he had achieved by that time. During his advertising career, Watson continued to use his knowledge of psychology and behavioral principles to affect human behavior for a different purpose (i.e., selling and promoting products).

Wechsler Intelligence Scale for Children, Fourth Edition

Renee Grizzle
Ball State University, Muncie, IN, USA

Synonyms

WISC-IV

Definition

The *Wechsler Intelligence Scale for Children – Fourth Edition* (WISC-IV; [17]) is the revision of the *Wechsler Intelligence Scale for Children – Third Edition* (WISC-III; [13]). Although David Wechsler died in 1981 and the Psychological Corporation currently prepares revisions of the Wechsler assessments, David Wechsler is cited as the author of the WISC-IV [2]. The WISC-IV is an individually administered assessment containing fifteen subtests that provide a comprehensive assessment of intellectual ability. The WISC-IV can be used with individuals aged 6–16 and contains normative tables for this age group [1].

Description

The fifteen subtests of the WISC-IV are divided into ten core subtests and five supplemental subtests. The core

subtests are: Similarities, Vocabulary, Comprehension, Block Design, Picture Concepts, Matrix Reasoning, Digit Span, Letter-Number Sequencing, Coding, and Symbol Search. The supplemental subtests are: Information, Word Reasoning, Picture Completion, Arithmetic, and Cancelation. The core and supplemental subtests comprise four broad areas of intellectual functioning called Composites or Indexes. The WISC-IV Composites are: Verbal Comprehension, Perceptual Reasoning, Working Memory, and Processing Speed. Scores from the Composites constitute the WISC-IV Full Scale Intellectual Quotient (FSIQ) which ranges from 40 (Exceptionally Low) to 160 (Exceptionally Superior) and is a global assessment of cognitive functioning [2]. The WISC-IV allows for intra-individual (ipsative) analysis of strengths and weaknesses in broad cognitive ability domains and in subtests. Although the Wechsler scales have been criticized for failing to identify a theory from which assessment constructs and scores can be interpreted, the WISC-IV remains one of the most widely used intelligence assessments worldwide [1].

The WISC-IV normative data were collected from a geographically diverse and nationally representative sample of 2,200 children. Samples were divided into eleven age groups; 200 participants were placed in groups representing single age groups from 6 years of age through 16 years of age. WISC-IV subtests yield raw scores which can be converted to age-equivalent scaled or composite scores. Percentile ranks and confidence intervals are also available for additional interpretation of test performance [19].

The Wechsler scales were created by clinical psychologist David Wechsler. Wechsler's training under Charles Spearman and Karl Pearson, as well as his experience with Army Alpha/Beta testing, most likely influenced the creation of his own battery of tests. In 1939, he created an adult test named the *Wechsler-Bellevue Intelligence Scale*, named for the Bellevue Psychiatric Hospital in which he would be employed as chief psychologist for over 30 years. A second form of the Wechsler-Bellevue Intelligence Scale was created in 1946. Eventually, the second form of the Wechsler-Bellevue Intelligence Scale would be modified to become the *Wechsler Intelligence Scale for Children* (WISC) in 1949. An assessment for young children was made possible with the creation of the *Wechsler Preschool and Primary Scale of Intelligence* (WPPSI) in 1967 [1]. The *Wechsler Intelligence Scale for Children-Revised* (WISC-R), the next revision of the WISC, was released in 1974 [9].

The Psychological Corporation continues to revise the Wechsler scales in the effort to improve the theoretical foundations, psychometric properties, developmental appropriateness, and user friendliness of the assessments [2]. Since 1974, the WISC has undergone two more revisions: the WISC-III in 1991 and the WISC-IV in 2003. In an effort to keep up with current standards of psychological assessment, the WISC-IV represents the most amount of change in a revision of all Wechsler assessments [1].

Internal consistency reliability for WISC-IV was calculated using a split-half analysis with normative sample data. Reliability coefficients for the composite scales ranged from 0.88 to 0.97 and additional internal consistency analysis suggests the WISC-IV is a reliable assessment for children with or without clinical diagnoses. Test-retest data for five age groups provide evidence of WISC-IV score stability over time. The *WISC-IV Technical and Interpretive Manual* [19] provides a discussion of internal structural evidence for the assessment that includes intercorrelational evidence as well as a cross-validation analysis. In addition, the WISC-IV has been found to correlate with other measures including the *Children's Memory Scale* (CMS), *Gifted Rating Scale-School Form* (GRS-S), *Adaptive Behavior Assessment System – Second Edition* (ABAS-II), and several other Wechsler scales [19].

The technical manual of the WISC-IV describes a broad range of uses for the test. In addition, test score results for children with Autistic Disorder, Asperger's Disorder, Expressive Language Disorder, Attention-Deficit/Hyperactivity Disorder, learning disabilities, and many other disorders are available to provide information that can be of help to the clinician [1]. The WISC-IV can be used in conjunction with the *Wechsler Individual Achievement Test – Second Edition* (WIAT-II; [20]) for normative and ipsative analyses due to the co-norming of the assessments. The use of these two assessments in conjunction provides information on specific cognitive deficits that may impact academic achievement as well as a prediction of future academic achievement [18]. Flanagan and Kaufman [1] report significant strengths of the WISC-IV that include strengthened factor structure, straightforward scoring criteria, and the inclusion of process scores and clinical validity data.

Relevance to Childhood Development

The WISC-IV is a standardized assessment that is widely used to assess the cognitive ability of children and adolescents. This assessment can provide valuable information as to the verbal and nonverbal cognitive abilities of the individual. The information provided by this assessment can provide a rationale or guideline for educational, treatment, or program planning tailored to the specific needs of the individual with the ultimate goal of facilitating appropriate development.

Wechsler Nonverbal Scale of Ability

The Wechsler Nonverbal Scale of Ability (WNV; Wechsler & Naglieri, 2005) is an individually administered test for assessing the general ability for individuals 4 through 21 years of age. The WNV was developed to measure general ability using questions that do not contain verbal content and to do so using a number of different types of subtests. Pictorial directions were developed to reduce or eliminate the need for verbal instructions to communicate the demands of the subtests, and no question requires a verbal response. These characteristics make the a test useful with populations that are diverse in terms of linguistic, educational, cultural, socioeconomic backgrounds, and handicapping conditions such as language disabilities and hearing loss. The WNV was designed to be useful across cultural and linguistic groups as well as national boundaries.

The WNV measures general ability with only so called "nonverbal" tasks in contrast to other versions of the Wechsler Scales that measure general ability with a group of verbal, arithmetic, and nonverbal subtests. The advantage of using nonverbal test questions to measure general ability is that the need for receptive language skills is minimized and the influence of expressive language and mathematic skills on the score is eliminated. Despite the fact that the WNV subtests are all nonverbal, they are diverse in their specific requirements. For example, some of the WNV subtests require visual-spatial problem solving, others demand recall of the sequence of information, and others demand paper and pencil skills. This variety of requirements in the subtests makes the WNV different from tests that use one type of items, such as the Naglieri Nonverbal Ability Test – Individual (NNAT-I; Naglieri 2003). The WNV measures general ability using subtests that vary in their specific requirements, but the NNAT-I uses one type of item format – the standard progressive matrix. The goal of both these tests is to measure the general ability for a wide variety of individuals using nonverbal test administration procedures and nonverbal test content. Despite the variability of subtest content and task demands, the subtests retain the essential goal of measuring *general ability nonverbally.*

Wechsler, David

Russell N. Carney
Missouri State University, Springfield, MO, USA

Life Dates

1896–1981

Educational Information

David Wechsler received his A.B. degree from City University of New York in 1916, and his M.A. degree from Columbia University in 1917 (where he was influenced by Robert S. Woodworth, Edward L. Thorndike, James McKeen Cattell, and Thomas Hunt Morgan). A few months later, he joined the army and worked as a psychologist at Camp Logan in Texas. In this capacity, he was involved with the administration of the newly developed Army Alpha and Beta tests (group intelligence tests for literate and illiterate recruits, respectively), and became acquainted with the tests' developer, Robert M. Yerkes. He also administered Louis Terman's 1916 version of the "Stanford-Binet" intelligence test to recruits who failed the group tests. In 1918, an assignment by the Army gave him the opportunity to study with famed measurement theorists Karl Pearson (of Pearson's product moment correlation coefficient or *r*) and Charles Spearman (of Spearman's general intelligence or *g*) at the University of London [5]. Discharged from the army in 1919, Wechsler accepted a fellowship at the University of Paris where he conducted experimental research. In 1922, he returned to New York City where he worked as a clinical psychologist at the Bureau of Child Guidance while completing his Ph.D. in experimental psychology at Columbia University (1925). It is worth noting that Wechsler's training as an experimental psychologist gave him a unique perspective as a clinician and test developer [4].

Accomplishments

Wechsler worked in private practice in clinical psychology from 1925 until 1932, at which point he became the chief psychologist in the Psychiatric Division of Bellevue Hospital – a position he would hold until 1967. In his work at Bellevue Hospital, his patients included adults from diverse socioeconomic and cultural backgrounds.

In 1935, Wechsler published a book that he later considered to be his major work: *The Range of Human Capacities* [7]. A central conclusion was that the range of human abilities (including intelligence) was fairly small. In 1939, he published the first edition of his classic *Measurement of Adult Intelligence* [8]. That same year, building on his experimental training and his rich experiences in both testing and clinical practice, Wechsler published his own instrument, the Wechsler-Bellevue Scale of Intelligence [2]. The test was published by Cattell's newly founded Psychological Corporation (which is now a subdivision of Pearson). The predominant IQ test of the time, Louis Terman's Stanford-Binet Intelligence Test (1916, 1937), had a number of limitations. The Stanford-Binet was primarily designed for children, used ratio IQ (mental age over chronological age, times 100), and yielded only one score. In contrast, Wechsler's new test was designed for adults, used deviation IQ (which worked with adults – ratio IQ did not), and yielded several scores: a full-scale IQ score, verbal and performance IQ scores, and scores resulting from individual subtests (i.e., information, comprehension, memory span, similarities, arithmetical reasoning, picture arrangement, picture completion, block design, object assembly, digit symbol, and as an alternate, vocabulary). Each subtest was designed to contribute equally to the overall score. The approach Wechsler took was prescient, in that through factor analysis, modern intelligence tests have a similar breakdown of scores: an overall IQ (reflecting *g*), several composite scores (each based on two or more subtests), and then a number of scores based on individual subtests.

Psychologists became acquainted with the Wechsler-Bellevue as a result of their exposure to it during World War II, and this led to a great demand for the test after the war. The test was renamed the Wechsler Adult Intelligence Scale (WAIS) when it was revised in 1955, and the most recent edition of this popular test is the WAIS-IV (2008). Wechsler viewed his test as a clinical instrument and believed that, through careful behavioral observation, it provided more information than just a rigid interpretation of the various numerical scores. The Wechsler-Bellevue served as a template for the development of a similar version designed for children, the Wechsler Intelligence Scale for Children (WISC, 1949), the most recent of which is the WISC-IV (2003). Additional tests designed by Wechsler include the Wechsler Memory Scale (WMS, 1945) and the Wechsler Preschool and Primary Scale of Intelligence (WPPSI, 1967), both of which continue to be used in more recent revisions, the WMS-III (1997) and the WPPSI-III (2002). Of these tests, the WAIS and the WISC in particular became the most widely used intelligence tests for their respective age groups, and they continue to hold these positions today.

Wechsler came to believe that intelligence could be operationally defined as "the aggregate or global capacity to act purposefully, to think rationally, and to deal effectively with his environment" [9]. He viewed intelligence not as a cause, but as an effect. Further, as a clinician, he emphasized the role of personality in the development of intelligence, and encouraged pattern or profile interpretation of individual and composite scores [3, 6].

Contribution

The year 1896 was a notable one for students of child behavior and development. That year the correlation

coefficient (r) was devised by Karl Pearson, and theorists Jean Piaget and Lev Vygotsky were born. So, too, was born an important theorist, clinician, and developer of a series of cognitive tests: David Wechsler.

