Samuel Kirk first proposed the term "learning disabilities" in 1963. When the initial United States federal special education law was passed in 1975, learning disabilities were included as one of the disability categories [3]. The definition remains the same today. The percentage of students identified with learning disabilities rose markedly in the early years following implementation of the federal law, leveling off in the late 1980s. Data from the U.S. Department of Education indicate that students with learning disabilities represent approximately one half of all students receiving special education services and about 5% of the overall school population [17].

There are several potential causes for learning disabilities. Traditionally, learning disabilities have been viewed as resulting from underlying neurological causes [8]. In fact, the term *minimal brain dysfunction* was used in the 1960s and 1970s as a synonym for learning disabilities [7]. Recent neuroimaging technologies (*functional magnetic resonance imaging* or *fmri*) have enabled scientists to pinpoint brain activity associated with academic tasks such as reading. There are documented differences in the brain functioning of individuals with learning disabilities, specifically *dyslexia* while reading [15]. These findings provide evidence that brain functioning differences are associated with learning disabilities. In addition, there is growing evidence linking learning disabilities to genetics. For example, learning disabilities has a recurrence rate of approximately 35–45% in susceptible families. This finding indicates that a single gene may be a contributing factor [10]. For some individuals, there appears to be a connection between genetic and environmental factors. Specifically, parents who have experienced reading difficulties may be likely to read less to their children [8]. Other environmental factors (e.g., children ingesting lead paint and alcohol and/or drug abuse by an expectant mother) can also lead to a child being at-risk for learning problems.

The federal law recognizes eight specific academic areas in which a student can exhibit a learning disability: (1) listening comprehension (receptive language), (2) oral expression, (3) basic reading skills (i.e., decoding and word recognition), (4) reading comprehension, (5) reading fluency, (6) written expression, (7) mathematics calculation, and (8) mathematics reasoning [5]. Dyslexia, a reading disorder characterized by poor decoding, poor spelling, and slow and dysfluent reading, is the most common type of learning disability [15]. However, many state departments of education do not use the term *dyslexia* in favor of the more general term, learning disability. Learning disabilities may co-occur with each other along with deficits in social and emotional disorders, and disorders in attention [4].

In addition, researchers have documented a *nonverbal learning disability* (NVLD), characterized by difficulties with fluid reasoning, spatial difficulties, organizational difficulties, poor problem solving skills, related mathematical weaknesses, and the lack of social ability to comprehend nonverbal communication cues [12]. Nonverbal learning disabilities are not specifically included in the federal definition.

Characteristics

Individuals with learning disabilities may encounter a range of problems in learning. However, no single individual likely displays all of the following characteristics. Individuals with learning disabilities may exhibit difficulty with language, memory, processing speed, and/or motor skills. These difficulties may result in poor cognitive strategies for learning, oral language difficulties, reading difficulties, writing difficulties, mathematical difficulties and/or poor social skills [7]. Attention problems are symptomatic for many students. Some characteristics are more likely to be exhibited at certain ages (e.g., children are more likely to be hyperactive than adolescents). Boys are four times more likely to be identified with a learning disability than girls, although there may be an equal number of girls with learning disabilities who go unidentified due to biological causes, cultural factors, or expectation pressures [7]. Learning disabilities become evident at different stages of life with the greatest impact occurring between the ages of 9 and 14 [7].

Assessment and Eligibility for Special Education Services

According to the guidelines of IDEA 2004, states may choose from a select number of assessment methods, including the IQ-achievement discrepancy method and the response to intervention method, to determine if a student is eligible for special education services under the learning disability category [5]. Prior to 2004, the IQ-achievement discrepancy model was used to identify a "gap" between a student's achievement and intellectual ability. Using this method, a child may be identified with a learning disability if he/she exhibits a severe discrepancy between achievement and intellectual ability in one or more of several academic areas under the learning disability category. However due to criticism that the IQ-achievement discrepancy model is a "wait to fail" method that does not yield information useful for academic interventions, beginning in 2004, states are no longer *required* to employ the IQ-achievement

discrepancy model. Instead, states "must permit the use of a process based on the child's response to scientific, research-based intervention"; and "may permit the use of other alternative research-based procedures for determining whether a child has a specific learning disability" [11].

The percentage of students identified as having a learning disability varies depending on the criteria used to determine eligibility. With increased pressure to implement *response to intervention (RTI)* strategies prior to referral for special education, it is hoped that the percentage of students in need of special education services will decrease. Ideally, insuring that all students receive appropriate instruction, beginning in kindergarten, and monitoring progress routinely will result in more effective instruction.

Despite controversy over the best way to assess learning disabilities, the construct of learning disabilities as characterized by *intraindividual* cognitive and academic strengths and weaknesses is valid [6]. "Fundamental to the concept of [learning disability] is the idea of 'unexpected' underachievement [13]. That is, individuals who are generally capable experience unexpected difficulty, based on specific cognitive processing weaknesses, in mastering certain academic tasks. For example, dyslexia has been characterized as a weakness "in a sea of strengths" [15, p. 58]. According to Wolf, individuals with learning disabilities can often also be highly creative thinkers or artists [18].

Effective Education of Students with Learning Disabilities

Early, effective instruction is important for minimizing the impact of learning disabilities. For early childhood students, researchers recommend embedding learning opportunities by incorporating practice into daily activities, and capitalizing on student's interests and motivation [2]. To successfully meet the needs of students with learning disabilities across all grades, teachers can differentiate instruction by using more than one instructional methodology. In order to meet the various academic needs of individuals, intervention strategies may include: increasing a student's access to instructional materials in a variety of formats, expanding test-taking options, extended time on tests, adjusting the complexity and nature of content material, providing accommodations, peer tutoring, direct instruction, explicit teaching, active and authentic learning opportunities, scaffolded instruction, reciprocal teaching and learning strategy instruction [7, 16]. Increasingly, technology (such as text-to-speech software and word processing programs) are useful for students with learning disabilities.

The National Organization on Disability provides information on transition to adulthood for individuals with learning disabilities, including post secondary education and employment [9]. Although individuals with disabilities are twice as likely *not* to complete college as peers without disabilities, there are special services provided for individuals with disabilities at the post secondary level. The employment rate (full or part time) for individuals with disabilities is only 35% as compared to the employment rate of individuals without disabilities at 78%. By promoting self-advocacy skills, educators can help students make successful transitions from high school to adulthood. IDEA, Section 504, and the Americans with Disabilities Act (ADA) provide overlapping protections to help ensure individuals have equal opportunities, are able to fully participate in their community, live independently and become economically self-sufficient [1, 14].

Learning disabilities are not isolated to the United States, but have been observed across cultures and languages. For example, there is documented evidence that individuals may experience difficulty learning both alphabet-based languages (such as English) and logographic or pictorial systems (such as Chinese) of written language [7]. Many famous, talented individuals are reported to have learning disabilities, including: Alexander Graham Bell, Winston Churchill, Cher, Tom Cruise, Walt Disney, and Magic Johnson.

Learning Readiness

Molly Millians
Marcus Autism Center, Atlanta, Georgia, USA

Synonyms

Academic readiness; Early academic skills; Pre-academic skills; School-entry skills

Definition

Learning readiness is the physical, motor, socio-emotional, behavioral, linguistic, and cognitive skills indicating preparedness to receive formal educational instruction.

Description

The terms learning readiness and school readiness were derived from educational reforms and the outcomes from model early childhood programs. Learning readiness is the observable traits that indicate young children are ready to receive early academic instruction. The term learning readiness is associated with school readiness. However, learning readiness and school readiness refer to different aspects of early learning and education. School readiness refers to the wide range of the skills children need to acquire to enter and to be successful in a school setting. Learning readiness indicates young children's ability to receive purposeful instruction.

In 1989, the National Education Summit was convened to discuss ways to improve education in the United States. The outcome from the National Education Summit was the formation of the National Education Goals Panel and the proposal of the National Education Goals. The National Education Goals are comprised of six objectives to improve education from preschool through twelfth grade in the United States. Learning readiness was included into Goal 1 that stated "by the year 2000, all

children in America will start school ready to learn" [5, p. 3]. The National Education Goals were incorporated into the Educate America Act of 1994.

In 1992, the National Education Goals Panel attempted to define learning readiness. The National Education Goals Panel identified five dimensions that indicate children are ready to learn and to enter school [10]. The five dimensions were physical well being and motor development, social and emotional development, approaches to learning, language development, and cognition and general knowledge [10, p. 23]. The premise was that adequate development in each of these domains would indicate that children would be ready to learn in school. The National Education Goals Panel dimensions of learning provided a broad description of learning readiness embedded within the term school readiness.

Model programs for early child education have attempted to define the skills children need to learn. Many of these programs were designed to prepare economically disadvantaged children for school. The Abecedarian Project in Chapel Hill, North Carolina, has been active since the 1970s. The purpose of the Abecedarian program is to provide quality services in an attempt to prevent developmental delays and low cognitive skills as a result of early deprivation. The program addresses the needs of children 3–6 months of age through early elementary school. Parent involvement and parent education are primary components of the program. Curriculum is geared to address children's linguistic and communication skills, as well as their cognitive, early academic, social, emotional, and motor skills. The program has been successful in preventing academic failure [9].

Since its inception in 1965, the Head Start Program has provided a comprehensive program to children of low income and at-risk families. This includes children of migrant, homeless, and refugee families. The early goals of the Head Start Program were to encourage ties to the communities, strengthen family interactions, and to ensure the overall well-being of children. This included early educational instruction to prepare children to enter school [10].

More recently, goals for Head Start have shifted to focus on developing children's cognitive and pre-academic skills. This includes providing language instruction for children who do not speak English as their primary language. In 2007, the Improving Head Start for School Readiness Act (P.L. 110–234) was signed into law. The Improving Head Start for School Readiness Act of 2007 required Head Start Programs to adjust their programs to align with the educational standards established by the No Child Left Behind Act of 2003. The adjustments to the Head Start programs called for systematic monitoring of children's progress and program accountability through the use of standardized measures, similar to the requirements for public schools outlined in the No Child Left Behind Act of 2003.

The Improving Head Start for School Readiness Act of 2007 indicated that children need to have acquired adequate language, listening comprehension, pre-literacy, and early mathematic skills before entering kindergarten. The Improving Head Start for School Readiness Act of 2007 stated that children need to demonstrate the use of critical thinking and problem solving skills, such as categorization. In addition, the law indicated that children need to be able to interact appropriately with peers and adults in order to function in a school environment. The focus of Head Start and other programs for economically disadvantage children has shifted from developing strong community ties to attempting to close the achievement gaps that emerge later in school [8].

As indicated through educational reforms and early childhood educational programs, children require adequate physical, motor, linguistic, behavioral, social and cognitive skills to be prepared to receive formal instruction. Specifically, children need to have developed the abilities to self-regulate, to pay attention, and to interact appropriately with peers and adults. Children need to exhibit the abilities to use language to express ideas, to think through problems systematically, and to begin to acquire early literacy and mathematic concepts [11, 12].

Self-regulation is a foundation for early learning and influences the other components of learning readiness. Self-regulation is the modulation of behavior, emotions, and responses according to the surroundings. Children who are ready to learn are able use self-control and organize their behavior in a structured setting. Self-regulated children are able to comply with rules and follow the expectations of a classroom. Children who are ready to receive formal instruction are motivated to learn more about topics and their surroundings. They demonstrate a lessening of exploratory behavior and begin to move through their environment in an organized manner [4].

Internal motivation includes taking the initiative, setting and reaching a goal, and evaluating performance. Children who are ready to learn exhibit the ability to pay attention. Children, who are able to sustain attention, exhibit an increase in persistence to complete a task or activity. They begin to filter out distractions and inhibit impulsive responses [4].

Interpersonal skills affect learning readiness. Children need to be able to work and play cooperatively with peers. Necessary interpersonal skills include sharing, waiting,

and taking turns. Interpersonal skills include listening to the teacher and peers to learn from their ideas [1, 2].

Language, cognitive functioning, and pre-academic skills are primary components for learning readiness. Children need to be able to express their ideas, needs, and wants in order to maneuver a learning environment. Language is also used to mediate children's responses to their environment. Cognitive skills include the ability to apply and to adjust problem-solving techniques, to make inferences and predictions through thoughtful observations, and to develop an understanding of symbolic relationships [7].