Wechsler's long career produced theoretical publications and products that influenced generations of psychologists up to and including those of the 21st century. His initial, 1939 intelligence test laid the groundwork for a series of well-received tests for adults (WAIS-IV, 2008), children (WISC-IV, 2003), and preschoolers (WPPSI-III, 2002). Alongside the Stanford-Binet Intelligence Test, Wechsler's IQ tests became the standards in their respective fields. Indeed, newly-developed tests are routinely correlated with Wechsler tests in order to provide evidence for construct validity (i.e., that they, too, are measuring the construct of "intelligence").

Of particular relevance to this volume, the Wechsler Intelligence Scale for Children continues to be used extensively to identify children with special needs (e.g., mental retardation, learning disabilities) to enable them to receive special education services. The test has also been used to identify high-functioning children for participation in gifted programs. Further, as suggested by Wechsler, the test has been used to aid in clinical diagnoses.

Wechsler's influence is ongoing, as tests in the Wechsler tradition continue to be developed, such as the Wechsler Individual Achievement Test (1992; now the WIAT-II, 2001), the Wechsler Abbreviated Scale of Intelligence (WASI, 1999) and the Wechsler Nonverbal Scale of Ability (WNV; Naglieri & Wechsler, 2006) [1]. Modern intelligence theorists and test developers owe much to the pioneering work of psychologist David Wechsler.

Weight

Shannon S. Rich, Sonia LeClere
Texas Woman's University, Denton, TX, USA

Synonyms

Body mass; Body weight; Obesity; Overweight

Definition

The vertical force exerted by body mass due to gravity.

Description

Body weight or body mass is considered a marker of risk for disease and overall health. In recent years, there has been a dramatic increase in overweight/obesity in both children and adults [19, 20]. The number of overweight children in the United States is four times greater than it was in 1965 [13], but this increase has not been limited to the United States. This worldwide increase in overweight children and adults has led the World Health Organization (WHO) to assert that obesity is one of the most critical health problems facing the United States and the world [27].

Assessment. In general, body weight or body mass is assessed through the calculation of body mass index (BMI). BMI is calculated as weight in kilograms divided by height in square meters. Center for Disease Control (CDC) BMI-for-age growth charts are often utilized in the classification of obesity [16]. In children, BMI between the eighty-fifth and ninety-fourth percentiles has been used to define at-risk for overweight and $\geq$95th percentile as overweight in children [12]. In children, it is critical to utilize BMI charts that are age and gender specific as BMI trajectories vary greatly across these domains.

In adults, the WHO has recommended a classification system in which a BMI between 18.5 and 24.9 is classified as normal weight, a BMI between 25.0 and 29.9 is classified as overweight and a BMI over 30 is classified as obese [27]. While BMI is still the primary assessment of body weight, waist circumference is increasingly being utilized, particularly in adults [27]. Waist circumference is measured midway between the lower costal margin and the iliac crest. The WHO has identified two classifications for waist circumference: risk for obesity – associated metabolic complications increased and risk for obesity – associated metabolic complications substantially increased. Men with waist circumferences between 94 cm and 101.5 cm as well as women with waist circumferences between 80 and 87.5 cm are classified as at risk for obesity – associated

metabolic complications increased. Men with waist circumferences greater than 102 cm and women with waist circumferences greater than 88 cm are classified as at risk for obesity – associated metabolic complications substantially increased.

Etiology. The increase in obesity globally is argued to be driven primarily by changes in environment as opposed to genetics [27]. However, genetics may determine whether or not an individual becomes obese within a particular environment. Researchers continue to search for genes that cause obesity as well as genes that predispose one to obesity [2].

Overweight and obesity are ultimately the result of an imbalance of energy intake and energy expenditure. Multiple factors have been identified as contributing to the increase in childhood obesity. The development of energy-saving devices and increase in the marketing and availability of energy-dense foods has created a toxic environment in the United States and many other industrialized countries [4]. A 15% per capita food increase has occurred since 1970 but children's exercise and physical activity have decreased [13]. Children are targeted by food companies advertising sugared cereal, candy, fast food, and soft drinks. Along with this increased energy intake, children are spending more hours a day in front of a television, computer, or gaming system [6]. Television watching rates and fast food consumption rates have increased among children from all ethnic groups, but rates have increased disproportionately in ethnic minority children [6].

Beyond the societal level, families play an important role in food consumption and physical activity patterns in children. Parents role model dietary behaviors and teach their children about food [1, 14]. Parent's child feeding practices such as pressuring a child to "clean their plate" or restricting less healthy foods have been associated with failure of the child to learn to self-regulate food intake and increased body weight [9, 15]. Parents also role model physical activity patterns [17] and encourage or discourage physical activity [21]. When both parents are active, a child is almost six times more likely to be active than if neither parent is active [17]. A family's access to a safe environment to engage in physical activity as well as financial and time resources may also impact parent feeding practices, dietary intake and physical activity.

Treatment/prevention. The alarming increase in childhood obesity has led to the development of many prevention and intervention programs [10]. Interventions with schools and caregivers have been identified as critical to change the behaviors of young children [8]. As children in the United States consume approximately one-third of their energy intake at school, many programs have sought to change school lunch services and limit access to soft drinks and candy at schools [26]. Increased physical education programs have also been the target of intervention programs as children in the United States acquire between 20 and 40% of their total physical activity while at school and many children only engage in physical activity at school [22]. While family and school interventions have been implemented, no single treatment program has been identified as successfully ameliorating childhood obesity.

Relevance to Childhood Development

While researchers were initially concerned that increased obesity in childhood would lead to health problems in adulthood, it is now evident that there are significant health problems associated with obesity in children during their childhood years [7, 18]. Beyond numerous physical health risks, children who are overweight or obese face serious psychosocial challenges. Overweight and obese children encounter early and frequent discrimination. Body size stigmatization has been shown to begin as early as 3 years old and continue throughout childhood [5, 25]. This rejection and harassment from peers is associated with poor self esteem, depression, withdrawal, decreased physical activity, and increased emotional eating [3, 11, 23, 24]. These psychosocial consequences create a vicious cycle in which overweight and obese children avoid active play situations out of a fear of embarrassment [11]. Therefore, the child avoids the activity that will allow him or her to reduce sedentary activity and increase caloric expenditure. The childhood obesity epidemic will remain the subject of continued investigation and intervention due to its significant impact on physical, social, and psychological development.

Definition

Werner syndrome is named after Otto Werner, a German physician (1879–1936), and is an extremely rare, autosomal (An autosome is a non-sex chromosome. It is an ordinarily paired type of chromosome that is the same in both sexes of a species.) recessive (A recessive gene is one that is not expressed unless there are two of them, one from each parent.), systemic disease associated with the dramatic, rapid appearance of aging in children.

Description

Epidemiology

Werner syndrome is extremely rare with only approximately 1,300 cases reported worldwide since 1916, with 1,000 of those coming from Japan [7]. The syndrome is estimated to affect 1 in 200,000 individuals in the United States in contrast with 1 in 20,000–40,000 individuals in Japan. In Japan, the frequency of heterozygote carriers of the condition within the general population is estimated as 1 in 180 [11].

Etiology

Werner syndrome is inherited in an autosomal recessive pattern, which means two copies of the gene in each cell are altered. Most often, the parents of an individual with an autosomal recessive disorder are carriers of one copy of the altered gene but do not show signs and symptoms of the disorder [9, 10].

Researchers have found that mutations in the WRN gene found on chromosome 8 are the cause of Werner syndrome [5]. The WRN gene provides instructions for producing the Werner protein, which plays a critical role in repairing damaged DNA. This is thought to perform several vital tasks in the cell, including the maintenance of the structure and integrity of a person's DNA. It also assists in making copies of DNA (replication) in preparation for cell division and transferring the information in genes to the cell machinery that makes proteins (transcription (Transcription is the process by which genetic information is copied from DNA to RNA, resulting in a specific protein formation.)).

More than 60 mutations in the WRN gene are known to cause Werner syndrome. Most of these mutations result in an abnormally short, non-functional Werner protein [2, 6]. Evidence also suggests that this shortened protein is not transported into the cell's nucleus where it normally interacts with DNA, leading to a loss of Werner protein function. Furthermore, the shortened protein is broken down more quickly than the normal Werner protein, reducing the amount of this protein in the cell. Without normal Werner protein in the nucleus, DNA replication, repair, and transcription are disrupted and cause health problems related to this condition [3]. Researchers are still determining how mutations in the WRN gene lead to the signs and symptoms of Werner syndrome.

Features

Individuals with Werner syndrome typically grow and develop normally until they reach puberty. The age of onset of this syndrome is variable and might occur in individuals in their mid teens or it may be delayed until an individual is as old as 30 years. The average age of patients at the time of diagnosis is 37 years. Additionally, no racial predilection has been reported and both sexes are affected equally.

The hallmark of this syndrome is a striking disproportion between the patient's real age and the patient's appearance. However, an early sign of Werner syndrome is the lack of a teenage growth spurt, which results in short stature of usually less than 1.60 m. Other signs and symptoms that appear when affected individuals are in their twenties or thirties include loss and graying of hair, hoarseness, thickening and wrinkling of the skin, muscle atrophy, a high-pitched voice, and cloudy lenses (cataracts) in both eyes [4, 8]. Overall, people affected by Werner syndrome have thin arms and legs and a thick trunk. As the syndrome progresses, affected people may experience additional skin problems, Type 2 diabetes, diminished fertility, arteriosclerosis (Arteriosclerosis is a thickening, hardening, and loss of elasticity of the arterial walls resulting in impaired blood circulation.), osteoporosis (Osteoporosis occurs when bones loose an excessive amount of their protein and mineral content, particularly calcium. Over time, bone mass, and therefore bone strength, is decreased. As a result, bones become fragile and break easily.) and some types of cancer [1]. Affected individuals typically have a characteristic facial appearance described as "bird-like" by the time they reach their thirties. This is said to be caused by a pinched nose and sunken cheeks because of fat loss. People affected by Werner syndrome usually live into their late forties or early fifties.

Treatment

Treatment for people with Werner syndrome centers on symptomatic management of the related diseases. Cataracts are removed, surgical intervention and hyperbaric oxygen therapy may be of use in the treatment of refractory skin ulcers, and heart disease, osteoporosis, arteriosclerosis, diabetes and cancer are treated. However there is no known cure for the condition. Early recognition of the syndrome is helpful, as screening for malignancies and associated diseases for the relatives of affected individuals

may be performed on a regular basis [7]. Genetic counseling is also recommended for the individual carrier and the relatives of the affected individual in order for the carrier status of all affected individuals to be established.

Werners Syndrome

►Werner Syndrome

Wernicke, Carl

Mary Joann Lang, David Morrison
Azusa Pacific University, Azusa, CA, USA

Life Dates

1848–1905

Educational Information

Carl Wernicke was born on May 15, 1848, in Upper Silesia. His secondary education was received while at the gymnasium in Oppeln. With his mother's determination, he got into Breslau University to study medicine. He remained at Breslau University for 6 months after graduation as an assistant in the Ophthalmology Department. He served as an army surgeon in the France-Prussian War of 1870, and then returned to the University as an assistant in the Psychiatry Department. Wernicke's mentor, Henrich Neumann, sent him to study neuroanatomy for 6 months in Vienna under Theodor Meynert. In 1874, while in Vienna, Wernicke published his famous work, *Der Aphasische Symptomencomplex* (The Aphasic Syndrome): *A Psychological Study on an Anatomical Basis* [4].

Accomplishments

Wernicke was appointed to assistant in the Berlin Clinic to work under Westphal in 1875. He remained there until 1878, when he began practicing medicine and neurology in his private practice producing many publications until 1881. One of the famous publications written during this time was his authoritative text, *Lehrbuch der Gehirnkrankheiten (1881)* that focused on the classification of brain diseases and classifying the localization of brain lesions.