Experience with early literacy and mathematics prepares children for classroom instruction. The acquisition of early literacy and mathematics are predictive of later academic achievement. Pre-reading skills that prepare young children for formal literacy instruction include exposure and use of a rich vocabulary, exposure to the different uses of language, and experiences with the uses of print [3, 8].

Early mathematic knowledge incorporates number skills such as counting using one-to-one correspondence, cardinality, and identifying amounts as more, less, or the same. Through play and interactions children learn to alter values by combining and taking away amounts. Also, pre-academic skills need to support formal mathematic instruction that include the ability to distinguishing shapes, patterns, and to recognize spatial relationships [6, 12].

In addition to cognitive and pre-academic factors, the readiness to learn is affected by children's physical and emotional well being. Children's readiness to learn is shaped by interactions with caregivers, their environment, and individual predispositions [13, 14].

Research, educational reform movements, such as the call for universal preschool, and comprehensive early childhood programs indicate the need for children and families to have access to quality interventions and programs to assist in preparing children to be ready to learn.

Left Dominant

►Left Handedness

Left Handedness

Raymond S. Dean, Matthew J. Holcomb
Ball State University, Muncie, IN, USA

Synonyms

Left dominant; Sinistral

Definition

Left-handedness is the expressed consistent preference for the use of the left hand over the right for germane activities in daily life.

Description

Handedness is defined and categorized in different ways. Most people define handedness as the hand that is preferred for the task of writing. Some researchers define handedness as the hand that is faster for manual tasks. Others define it as the preferred hand, regardless of its abilities. Whereas some people always use their right hand or their left hand for most activities, others use one hand or the other depending on the activity. Still other people have mixed hand usage for most functions. At one time it was thought that left-handedness was a behavioral sign of right cerebral hemispheric dominance for language.

Lefthanders usually prefer using their left hand for tasks; however, there is sound method for predicting which hand a lefthander will choose for a given task. Rarely, if ever, is a left handed individual entirely dependent upon using their left hand to accomplish all tasks. Typically, left-handed children usually are more flexible in their hand usage than right-handers; this may be because they are forced to function in a world designed for right-handers. Left-handed children can be placed at a disadvantage due to the prevalence of right-handed tools typical in society. For example, scissors, a very common tool in many children's lives are often molded in a way that makes them difficult to use for a left-handed child. Additionally, items such as school desks and computer mouse have been traditionally made with right handed individuals in mind.

Demographics

It has been estimated that 90–95% of the general population is right-handed, making left-handedness relatively uncommon. Overall, left-handedness appears to occur more frequently in men than in women, as well as occurring more frequently in both mono and dizygotic twins. Additionally, research has shown a higher than normal percentage of left-handedness in a number of childhood disorders including autism, mental retardation, and dyslexia. Researchers generally agree that the causes of left-handedness are commonly considered to be part genetic and part environmental. However, Dean and Rattan [2] and others showed the existence of genetic and pathologic left-handedness. With congenital problems being more likely with pathologic lefthanders over right.

There is no standard measure for determining degrees of handedness. Some scientists believe that there are only two types of handedness: right and non-right. These researchers believe that true left-handedness is rare and that most lefthanders are really mixed-handed. Others believe that ambidexterity – the equal use of both hands – is a third type of handedness, and some think that there are two types of ambidexterity. Other scientists believe that handedness should be measured on a continuum from completely right-handed to completely left-handed.

Traditionally, this has been measured on a lateral preference scales with very few people exhibiting a pure preference for either left or right handedness.

Much of the debate centering on research findings having to do with handedness comes back to the issue of how handedness was determined. With the variety of methods that are available to researchers in defining handedness there has been little consistence in the research.

Basis of Handedness

The physical evidence for a basis in handedness is not well-understood by researchers. Over the years left-handedness has been associated with physical and psychological causes. Additionally, in many cultures left-handedness is regarded with superstitious beliefs and considered due to supernatural occurrences.

Until the 1960s, the general theoretical consensus of handedness was that it predicted brain lateralization. Each hemisphere of the brain has some specific functioning that is lateralized to that hemisphere. For example, in the nineteenth century Paul Broca identified the left hemisphere as the major area of speech production in the brain.

Carl Wernicke later identified another region in the left hemisphere that was responsible for language comprehension. These findings help perpetuate the idea that handedness was indicative of brain lateralization.

In 1987, Geschwind, Behan, and Galaburda (GBG) published the Theory of Left-Handedness that attributed left-handedness to brain injury or trauma suffered inutero. GBG also suggested that chemical variations in the womb such as higher levels of testosterone could influence handedness.

Lifespan Development

It is commonly believed amongst researchers that handedness is not a clearly established trait in infants. In fact, many believe that babies are born as ambidextrous, and that changes in handedness can occur several times over the first few years of life. Toddlers usually go through a phase in which the use of one hand is preferred for some activities and not for others. Typically, handedness is decided by the time a child reaches 3 years of age; although it is not uncommon for a child to continue to switch handedness preferences through preschool.

Problems Associated with Left-Handedness

There are a number of difficulties associated with being left handed and interacting with a predominately right handed environment. Many of these problems are simply annoying, but a few can cause physical injury or serious problems. Due to the overwhelming percentage of people who are right handed, most systems and tools are designed with right-handed individual in mind. For example, most screws are designed for left-to-right turning, which is easier for right handed individuals to accomplish. Some other items that are designed specifically for right-handed individuals are: scissors, calculators, sports equipment, musical instruments, computers, desks, and telephones.

Writing is another area that is generally a problem for children with left-handedness. In many cultures, the avoidance of left-handedness has led to pressure for children who are left handed to learn to write right handed. In the U.S. this was a problem, but seems to be dwindling at least on the part of parents and teachers. Children may still feel pressure to perform tasks such as writing right handed because of peer pressure. Teachers may still label a left-handed child's writing as sloppy or illegible due to an unconscious reaction to writing that looks different from other children's. Additionally, children who are left-handed may be more prone to difficulties with writing as they may hook their wrist to be able to see what they are writing; which can produce sloppy handwriting.

There is a general trend over the course of history to attribute a number of bad things to left-handed individuals. For example, in history there are numerous instances where left-handed individuals were association with physical, emotional, and behavioral disorders. While not seen in the same extent today, left-handedness has been shown by researchers to put people more at risk for schizophrenia, bipolar disorder, posttraumatic stress disorder, migraine headaches, and language processing disorders such as dyslexia and stuttering.

Leiter International Performance Scale: Revised

David Michalec
Nationwide Children's Hospital/The Ohio State University, Westerville, OH, USA

Definition

The Leiter International Performance Scale – Revised (Leiter-R) is an individually administered instrument designed to assess the cognitive functioning of children and adolescents ages 2 years, 0 months to 20 years, 11 months of age. The Leiter was revised in 1997. The Leiter-R was specifically developed for children and adolescents with communications disorders, cognitive delays, English as a second language, hearing impairments, motor impairments, traumatic brain injury, attention-deficit disorder and certain types of learning disabilities as well as other populations (e.g., autism spectrum disorders) for which traditional intelligence tests may not be appropriate or valid.

Description

The Leiter-R includes two groupings of subtests. The Visualization and Reasoning Battery contains ten subtests and generates Brief IQ (ages 2–20), Full Scale IQ (ages 2–20), Fluid Reasoning Index (ages 2–20), Fundamental Visualization Index (ages 2–4) and Spatial Visualization (ages 11–20) scores. The Attention and Memory Battery also contains ten subtests and generates Memory Screener (ages 2–20), Associative Memory (ages 6–20), Memory Span (ages 6–20), Attention (ages 6–20), Memory Process (ages 6–20) and Recognition Memory (ages 6–20) scores. Additionally, the Leiter-R includes four rating scales, which can be completed the by the examiner, parent, the child or adolescent being tested (Self) and teacher, which provide multidimensional behavioral observations.

The current revision of the Leiter-R was organized around four primary issues: the need for early identification of cognitive delays, the need for measurement of small increments of improvement in cognitive ability, the need for a reliable and valid scale of intelligence regardless of language or motor ability and the need for transition planning for entering the world of work.

In fitting with the primary focus of the most recent revision, The Leiter-R is particularly useful in the assessment of younger children with little or no language skills including those with expressive and receptive language deficits and those with Autism Spectrum Disorders. This measure allows the evaluator to obtain an estimate of intellectual functioning without being overly concerned that the oral language or verbal mediation required of a verbally administered measure (e.g., traditional measures of intellectual functioning) is negatively impacting the child's performance. Although many of the tasks from the Visualization and Reasoning Battery are based on a matching paradigm and therefore may not generalize broadly to other cognitive skills, the ability to demonstrate clear cognitive strengths and weaknesses outside of the influence of language functioning is a huge asset for treatment planning.

The Leiter-R offers several updates from the earlier version including new normative data (based on 1993 census data), light weight, laminated picture cards and foam shapes that are brightly colored and child friendly and an easel format for administration. The total normative sample matches the US population well on important stratifying variables. Internal consistency reliabilities are adequate although test – retest changes for the composite scores have been found to be somewhat large. Factor analytic studies have supported the theoretical underpinnings of the test. The Leiter-R correlates well with other accepted measures of intellectual functioning including the WISC-III. The Leiter-R is also felt to be largely culturally free and studies have found the measure to be valid across a number of cultural and ethnic groups.

Leukemia

Margaux Barnes, Avi Madan-Swain
University of Alabama Birmingham, Birmingham, AL, USA

Synonyms

Acute leukemia

Definition

Leukemia is a cancer of the blood and blood forming organs, including the bone marrow, lymph nodes, and spleen.

Description

Leukemia is the most common pediatric cancer diagnosis, comprising approximately 30% of all childhood cancers. Acute lymphoblastic leukemia (ALL) accounts for about 80% and acute myelogenous leukemia (AML) about 15% of pediatric leukemias; while chronic myelogenous leukemia (CML) and juvenile myelomonocytic leukemia (JMML) are infrequent. Annually approximately 3,000 new cases of ALL and 500 of AML are diagnosed in the United States [3].

The hallmark of leukemia is bone marrow dysregulation. The bone marrow makes red blood cells which carry oxygen, white cells, which fight infections, and platelets, which help clot blood. Leukemia is a cancer of the early blood forming cells and most commonly affects the white blood cells, also known as leukocytes. Sometimes certain types of immature white blood cells, often known as blasts, undergo a random mutation that can cause the cells to grow and multiply unchecked. The blasts suppress normal bone marrow function, which results in decreased red blood cells, decreased platelets, and decreased functional white blood cells.

Leukemia is diagnosed in all age groups with peak incidence between ages 2 and 5 years of age. Leukemia rates vary by age, gender and race. For example, males are more likely to be diagnosed with ALL as compared to females in children under the age of 15. Similarly, ALL rates are significantly lower in African American children than Caucasian children; but no ethnic differences are noted among children diagnosed with AML [3].

There are no known causes for ALL. However, increased risk for ALL is associated with genetic conditions such as Down syndrome, neurofibromatosis, Schwachman syndrome, Bloom syndrome, Li-Fraumeni syndrome, Klinefelter syndrome, or if a child has received medications to suppress the immune system such as after organ transplantation. There also is a 2–4 times higher incidence of ALL in siblings than in children in the general population. Finally, children who have received prior chemotherapy or radiation treatment for other types of cancer are also at risk for developing leukemia.

Clinically, children may present with low-grade fever, signs of infection, fatigue, increased bruising or bleeding, and facial pallor. When the diagnosis of leukemia is suspected the child is referred to a Pediatric Hematologist/Oncologist for a full evaluation, which includes a thorough physical examination, blood tests, and a needle aspirate of the bone marrow. Based on this work-up, the specific leukemia type is confirmed, and chemotherapy is begun to treat the condition.