In 1885, Wernicke succeeded Neumann's position at the Allerheililgen Hospital and also became the chair of the Department of Neurology and Psychiatry at Breslau University Hospital in 1890. For 20 years Wernicke had great success, as the Breslau Clinic became a major center for neuropsychological investigations. Many famous scientists, such as Hugo Liepmann and Karl Kleist, studied and developed their basic concepts while at the Breslau Clinic. Wernicke's relationship with the University soured and he accepted a position as head of the Klinik fur Psychiatrie und Neurology in Halle in 1904. Unfortunately, Wernicke's life was cut short in 1905, when he was tragically killed in a car accident. His contributions to the field of neurology and psychiatry live on as neuroscientists continue to study aphasia and related areas of interest [4].

Contributions

While still a young physician-in-training, Wernicke saw many patients who had difficulty comprehending language. While the patients had fluent speech, their speech had little if any meaning. They had difficulty finding the right words to say and, consequently, produced many neologisms (made-up words only understood by the speaker). Wernicke had the opportunity to perform an autopsy on one of the patients. As noted in Saffran [4], the results of the autopsy indicated a stroke (cerebral infarct) involving the middle third of the posterior superior temporal gyrus of the left hemisphere that further extended into the middle temporal gyrus. This area lies extremely near to the primary auditory cortex, which led Wernicke to suggest the region is apart of the auditory association cortex. In addition to the speech area in the frontal lobe, as discovered earlier by Pierre Paul Broca, Wernicke concluded that the region he examined must be another language center in the left hemisphere [2].

Wernicke assumed that the sensory and motor centers for language must be connected if a child has to learn the sounds of their primary language before they have the ability to produce them. He predicted that if the connection between the sensory and motor centers was disrupted, then production would be impaired while comprehension would be preserved because the superior temporal area would not be disrupted [1].

Wernicke's aphasiac syndrome is still very important to studies of the brain being done today. Individuals with this identified syndrome experience difficulty with word comprehension and speech production. This syndrome can have a huge, negative impact on communication, often without anyone knowing something is wrong [3]. Recent studies have supported that the superior temporal lobe is involved in how one perceives and produces spoken language. While questions still remain on where the exact mechanisms are located that support the processes defined by Wernicke, he opened the door and made it intriguing to study the superior temporal lobe of the brain [2].

Wernicke's Aphasia

►Childhood Aphasia

Wernicke's Area

Robert Walrath
Rivier College, Nashua, NH, USA

Synonyms

Planum temporal

Definition

Area of the brain located in the middle to posterior (to the lateral fissure) portion of the superior temporal gyrus (temporal lobe) of the left hemisphere.

Description

Wernicke's area is primary to language comprehension of individual words. Damage to the area results in *Wernicke's Aphasia*, which is characterized by fluent and meaningless speech and poor speech comprehension.

Wertham, Frederic

Daniel Patanella[1], Chandra Ebanks[2]
[1]New York City Department of Education, New York, NY, USA
[2]Florida International University, Miami, FL, USA

Life Dates

1895–1981

This work represents the scholarship of the author and does not imply any official position of the New York City Department of Education.

Educational Information

Wertham earned his M.D. from the University of Wurzburg in 1921.

Accomplishments

Wertham taught at John Hopkins University and practiced at the Phipps Psychiatric Clinic prior to moving to New York City. Originally, his expertise lay in neuroanatomy, but after immigrating to the United States in the 1920s he gradually shifted his focus to applied social problems such as racism and the lack of adequate mental health services for the poor. Wertham's testimony figured prominently in the landmark *Brown v. Board of Education of Topeka* desegregation case, and in Harlem, Wertham established the Lafargue Clinic, a mental health facility that charged minimum fees. He was also the only psychiatrist appointed as a consultant to Senator Kefauver's 1950 Senate Subcommittee for the Study of Organized Crime.

In the late 1940s, Wertham began to write about comic books [8]. In the United States and elsewhere, many parents, teachers, clergy, and politicians were uncomfortable with the pulp adventures their children were reading and Wertham added his voice to theirs. To Wertham, comic books were not merely morally objectionable; they were an increasingly important causal factor for sexual deviance and juvenile delinquency, and Wertham sought to warn the American public through his largely anecdotal writings. The conclusions Wertham drew were based upon his experience as an expert witness in court cases, as well as his extensive psychiatric work with children, particularly at the Lafargue Clinic. Wertham's [5] popular book *Seduction of the Innocent* (1954), in tandem with his key role in the 1954 Senate Subcommittee on Juvenile Delinquency, best encapsulates his legacy, as these contributions led directly to the formation of the Comics Code Authority and the redefinition of comic books in the United States throughout most of the latter twentieth century as being primarily a source of children's entertainment that needed to be closely regulated by its industry. It is important to note that his disdain of experimental psychology, as well as his argumentative and forceful writing style, earned him criticism within the field of social science even during his salad days [4].

Wertham continued to work at the Lefargue clinic and critique objectionable content in children-oriented mass media for the remainder of his career, although with considerably less popular attention [6, 7].

Contributions

Wertham is best-remembered as an exemplar of children's advocacy and as a crusader from the social sciences. To a degree, his concerns with media effects on children's behavior and social learning can be construed as a precursor to Albert Bandura's better-known research. Wertham, however, decried the positivist and empiricist trends within laboratory research such as Bandura's, which also makes him a forerunner of post-modern social scientists like Richard Shweder. Still a controversial figure decades after his death, Wertham was the subject of equivocal reappraisals in the late 1990s in such books as *Seal of Approval* and *Pulp Demons* [1, 2, 3].

White Matter

Anne Fierro Vanderlaan
Saybrook University, Meridian, ID, USA

Synonyms

Axon

Definition

White matter is myelin that is white in color and it is the insulation casing of the nerve fibers [5].

Description

Inside the brain the first layer is gray matter that contains nerve cell bodies. The next layer is a white substance that contains myelinated nerve fibers. This is where communications distribute between the gray matter and white matter throughout the nervous system [1].

The notion is that myelination of axons is important in childhood development of cognitive functions particularly with working memory and reading abilities [4].

In the spinal cord the outer layer is white matter that is made up of bundles ascending and descending myelinated axons. The inner core is gray matter mainly short neural cell and unmyelinated axons [3].

Damage to the white matter by lack of oxygen at birth or transplacental viral infection may cause periventricular leukomalacia and may develop into cerebral palsy depending on where the brain was impacted [2].

Whole Language Approach

Jackie Laney
University of Tennessee, Knoxville, TN, USA

Synonyms

Comprehensible input; Integrated language; Literature based instruction; Natural learning; Problem-based learning; Student-centered instruction holistic learning

Definition

The whole language approach is an instructional philosophy on teaching reading and writing. It is based on three constructivist assumptions: (1) learning cannot be separated from its context, (2) each learner's purpose for learning is integral to what is learned, and (3) knowledge gained by each learner is socially constructed through negotiation, evaluation, or transformation [1].

Description

Instruction in classrooms that follow the whole language approach is planned around thematic units integrating various disciplines. Spelling, reading, writing, speaking, and grammar are integrated into the instruction and are not taught as separate components. The planned literacy events serve functions and are authentic, not skill-based lessons. The activities planned must include the four dimensions of teaching and learning, which are: explicitness, systematicity, mindfulness, and contextualization. Genuine literature is used as opposed to nonsensical, decodable texts. Writing opportunities are genuine as well in that they serve purposes. In addition, the whole language classroom must promote engagement and offer demonstrations of effective reading behavior [1, 2].

History

The whole language approach to literacy learning traces its roots back to the works of Piaget, Chomsky, and Vygotsky. In the 1980s researcher Kenneth Goodman progressed the whole language movement by focusing on four beliefs about learning. First, students are central to learning bringing universal commonalities and differences to the classroom. They take ownership of their learning by setting their

own goals and purposes for reading and writing. Second, teachers do not control learning in the classroom; they guide their students as they construct their own meaning through problem solving. Third, language is key to learning. Language use demonstrates thought symbolically, and it allows students to interact socially. Finally, the whole language approach builds on the belief that we learn by using language as we learn that particular language [1, 3].

Criticism

The whole language approach acknowledges that reading outcomes of learners are created by how learners are taught to read. Proponents of the whole language approach reject the use of decodable, nonsensical texts and the direct instruction of decoding skills and phonics instruction. Many researchers disagree with this top-down approach and endorse direct instruction of discrete skills. The whole language approach is considered by many in the field of literacy research as the antithesis of phonics-based reading instruction [1].

Relevance to Childhood Development

Based on Vygotsky's belief that language is internalized through social interaction, the whole language approach emphasizes the social aspect of learning and meaning construction. In addition, the whole language approach requires language experiences, both oral and written, be genuine by serving purposes for the learners. Whole language classrooms are risk free for students since no one meaning is considered correct. Learner engagement is reinforced as learners bring their own goals and purposes to the classroom [2].

Whorfian Hypothesis

Seongwon Yun, Shelia M. Kennison
Oklahoma State University, Stillwater, OK, USA

Synonyms

Linguistic determinism; Linguistic relativity; Sapir-Whorf hypothesis

Definition

The hypothesis suggests that human thought is influenced by the language one speaks.

Description

The term *Whorfian Hypothesis* takes its name from Benjamin Lee Whorf (1876–1941) who claimed that the language one speaks influences one's thinking [7]. Whorf was an amateur linguist who studied with the anthropologist Edward Sapir in the 1920s and 1930s. The term Sapir-Whorf Hypothesis is also used to refer to their view that language determines thinking. Linguistic determinism and linguistic relativity are also terms referring to the notion that the characteristics of one's language shape one's cognition.

The hypothesis was developed following observations of cross language differences in linguistic structure and speculations about how such differences might impact speakers' thinking. For example, Whorf noted that in the Hopi language, there was little to no grammatical marking for tense. Utterances describing events occurring in the present were similar to utterances describing events occurring in the past and in the future. It was suggested that Hopi speakers think about time differently from speakers of other languages in which tense is a prominent feature of the grammar, such as English where there are suffixes added to verbs to indicate tense.

The processing of color terms has received a great deal of attention in relation to the Whorfian Hypothesis. Languages differ in the number of words referring to color. Berlin and Kay [1] pointed out languages have between 2 and 11 color terms. Across languages, there is a hierarchy of color terms. If a language has only two color terms, they are used to refer to *dark* and *light*. If a language has three color terms, the third color term is always *red*. If a language has four color terms, the fourth color term is *yellow*. Languages with five and six color terms have *blue* and/or *green* [1]. In a well-known test of the Whorfian Hypothesis, Heider and Olivier [3] investigated the color perception of speakers of a language in which there were just two color words. The language was Dani, which is spoken in Indonesia New Guinea. Contrary to the predictions of the Whorfian Hypothesis, the results showed that the recall of color was similar, rather than different, for Dani and English speakers [3]. In 2000, Roberson, Davis, and Davidoff conducted a similar investigation of the color processing of English, Dani, and Berinmo speakers [6]. Berinmo is spoken in Papua New Guinea and has five color terms. The results provided evidence for the influence of language in color cognition.

Over the last four decades, there is growing evidence that differences in number processing may also be linked

to differences in language. For example, Piraha is a language spoken in the Amazon region of Brazil. It has few words to refer to numbers. Studies of Piraha speakers have found that they show poor performance when reasoning about and remembering quantities [2, 5].

Without a doubt, the extent to which language influences thinking remains unclear. Most researchers reject what has come to be known as the strong version of the Whorfian hypothesis, which is the claim that language strongly determines what can be thought or perceived. In accordance with this view, if one's language does not have a word for something, such as a color, one cannot perceive it. However, most researchers are comfortable with what has come to be known as the weak version of the Whorfian Hypothesis, which is the view that one's language influences one's cognitive processes, particularly memory [4].