At diagnosis children are categorized as having low, intermediate, or high risk based on both the child's clinical features, chromosomal abnormalities noted in the leukemia cells, and response to chemotherapy. Higher risk factors include low or high age (i.e., children under the age of 1 year or older than 10 years of age), a white blood cell count greater than 50,000, leukemia subtype, central nervous system disease (i.e., blasts in the spinal fluid), certain chromosomal alterations in the leukemia cell, and slow response to initial treatment. These factors would require more aggressive treatment.

Medical treatment protocols for ALL typically include the following stages: Induction, Consolidation, Delayed Intensification, and Maintenance. The Children's Oncology Group (COG) conducts randomized clinical trials to determine the best therapy for each treatment phase. The goal of clinical trials is to increase cure rate for leukemia and reduce the toxicity of the therapy. Current ALL standard risk treatment protocols are 2 to 2-and-a-half years for girls and 2-and-a-half to 3 years for boys. After the first 6 months most of the chemotherapy is generally administered on an outpatient basis. High risk ALL protocols may require more frequent inpatient chemotherapy admissions. Treatment for AML usually requires 4–5 months of intensive chemotherapy administered as an inpatient. Some AML patients may receive a bone marrow transplant.

Induction is the initial treatment phase for ALL and usually lasts 4 weeks. Children receive chemotherapy orally, intravenously, as well as intrathecally (i.e., injected into the fluid surrounding the brain and spinal cord). The goal of this phase is to induce remission. Remission is defined as an absence of signs and symptoms of leukemia, a return to normal of blood and bone marrow values, and less than 5% leukemia cells in the bone marrow. Approximately 95% of children with ALL achieve remission

within 4 weeks of beginning therapy. Once in remission the *consolidation* phase of therapy is initiated and lasts from 4- to -6 months. During this period the child receives repeated cycles of systemic chemotherapy agents as well as continued intrathecal chemotherapy to eliminate any remaining leukemia cells. For certain types of leukemia, or if leukemia cells were present in the spinal fluid at the time of diagnosis, radiation therapy may be given to the brain and the spinal column. During *delayed intensification* the child receives chemotherapy agents similar to those received in the first 6 months of treatment (i.e., during induction and consolidation). Research shows that both low and high-risk ALL patients benefit from Delayed Intensification. *Maintenance* therapy is the final phase of treatment and generally lasts 2–3 years. Maintenance is much less intensive than the previous treatment and consists mostly of oral medications administered at home, as well as intermittent intravenous and intrathecal medications given in the outpatient clinic. Bone marrow transplant may be necessary for children with high-risk features including relapse, and treatment-resistant diseases, or other disease subtype factors that increase the likelihood that standard treatment will be unsuccessful.

Currently, approximately 75% of children are cured (i.e., they remain disease free 2 years after completion of treatment). More relapses or recurrences occur either on therapy or within 2 years after completion of therapy. Late relapses (beyond 5 years) are rare. If the leukemia returns, another remission will often be achieved with more aggressive medical therapy. Many children will stay in remission with additional chemotherapy, but a bone marrow transplant may be recommended for some children. Approximately 50% of children will be cured from AML with chemotherapy and, if available, a bone marrow transplant using a matched related donor.

Relevance to Childhood Development

Children vary in the way they cope with the news of their cancer diagnosis and treatment [3, 4]. Coping responses may include withdrawal, becoming very scared or worried, and/or lashing out in anger. During induction the child learns to deal with painful procedures, cope with the physical symptoms and side effects (e.g., nausea, vomiting, fatigue), adjust to interruptions in school and social activities, adjust to the hospital environment, and manage emotional reactions and responses. During the middle to later phase of treatment the child learns to deal with physical side effects (e.g., weight gain on steroids, hair loss), adhere to treatment regimen, and try to maintain academics, social activities, and communication with close friends. After completion of treatment the child learns to acknowledge concerns over relapse or recurrence, make meaning of their cancer experience and shift roles from being a "cancer patient" to being a survivor [1].

Due to improved medical treatment more children are surviving and consequently increased emphasis is being placed on medical, psychological, and learning late effects. Potential medical late effects include short stature, delayed pubertal development, infertility problems, and neurocognitive deficits. Neurocognitive late effects secondary to intrathecal chemotherapy and radiation therapy include problems with executive function including short attention span, problems with organization, decreased processing speed, difficulties with visual-spatial and visual-motor tasks, problems with visual memory, and academic difficulties with reading comprehension and math calculation [2]. Some ALL survivors also are at risk for development of anxiety, symptoms of posttraumatic stress, problems with identity, and decreased self-esteem [4]. However, there also is some evidence of positive growth from going through the cancer experience.

Lexapro®

Anisa Fornoff
Drake University, Ankeny, IA, USA

Synonyms

Escitalopram

Definition

A prescription medication FDA approved for the treatment of major depressive disorder and generalized anxiety disorders.

Description

This medication is a selective serotonin reuptake inhibitor available in a tablet or as an oral solution.

The recommended starting dose for this medication is 10 mg taken once a day. Maximum suggested dose is 20 mg a day. This medication should only be taken as directed by a doctor. This medication may need to be taken for four weeks before improvement in symptoms is seen.

This medication should be taken with or without food. Avoid drinking alcohol. Tell your doctor if you have a history of a seizure disorder or liver disease.

Concomitant use in patients taking monoamine oxidase (MAO) inhibitors is not advised. Serotonin syndrome may occur with the use of certain other serotonergic drugs.

Some side effects are listed here: headache, drowsiness, constipation, difficulty sleeping, decreased sexual desire, decreased appetite and weight loss, diarrhea, and dizziness. Certain side effects may go away during treatment. Tell your doctor immediately if you notice the following: confusion, irregular heartbeat, muscle pain, shortness of breath, or swelling.

If you choose to stop taking Lexapro®, you are encouraged to tell your doctor and slowly taper this medication to prevent withdrawal symptoms.

This medication should be stored out of reach of children and pets and away from light, heat, and moisture.

Relevance to Childhood Development

Lexapro® is not FDA approved for use in children.

A medication guide must accompany this medication containing information related to the increased risk of suicidal thinking and behavior in children, adolescents, and young adults compared to those not taking the medication. Doctors will monitor patients closely for worsening of symptoms, change in behavior, and thoughts of suicide. Patients are strongly encouraged to notify their health care provider to report sudden changes in mood, behavior, thoughts, or feelings.

Women should let their doctor know if they are pregnant or planning to become pregnant. Talk with your doctor if you plan to breastfeed, as this medication enters the breast milk.

Life Events

Beatriz Olaya Guzmán[1], Cecilia A. Essau[2]
[1]Edifici B. Universitat Autònoma de Barcelona, Spain
[2]Roehampton University, London, UK

Synonyms

Negative life events; Stressful life events; Undesirable life events

Definition

Life events have been defined as a social experience or change with a specific onset and course that has a psychological impact on the individual [7]. This definition makes no assumption about the type, duration and effects of the events. Some common examples of life events include parental divorce or separation, school change, house relocations, and bereavement.

Description

All individuals experience hundreds of life events throughout their life time that differ in magnitude, duration and meaning. Some of these events are major and involve high level of change (e.g., death of a love one), and some events are minor and have little impact on their own (e.g., minor accident). Life events are important as they could facilitate positive growth and adaptation, or they could contribute to illness and disturbances. Studies on life events have focused on two major areas:

(1) Description of events throughout the life span: This line of research has focused on the developmental nature of life events and has identified several characteristics of life events. First, some biological (e.g., physical growth) and social events (e.g., school transitions) are age-related in that they occur frequently during childhood and adolescence. Although such life events are part of development, they may be problematic if they occur at different (than expected) point in the life span. Second, although some events are unique of particular individuals, some (e.g., war) may affect on the entire culture. Finally, developmental approach also stresses the importance of historical or cohort effects of events. For example, those who experienced adolescence during the 1930s economic depression have a different event history than those who experienced adolescence during the 1960s economic affluence.

(2) Impact of life events during childhood and adolescence: This line of research is concerned with the relationship between life events and psychological/physical disorders. Some studies investigated the mechanisms through which exert their effects on individuals, and some examined factors that predicted the outcomes of life events on the individual's development.

Assessment of Life Events

Impact of life events have traditionally been examined using self-report questionnaires or life events checklists. In such studies, the number of events experienced over a given period of time can be counted. The problem of this method is an assumption that all events have the same effect. Although this problem could be reduced by giving a stress score which lead to change in the child's life such life change units have been reported to be insensitive to individual differences that surround life events. Another important issue is to determine whether the events are the cause, consequences of psychological disorders, or of it is an illness-related behaviour [15].

A major advantage of using checklists is that they are easy to administer without much training requirement. As such they are economical. Some examples of life events checklists are: Life Events Checklist (LEC; [11]); Life Event Record (LER; [3]), Brief Adolescent Life Event Scale (BALE; [17]), Adolescent Perceived Events Scale (APES; [4]).

Another approach to measure life event is through interviews. The use of interview is time consuming, however, this factor is outweighted by the quality of information collected [9]. The ability to collect information surrounding a life event enables the evaluation of the personal meaning that a life event contains [2]. When studying children, it is unclear from whom the information about life event should be collected. For the under 8-year olds, parent's report is regarded as the most reliable informant because of children's lack of cognitive skills to recall information in an accurate way, and children's awareness of important sources of life events. When studying adolescents, adolescents themselves have been considered as the best source of information [13].

Some examples of commonly used interviews for the assessment of life events are:

Life Events and Difficulties Schedule (LEDS; [2]), and Stressful Life Events Schedule (SLES; [18]).

Relevance to Childhood Development

Research conducted during the past few decades have shown life events to be related to the onset of a wide range of psychiatric disorders, such as depressive, anxiety, substance use, and conduct disorders. For example, since the 1970's, studies have noted the influence of negative/stressful life events on the onset of depression, and research has shown that stress is specifically predictive of depressive symptoms in children and adolescents [9, 14]. Life events predict subsequent depressive disorder, and those which are chronic in nature (e.g., chronic family turmoil) also influence the persistence of depressive symptoms [6]. The types of life events which act as risk factors for major depressive disorder seem to differ in boys and girls. In Reinherz et al.'s study [16], for example, the death of a parent before age 15, pregnancy, and an early onset of

health problems (e.g., respiratory disorders, mononucleosis, arthritis and headaches) which interfered with daily functioning were antecedent risks for major depressive disorder in females; in males it was the remarriage of a parent [16].

In a study by [1], depressed adolescents tended to use more negative alternatives (e.g., becoming intoxicated, isolating themselves, or running away from home), whereas the non-depressed adolescents generally used positive alternatives (e.g., minimizing the importance of the events) in dealing with the life events experienced. According to several other authors, major depressive disorder was generally positively correlated with emotion-focused strategies [4] and cognitive avoidance [5], and negatively correlated with problem-focused coping [4]. In Nolen-Hoeksema et al.'s study [14], the association between life events and depressive disorders was related to chronic disruption in the child's environment; among older children, the impact of life events on depressive disorders was mediated by pessimistic explanatory style, and among girls by self-perceived body image, self-esteem, and self-efficacy.

Children who were exposed to high stress levels were especially likely to become depressed if the mothers were currently symptomatic [10]. Thus, the presence of the mother to help buffer the ill effects of stress may moderate the impact of stressors on children's probability to develop depressive disorders. In Goodyer et al.'s study [8], adolescents whose mothers had a history of psychiatric disorder were exposed to more negative events than those whose mothers had no such history. Thus, both lifetime maternal psychiatric disorder and increased exposure to undesirable life events significantly exerted an increased risk for major depressive disorder in adolescents.

It should, however, be stated that life events appear to be a nonspecific risk factor for major depressive disorder; that is, negative life events increase the risk of both depression and a number of other psychiatric disorders. As shown by [12], parental loss before the age of 17 years was significantly related to the presence of five major psychiatric disorders.

Life Satisfaction

David N. Miller
University at Albany, SUNY Division of School Psychology, Albany, NY, USA

Synonyms

Quality of life; Well-being

Definition

Life satisfaction is a cognitive appraisal process in which individuals subjectively assess life quality on the basis of their own unique set of criteria.

Description

In recent years there has been an increased emphasis on examining the positive aspects of human nature. This movement, known as positive psychology, has been defined as "the scientific study of ordinary human strengths and virtues" ([10], p. 216). One topic within the domain of positive psychology that has attracted substantial interest is how and why individuals, including children and adolescents, experience their lives in positive ways [5]; that is, there has been increased interest in examining those variables that contribute to the development of subjectively perceived life satisfaction.