Wide Range Assessment of Memory and Learning

David Ritchie, Barry Nierenberg
Nova Southeastern University, Fort Lauderdale, FL, USA

Synonyms

WRAML2

Definition

The *Wide Range Assessment of Memory and Learning* – second edition (WRAML2), is an assessment measure of an individual's memory functioning for immediate and delayed memory as well as verbal, visual and global memory deficits.

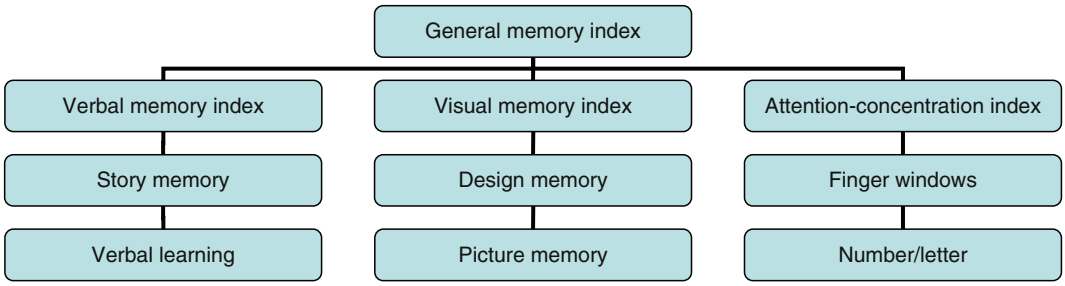
Description

Structure

The WRAML2 was published in 2003 and is an individually administered assessment of memory and learning. This assessment can be administered to individuals from 5 to 90 years of age. It is comprised of six core subtests, seven delay memory tasks, two working memory subtests and four recognition subtests. The sum of scaled scores for the six core subtests combine to form a general memory index. Within the general memory index, there are three sub-indexes: a verbal memory index, a visual memory index and an attention and concentration index. In addition to the six core subtests, the WRAML2 has seven optional subtests which yield scaled scores for assessing working memory, delay recall and recognition (Fig. 1).

The verbal memory index assesses the individual's ability to remember and learn information presented in verbal form. This index is comprised of the story memory and verbal learning subtests. Story Memory asks the individual to listen to two short stories and then orally recall information, assessing recall for meaningful auditory information. The verbal learning subtest asks participants to listen to a list of common single-syllable words and recall as many as they can immediately, across four consecutive trials. This subtest evaluates auditory memory for information that is not presented within a context and assesses the individual's ability to actively learn unrelated verbal information [4].

The visual memory index assesses the individual's ability to remember and learn information presented to them visually. This index is comprised of the design memory and picture memory subtests. Design memory is a subtest that asks the individual to draw, from memory, a geometric design presented to them on a card for five seconds and not allowed to commence drawing until after a ten second delay. This subtest assesses short-term, visual encoding of new and unfamiliar information. Due to the level of motor difficulties experienced by some younger and older individuals, there is a short copy task at the beginning of the subtest to achieve a baseline for differentiating memory deficits from motor deficits. Picture memory is a subtest that asks the individual to compare a stimulus picture with a response picture of a complex scene. The object is to identify as many of the elements that have "been moved, changed or added" from the first scene on the second scene [4].



Wide Range Assessment of Memory and Learning. Fig. 1 The general structure of the core indexes and their comprised subtests.

The attention and concentration index assesses the individual's ability focus and maintain attention and concentration on a task. This index is comprised of the finger windows and number letter subtests. Finger windows is a subtest that asks the individual to repeat a sequence of responses initiated by the examiner who puts a pencil eraser through asymmetrical holes in a card held perpendicularly to the table. Then the examiner asks the individual to place their finger through the same holes in order. This subtest measures an individual's ability to successfully attend to a sequence of visual steps and repeat them immediately. Number letter is a subtest that asks the individual to attend to a string of numbers and letters presented orally and repeating back the information immediately in a rote format. This subtest measures the individual's ability to attend and repeat back symbolic information that is novel and presented orally [4].

The optional, delay recall and recognition subtests allow for a deeper analysis of memory functioning and have been co-normed with the six core subtests to bolster the validity of comparisons [4]. Sentence memory, sound symbol (8 & up), verbal working memory (9 & up) and symbolic working memory (9 & up), make up the optional subtest group. Story memory delay recall, verbal learning delay recall and sound symbol delay recall (8 & under) comprise the delay recall subtests. Story memory recognition, verbal learning recognition, design memory recognition and picture memory recognition are included in the recognition subtests. Combining the subtest scaled scores on the working memory subtests and summing the recognition subtests will yield a working memory sum and general recognition sum, respectively.

Standardization

The WRAML2 was standardized utilizing a representative national sample of participants aged 5 through 90 years of age. Testing was conducted from March 2002 through June 2003. The sample consisted of 1,200 children and adults spread out over 15 age groups consisting of 80 individuals per group. Standardization was based upon the March 2001 U.S. Census in terms of gender, race/ethnicity, educational attainment and geographic region [4]. States were split up into four geographic locations to ensure a proportionate amount of the sample was represented from each (for further detail see the WRAML2 Administration and Technical Manual).

Difference from WRAML to the WRAML2

The first edition of the *Wide Range Assessment of Memory and Learning* (WRAML) that was published in 1990 was the first standardized test to assess the memory functioning of children. One major revision to the WRAML2 was expanding the age range to 5–90, from 5–17 on the original version. The attention and concentration index score (replacing the Learning Index from the WRAML) and working memory index subtests were added. Through adding additional subtests on recognition, examiners can now get a general recognition sum from summing scaled scores on verbal recognition (composed of story recognition and verbal learning recognition) and visual recognition (composed of design recognition and picture memory recognition). The authors also included additional supplementary data for qualitative analyses. Finally, verbal working memory, symbolic working memory, story recognition, design recognition, picture memory recognition and verbal learning recognition are additions to the WRAML2.

Relevance to Childhood Development

Learning disability, traumatic brain injury, attention deficit-hyperactivity disorder, seizure disorder, primary psychiatric disorder, phenylketonuria, idiopathic mental retardation, brain tumor, leukemia, stroke, and encephalitis are the leading referral questions for pediatric neuropsychological cases [2, 5]. Each of these pathologies will present with myriad of symptoms which may affect the

normal developmental course of the child if left undiagnosed and untreated. Memory, attention and concentration are essential to a child's educational development [1] and are most likely to be impaired in childhood pathologies, especially traumatic brain injuries [2]. The WRAML2 aids in the diagnosis of disorders which would hamper the child's academic achievement, guiding caretakers and professionals in proper intervention and remediation to ensure maximal growth and development [3].

Williams Syndrome

Caroline McKnight, Rachel Kitson, Beth Anne Newman
University of North Carolina, Chapel, NC, USA

Synonyms

Williams-Beuren syndrome

Definition

Williams syndrome (WS) is a genetic disorder that occurs in approximately 1 in 20,000–50,000 births. It is often characterized by health problems, in particular cardiac abnormalities, distinctive facial characteristics, loquaciousness, intellectual disability or significant learning difficulties and a social nature typically described as "delightful."

Description

Historical Perspective

WS was identified by a cardiologist in New Zealand, J.C.R. Williams in the 1960s. He had seen several patients with a condition that was distinguished by supravalvular aortic stenosis or SVAS (a heart defect), stereotypic facial features and intellectual disability. Dr. A.J. Beuren, of Germany, also had experience seeing patients with SVAS and idiopathic infantile hypercalcimia and believed they were part of the same disorder. It was not until the mid-1990s that it was identified as a genetic disorder and the complexity of the disorder was better understood.

Genetics of WS

WS is a syndrome caused by a deletion of several genes on chromosome 7q11.23. Deleted genes involved in the phenotype include elastin (ELN), LIM kinase-1 (LIMK1) and RFC2 gene among others. WS is most commonly caused by a random genetic mutation and not through inheritance. Individuals with WS have a 50% chance of passing the disorder on to offspring, however.

Facial Features

Individuals with WS typically have a stellate or lacey pattern in the irises of their eyes, small stature, broad forehead, prominent eyes, full cheeks, a small upturned-nose, full lips and large ears and are often described as being "cute." They also may have a long philtrum (i.e., the space between the nose and upper lip is elongated), a depressed nasal bridge, small head and long neck.

Early Development Issues

Infants with WS may struggle with feeding problems (e.g., poor suck/swallow reflex, gagging and reflux) extended colic, failure to thrive, and cardiac abnormalities (e.g., SVAS and heart murmurs). In some children, parents and physicians first become concerned when a heart murmur is discovered. The diagnosis of WS is confirmed by a *f*luorescent *i*n *s*itu *h*ybridization (FISH) test when only one copy of the elastin gene is found (in non-WS individuals, there are two copies of the elastin gene). Young children with WS may also experience dental abnormalities such as small, widely spaced and pointed teeth that are likely due to hypocalcaemia.

Cognition

Individuals with Williams syndrome (WS) have a unique cognitive profile of strengths and weaknesses. Typically, individuals with WS have a scattered profile of cognitive abilities in which their visual spatial processing abilities are markedly impaired but facial processing and language, however, remain relatively intact. The general cognitive ability of individuals with WS ranges from moderate intellectual disability to below average when compared to same age peers. Although the majority of individuals with WS have a significant deficit in general cognitive

functioning, there is great variability in cognitive abilities, often making the reliance on general IQ inappropriate. Furthermore, individuals with WS tend to have higher verbal intelligence than nonverbal intelligence. Other cognitive skill areas in which individuals are limited include conceptual knowledge, conversation tasks of number, weight, and substance, and mathematics and applying mathematical skills in everyday life.

Visual-Spatial Processing

Visual spatial processing abilities are significantly impaired in individuals with WS. Constructive and perceptual tasks that demand copying block designs, pictures, and hierarchical figures and judging line orientation, are exceedingly difficult for individuals with WS. In addition, individuals with WS often demonstrate a local processing bias by attending only to the details of the stimuli while neglecting the global aspects of the stimuli. Current research is investigating the possibility that specific genes may contribute to deficits in this area. It has been further suggested that deficient visual-spatial skills are the consequence of poor motor planning and general motor skills, possibly resulting from a weak dorsal stream in the brain. The varying assessment tools and comparison groups (i.e., typically developing individuals vs. individuals with special needs) used to measure the deficit have played a role in the lack of a global understanding of the impact and origins of visual-spatial processing in persons with WS.

Language

The WS population is generally known for being particularly talkative and outgoing, contributing their highly social profile. Such observations have led researchers to examine language abilities as a relative strength in relation to other cognitive deficits. In fact, the various aspects of language development in WS have received the most published research of any domain. These studies have yielded mixed results ranging from typical (but delayed) development in some language domains to atypical in others. Once again, the unique aspect of the domain examined (e.g., grammar, syntax, oral fluency, conversational skills, comprehension, narrative ability, vocabulary, early development, etc.), along with the varying sample sizes and control groups examined makes comparison of results across studies difficult. Regardless of the strength of their language skills, people with WS as a general rule, and at least superficially, are regarded as relatively loquacious and good-natured.

Fine and Gross Motor Skills

Fine motor skills are another area of deficit of the WS profile. Motor deficiency has been noted specifically in the writing skills (e.g., legibility, handedness) of individuals with WS, and simple tasks such as using utensils (e.g., to cut, apply pressure, or spread butter on bread) and tying shoes. Researchers have hypothesized that limited visual-spatial skills and poor muscle tone and development (another characteristic of WS) may contribute to difficulties with gross and fine motor skills. Fine motor movements especially require fairly sophisticated visual-spatial and motor integration. Children with WS have also been documented as developing delayed or confused handedness, and may display some ambidexterity – using their left hand for certain tasks and their right hand for others.

Social Affinity

Individuals with WS are often characterized as extremely friendly, outgoing, agreeable and empathetic. Reports of their social behavior indicate that they initiate and engage in conversations with others easily and sustain eye contact. Despite these positive social attributes, however, individuals with WS are often reported to be overly friendly, have little inhibition with strangers and are sometimes seen as attention seekers. While they are markedly compassionate and attuned to the feelings and moods of others, many individuals can become distracted and overly distressed by others' problems. Despite their yearning for social interaction and friendship, persons with WS have difficulty making and sustaining friendships. With peers, they may become bossy or have difficulty taking turns. In addition, they may need guidance on respecting the personal space of others and could benefit from other social skills training in order to promote positive peer relations.

Musicality

Early anecdotal and qualitative accounts have asserted that individuals with WS display superior interest, emotional response, and talents with regard to music when compared to the typically developed population. Although their fine motor skills may impede their ability to play certain instruments and many people with WS are unable to read music, abnormalities such as fearfulness of specific sounds (auditory allodynia) and a lowered pain threshold for loud sounds (odynacusis) have been hypothesized reasons for the particular interest in music or sound. However, only eight published studies have examined this characteristic in a research setting, and results are mixed regarding the hypothesized savant musical abilities. Larger standardized studies may help elucidate this suggested phenomenon.

Educational Implications

The majority of children with WS receive special education services and have an individual educational plan

(IEP). Students with WS often receive speech therapy and are in classrooms where an aid is present. In addition, some students are provided a one-on-one aid within the classroom. Most parents of children with WS report being the sole providers of information to school personnel related to the etiology of the disability.

Relevance to Childhood Development

Although WS is a rare disorder, it has implications for better understanding patterns of unique strengths and weaknesses in child development. By studying individuals with WS as well as individuals with other developmental disabilities, we may be better informed about typical development. Furthermore, research on individuals with WS has yielded important findings of brain functioning and linkages between genotype and phenotype.

Wisconsin Card Sort Test

►Wisconsin Card Sorting Test

Wisconsin Card Sorting Test

Marie C. McGrath
Immaculata University, Immaculata, PA, USA

Synonyms

Card-sorting test; WCST; Wisconsin card sort test

Definition

A test of executive functioning ability that requires subjects to sort cards, altering the chosen sorting approach based on feedback received at unannounced intervals during the task.

Description

The Wisconsin Card Sorting Test (WCST) is a commonly-used psychological assessment instrument designed to assess *executive functioning* abilities. Executive functions encompass a variety of cognitive abilities that are critical to successful performance of cognitive and behavioral tasks, including: sustained attention; goal selection; planning; problem solving; abstract reasoning; organization; initiation; self-monitoring; error detection and correction; creativity; and self-awareness.

The WCST has been referred to as the "prototypical executive functioning task in neuropsychology" ([4], p. 55). The WCST requires individuals to sort 64 or 128 cards (depending on test form). These cards depict symbols that vary in terms of color, shape, and number. The sorting rule changes throughout the task, permitting examination of the individual's ability to switch among sorting categories without randomly responding or persisting with previously successful strategies. The WCST was originally normed for use with adults ages 60 and below. Later, norms for children, adolescents, and older adults were developed. In addition to the traditional version of the test, which requires the test-taker to sort cards by hand, computerized versions of the task are available.

Lezak [3] argues that, since the WCST's validity depends upon the task's novelty, the test should generally be used as a one-time measure of functioning. Gioia et al. [2] note that children who have difficulty on shifting tasks such as the WCST may also have difficulty when asked to transition between settings or activities. However, they caution that difficulty with standardized tasks of shifting ability, such as the WCST, does not always predict difficulty in applying the skill in other settings, given the differences between the WCST's task requirements and the executive functioning demands of most "real world" tasks.

Wisdom

Anne Fierro Vanderlaan
Saybrook University, Meridian, ID, USA

Synonyms

Common sense; Enlightenment; Knowledge; Understanding

Definition

Wisdom is defined as using knowledge that is truthful, discerning, and having a keen insight.

Description

Wisdom may be considered "social intelligence" (e.g., [2]) and the ability to understand the personalities of others, combined with logical reasoning. A wise person uses emotional intelligence and intellectual ability, and also has a strong sense of purpose in life. Research shows wisdom is no longer thought to be related to age [1].

Witmer, Lightner

Heather N. Arduengo, Angela D. Mitchell
Texas Woman's University, Denton, TX, USA

Life Dates

1867–1956

Introduction

Lightner Witmer's importance to the field of psychology is evidenced by his work in school and clinical psychology as he made significant contributions to both fields. The majority of Witmer's clinical work involved the assessment and treatment of learning and behavioral problems in school children in a clinic setting.

Educational Information

The eldest of three children, Lightner Witmer attended the University of Pennsylvania and received his B.A. in 1888. Witmer taught briefly at a secondary school before he entered the graduate psychology program at the University of Pennsylvania under the supervision of James McKeen Cattell. When Cattell transferred to Columbia University, Witmer moved to Leipzig, Germany to earn his PhD and studied under Wilhelm Wundt, another prominent figure in psychology. He was awarded his Ph.D in 1893.

Upon graduation, Witmer returned to the University of Pennsylvania, where he took over Cattell's laboratory and served as a member of the University of Pennsylvania faculty for 45 years. Initially, Witmer continued his experimental research; however, he later began to focus his research interests on making scientific psychology more "practical." Witmer retired from the University of Pennsylvania in 1937.

Accomplishments

In 1892, Witmer along with other historical figures in psychology including William James, G. Stanley Hall, and James McKeen Cattell founded the American Psychological Association.

In 1894, the University of Pennsylvania organized a special series of courses for public school teachers, and Witmer provided his expertise to teachers in these courses. One of his students approached him about a 14-year-old boy who had an unusual spelling problem. The teacher stated the boy was having difficulty learning how to spell although he was progressing well in other subjects. Witmer treated the problem successfully, and this case, along with many other similar cases, marked the

beginning of Witmer's clinical work. In 1896, Witmer founded the first psychology clinic in the United States to provide such services to the general public.

In 1907, Witmer founded the journal entitled *The Psychological Clinic*, which he edited for 29 years. This journal included research reports, theoretical articles, case studies, and book reviews. *The Psychological Clinic* was the only journal specifically devoted to the development of the field of clinical psychology. In Witmer's article in the journal's first issue, he called for a new profession and proposed that it be termed *clinical psychology.*

Contributions

Witmer is considered to be the founder of clinical psychology and school psychology. Witmer was the first to express the idea of clinical psychology as an emerging field and played a major role in its conceptualization and development. The founding of his clinic in 1896 further evidenced his role in clinical psychology.

His contribution to the field of school psychology is also prominent. Most of Witmer's cases were referrals from schools and included problems relating to severe speech defects, hyperactivity, dyslexia, and other learning disabilities. To honor Witmer's contribution to the field, Division 16 (School Psychology) of the American Psychological Association offers an annual Lightner Witmer Award. This award is presented to school psychologists who have demonstrated exceptional scholarship early in their careers.

Woodcock, Richard W.

Anna Mazur-Mosiewicz, Raymond S. Dean
Ball State University, Muncie, IN, USA

Life Dates

1928–Present

Introduction

Dr. Richard W. Woodcock is an internationally renowned psychologist, psychometrician, and statistician. He is an author of numerous cognitive, achievement, and neuropsychological test batteries, including the Woodcock-Johnson III and Dean-Woodcock Neuropsychological Assessment System. Dr. Woodcock is credited for his

work in developing and introducing the Cattell-Horn-Carroll (CHC) theory and the Rasch statistical methods into individual psychometric measures. Dr. Woodcock has profound backgrounds in the fields of psychology, cognitive theories, and neuropsychology. Additionally, he is known for the integration of these fields into psychological testing [2–4, 8].

Education Information

Dr. Woodcock holds a B.S. degree in Psychology, an M.Ed. degree in Special Education, and an Ed.D. in Psycho-Education and Statistics from the University of Oregon. Following a Postdoctoral Fellowship in Neuropsychology at Tufts University School of Medicine, Dr. Woodcock accepted a position of Assistant Professor of Psychology and Director of the Reading Clinic at Western Oregon University from 1957 to 1961. He served as an Associate Professor of Special Education at the University of Northern Colorado from 1961 to 1963. In 1963, Dr. Woodcock was awarded a Research Professor of Special Education, Senior Scientist, and Acting Director of the Institute on Mental Retardation and Intellectual Development at the George Peabody College at Vanderbilt University. During his time at the Vanderbilt University, he directed the Peabody-Chicago-Detroit Reading Project. Dr. Woodcock took on the position of Editor and Director of Research for the American Guidance Service and served in that role from 1968 to 1972. From 1985 to 1988, Dr. Woodcock served as a Visiting Scholar in the Division of Special Education and Rehabilitation at the University of Arizona, and in 1988 he accepted the position of Visiting Scholar in the Department of Psychology at the University of Southern California. He was Research Professor of Psychology at the University of Virginia from 1993 to 1998. Currently, Dr. Woodcock serves as the Director of Measurement/Learning/Consultants, a test development and research organization that he founded in 1972 [1].

Accomplishments

Dr. Woodcock's work became well-known for introducing a number of psychometric features in the area of psychoeducational and cognitive assessment, which included co-normed batteries, theory-based test construction, expansive coverage of content, application of tests across the life span, age and grade norms, parallel forms in languages other than English, and cross-language equating. Dr. Woodcock is a Diplomate of the American Board of Professional Psychology (ABPP) and a Fellow of the American Psychological Association. He also is a recipient of the Senior Scientist Award granted by the American Psychological Association, Division of School Psychology in recognition of significant contributions to the field of school psychology [1].

Contributions

Dr. Woodcock contributed to the field of school psychology and neuropsychology through the reinforcement of the CHC theory of cognitive abilities and the Rasch statistical method, which is used to equalize increases in item difficulty, into widely used clinical measures. He is also an author of *W scores*, which are a special transformation of the Rasch ability scale that are suited for use as an intermediate step in the interpretation of test performance. Moreover, Dr. Woodcock modeled the scientific-empirical test development principles, which became the standard of modern test development [5–7, 9].

Dr. Woodcock has authored and published numerous major psychoeducational, cognitive, and neuropsychological assessment batteries, including the Colorado Braille Battery, the Peabody Rebus Reading Program, the Goldman-Fristoe-Woodcock Auditory Skills Test Battery, the Woodcock Reading Mastery Tests–Revised, the Woodcock-Johnson® Psycho-Educational Battery–Revised (WJ-R®), the Batería Woodcock-Muñoz: Pruebas de habilidad cognitiva–Revisada, the Batería Woodcock-Muñoz: Pruebas de aprovechamiento–Revisada, the Woodcock Language Proficiency Battery–Revised, English and Spanish Forms, the Scales of Independent Behavior–Revised, the Woodcock-Muñoz Language Survey, English and Spanish Forms, the Woodcock-McGrew-Werder Mini-Battery of Achievement, the Woodcock-Johnson III Tests of Cognitive Abilities, the Woodcock-Johnson III Tests of Achievement, WJ III NU Tests of Achievement, WJ III NU Tests of Cognitive Abilities, and the Dean-Woodcock Neuropsychological System.

Woodcock-Johnson III Tests of Achievement

Raymond S. Dean
Ball State University, Muncie, IN, USA

Synonyms

WJ-III; WJ-III-ACH

Definition

The Woodcock-Johnson III Tests of Achievement (WJ-III-ACH) is an individually administered standardized assessment battery of academic achievement.

Description

As part of the Woodcock-Johnson – Third Edition (WJ-III), the WJ-III-ACH provides a comprehensive measure of general achievement ability, as well as measures of oral language ability and specific achievement skills. It has been co-normed with the Woodcock-Johnson III Tests of Cognitive Abilities (WJ-III-COG), which allows for more accurate comparisons among an individual's achievement skills, oral language ability, and cognitive abilities than would the use of different measures. The WJ-III-ACH can also be administered independently of the WJ-III-COG, or with other assessments, depending on the needs of the practitioner. In general, the WJ-III-ACH is designed for use with individuals aged 5–95 years, or in grades kindergarten through grade 18. However, some subtests are appropriate for use with individuals as young as 2 years of age, or in preschool.