Research on life satisfaction has been conducted from social indicators, marketing, and quality of life perspectives [11]. However, much of the recent research in this area has been most influenced by the work of Diener and his colleagues [1, 2], who conceptualize life satisfaction as one of three important components (the others being positive and negative affect) within the larger domain of subjective well-being. This perspective conceptualizes life satisfaction as "a cognitive judgmental process in which individuals assess the quality of their lives on the basis of their own unique set of criteria" ([9], p. 164).

Although the appraisal of life satisfaction is a cognitive one, it is largely based on the positive experiences and emotions that collectively contribute to subjective well-being. However, these cognitive judgments are largely independent from an individual's immediate and emotional interpretation of a particular event; reports of life satisfaction "are believed to transcend momentary emotional experiences within and across life situations and are thus considered more stable than affective states when assessing life quality over time" ([11], p. 28). That said, researchers are recognizing that life satisfaction is tied to specific, concrete experiences, and that it yields unique variance not accounted for by assessing more global life satisfaction indices alone. This has lead to the development of measures that assess satisfaction within specific domains, such as students' perceptions of school satisfaction [11].

Most of the research on life satisfaction to date has been conducted with adults, with research involving child and adolescent samples having begun only recently. Research suggests that although most children and adolescents are generally satisfied with their lives, a minority appear very dissatisfied [7]. Low life satisfaction is associated with several adverse outcomes, including those related to internalizing problems (e.g., depression, anxiety) and school adjustment. In contrast, high life satisfaction functions as a psychological strength and actively fosters resilience and well-being [7]. For example, in a study examining the characteristics of adolescents who reported high levels of global life satisfaction, Gilman and Huebner [6] found that high life satisfaction was associated with mental health benefits that were not found among youth reporting comparatively lower life satisfaction levels.

Moreover, school experiences can strongly influence life satisfaction in children and adolescents. Behavioral contexts (e.g., grades received; in-school conduct), social contexts (e.g., school climate), and cognitive contexts (e.g., academic personal beliefs; attachment to school) associated with schools are all linked to students' global life satisfaction [11]. Some research has suggested that academic achievement in school is moderately correlated with adolescents' global life satisfaction [6] and school satisfaction [3]. Suldo and Shaffer [12] found that middle-school students with the highest reported levels of subjective well-being had superior grades in courses and superior scores on standardized achievement tests. In contrast, lower levels of life satisfaction have been associated with problem behaviors in school, including disruptive and acting-out behaviors [11].

Over the past decade, several psychometrically sound life satisfaction scales for children and adolescents have been developed on the basis of unidimensional or multidimensional models. Most reviewed measures to date have adequate internal consistency reliability and acceptable test-retest reliability across several time frames (up to a year), and have also demonstrated strong evidence of various types of validity [4, 11]. To date, most measures have been self-reports and have been primarily used to illustrate similarities and differences between life satisfaction and related psychological constructs, such as self-concept [7].

The assessment of life satisfaction in children and adolescents is still in its beginning stages and more research is needed. It is clear, however, that assessing constructs such as life satisfaction provides a broader, more comprehensive perspective of psychological functioning, and that assessing problems in the absence of strengths provides an incomplete and distorted picture of children and youth [8]. Given that life satisfaction is a meaningful indicator and determinant of well-being in

children and adolescents, school and clinic-based mental health professionals should become well-versed in its assessment as well as interventions to promote it.

Limbic System

Chad A. Noggle[1], John Joshua Hall[2]
[1]SIU School of Medicine, Springfield, IL, USA
[2]The University of Arkansas for Medical Sciences, Little Rock, AR, USA

Definition

The Limbic System is a network of brain structures that together play a pivotal role in emotional processing and regulation as well as aspects of memory.

Description

The Limbic System represents one of the three divisions of the Telencephalon, in addition to the Basal Ganglia and the Cerebral cortex. Anatomically, the Limbic System is a network of structures that surround both the basal ganglia and the thalamus [1]. These structures include, but are not limited to, the Hippocampus, Dentate Gyrus, Cingulate Gyrus, Septal areas, Amygdala and aspects of the Diencephalon [4]. From a functional standpoint the Limbic System is best conceptualized as a holistic system as few one-to-one structure-function relationships have been established. Rather, many of the structures included within the system demonstrate overlapping roles in the modulation of the various functions regulated by the limbic system. Specifically, the Limbic System, in concert with aspects of the Frontal lobes and Temporal lobes, are involved in the control of memory and emotion [2]. This corresponds with aspects of emotional processing and regulation as well as aspects of recent memory [4]. Beyond these areas, which are most commonly linked with the interconnections and workings of this network of structures, the Limbic System has also been associated with autonomic functions (e.g., arousal), and olfaction [4]. Furthermore, the limbic system has been found to play a pivotal role in mediating the drives or instincts that assist in the attainment of fundamental biological needs [2].

In terms of the Limbic Systems role in memory, explicit memory, including semantic and episodic memory, represents the domain of memory that is dependent upon the network. However, there is greater reliance on the actions of the Hippocampal formation, Amygdala and Rhinal cortices in comparison to other structures of the Limbic System [3]. In addition, the Prefrontal cortex as well as additional structures of the Temporal lobe that do not fall under the umbrella that is the Limbic System, are linked to the aforementioned domains of memory [3]. Yet, the key component still remains to be the Hippocampal

formation as it has been specifically linked to memory acquisition [5]. The role of the Hippocampal formation in memory has been best seen in individuals with bilateral injuries of the Hippocampus, such as the classic case of H. M. who following bilateral Hippocampal resection presented with dense anterograde amnesia in which he had severe difficulties in learning new information.

Aside from those structures included as part of the network, the Limbic System has also been closely related to the Hypothalamus. It is this connection that provides for the integration and organization of autonomic processes related to the emotional expression of behavior [5]. In terms of those structures viewed as playing more prominent roles in the regulation of emotions, the Cingulate gyrus and Amygdala constitute those of greatest interest. While the Amygdala has been linked to aspects of fear conditioning, in addition to strengthening stored memories by linking emotional cues to the information to be recalled, the Cingulate gyrus plays a vital role in controlling the experience of emotion [2]. Again, this is related to its projections to the Hypothalamus, which is then responsible for directing the autonomic and endocrine effectors of emotion [2]. However, while this relationship and the workings of the Hypothalamus may impact the experience of emotion, higher cortical areas, such as the Frontal lobes, constitute the gateway that in turn determines what behavior is exhibited in response to the emotional experiences. This is the basis of inhibition.

Finally, the manner in which the Limbic System is involved in mediating drive and/or instincts for basic survival is largely related to the bidirectional nature of the Limbic-Hypothalamus link. Specifically, while emotional reactivity, as processed by the Limbic system, transmits to the Hypothalamus to mediate concurrent organization of autonomic responses to the emotionally stimulating environment, the Hypothalamus is the starting point in terms of signaling when there is a biological need, this impulse is then passed along to the Limbic System to assist in increasing arousal and processing the nature of the stimuli.

Definition

Literacy is the ability to articulate one's thoughts, listen, read and write.

Description

The National Literacy Trust (NLT), a non-profit organization for the enhancement of an individual's life through literacy, defines literacy as the ability to speak, listen, read,

and write in order to fulfill one's potential. The NLT argues that speech, language, and communication skills are essential in developing reading and writing competency [5]. Literacy does not refer to a single ability but to different types and levels of skills. At one end of the spectrum are the early developing skills in young children that are essential to literacy growth. These are referred to in the literature as emergent and early literacy skills. At the other end of the spectrum are the essential skills for functioning adults, identified by the National Assessment of Adult Literacy (NAAL) as prose, document, and quantitative literacy [4].

Much of the research in the last decade has focused primarily on the reading development of young children. According to the most recent National Assessment of Educational Progress (NAEP) report, approximately one fourth of fourth graders fail to exhibit basic levels of reading skills and one tenth of fourth graders fail to demonstrate basic writing skills. In particular, children in low-income households display disproportionate literacy and writing skills [3, 7]. Furthermore, the NAAL 2003 report indicates that there are 11 million adults in the United States who are illiterate. Furthermore, 14% of adults (30 million) are performing below basic at the most simple and concrete literacy level [4].

Emergent and Early Literacy

Understanding the multidimensional aspects of literacy is crucial to reducing the illiteracy rate. At the beginning level, researchers often refer to two types of literacy skills that are considered to be the precursors to literacy development: emergent and early literacy. Emergent literacy refers to a broader concept of literacy that starts prior to formal instruction and leads to an awareness of print. Embedded within this concept are specific skills that relate to reading development. These skills are an awareness of print, relationship of print to speech (i.e., understanding the differences between oral and written language), comprehension of text structures (i.e., knowledge of grammar and organization of stories), phonological awareness (i.e., sensitivity and awareness of sounds in oral language), and letter knowledge (i.e., knowledge of the alphabet and related sounds) [2].

The other type of literacy skill, early literacy, refers to the discrete basic skills that are the foundation for reading success. Researchers have examined skills such as letter knowledge, phonological awareness, concepts of print, and naming of letters, colors, and objects to determine acquisition rates and prediction of later achievement [2]. Students are expected to learn the aforementioned skills during the first formal years of education. Knowledge of letters and phonemic awareness have been found to bear a strong and direct relationship to the success and ease of reading acquisition [1, 6]. This relationship is strong despite the instructional approach used. The predictive strength of these two skills suggests that the letter-to-sound relation is of special interest to beginning readers [1].

The letter-to-sound relation is referred to in the literature as phonological awareness, which refers to the sensitivity of sounds in spoken words as well as the ability to manipulate the sounds. Phonological awareness is but one skill within the abilities of phonological processing. The ability to manipulate sounds in oral language encompasses a broad range of skills that are hierarchically arranged. In the beginning, phonological awareness activities may include rhyming or identifying words with similar beginnings or endings. Later phonological activities require more manipulation at the phoneme level (i.e., segmenting or blending activities). Phonological processing abilities include three types of skills: phonological awareness, phonological coding, and retrieval of phonological codes. Phonological coding refers to the ability to hold phonological information in working memory, while retrieval of phonological codes refers to the rate at which an individual can access the phonological information. Each of these processing abilities is implicated in the varying levels of literacy achievement. In addition to being able to manipulate sounds in oral language, knowledge of the written symbols that represent sounds in language is also important. Letter naming fluency in particular has been found to be a good predictor of reading success. The acquisition of letter knowledge typically follows a gradual accumulation of alphabet knowledge from 3 to 7 years old.

During the formative years of literacy acquisition, students are learning to read. By the time students reach third grade, they are reading to learn. Accordingly, the building blocks of later years focus primarily on fluency and comprehension. Developing reading fluency is critical to becoming a competent reader. Research suggests that fluent readers are more likely to comprehend what they read and are more likely to seek out reading opportunities [2].

Adult Literacy

The skills necessary for developing fluent reading are the building blocks for literacy activities in adulthood. While literacy in earlier years focuses on learning the skills necessary for fluent reading, literacy in teen to adulthood years focuses on functional literacy. The NAAL, in its assessment of adult literacy, addresses prose, document, and quantitative literacy. Prose literacy is defined as the ability to search, comprehend, and use information from

continuous texts such as news articles and instructional materials. Document literacy is the ability to search, comprehend, and use information from noncontinuous texts such as job applications, maps, and food labels. Quantitative literacy refers to the ability to identify and perform computations using numbers embedded in printed materials (e.g., balancing checkbooks). These literacy tasks require seven types of literacy skills: the ability to search text efficiently, to infer from texts, to decode and read fluently, to apply knowledge, to understand the structure and meaning of sentences, to identify the calculations required to solve a problem, and to perform the calculations [4]. In summary, literacy refers to the range of skills that are essential for an individual to realize his or her potential. It is the ability to understand oral and written materials and communicate one's intentions clearly.

Synonyms

Reading development; Writing development

Definition

Literacy typically includes the two areas of reading and writing. Literacy development refers to the on-going development of skills needed to successfully communicate through written communication.

Description

Communication through written texts is a two-sided conversation. Writers capture their thoughts and ideas in written text and the reader actively receives and responds to written texts. Reading for understanding requires an active thinking process that is influenced by the reader's prior knowledge and experiences [6]. This active thinking process develops over time in a natural state that "mimics children's natural development of oral language skills" [7].

Literacy development is reported to be a natural process that begins at birth. The "pre-reading stage" [3] or *stage 0*, involves caretakers reading to, speaking to, and modeling writing. Chall describes this stage as the moment in literacy development where children are acknowledging the surrounding print and spoken language. The next stage is referred to as *stage 1*. This stage begins in the early primary years when children learn about the *alphabetic principle* and is referred to as the "Initial Reading or Decoding Stage."

The next stage is referred to as stage 2, which involves readers building automaticity with the associations acquired in stage 1. During stage 2, readers participate in continual practice and are exposed to an abundance of print at an independent or easy level, which assists readers with acquiring automaticity. Stage 3 begins reading to learn during grades 4–8 where children are refining their print skills and stage 4 occurs during the High School years as students are developing multiple perspectives, Finally, stage 5 transpires during college years and beyond.

Relevance to Childhood Development

Literacy Development encompasses perspectives inclusive among theorists over the past 80 years, from the 1930s to present. Several different theories of development include: Piaget's Theory of Cognitive Development (1969), Maturation Theory (1931), Holdaway's Theory of Literacy Development (1969), Stage Models of Reading (1983), Emergent Literacy Theory (1985), and Family Literacy Theory (1983). The culmination of these theories is relevant to child development as they impact the teachers' knowledge and understanding of child development. This realm of knowledge is essential in providing appropriate literacy instruction.

Definition

A prescription medication FDA approved for the management of bipolar disorder and treatment of mania in patients with bipolar disorder.

Description

This medication works in the central nervous system, but the exact way this medication works is not known. Lithium is available in short acting capsules, short acting tablets, and short acting syrup. It is also available in both long acting capsules and tablets. Other reasons this medication may be taken, which are not FDA approved, are as an augmenting agent for depression, aggression, post-traumatic stress disorder, and conduct disorder in children.

The recommended starting dose for this medication in short-acting form is 300–600 mg taken three times a day. For long-acting dosage forms, the recommended starting dose is 300–600 mg three times a day or 450–900 mg twice a day. Maximum suggested dose is 1,800 mg a day. Doses for children over the age of 12 are generally similar to doses for adults. This medication should only be taken as directed by a doctor. It may take 1 or 2 weeks to see the effects of this medication.

Lithium may be taken with food if it upsets your stomach. It is recommended to limit caffeine intake and avoid drinking alcohol. It is recommended to drink two or three liters of water daily. Use caution in hot weather and in activities that may make you sweat. Inform your doctor if you have heart disease or kidney disease. Also, tell your doctor if you are dehydrated or have low sodium. It is very important that you do not take more of this medication than your doctor prescribed. Your doctor will monitor lithium levels in your blood. The slow release or sustained release products must be taken whole, do not crush or chew.

Some side effects are listed here: swelling, changes in heart rhythm, dizziness, sedation, restlessness, headache, fatigue, dry or thinning hair, changes in thyroid function, upset stomach and diarrhea, increase in urination, weight

gain, and blurred vision. Certain side effects may go away during treatment. Tell your doctor immediately if you notice the following: diarrhea, tremors, lack of coordination, muscle weakness, blurred vision, seizures, or slurred speech. These may be signs of an overdose of this medication. If these should occur, seek medical attention immediately.

This medication should be stored out of reach of children and pets and away from light, heat, and moisture.

Relevance to Childhood Development

Lithium is not FDA approved for use in children younger than 12 years old. This medication may cause weakened bones in children.

Women should let their doctor know if they are pregnant or planning to become pregnant. This medication has been shown to cause adverse effects to the fetus. Talk with your doctor before breastfeeding.

Locke, John

Erin Hambrick
University of Kansas, Lawrence, KS, USA

Life Dates

1632–1704

Introduction

John Locke, an English politician, doctor, and philosopher, was a forerunner of British ►Empiricism and is referred to by some as the father of cognitive psychology. Locke's view of the mind and the origin of knowledge and ideas was reductionist and individualistic; he believed that at birth no innate ideas exist and that all knowledge is derived from personal experience.

Educational Information

Locke, similar to most wealthy children of his era, was homeschooled until he was granted admission to Westminster school. Westminster was a private grammar school for privileged and intelligent adolescents and was where he became proficient in many different languages, such as Latin and German. Locke was named the Westminster School King's Scholar and was subsequently granted admission to Oxford University. After achieving his undergraduate degree, Locke received his master's in medicine and indulged in other educational interests such as philosophy (Locke was especially well read in both Plato and Descartes) and government. By 1650, he had obtained his master's and decided to stay at Oxford to teach for the next few decades.

Though the schools Locke attended largely influenced his education, Locke's father, Locke's bent toward travel, and the political zeitgeist of his time had just as large an impact. Locke's father was a respected political radical who believed in ▶parliament rule (or rule by the people) instead of monarchical rule. Locke grew up in what has been named the "Glorious Revolution": a time in English history when political unrest and change inspired many to become radical thinkers and to challenge not only political but philosophical hegemony.

Accomplishments

Locke's most well known accomplishments are his writings, which were largely penned during the 1690s. Locke's *An Essay Concerning Human Understanding* has widely influenced philosophical and psychological thought pertaining to the processes of the mind and the origin knowledge. Locke's *Two Treatises on Government* was partly a polemic against monarchy and influenced the decision of America's founding fathers to establish a democracy instead of a monarchy in the New World. Locke also wrote religious pieces, such as *Letters Concerning Toleration*, which influenced the Protestant Reformation in England and which precipitated America's laws on the separation of church and state. A lesser-known piece by John Locke is *Some Thoughts Concerning Education*, which is a compilation of letters Locke wrote to friends on how to parent their children. Though Locke was never a father, he believed that his ideas on knowledge acquisition made him a resource for parents in search of how to help their children develop appropriately. In addition to his writings, Locke was an influential leader at Oxford. He was named the Censor of Moral Philosophy and opened an experimental lab on Oxford's campus. Though Locke was a trained physician, medicine was more of a hobby to him than a profession.

Contributions

Locke's contributions to psychology are prodigious. Locke, in contrast to many of his philosophical contemporaries, abandoned the question of whether or not there is an actual reality and assumed the workings of the mind were real and could be studied. In order to understand the way the mind worked, Locke took an historical, reductionist approach. Locke derived his understanding of knowledge acquisition by breaking knowledge down into its smallest parts (sensory experiences) and by considering the developmental history of each person (at birth people have little or no knowledge and then accumulate it as they develop). Lockean thought marked a philosophical shift from the use of logic to understand reality to empiricism, or the use of systematic observation to understand reality. For example, Locke decided that because at birth we require other people and sensory experiences to grow, that each person is born a blank slate and this blank slate is influenced solely by experience. Or, that all knowledge and ideas are derived from observable, concrete sensory input instead of from innate or genetically predisposed tendencies. Locke asserted that if we are willing to attend to stimuli, then sensory input is acquired passively. Once this input has reached our mind, then our mind actively reflects on (or perceives) the input and associates this new input with previous experiences. This process of reflection and association results in complex thoughts, and throughout our lives we have increasingly more sensory input that gives rise to more complex thoughts and thus more knowledge.

Locke's delineation of the process of association has especially influenced psychology. In cognitive psychology, association has influenced memory research; many cognitive psychologists believe that we retrieve memories by thinking of an idea that is associated with past experiences and/or by having new experiences that are associated with past experiences. In behavior psychology, the principle of association was applied learning theory. Behaviorists assert that we associate certain behaviors with particular outcomes and thus either increase or decrease that behavior depending on that behavior's associated consequences.

Locke's "blank slate at birth" or "▶tabula rasa" belief also had strong humanitarian implications. To say that each person is born a blank state essentially means that all people are equal at birth. Thus, Locke's view of the nature of knowledge caused him to antagonize the patriarchal views of his time and possibly jump-start the feminist movement [3]. Also, this belief landed Locke on the nurture side of the ubiquitous nature-nurture debate in psychology, a debate that may never be fully

resolved but that will always be important to both clinical and experimental work.

Possibly the most important contribution Locke had to psychology was his role in founding British Empiricism, a scientific school of thought that believed knowledge can only come from observable experiences. Empiricists also believed that the further one's conclusions moved from directly observable experiences, the more likely one was to make a thinking error. Though Locke would not have been a proponent of the psychological method of ►introspection that succeeded him (which depended on the self-report of private, unobservable thoughts), his empirical work did encourage the study of the mind simply because he was one of the first to unequivocally claim that the mind was real and could be studied.

Further, several of Locke's theories on how to raise children are still present in child rearing practices today. For example, because Locke believed that all knowledge is learned via experience, he encouraged parents to provide young children with as many sensory experiences as possible. We now know that certain sensory experiences must be present during critical and sensitive periods in the first years of life to facilitate normal development. In older children, Locke believed knowledge was the path to reason, and that if one had multiple divergent experiences then one would be capable of reasoning in a moral, upright fashion [1]. According to Locke, gaining knowledge via experience was the ultimate path toward righteous, pro-social actions. Thus, Locke influenced many human rights movements. Further, Locke may have influenced person-centered, Humanistic thought by his contention that because everyone has had different sensory experiences, differences between people must be tolerated. Further, Locke thought that when trying to understand and tolerate others we must make an effort to understand their phenomenological worldview.

Locke can also be credited for promoting public collections of items, which are today called museums, zoos, and encyclopedias. Because he believed that sensory experiences gave rise to complex ideas, he encouraged collections that would provide experiential learning.

Locus Coeruleus

Chad A. Noggle
SIU School of Medicine, Springfield, IL, USA

Definition

►Locus Coeruleus: The Locus Coeruleus is a cluster of neurons in an area of the hindbrain known as the Pons that contains over half of the norepinephrine-based neurons of the central nervous system.

Description

The Hindbrain represents the lowest and most posterior division of the human brain. The Pons is a structure within the Hindbrain, that in addition to its' link with motor and sensory action, houses the Locus Coeruleus, which lies just beneath the fourth ventricle. The Locus Coeruleus is a grouping of neurons that contains over half of the Norepinephrine neurons in the Central Nervous System [3]. Norepinephrine is an essential neurotransmitter of the Central nervous System that plays a vital role in regulating sleep-wake cycles, memory, attention, hormones through its influence on the Hypothalamus, Cerebral blood flow, and motor behavior [4]. One of the catecholaminergic neurotransmitters [2], norepinephrine's influence can be either inhibitory or excitatory [1]. In addition, Norepinephine is commonly indicted with Serotonin in the manifestation of depressive and anxiety disorders as it plays a vital role in the regulation of mood. The holistic impact Norepinephrine has on the CNS is directly related to the widespread ascending noradrenergic projections from the Locus Coeruleus and rostral tegmental area to aspects of the Forebrain, Cerebellum and Spinal Cord [1], that thus correspond with Norepinephrine's influence on the broad aforementioned functions.

Locus of Control (External and Internal)

David Brandwein
Kean University, Union, NJ, USA

Synonyms

Locus of control reinforcement

Definition

The internal-external locus of control construct ([8]), describes the extent to which one perceives there to be a causal connection between one's behavior or cognition and subsequent outcomes.

Description

The concept of locus of control was developed by ►Julian Rotter in the 1960s. In looking to bridge two different branches of psychology (behavioral and cognitive), he believed that behavior was greatly influenced by rewards and punishments, and these rewards and punishments shaped how people understand the results of their own actions. Rotter ordered people on a continuum according to how much they attribute the cause of events in their lives to their own actions, motivations, or competencies (internal control) versus how much they assume the cause of these events to be determined by other forces such as luck, chance, or powerful others (external control). Based on Rotter's conception of locus of control, Nowicki and Strickland [4] developed the Locus of Control Scale for Children, which is still in use today.