The WJ-III-ACH is organized into five broad academic domains: Reading, Math, Written Language, Oral Language, and Academic Knowledge. Each of these domains is divided into several cluster scores, with a total of 19 cluster scores available in the WJ-III-ACH. For example, the Reading, Math, and Written Language domains each include measures of basic skills, higher-level or application skills, and fluency/automaticity. Administration of these measures enables practitioners to obtain the Broad Reading, Broad Math, and Broad Written Language cluster scores, as well as the supplementary clusters of Academic Skills, Academic Fluency, and Academic Applications. The WJ-III-ACH also provides an overall measure of general achievement skills termed Total Achievement. In line with the theoretical basis of the WJ-III-COG, the WJ-III-ACH provides measures of five of the broad abilities identified in CHC theory: Reading-Writing (*Grw*), Quantitative Knowledge/Mathematics (*Gq*), Comprehension-Knowledge (*Gc*), Auditory Processing (*Ga*), and Long-Term Retrieval (*Glr*).

The WJ-III-ACH is available in two equivalent alternative forms: Form A and Form B. Each form is comprised of 22 subtests and is broken into two parts: the Standard Battery (Tests 1–12) and the Extended Battery (Tests 13–22). In general, administration of Tests 1 through 11 and Test 19 is needed in order to obtain measures of the five broad academic domains. However, depending on the purpose of the assessment, the practitioner is able to select and administer any combination of subtests that will provide the most relevant information. Additional information on the selection of subtests and the dynamic nature of subtest selection based on practitioner needs is available in the WJ-III-ACH Examiner's Manual.

Administration of the WJ-III-ACH subtests results in raw scores that can be converted to age- or grade-based standard scores, age- and grade-equivalents, and percentile ranks. Additionally, computer scoring software (WJ-III Compuscore and Profiles Program) can be used to calculate the relative proficiency index (RPI) and to convert WJ-III-ACH raw scores into W scores, *z* scores, *T* scores, stanines, and normal curve equivalents (NCEs). Normative and ipsative analysis of an individual's scores can help practitioners determine if the individual presents with any significant strengths or weaknesses in a wide range of both broad and narrow achievement skills. Specifically, the computer scoring software allows practitioners to conduct intra-individual discrepancy analyses, such as between cluster scores or broad academic domains. When the WJ-III-COG is administered in conjunction with the WJ-III-ACH, ability/achievement discrepancy analyses are also available.

Historical Background

The WJ-III-ACH is the third rendition of Woodcock-Johnson measures of achievement skills. The series began

in 1977 with the Woodcock-Johnson Psychoeducational Battery (WJPEB), which consisted of Tests of Cognitive Ability, Tests of Achievement, and Tests of Interest Level. The Tests of Achievement consisted of ten subtests measuring reading, mathematics, written language, and knowledge. Although the WJPEB was not based on any particular theoretical framework, the next edition of the test, the Woodcock-Johnson Psychoeducational Battery – Revised (WJ-R), was based largely on Cattell [5] and Horn's [6] work with *Gf-Gc* theory. Published in 1989, the WJ-R consisted of the WJ-R Tests of Cognitive Ability (WJ-R-COG) and the WJ-R Tests of Achievement (WJ-R-ACH). The WJ-R-ACH consisted of 14 subtests again measuring reading, mathematics, written language, and knowledge. After Horn's *Gf-Gc* theory was meshed with John Carroll's three-stratum theory to create the CHC theory, Richard Woodcock adapted and applied that theory to create the Woodcock-Johnson III (WJ-III), which was published in 2001. Based upon the CHC theory, the WJ-III consists of the WJ-III Tests of Cognitive Ability (WJ-III-COG) and the WJ-III Tests of Achievement (WJ-III-ACH).

Psychometric Data

The WJ-III-ACH normative data were collected in the U.S. from a nationally representative, geographically diverse, and economically diverse sample of 8,818 individuals. The overall sample was divided into categories by age, including the preschool sample, the kindergarten through twelfth grade sample, the college/university sample (undergraduate and graduate), and the adult sample. In 2007, the Woodcock-Johnson III Normative Update (WJ-III-NU) was created by re-calculating the pre-existing normative data to match the 2005 U.S. Census data. More detailed information on the normative sample for the WJ-III-ACH is available in the WJ-III Technical Manual and the WJ-III-NU Technical Manual.

Reliability statistics for the WJ-III-ACH were calculated using the split-half procedure for non-speeded tests and Rasch analysis procedures for speeded tests and tests with multiple-point scored items. Twenty of the twenty-two WJ-III-ACH subtests obtained median reliabilities of 0.80 or higher, with nine subtests obtaining median reliabilities of 0.90 or higher. All nineteen cluster scores obtained median reliabilities of 0.80 or higher, with sixteen cluster scores obtaining median reliabilities of 0.90 or higher. Test-retest measures of the WJ-III-ACH speeded tests resulted in reliabilities ranging from 0.76 to 0.96. Extended retest interval data from test-retest measures of selected WJ-III-ACH subtests support the reliability of the WJ-III-ACH at extended retest intervals. Additional interrater reliability studies conducted for WJ-III-ACH subtests requiring subjective scoring (i.e., Writing Samples, Writing Fluency, and Handwriting) resulted in interrater correlations ranging from 0.78 to 0.98. Evidence for the equivalence of Form A and Form B of the WJ-III-ACH includes item difficulty analysis, response ogive analysis, standard error comparisons, and alternate form correlations.

Validity evidence for the WJ-III-ACH includes test content evidence (e.g., the process of item development), developmental patterns evidence (e.g., growth curves for nine cluster scores), and internal structure evidence (e.g., test score intercorrelations, confirmatory factor analysis). Evidence for the validity of the WJ-III-ACH is also provided by the results of special study samples, including the correlations between the WJ-III-ACH and a wide range of other widely-used achievement assessments. More detailed information about and discussion of the validity evidence for the WJ-III-ACH is available in the WJ-III Technical Manual.

Ball State University, Muncie, IN, USA

Synonyms

WJ-III; WJ-III-COG

Definition

The Woodcock-Johnson III Tests of Cognitive Abilities (WJ-III-COG) is an individually administered standardized assessment battery of cognitive functioning.

Description

As part of the Woodcock-Johnson – Third Edition (WJ-III), the WJ-III-COG provides a comprehensive measure of general ability, as well as measures of specific cognitive functions. It has been co-normed with the Woodcock-Johnson III Tests of Achievement (WJ-III-ACH), which allows for more accurate comparisons among an individual's cognitive abilities, oral language ability, and achievement skills than would the use of different measures. The WJ-III-COG can also be administered independently of the WJ-III-ACH, or with other assessments, depending on the needs of the practitioner. In general, the WJ-III-COG is designed for use with individuals aged 5–95 years; however, some subtests are appropriate for use with individuals as young as 2 years of age. The WJ-III-COG also provides special normative tables for college and university students.

Unique among assessments of cognitive and intellectual functioning, the WJ-III-COG is based on the Cattell-Horn-Carroll (CHC) theory of cognitive abilities. The WJ-III-COG measures seven broadly defined abilities identified in CHC theory: Long-Term Retrieval (*Glr*), Short-Term Memory (*Gsm*), Processing Speed (*Gs*), Auditory Processing (*Ga*), Visual-Spatial Thinking (*Gv*), Comprehension-Knowledge (*Gc*), and Fluid Reasoning (*Gf*). These broad CHC theory abilities are grouped into three larger performance clusters: Verbal Ability (*Gc*), Thinking Ability (*Glr*, *Gv*, *Ga*, *Gf*), and Cognitive Efficiency (*Gs*, *Gsm*). The WJ-III-COG also provides an overall measure of general cognitive ability termed the General Intellectual Ability (GIA), as well as a brief measure of general cognitive ability termed the Brief Intellectual Ability (BIA).

Comprised of twenty subtests, the WJ-III-COG is broken into two parts: the Standard Battery (Tests 1–10) and the Extended Battery (Tests 11–20). Administration of Tests 1 through 7 and 11 through 17 provides measures of the seven broad CHC factors. However, depending on the purpose of the assessment, the practitioner is able to select and administer any combination of subtests that will provide the most relevant information. Additional information on the selection of subtests and the dynamic nature of subtest selection based on practitioner needs is available in the Examiner's Manual.

Administration of the WJ-III-COG subtests results in raw scores that can be converted to age- or grade-based standard scores, age- and grade-equivalents, and percentile ranks. Additionally, computer scoring software (WJ-III Compuscore and Profiles Program) can be used to convert WJ-III-COG raw scores into W scores, *z* scores, *T* scores, stanines, and normal curve equivalents (NCEs). The computer scoring software can also calculate an individual's predicted achievement scores and relative proficiency index (RPI). Normative and ipsative analysis of an individual's scores can help practitioners determine if the individual presents with any significant strengths or weaknesses in a wide range of both broad and narrow cognitive abilities. Specifically, the computer scoring software allows practitioners to conduct intra-individual discrepancy analyses, such as between performance clusters or between CHC factors. When the WJ-III-COG is administered in conjunction with the WJ-III-ACH, ability/achievement discrepancy analyses are also available.

Historical Background

The WJ-III-COG is the third rendition of Woodcock-Johnson measures of cognitive abilities. The series began in 1977 with the Woodcock-Johnson Psychoeducational Battery (WJPEB), which consisted of Tests of Cognitive Ability, Tests of Achievement, and Tests of Interest Level. The Tests of Cognitive Ability measured both verbal and nonverbal functions, as well as a wide range of mental processes, and resulted in an overall cognitive ability score termed the Broad Cognitive Ability (BCA). Although the WJPEB was not based on any particular theoretical framework, the next edition of the test, the Woodcock-Johnson Psychoeducational Battery – Revised (WJ-R), was based largely on Cattell [1] and Horn's [2] work with *Gf-Gc* theory. Published in 1989, the WJ-R consisted of the WJ-R Tests of Cognitive Ability (WJ-R-COG) and the WJ-R Tests of Achievement (WJ-R-ACH). The WJ-R-COG measured seven broad abilities identified in *Gf-Gc* theory: Long-Term Retrieval (*Glr*), Short-Term Memory (*Gsm*), Processing Speed (*Gs*), Auditory

Processing (*Ga*), Visual-Spatial Thinking (*Gv*), Comprehension-Knowledge (*Gc*), and Fluid Reasoning (*Gf*). After Horn's *Gf-Gc* theory was meshed with Carroll's three-stratum theory to create the CHC theory, Richard Woodcock adapted and applied that theory to create the Woodcock-Johnson III (WJ-III), which was published in 2001. Based upon the CHC theory, the WJ-III consists of the WJ-III Tests of Cognitive Ability (WJ-III-COG) and the WJ-III Tests of Achievement (WJ-III-ACH).

Psychometric Data

The WJ-III-COG normative data were collected in the U.S. from a nationally representative, geographically diverse, and economically diverse sample of 8,818 individuals. The overall sample was divided into categories by age, including the preschool sample, the kindergarten through twelfth grade sample, the college/university sample (undergraduate and graduate), and the adult sample. In 2007, the Woodcock-Johnson III Normative Update (WJ-III-NU) was created by re-calculating the pre-existing normative data to match the 2005 U.S. Census data. More detailed information on the normative sample for the WJ-III-COG is available in the WJ-III Technical Manual and the WJ-III-NU Technical Manual.

Reliability statistics for the WJ-III-COG were calculated using the split-half procedure for non-speeded tests and Rasch analysis procedures for speeded tests and tests with multiple-point scored items. Eighteen of the twenty WJ-III-COG subtests obtained median reliabilities of 0.80 or higher, with six subtests obtaining median reliabilities of 0.90 or higher. All 23 cluster scores created from combinations of two or more subtests obtained median reliabilities of 0.80 or higher, with twenty cluster scores obtaining median reliabilities of 0.90 or higher. Test-retest measures of the WJ-III-COG speeded tests resulted in reliabilities ranging from 0.69 to 0.87. Additionally, extended retest interval data from test-retest measures of selected WJ-III-COG subtests support the reliability of the WJ-III-COG at extended retest intervals.