An important aspect of locus of control has to do with the concept of expectancy, which is related to events that will happen in the future. Locus of control is grounded in expectancy-value theory, which describes human behavior as determined by the perceived likelihood of an event or outcome occurring contingent upon the behavior in question, and the value placed on that event or outcome. More specifically, expectancy-value theory states that if (a) someone values a particular outcome and (b) that person believes that taking a particular action will produce that outcome, then (c) they are more likely to take that particular action.

An alternative conception of locus of control was proposed by Levenson [3]. Instead of conceiving locus of control along a one-dimensional continuum (internal to external), Levenson proposed three independent dimensions: Internality, Chance, and Powerful Others. According to Levenson's view of locus of control, a person can choose each of these dimensions of locus of control independently as well as together. For example, a person might simultaneously believe that both oneself and powerful others influence outcomes, but that chance does not. Researchers in ►health psychology have embraced Levinson's conceptualization, and Wallston, Wallston & Devillis [10] developed the Multidimensional Health Locus of Control Scales to evaluate how locus of control relates to health and illness.

Relevance to Childhood Development

The variable of locus of control is of significant influence on child behavior and development.

Research completed in academic contexts ([2]) found that a belief in destiny was a major determinant in school achievement. In short, internal students feel outcomes (both negative and positive) are derived from a basis of empowerment, whereas external students view such outcomes from a basis of disengagement.

Other research ([6]; [9]; [1]) revealed that an external locus of control was associated with increasing tendencies for lower levels of academic achievement, negatively associated with performance in areas of reading, mathematics, and teachers ratings of study habits, and reading attitudes and aptitudes, while internality was found to be a positive factor in predicting academic performance, particularly with regard to attitudes about the reading experience.

Locus of control has also been shown to be associated with other psychological characteristics and perceptions. Nunn [5] found significant relationships between an internal locus of control and positive perceptions of adjustment within the home, school, and peer relations., and Nunn & Nunn [7] have also shown that students who are considered at-risk for educational failure have developed more external views of themselves, are more anxious, have lower self-esteem, and exhibit more symptoms of depression than students who are successful. Tesiny et al. [9] also found that external locus of control was significantly associated with both depression scores and academic achievement measures, e.g., reading, math, teacher rating of study habits, and peer nominations of children who exhibited symptoms of depression.

Longitudinal Methods

Xenia Anastassiou-Hadjicharalambous, Maria Stylianou
University of Nicosia, Nicosia, Cyprus

Definition

The term longitudinal methods represent a research design in which participants are repeatedly assessed over an extended period with repeated evaluations which are often spread across at least several years.

Description

It is quite common to distinguish between two types of longitudinal designs: the panel study and the cohort study.

Panel Study

In the Panel Study a sample, often a national representative sample is evaluated at different points in time [6]. Studies utilizing this approach can potentially reveal behavioral patterns and attitudes that could not be addressed by other designs. Depending on the aim of the study the participants could be evaluated on the assessments on a regular basis (i.e., continuous panel) or on certain assessments during predetermined intervals (i.e., interval panel). This approach allows the utilization of sophisticated statistical analyses that may potentially determine causal influences over time and therefore offers unique information for the investigation of the developmental aspect of a phenomenon. For instance, is parental stress implicated in the child's development? Is parental psychopathology implicated in the child's psychopathology? How does it develop? Does anxiety symptomatology precede depressive symptomatology or vice versa? What is the developmental course? An illustration of a panel study is the British Household Panel Study (BHPS) which started in 1991 [8]. The wave 1 panel consisted of a national representative sample of 10, 300 participants in 5, 500 households drawn from 250 areas of Great Britain. Assessments are carried out in an annual basis annually

across six main areas of interest: health, household organization, labor market behavior, income and wealth, housing and socioeconomic values. The resulting data base is a key data resource for social science researchers.

Cohort Study

In a cohort study a sample of at least one cohort (sometimes the entire cohort) is evaluated across at least two points in time [6]. For research purposes, a cohort consists of individuals who share a significant life event or a characteristic within a given time period. This characteristic could be of varied nature. For instance, being born in 1940–1945, having a certain disease, having a certain education, and having a certain employment status and so on. Cohort studies are often a useful alternative to randomized control studies in which ethical concerns are applicable. For example a randomized control study for the investigation of the impact of inept parental discipline practices on the child's development and well being would be unethical. Consequently an ethical alternative would be to identify parents who generate incompetent practices and follow them across time to determine whether inept parental practices are implicated in the child's psychopathology. A classic illustration of a cohort study is the National Child Development Study (NCDS) which was initially motivated by the concern for perinatal mortality [9]. The NCDS follows all children born in Great Britain between 3 and 9 March 1958 (about 17,000 participants) and monitors their physical, educational and social development. The study aims to improve understanding of the factors affecting human development over the whole lifespan and it is a popular database for social science research.

Advantages

The significant advantage of the longitudinal methods lies upon their unique ability to trace developmental trajectories [2, 3]. Given that each individual has his/her unique genetic makeup the longitudinal design allows intra-individual variability to be minimized.

Drawbacks

A significant drawback of longitudinal methods is the problem of attrition or loss of participants across time due to factors such as decision of participants to withdraw, unexpected life events such as death, movement and so on [7]. The problem with attrition lies in the possibility that the individuals who withdraw from the study may vary in a systematic way from those who remain in the study, making the generalisability of the results hard to make. For instance in the USA those individuals that are more likely to move from place to place, are at the same time those individuals who derive from lower socio-economic status. Menard [1] refers to a study of adolescent drug abuse in the USA in which 55% of participants withdrew from the study making the results difficult to interpret. Of course attrition rates do not typically reach as high as 55%, but when the attrition is high caution should be exercised in the interpretation of the results.

A further problem inherent in the longitudinal design is that a panel conditioning effect is plausible [3–5]. In other words, the possibility that ongoing participation in a longitudinal study could itself potentially affect how participants behave. Menard [1] cites a study of caregiving in families and reports that 52% of the participants reported that their participation in the study drove them toward providing different care for the family.

A third problem inherent in the longitudinal methods is the significant financial cost coupled sometimes with poor planning of the design which often results in large data pools without valuable research output.

Finally a further shortcoming inherent in the longitudinal methods are the normative and nonnormative changes that occur in society across a given time threshold that are always different to the conditions of another time point in history [3–5]. For instance individuals born in 1940 and followed for 20 years had different historical conditions to those born in 1990 and again followed for 20 years. It is not only the individual that changes, the world itself changes as well. For example, if the results of a longitudinal design found that individuals born between 1990–1995 reported different opinions about energy conservation in the first wave of data collection, that occurred in 2000, in relation to the fourth wave of data collection, that occurred in 2009; Does this indicate a developmental change of these individuals or a change in the world? Consequently in interpretations of the findings of longitudinal designs historical conditions need to be taken into consideration.

Longitudinal Research

Audrey McKinlay
University of Canterbury, Christchurch, Canterbury, New Zealand

Definition

Longitudinal research refers to the analysis of data collected at multiple points in time.

Description

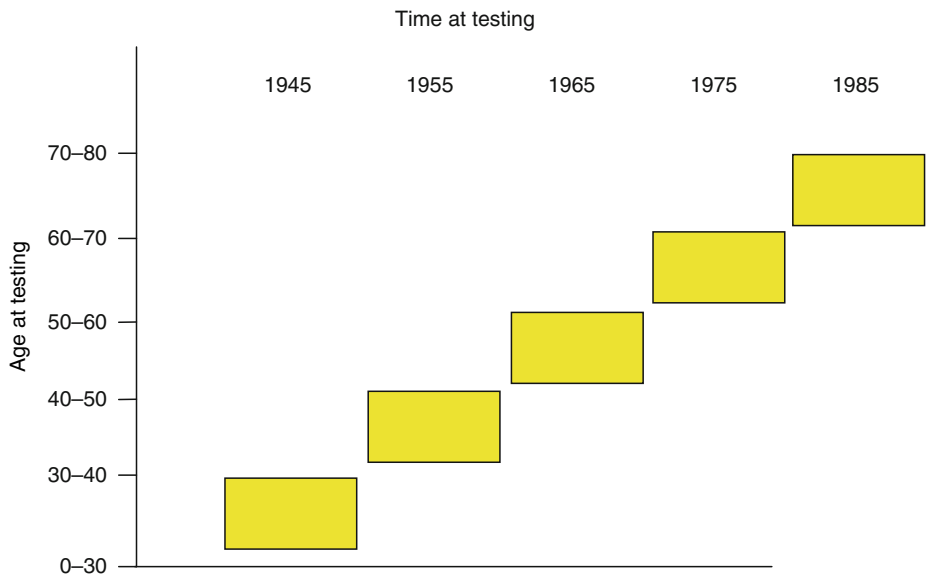
Longitudinal Design

Using this longitudinal research it is possible to examine changes over time. As shown by the yellow squares in Fig. 1, in research that uses a longitudinal design a single group of participants is followed and assessed at multiple points of time. For example, to examine the effects of poor nutrition in early life on aging, data could be collected from a group of young poorly nourished individuals who could then be followed over time. In this example, one of the advantages of using a longitudinal design would be that it would enable the researchers to identify what changes were due to aging compared to those that are due to other factors such as the habits of the individual i.e., smoking.

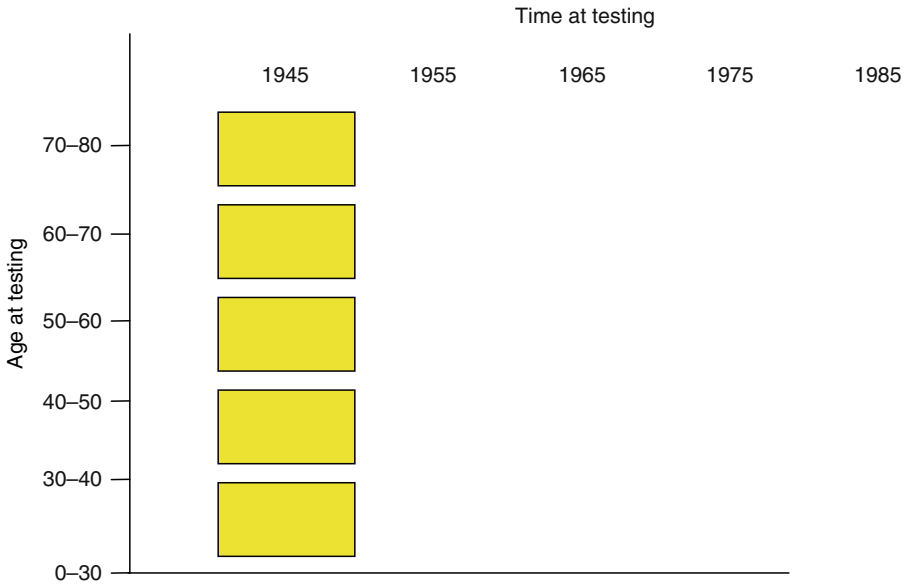
An example of one well known study which uses is longitudinal design is the Baltimore Longitudinal study which was initiated in 1958 and has examined a number of issues related to aging (e.g., [1]). The Baltimore Longitudinal study has over 1,400 volunteers (age between 20–90 years). The aim of this study is to examine what happens as people age.

Cross-Sectional Design

By comparison, in cross-sectional design information from different subgroups is collected a single point in time (see Fig. 2). A major disadvantage of a cross-sectional design which collects data at a single point in time is that any findings may be compromised by cohort effects. Cohort effects refer to findings that are due to factors e.g., education, religion, or cultural expectations.



Longitudinal Research. Fig. 1 Shows how a longitudinal design can be used to examine the effects of aging. The participants in this design were first assessed between 0–30 years of age. The same individuals were assessed on five separate occasions, the final assessment taking place when they were between 70–80 years of age.



Longitudinal Research. Fig. 2 Shows how a cross-sectional design can be used to examine the effects of aging. In the design depicted above sub-groups of participants between 0–80 were evaluated at one point in time (1945).

Long-Term Potentiation

Definition

In neuroscience, long-term potentiation refers to a long-lasting change in synapse transmission that results from the simultaneous activation of two neurons. The result is enhanced synaptic transmission, or the improvement in the ability of two neurons to communicate with one-another across a synapse.