Validity evidence for the WJ-III-COG includes test content evidence (e.g., the process of item development), developmental patterns evidence (e.g., growth curves for the seven CHC factors), and internal structure evidence (e.g., test score intercorrelations, confirmatory factor analysis). Evidence for the validity of the WJ-III-COG is also provided by the results of special study samples, including the correlations between the WJ-III-COG and a range of other widely-used cognitive assessments. More detailed information about and discussion of the validity evidence for the WJ-III-COG is available in the WJ-III Technical Manual.

Working Memory

Marci S. DeCaro[1], Denise E. Maricle[2]
[1]Vanderbilt University, Nashville, TN, USA
[2]Texas Woman's University, Denton, TX, USA

Synonyms

Executive control; Executive functioning; Shifting attention; Short-term memory

Definition

Working memory can be defined as the cognitive system involved in the temporary storage and processing of a limited amount of information. At the same time, the term working memory is conceptualized and defined differently by researchers from different fields, and there are many definitions of working memory. For example, [18] defines working memory as a limited capacity system that provides temporary storage to manipulate information for complex cognitive tasks such as learning and reasoning. [19] state that working memory is the system or mechanism underlying the maintenance of task relevant information during the performance of a cognitive task. [16] claims that working memory refers to the system for temporarily maintaining mental representations that are relevant to the performance of a cognitive task in an activated state. Finally, [9] posits that working memory refers to the relatively small amount of information that one can hold in mind, attend to, or maintain in a rapidly accessible state at one time. Thus, according to most researchers, working memory is a system with multiple components or a collection of interrelated processes that carry out several important cognitive functions simultaneously. A few researchers have postulated that working memory and executive functioning are intertwined, if not the same thing [7].

Description

Working memory is the cognitive system involved in the temporary storage and processing of a limited amount of information with immediate relevance to the task at hand. The functions of working memory are to hold information in mind, to internalize the information, and to use the information to guide behavior without the aid of or in the absence of external cues [18]. There is substantial variation in working memory capacity among individuals and working memory capacity varies dramatically based on the type of information being recalled [16].

Working memory also functions to retrieve information from long-term memory and keep irrelevant information from entering the focus of attention. For example, mentally solving a multi-step math problem requires holding intermediate results in a short-term store while processing this information and keeping distractions at bay. This memory system is important for many high-level cognitive functions, such as general intellectual ability, reasoning, comprehension, problem solving, and analytic skill [8].

Working memory involves the ability to control the focus of attention in addition to supporting the short-term storage of information. In this way, working memory has been distinguished from short-term memory capacity. *Short-term memory capacity* involves the short-term storage of a limited amount of information.

Working memory includes components for storing phonological or verbal features, visual features, spatial locations, and integrated episodes. It also includes an executive attentional component for controlling access to these stores. According to [3] model of working memory, short-term storage and rehearsal of information is primarily accomplished through domain-specific systems – the *phonological loop* for verbal information and the *visuo-spatial sketchpad* for visual images. A domain-general *central executive* coordinates the operation of these storage systems and others, such as long-term memory. The central executive has been linked to the ability to control the focus of attention and allows memory representations to remain highly active in the face of distraction. It is this attention ability that has specifically been shown to drive the relation between working memory and performance. For this reason, working memory capacity is often conceptualized as executive attention [13]. A fourth component has also been added to this model – an *episodic buffer* that integrates information from the phonological loop, the visual-spatial sketchpad, and long-term memory [2].

Although working memory is conceptualized as a cognitive construct supporting complex thinking, it can also be thought of as an individual differences variable, meaning some people have more of this capacity and some have less. With this variability in mind, measures have been developed to assess individual differences in working memory capacity, in order to assess the role of this cognitive construct in performance. A variety of working memory assessments have been developed. Commonly used measures, such as reading span, operation span, and counting span, are designed to assess working memory storage while also processing other information. For example, the Reading Span task (RSPAN) [10] requires individuals to process sentences while actively maintaining a small number of letters in memory. Other assessments include the spatial span test, n-back test, backwards digit span, star counting test, and several others. Many of these assessments can be obtained at the website of Randall Engle: http://www.psychology.gatech.edu/renglelab/ (see also http://www.york.ac.uk/res/wml/TestsofWM.htm). It should be noted that the use of many of these measures has been largely with healthy young adults. Modifications may be necessary with children or other populations, such as de-emphasizing accuracy or simplifying the processing component of the task [8].

Neuroimaging has recently demonstrated that different regions of the brain are involved in the multiple components of working memory [4, 11]. The prefrontal cortex (PFC) is a necessary neural substrate for working memory, but imaging studies have shown that other areas are involved as well. Recent evidence suggests that the dorsolateral PFC but not the ventrolateral PFC is involved in the manipulation of working memory tasks. Additionally, imaging studies suggest that verbal working memory tasks activate the region associated with Broca's area and motor areas of the frontal cortex associated with speech production in the left hemisphere. In contrast spatial working memory tasks activate the right parietal and frontal cortex [16].

Relevance to Childhood Development

Working memory plays an essential role in complex cognition and is closely related to the ability to learn. Measures of working memory are good predictors of children's cognitive abilities, associated with such skills as early reading development and scholastic attainment [21]. Deficient memory abilities can prevent children from acquiring the skills and knowledge necessary for academic success [1, 14].

There is consensus that memory in general, and working memory in particular, develops over the age span. Children's performance on tasks of working memory continues to improve throughout childhood, reaching adult capacities in early adolescence. Working memory capacity and efficiency is highly influenced by attention and cognitive efficiency (speed of carrying out mental processes).

Research on working memory in children has closely aligned with that of adults. For example, as with adults, children's performance on working memory tasks appears to involve both domain-free attention and domain-specific storage factors. And the domain-general central executive component of working memory is more strongly associated with cognitive abilities than simple storage [15].

Writing Skills

Synonyms

Written communication skills; Written expression skills; Written language skills

Definition

The skills used to communicate one's knowledge in written/text format so that others fluent in that language can read and understand the ideas being presented.

Description

Writing skills are generally taught through direct instruction, with mastery of more basic skills required before mastery of higher order skills can effectively take place. The most basic skills are those involved in handwriting. These include writing posture, grip on the writing utensil, letter formation and avoidance/correction of reversals, spacing of letters and words, slant of letters, alignment of letters and words, and rate/fluency of production. Higher order writing skills include: spelling, which incorporates accurate phoneme/grapheme correspondence, orthography, and morphology; punctuation and capitalization; and editing. Beyond these

basic writing skills another level of written expression exists that further contributes to the complexity of written language. These skills include accurate use of grammar and syntax, vocabulary, structure/style, revision, and knowing and writing appropriately for one's audience.

XO Syndrome

Carol Patrick
Fort Hays State University, Hays, KS, USA

Synonyms

Bonnevie-ullrich-turner syndrome; 45 X 0

Definition

XO syndrome is a disorder of the sex chromosomes, occurring in females, in which one of the two X chromosomes is completely or partially absent. XO syndrome causes a number of symptoms that vary greatly among individuals, but generally include small stature, amennorhea and infertility.

Description

Prevalence

Estimates of the prevalence of XO syndrome vary from study to study, with the most common estimate being 1 in 2,500 live female births. However, lower prevalence rates, as low as 1 in 5,000–8,000 female live births, have been reported in some studies.

Many more XO syndrome babies are conceived than born. Approximately 1–2% of females conceived are missing an X chromosome; however, most are miscarried early in the pregnancy, usually during the first trimester. Ten percent of all miscarriages are thought to be caused by XO syndrome. Ultrasounds of some XO syndrome babies who make it to the second trimester show abnormalities that are connected with an increased chance of miscarriage, such as hydrops fetalis (edema of some fetal tissue, including the fetal subcutaneous tissue, which can result in a fetal form of heart failure).

Causes

Humans are typically born with 23 pairs of chromosomes, one member of each pair coming from the biological father and the other from the biological mother. One pair of chromosomes is the sex chromosomes, those that determine a person's biological sex. A person with two X chromosomes (one from each parent) is female, and a person with one X chromosome and one Y chromosome (from the mother and father, respectively) is male.

XO syndrome typically occurs when a child receives an X chromosome from one parent, but no X or Y chromosome from the other. This condition is called monosomy X. The child is considered to be female because no Y chromosome is present. At least one study found the X chromosome received is approximately equally likely to come from the father or mother. Other studies have found differing results, including as high as 90% of the "missing" chromosomes coming from the father.

Another genetic pattern for the disorder called Turner syndrome is mosaicism. It is estimated that approximately 35% of cases originate in this manner. A mosaic occurs when cells in the person's body do not have the same

Sam Goldstein & Jack A. Naglieri (eds.), *Encyclopedia of Child Behavior and Development*, DOI 10.1007/978-0-387-79061-9,

number of chromosomes. For example, one cell may have 46 chromosomes, and another 45.

Diagnosis

During pregnancy, a test called amniocentesis is used to collect genetic material for study. Ultrasounds can sometimes show abnormalities in the fetus suggestive of XO syndrome, but a karyotype of the blood is considered the definitive test for diagnosis of the syndrome, and the particular variation of the syndrome that the person may have (monosomy X, mosaics, etc.).

Symptoms

No two women with XO syndrome share the exact same symptoms. Although the disorder manifests itself differently in each woman who has it, certain symptoms are seen with some frequency. For example:

- Lack of/underdeveloped ovaries
- Infertility
- Failure to experience menarche (the beginning of menstruation)
- Inadequate production of estrogen
- Osteoporosis (later in life)
- Short stature
- Webbed neck
- Heart defects (e.g., coarctation of the aorta and aortic valve abnormalities)
- Aortic dissection
- Mitral valve prolapse
- Lymphedema (swelling or "holding water", especially in the hands and feet)
- Impaired spatial perception
- Broadening of the chest (shield chest)
- Widely spaced nipples
- Short neck
- Low neck hairline
- Short metacarpal IV (in hands)
- Cubitus valgus (arms turn out at elbows)
- Drooping eyelids
- Narrow jaw
- Narrow nails
- Deep set nails
- Low-set ears
- Increased weight, obesity
- Poor breast development
- Horseshoe kidney
- Visual impairments
- Ear infections and hearing loss
- Type II diabetes
- High blood pressure

Treatment and Prognosis

Treatments are generally geared to the specific symptoms of each XO syndrome patient. Certain serious symptoms (particularly those of the cardiac system) require close monitoring. Both growth hormone and estrogen replacement therapy are used in many XO females to increase stature and cause the onset of menstruation. Surgery is often done early in life to reduce webbing of the neck. Most females with XO syndrome have a normal life expectancy.

XXXY Syndrome

Adeline Low
Psychology, Kuala Lumpur, Wilayah Persekutuan, Malaysia

Synonyms

Barr-Shaver-Carr syndrome; 48 XXXY syndrome

Definition

The XXXY syndrome is a sex chromosome that affects one in 17,000 boys. It can also be called 48, XXXY syndrome because such individual has 48 chromosomes instead of the normal 46, due to the extra two sex chromosomes. Most researchers believe that 48, XXXY syndrome is a variation of Klinefelter syndrome (XXY syndrome), with the 47, XXY syndrome's dysmorphic features being mild, multiple and widespread in the 49, XXXXY syndrome and intermediate level of the spectrum in 48, XXXY. In Klinefelter cases, 80% of them are the karotype of 47, XXY, while the remaining 20% are the different

variants, including mosaicism. Among all the variants, 48, XXXY is the commonest observed. With the addition of each X chromosome, there is a significant increase in somatic malformations and mental retardation.