Description

Long-term potentiation is an example of synaptic plasticity; the ability of the connection, or synapse, between two neurons to change in strength. It may help explain how short-term memories are encoded into long-term memory, as well how some types of human and animal learning occur. Evidence for its role in learning has been found in humans where long-term potentiation has been demonstrated to be characteristic of the cells in the neocortex and hippocampus.

Lovaas, Ole Ivar

Joy Jansen
Neurology, Learning, and Behavior Center,
Salt Lake City, UT, USA

Life Dates
(1927–Present)

Introduction
Dr. Lovaas is an internationally-renowned and influential clinical psychologist who has devoted the last forty years in establishing, implementing and evaluating programs to help children with autism develop essential life skills to improve the quality of life.

Educational Information
Originally from Norway, Dr. Lovaas came to the United States to advance his knowledge and research at the University of Washington, where he received his doctorate of philosophy. Dr. Lovaas' focus of study was the environment and how it affects behavior and in the early 1950s began working with children with autism. His approach autism was influenced by Dr. Skinner and used the underlying concept of behaviorism, also known applied behavior analysis (ABA). Using the ABA method, Dr. Lovaas has demonstrated, through consistent and dedicated work, ABA is a valuable and effective tool in assisting children with autism as well as children with other psychological conditions.

Accomplishments
Early in his career Dr. Lovaas founded the Lovaas Institute for Early Intervention (LIFE) and took a professorship at the Unicles (UCLA). LIFE is internationally recognized organization for its success in working with children with autism.

Contributions
Through his work, Dr. Lovaas developed a model known as the Lovaas Model of ABA. The Lovaas Model utilizes the principles of ABA, however, he expands beyond the classic ABA model by considering the time of implementation relative to a child's unique needs.

Current Involvement
Currently, Dr. Lovaas is a Professor Emeritus of Psychology and continues to teach at the University of California at Los Angeles (UCLA). In addition, Dr. Lovaas has authored more than 70 publications throughout his career and is the author of two books, *Teaching Developmentally Disabled Children*: *The Me Book* in 1981 and, in 2002, wrote, *Teaching Individuals With Developmental Delays: Basic Intervention Technique.*

Low Birth Weight

Anna Mazur-Mosiewicz, Raymond S. Dean
Ball State University, Muncie, IN, USA

Synonyms
LBW

Definition
Low birth weight (LBW) is defined as a birth weight of 2,500 g or less in a liveborn infant. The LBW infants further subdivided into two groups: very low birth weight (VLBW) infants, who are born with birth weight equal or below 1,500 g, and extremely low birth weight (ELBW) infants, who are born weighting 1,000 g or less [1, 3]. LBW indicates an increased risk of mortality and morbidity.

Description
Infants with LBW belong to two general categories: infants who have LBW due to premature birth, and infants with

intrauterine growth restriction (low for gestational age), which is typically related to problems with *placenta*, maternal health, or to *birth defects*. To differentiate premature LBW from mature growth-retarded LBW several types of data are necessary and include obstetrical history, newborn physical examination, and examination for maturational age. In general, the LBW infants are four times likely than infants born with normal weight to die in their first month of life. These who survive are two to three times more likely to suffer from short and long-term disabilities [2–4].

The percentage of all newborns born with low weight in the United States is around 7%. However, percentage of the LBW infants is higher in minority groups, particularly African-Americans, and the percentage of the African-American babies born with LBW is more than double of that for the Caucasian-American newborns [1, 3].

Risk factors for LBW are largely preventable. They include poor maternal nutrition, adolescent pregnancy, use of alcohol and drugs, premature births, smoking, multiple births, and sexually transmitted diseases. The use of assisted reproductive technology additionally accounts for a disproportionate number of LBW and VLBW infants in the United States, which is partially due to increases in multiple gestations and higher rates of LBW among singleton infants conceived with this technology.

Relevance to Childhood Development

Children born with LBW are at high risk of several types of neonatal complications. Generally, the lower the weight of infants, the greater the risk for complications. Clinical problems most commonly associated with LBW are *hypothermia*; *hypoglycemia*; *aphnea*; *metabolic acidosis*; *hypoglycemia*; *perinatal asphyxia*; respiratory problems, particularly the *Respiratory Distress Syndrome* and *aphnea of prematurely*; fluid and electrolyte imbalances, which increases risk of *dehydration*, *fluid overload*, *hypernatremia*, *hyponatremia*, *hyperkalemia*, *hypocalcemia*, and *hypermagnedemia*; *hyperbilirubinemia*; *anemia*; impaired nutrition; infections; and *sudden infant death syndrome* [1, 3, 4].

Additional long-term problems related to LWB include chronic neurological problems such as *intraventricular hemorrage*, *periventricular leukomalacia*, and increased risks for *cerebral palsy*; *developmental delay*; ophthalmologic complications; hearing deficits; lung disease; adult-onset *diabetes*; *coronary heart disease*; high blood pressure; intellectual problems; sensory disabilities; physical disabilities; and psychological and emotional distress [2, 5].

Luria, Alexander Romanovich

David Morrison, Mary Joann Lang
Azusa Pacific University, Azusa, CA, USA

Life Dates

(1902–1977)

Introduction

Alexander Romanovich Luria (1902–1977) is a world-renowned Russian psychologist/scientist who is best known for his theories about localization and cerebral organization of mental functions. Luria's impact on the Western scientific community continues to be significant three decades after his death. Luria has left an enduring legacy that is widely respected in the scientific community [2]. Although he is often referred to as the father of neuropsychology, this interest developed much later in his professional career. Luria has been widely celebrated and honored outside of the Soviet Union, yet his contributions have not been fully recognized by his native country of Russia [3].

Luria was born in Kazan, Russia in 1902. He died in Moscow of heart failure in 1977. In 1933, Luria married Lana Linchina, also a scientist, and together they had one daughter, Elena Alexandrovna Luria, herself a distinguished microbiologist.

Luria is highly regarded in the field of neuropsychology. Despite extraordinary advances in the field of neuroscience, his contributions have been so significant that, according to Tupper [11], he is the most cited soviet scholar in North American literature. Due to this distinction, he is sometimes regarded as the father of neuropsychology.

Luria is described by his student, friend and colleague, Goldberg [2] as a "complex man living in a complex time." A.R. Luria came from a well-educated family. His father and mother were both well-respected physicians. His father taught at the Kazan Medical School. Luria identifies his family as being part of the Russian "intelligentsia." Luria was greatly impacted by the tumultuous times of pre-revolution Russia and the subsequent chaotic post-revolution cultural shift on Russian society. Luria identifies that the revolution freed the younger generation, regardless of social standing, to explore and discuss new philosophies and social systems. However, Luria indicates that despite the openness to these new opportunities, it was not necessarily conducive to "highly organized scientific inquiry." Luria's expansive and shifting intellectual pursuits and interests are considered to be a result of the social and political culture in which he lived [8].

Despite the challenges that confronted him, Luria is considered one of the most influential Soviet scientists of his time. His collaboration with Lev Vygotsky led to extensive and enduring contributions that are recognized throughout the world. Luria is best known for his contributions in developing a comprehensive theory of brain functioning, which remains as the cornerstone for brain-behavior research. His influence in the field of neuropsychology continues to be foundational for many academic programs of study. He is frequently cited in neuropsychology literature, and is best known for his conceptualization of brain organization. However, during the course of his career, his interest went well beyond the more narrow recognition of neuropsychology, and included such areas as child development, educational and rehabilitative interventions, instructional methods, mental retardation, and linguistic phenomena such as aphasia [3, 11].

Educational Information

Luria's education started within the tumultuous political backdrop of the Russian Revolution. From 1912 to 1918 he attended the gymnasium, a secondary school, preparing him for university studies. He completed his secondary studies at the age of 16, at which time he received his diploma. In 1918 he entered Kazan University and pursued studies in the Social Sciences. He describes his studies at Kazan University as being chaotic. He became absorbed with questions concerning man's role in shaping society. In 1921 he completed his studies in the Social Sciences and continued his studies in the Medical Department of Kazan University. In addition, he pursued his interest in psychology and concurrently enrolled at the Pedagogical Institute, as well as the Kazan Psychiatric Hospital. Luria was influenced by such notable scholars as Sigmund Freud, Alfred Adler, Jung, and Pavlov. His interest in psychoanalytic research led to the formation of the Kazan Psychoanalytic Association. He later joined the staff of the Moscow Institute of Psychology. His work with Vygotsky, which started in 1924, clearly shaped and greatly influenced his life's work. His regard for Vygotsky as a genius is well documented. Weekly collaborations with Vygotsky, Leontiev and Luria led to the development of research questions in cognitive psychology, such as perception, memory, attention, speech, problem solving, and motor activity. These weekly meetings, known as the "troika," laid to the foundation for a new comprehensive approach to human psychology, which would incorporate the notion that, as higher processes take shape, the entire structure of behavior is changed [8, 10].

The late 1930s are considered to be a critical turning point in Luria's career [2]. At this time Luria added a medical degree to his full professorship, became more involved with the biological aspects of psychology, which led to his contributions in neuropsychology. Luria's interest in cognitive, cultural, and developmental research most certainly influenced his approach to neuropsychology.

Luria returned to Moscow in 1934. At that time, he worked in the Moscow Medical Genetic Institute as head of the Laboratory of Psychology. He also headed the Laboratory of Pathopsychology in the All-Union Institute of Experimental Medicine. His research focus at the Moscow Medical Genetic Institute was on twins, where he studied the role of heredity and external factors in the development of mental processes.

World War II was particularly devastating on the citizenry of the Soviet Union. Luria was commissioned to organize a rehabilitation hospital to treat soldiers with brain and peripheral nerve injuries. The task of the hospital had two primary goals: Devise methods of diagnosing local brain lesions and of recognizing and treating complications such as inflammation and secondary infection that were caused by wounds. Second, he was to develop rational, scientifically-based techniques for the rehabilitation of destroyed functions. The extensive and dedicated effort by Luria and his staff led to the development of his theories of brain function and methods for the remediation of focal brain lesions. It was during this time that he developed the systematic approach to the brain and cognition, which has come to be known as the discipline of neuropsychology. Following the war, Luria continued his research activities in neuropsychology.

Contributions

David E. Tupper, in an article discussing Luria's influence on worldwide neuropsychology, discussed Luria's contributions. Basically, according to Tupper, Luria has provided contributions in at least five major areas. These areas include:

Cultural-historical Development of Higher Psychological Functions; Functional Units of the Brain; Qualitative Analysis of Neurodynamic Factors; Syndrome Analysis; Systemic Localization of Brain Function, and Verbal Regulation of Behavior [11].

Cultural Historical

Luria and Vygotsky's lifespan overlapped 32 years. Vygotsky began his research on issues in education, and focused on the education of handicapped and retarded individuals. He believed in the interaction between the mind (internalized modes of behavior) and the environment. One of Vygotsky's major theories is titled the *zone of proximal development*, which discusses the difference between what a student can actually do without help and what he/she can do with help. This model was developed by Vygotsky to argue against the use of standardized tests to gauge students' intelligence. He believed that when exploring what the child knows to determine intellectual ability, it is more beneficial to explore the student's ability to solve problems independently. Through his efforts, Vygotsky became a major figure in Luria's life from the beginning of their interactions. Luria's writings and scientific research were slowly influenced by Vygotsky. Luria based his concepts of higher order psychological functions on the theories of Vygotsky. Luria further expanded on Vygotsky's model, using qualitative analysis to help both in depth and breadth, in order to further explain higher order thinking that has impacted the fields of neurology, psychology, and neuropsychology [1, 10].

Functional Units of the Brain

Luria's most enduring contribution to the field of neuropsychology is his theory on the functional organization of the brain. According to Luria, the brain is made up of three main blocks or functional units incorporating basic functions. Luria conceptualized the cortex as working in the following way: Sensory input enters the primary sensory zones, is elaborated in the secondary zones, and is integrated in the tertiary zones of the sensory, or posterior, unit. Luria (1974, p. 43) also proposed that each of these units is "hierarchical" in structure and consists of at least three cortical zones built one above the other. A primary "projection" area receives impulses. A secondary "projection-association" area processes incoming information and programs information for projection to efferent pathways. The tertiary "zones of overlapping" area is last to develop and is responsible for complex forms of mental activity, which requires the integrated participation of many cortical structures. According to Luria, these units and zones, when functioning properly, work together to regulate all of our behaviors, from waking and sleeping, to hearing and seeing, and thinking and problem solving [4, 5].