Description

The symptoms and effects of Klinefelter syndrome increase with each additional X chromosome present in the male. Thus, males with 48, XXXY syndrome experience similar symptoms as males afflicted with 47, XXY chromosome, only to a greater degree. The characteristics of 48, XXXY syndrome in a male can be categorized into physical and mental effects. The most apparent physical effect of 48, XXXY syndrome is the decrease of a male's production of testosterone and on his male features. Many of these individuals also experience significant breast growth, as well as significantly smaller penis size. One of the major effects of the 48, XXXY syndrome is infertility. This syndrome causes increased amounts of two hormones, follicle stimulating hormone (FSH) and luteinizing hormone (LH). This results in hyalinization and fibrosis in the seminiferous tubules, where the sperm are normally located. As a result, 48, XXXY males often have smaller and firmer testicles, which then prevents the production of sperm. Other than that, a 48, XXXY individual has less facial and pubic hair growth. Most people with this syndrome are also weaker in strength and are clumsier. It is important to note that this syndrome happens before conception and is not related to any environment, lifestyle, or parental dietary factors.

Relevance to Childhood Development

Mentally, individuals affected by the 48, XXXY syndrome experience significant deficits in developmental and learning abilities. A large majority of these people have difficulties in learning new knowledge or skills including basic academic, speech, and language skills. Some of them are also affected intellectually as they are diagnosed with mental retardation or obtain lower IQ scores. Many 48, XXXY individuals find it hard to interact with others socially and tend to be more shy, anxious or immature than their peers. Due to their condition, individuals with 48, XXXY syndrome are also exposed to higher likelihood of high stress levels, depression and anxiety.

XYY Syndrome

Annmarie Roberston
Niagara University, NY, USA

Synonyms

Diplo-Y Syndrome; Polysomy Y; 47, XYY Karyotype; 47, XYY Syndrome; XYY Chromosome Pattern; YY Syndrome

Definition

XYY syndrome (47, XYY) is a rare chromosomal disorder that affects males [1]. It is caused by the presence of an extra Y chromosome. Males normally have one X and one Y chromosome. However, individuals with this syndrome have one X and two Y chromosomes. Associated characteristics may include behavioral problems and learning disabilities. Intelligence is usually normal, although IQ, on average, is 10–15 points lower than non-affected siblings [1].

Description

Most often, the extra Y chromosome causes no unusual physical features or medical problems. 47, XYY boys demonstrate an increased growth velocity during earliest childhood, with an average final height approximately 7 cm above expected final height [2]. Severe acne was noted in a very few early case reports, but dermatologists specializing in acne now doubt the existence of a relationship

between acne and 47, XYY. Testosterone levels (prenatally and postnatally) are normal in 47, XYY males [2]. Most XYY males have normal sexual development and usually have normal fertility [2]. Since 47, XYY is not characterized by distinct physical features, the condition is usually detected only during genetic analysis conducted for other purposes [2].

Causes and Incidence: 47, XYY is not inherited, and is viewed as the product of any atypical event during the formation of sperm cells [2]. An error in chromosome separation during metaphase II called nondisjunction can result in sperm cells with an extra copy of the Y chromosome. If one of these atypical sperm cells contributes to the genetic makeup of a child, the child will have an extra Y chromosome in each of the body's cells [1].

In some cases, the addition of an extra Y chromosome results from nondisjunction during cell division during a post-zygotic mitosis in early embryonic development [2]. This can produce 46, XY/47, XYY mosaics. About 1 in 1,000 boys are born with a 47, XYY karyotype [1]. The incidence of 47, XYY is not affected by advanced paternal or maternal age.

Relevance to Childhood Development

47, XYY boys have an increased risk of learning disabilities (in up to 50% of cases) and delayed speech and language skills [1]. A national survey of US children conducted in 2004 for the Center for Disease Control and Prevention found that 10% of 47, XYY boys had a learning disability [2]. As with 47, XYY boys and 46, XXX girls, IQ scores of 47, XYY boys average 10–15 points below their siblings [2]. It is important to realize that this amount of variation – an average difference of 12 IQ points – occurs naturally between children in the same family [1]. Developmental delays and behavioral problems are also possible, but these characteristics vary widely among affected boys and men, are not unique to those with 47, XYY and are managed no differently than in XY males [1]. Lastly, aggression is not seen more frequently in 47, XYY males [1].

Treatment and Intervention: No noted intervention is required at birth, however, school performance should be monitored, and intervention implemented where necessary particularly with respect to speech and language development. Referrals should only be made if necessary; these may include to the school/clinical psychologist [1]. There is increasing evidence that a supportive environment is beneficial. It has also been shown that those diagnosed antenatally tend to have a better outcome. It is thought this may be due to the children being treated and encouraged appropriately, rather than being regarded as a "problem child [2]." There is no increased risk of other pathology.

Young Caregivers

Christina Marbach
LPC, Garden Ridge, TX, USA

Synonyms

Caregiving youth; Young carers

Definition

Many definitions for "Young Carers" exist in qualitative and quantitative research which has been conducted in the United Kingdom (UK), Australia, and Canada. For example, in 1998, the Carers National Association (now Carers UK) developed the following definition of a young carer: "Anyone under the age of 18 *whose life is in some way restricted* because of the need to take responsibility for the care of someone who is ill, has a disability, is experiencing mental distress, or is affected by substance misuse" [7, p. 6]. In the United States, there is not an official definition of young caregivers as there is in other countries. However, the American Association of Caregiving Youth (AACY) adopted the term "Caregiving Youth" to describe children engaging in caregiving roles.

Description

Within Western civilization, childhood and adolescence is considered a "protected" stage of life, where there is not an expectation that children and teenagers will take on a significant amount of responsibility such as caregiving [3]. According to the National Alliance for Caregiving and the United Hospital Fund Study [10], 1.3–1.4 million children in the United States provide some form of caregiving to a sick and/or disabled person. Given that many children reside with a parent, grandparent, or sibling with a disability, many children may be called upon to provide care to family members with whom they reside [13, 14].

Frank [6] stated that young carers can be classified into three different levels of caring (a) Sole Carer; (b) Supportive Carer; and (c) Sibling Carer. First, a sole carer (or primary caregiver) is a child who is the only person in the home who can provide care because no other adults are available. Second, a supportive caregiver or auxiliary [13, 14] is defined as someone who assists a capable adult who is the primary caregiver. Finally, a sibling carer is a child who helps care for a sibling with a disability or chronic illness.

Warren [16] explored the types of activities young caregivers are engaged in compared to non-caregiving peers. Warren found young caregivers were engaged in (a) domestic tasks; (b) general care and other tasks; (c) personal and intimate care; and (d) emotional support. Warren's categories of activities are consistent with those described by Frank [6] that included (a) practical tasks and responsibilities (such as cooking, housework, shopping, physical care, and personal care and toileting) and (b) emotional issues. Warren found that young caregivers engaged in significantly more housework than non-caregiver peers who were primarily responsible for their own bedrooms. Young caregivers were also engaged in tasks such as assisting with financial paperwork, providing care to younger siblings, giving medication, assisting with toileting and showering, and assisting with drinking and eating.

Relevance to Childhood Development

Although the caregiver role may result in stress for the child, some positive outcomes include family unity, increased preparation for adulthood, sense of responsibility, and compassion for others [12, 15]. While the field of caregiving has been greatly explored and family caregiving research is well established, the area of young caregivers remains in its infancy with less than 15 years of existing research literature. The United Kingdom (UK) has been in the forefront of research and policy related to young caregivers [1, 3, 4]. The research on young carers in the UK has led to a significant amount of public policy geared toward the assessment, support, and protection of young carers [3, 6].

Definition

A prescription medication FDA approved for the treatment of major depression, obsessive-compulsive disorder, panic disorder, post-traumatic stress disorder, premenstrual dysphoric disorder, and social anxiety disorder.

Description

This medication is a selective serotonin reuptake inhibitor available in a tablet or as an oral solution.

The recommended starting dose for this medication is 25 or 50 mg taken once a day. Maximum suggested dose is 200 mg a day. This medication should only be taken as directed by a doctor. This medication may need to be taken for four weeks before improvement in symptoms is seen.

Concomitant use in patients taking monoamine oxidase (MAO) inhibitors is not advised. Serotonin syndrome may occur with the use of certain other serotonergic drugs.

Some side effects are listed here: decreased sexual desire, decreased appetite and weight loss, diarrhea, dizziness, drowsiness, headache, shaking, and trouble sleeping.

Relevance to Childhood Development

Zoloft® is FDA approved for the treatment of obsessive compulsive disorder in children ages 6–17. Children may be monitored for appropriate growth and weight while taking this medication as it may decrease their appetite.

A medication guide must accompany this medication containing information related to the increased risk of suicidal thinking and behavior in children, adolescents, and young adults compared to those not taking the medication. Doctors will monitor patients closely for

Sam Goldstein & Jack A. Naglieri (eds.), *Encyclopedia of Child Behavior and Development*, DOI 10.1007/978-0-387-79061-9,

worsening of symptoms, change in behavior, and thoughts of suicide. Patients are strongly encouraged to notify their health care provider to report sudden changes in mood, behavior, thoughts, or feelings.

Zone of Proximal Development

Sarah Kozel Silverman
Ohio State University, Columbus, OH, USA

Synonyms

Scaffolding; Zo-Ped; ZPD

Definition

The zone of proximal development is the hypothetical space between that which one can accomplish alone and that which one cannot accomplish, even with assistance. Lev Vygotsky has defined the ZPD as, "the distance between the actual developmental level as determined by independent problem solving and the level of potential development as determined through problem solving under adult guidance, or in collaboration with more capable peers" ([1], p. 86).

Description

Lev Vygotsky, an early twentieth century Russian psychologist, initially theorized and explored the ZPD as a means of understanding the circumstances under which children learn best. According to Vygotsky, ideal learning situations should be aimed at the middle of the zone of proximal development. In other words, learning tasks should not be so easy that children can accomplish them without any assistance, but they should not be so difficult that children cannot accomplish them, even with the help of an expert. Over time, the zone of proximal development changes. As individuals master easier tasks, they are more prepared to conquer difficult tasks. Thus, the process of learning drives the ZPD forward.

According to Vygotsky, experts can play an important role in advancing the learning of novices. The expert may be a teacher whose task is to provide the support necessary for a novice student to accomplish a task or solve a problem she or he is unable to complete alone. These supports are often referred to as *scaffolding*. Importantly, scaffolding a task or problem-solving experience does not mean the expert completes the task. Instead, the expert may provide information or pose prompting questions designed to help the novice solve the problem.

Relevance to Childhood Development

The zone of proximal development was initially conceptualized as a means of understanding the progress of children's learning and teachers' role in that progression. It can be used as a tool for assessing the appropriateness of a task – both in and out of the classroom – and for identifying the limitations of children's abilities at a particular point in development. Two important notes about the uses of ZPD are warranted. First, Vygotsky was deeply concerned with the role of social context in learning. Tasks appropriate for an individual in one setting may be different for other individuals or in other settings. Second, the ZPD should progress with development. The zone is not static and must frequently be reassessed in order to ensure tasks are neither too easy nor too difficult.

Definition

A prescription medication FDA approved for the treatment of schizophrenia, acute manic or mixed episodes associated with bipolar disorder, maintenance treatment of bipolar disorder, and acute agitation in people with schizophrenia or bipolar mania.

Description

This medication is an atypical antipsychotic available in tablet, orally disintegrating tablet, or injection.

The recommended starting dose for the oral tablets is 5 or 10 mg once daily. Maximum recommended dose is 20 mg a day. This medication should only be taken as directed by a doctor. The intramuscular injection form of this medication is generally just used in the hospital setting.

Some side effects are listed here: twitching or muscle movements you cannot control, sleepiness, headache, dizziness, nausea, chest pain, anxiety, weight gain, and weakness. Zyprexa® may cause an increase in blood sugar levels and cholesterol levels. This medication may cause weight gain. Elderly patients with dementia-related psychosis taking this class of medications are at increased risk of death. This medication may cause lightheadedness when going from a lying or sitting position.

Relevance to Childhood Development

Zyprexa® is not FDA approved for use in children. Children and adolescents will be monitored closely if a doctor prescribes this medication for childhood-onset schizophrenia.