Syndrome Analysis

One way that Luria assisted in the diagnosis and treatment of patients was his ability to use syndrome analysis (see Luria, 1980, pp. 392.). He was among the first neuropsychologist to clearly state that no simple, unequivocal relation between symptom and localization can be proved. There is, as a rule, no specific way to determine which areas of the cortex could be affected on the basis of a neuropsychological symptom, such as specific disturbances of gnosis or praxis (Online Book).

> If mental activity is a complex functional system, involving the participation of a group of concertedly working areas of the cortex. . .a lesion of each of these zones or areas may lead to disintegration of the entire functional system, and in this way the symptom or "loss" of a particular function tells us nothing about its "localization." (Luria, 1972, p.35)

Understanding neurodynamic factors that may precipitate a patient's signs and symptoms is facilitated by Luria's concept of syndrome analysis and qualitative analysis. These applications to clinical thinking provide for a discussion regarding "neurodynamic change." Currently, this process, with regard to the practice of neuropsychology in North America, is used in concert with a more quantitative approach to understanding brain behavior relationships.

Systematic Localization of Brain Function

Luria structured the neuropsychological assessment of brain functioning on the basis of a systemic way of thinking. Two questions guide this approach as presented by (Online Book):

1. Which processes are involved in the cognitive functions in consideration?
2. What cerebral structures support the functional system and constitute the neuronal basis for the function in consideration?

The relationship between symptom and localization can be very complex. A symptom can result from lesions in both the anterior and posterior cortical areas of the brain [7]. A circumscribed cortical lesion can simultaneously affect many functional systems and, as a result, lead to various manifestations of symptoms. In summary, this concept of complex brain behavior relationships is essential to understand for practitioners and researchers exploring neuropsychological problems and correlating these problems to brain function.

Summary

It is important to understand the theoretical and methodological differences between a qualitative approach to understanding brain function as proposed by Luria, and the North American approach, which is more quantitative, to understanding brain behavior relationships. Luria based his theories on clinical experience, and his research focused on attempts to develop a theory of neuropsychological functioning based on analyzing and synthesizing information into a meta-theory. Luria often based this process on Vygotsky's earlier work and theories. In contrast, in North America neuropsychology has been derived from a more psychometric or quantitative approach to understanding brain behavior relationships. Standardized tests are the norm in terms of understanding brain behavior relationships in clinical populations. Despite his disregard for methodological considerations such as standardization, quantification, validation and reliability, several standardized tests have been or are being developed that incorporate both the qualitative approach supported by Luria and the quantitative information that has been historically used in North America [2, 9].

Publications

Much of Luria's work has yet to be translated from Russian to English. The following is a partial list of books that have been translated into English.

Ape Primitive Man and Child: Essays in the History of Behavior (1992)
Cognitive Development: Its Cultural and Social Foundations (1976)
The Making of Mind: A Personal Account of Soviet Psychology (1979)
Higher Cortical Functions in Man (1980)
The Man With a Shattered World: The History of a Brain Wound (1987)
The Mind of a Mnemonist: A Little Book About a Vast Memory (1987)
The Human Brain and Psychological Processes (1966)
Nature of Human Conflicts (1981)
The Neuropsychology of Memory (1976)
Traumatic Aphasia: Its Syndromes, Psychology and Treatment (1970)
Working Brain: An Introduction to Neuropsychology (1973)

Magnetic Resonance Imaging

Lauren Connell Pavelka
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Nuclear magnetic resonance imaging (NMRI)

Definition

Magnetic resonance imaging (MRI) is a medical imaging technique that uses high-strength magnetic fields and pulses of radio wave energy to investigate internal structures and functions of the body.

Description

The MRI scanner contains a magnet that forces hydrogen atoms in the body to align, which produces recordable, measurable images. These images are called slices, and are used to diagnose abnormal structures or functioning within the body. The quality of MRI is often superior to x-ray, computerized tomography (CT), or ultrasound, in providing cardiovascular, musculoskeletal, neurological, and oncological imaging.

Important in neuropsychology, MRI is useful in detecting problems of the nervous system such as dementia, Alzheimer's disease, tumors, aneurysm, nerve injury, herniated discs, and neurological damage caused by stroke.

Unlike x-ray and CT, MRI does not use radiation or have any known carcinogenic effects. Though generally safe, caution is given with the powerful magnetism of MRI, which could affect pacemakers, artificial limbs, and other medical devices.

Relevance to Childhood Development

As previously indicated, serious and long-lasting health concerns have not been reported with MRI. Similarly, there are no known risks uniquely to children. However, because it is essential for children to keep still during the procedure in order to attain clear imaging, mild sedatives are commonly administered.

Magnetic Resonance Imaging (MRI)

Synonyms

Nuclear magnetic resonance imaging (NMRI); Magnetic resonance tomography (MRT)

Definition

Magnetic resonance imaging is a form of medical imaging that measures the response of the atomic nuclei of body tissues to high-frequency radio waves when placed in a strong magnetic field, and that produces images of the internal organs.

Description

Magnetic resonance imaging is a medical imaging technique most commonly used in radiology to visualize detailed internal structure and limited function of the body. In many cases MRI gives different information about structures in the body that can be see with an X-ray, ultrasound, or computed tomography (CT) scan.

Sam Goldstein & Jack A. Naglieri (eds.), *Encyclopedia of Child Behavior and Development*, DOI 10.1007/978-0-387-79061-9,

MRI also may show problems that cannot be seen with other imaging methods. Magnetic resonance imaging provides much greater contrast between the different soft tissues of the body than computed tomography (CT) does, making it especially useful in neurological (brain), musculoskeletal, cardiovascular, and oncological (cancer) imaging. MRI uses a powerful field to align the nuclear magnetization of hydrogen atoms in water in the body. Radio frequency fields are used to systematically alter the alignment of this magnetization, causing the hydrogen nuclei to produce a rotating magnetic field detectable by the scanner. This signal can be manipulated by additional magnetic field to build up enough information to construct an image of the body.

Magnetic resonance imaging is a relatively new technology with the first image being published in 1973. The first studies performed on humans were published in 1977. Magnetic resonance imaging was developed from knowledge gained in the study of nuclear magnetic resonance. In its early years the technique was referred to as nuclear magnetic resonance imaging (NMRI). However, because the word *nuclear* was associated in the public mind with ionizing radiation exposure, it is now generally referred to simply as MRI. However, scientists still use the term NMRI when discussing non-medical devices operating on the same principles.

MRI contains no ionizing radiation. To date, there have been no documented significant side effects of the magnetic fields and radio waves used on the human body. Depending on the area being studied, a patient may be asked to not eat or drink anything for 4-6 hours. Other preparations are usually not needed. The strong magnetic fields created during an MRI can interfere with certain implants, particularly pacemakers and cochlear implants. Persons with cardiac pacemakers cannot have an MRI and should not enter an MRI area. Brain aneurysm clips, certain artificial heart valves, and artificial joint or older types of vascular stents may prevent patients from having an MRI. Since the MRI contains a magnet, all metal-containing objects such as watches, jewelry, credit cards, hairpins, etc., are not allowed into the scanner area and can be dangerous if overlooked.

Mainstreaming

Grace Boyd, Andrea Morillas-Brown, Brett R. Nelson
California State University, San Bernardino,
San Bernardino, CA, USA

Synonyms

Full inclusion; Inclusion; Inclusive education; Integration

Definition

Mainstreaming is most generally defined as the practice of educating students with disabilities in age-appropriate general education classes including specialized instruction [10, 12] without regard to the severity of the child's disability [13].

Description

In schools today there has been a shift in having children with disabilities participate in a natural setting with their typical peers [3, 11]. This practice is known in the educational setting as mainstreaming. According to a report from the United States Department of Education [6], 95% of students with disabilities are enrolled in a traditional school, with 52% included in the general education curriculum.

The decision to use mainstreaming is dependent on the individual child's needs and level of functioning and therefore it is not effective with all students with disabilities (NASP). Several other important factors must be considered before placing a student with a disability in an inclusive environment [8]. These factors include family goals, professional advice, willingness and level of experience of the school staff, and adaptability of the curriculum [1].

Once the decision has been made to place a child into an inclusive environment, modifications to the general education curriculum may be necessary to help support the educational needs of the student with a disability. According to the National Association of School Psychologists (1993), there are a variety of steps to consider in order for mainstreaming to be successful. The first important element is to identify the individual student's approach to learning as well as their strengths. The next factor is to evaluate the learning environment to determine if there are things that would hinder the academic success of the child (i.e., seating, lighting, noise). An additional step in this process is to consider the student's educational goals and incorporate them into the curriculum when appropriate. A final component of including a child through adaptation of the curriculum is to modify

the instruction in various ways including teaching style, subject content, and assistive materials.

Relevance to Childhood Development

Varying Standpoints of Inclusion or Opposing View of Inclusion

Since the start of the practice of inclusion in the early 1990s [7], various studies have examined the outcomes of students with disabilities placed in general education and have found positive results (e.g., [5, 13]). However, the use of inclusion has become a highly controversial educational issue with a mixed amount of support and opposition [10].

The Criticisms of Inclusion. The individuals that oppose the inclusion of children with disabilities in general education feel strongly about maintaining separate provisions within the schools [7]. It is argued that this separation between general education and special education must be preserved in order to continue to increase the academic standards within the schools (Farrell). This group believes that a child with a disability will have more educational success if they are placed in special education classrooms because of the more intensive and specialized instruction as compared to a general education classroom [4]. Additionally, it is claimed that in a school system that evaluates children on the basis of academic ability, it seems conflicting to have a classroom of students with different academic potentials placed together (Farrell). Some feel that even when children with disabilities are put into inclusive education they will continue to be segregated among the nondisabled students because of the differences in abilities within the classroom and will consequently not be included in the education with others [9]. In light of the criticisms of the use of inclusion in schools, others hold a positive viewpoint of this approach and the research bolsters these optimistic claims.

The Benefits of Inclusion. The empirical findings have shown many encouraging outcomes for students with disabilities who would otherwise be placed in special education classrooms. For example, in a 2-year longitudinal study Cole and Meyer [4] compared children with a variety of developmental disabilities in segregated and inclusive classrooms. They found that the educational skills of both groups did not differ, however, the social competence of the children in the fully inclusive classroom exceeded those of the segregated students. Other studies have revealed that inclusion has led to positive influences in the development of important and meaningful relationships that otherwise may have ceased to occur, including increased acceptance of others, higher expectations, a greater potential to become independent, improved social competence, and higher amounts of social support [2, 9]. Additionally, findings suggest that the potential to improve academic and social skills is facilitated with the nondisabled peers acting as role models and positively influencing his or her disabled counterpart [14]. Furthermore, it has been found that inclusion benefits children with disabilities in conjunction with the typical children in the classroom by encouraging a greater sense of awareness and understanding of others with disabilities [13]. In order to ensure that combining students with disabilities with their typical peers is a positive experience, it is important to explain to the typical peers about others with disabilities and encourage these students to ask questions regarding this topic [11]. As an effect of the positive impact of inclusion on the progress and the ultimate well-being of students with disabilities several influential associations contend that inclusive education is an important system [7] and thus seems to be a valuable component to continue pursuing in the school setting.

Conclusion

On the whole, the practice of mainstreaming is leading an important path to improve the educational opportunities of many students with disabilities. In order for this practice to be successful, the classroom environment must be individualized to tailor the needs for each student. Although there are differing opinions on the use inclusion and its benefits, hopefully in the years to come it will continue to develop within the educational setting and provide various advantages for all children with disabilities.

Definition

Malnutrition occurs when your body does not get enough nutrients. The condition may result from an inadequate

or unbalanced diet, digestive difficulties, absorption problems, or other medical conditions.

Malnutrition can occur because of the lack of a single vitamin in the diet, or it can be because a person isn't getting enough food. Starvation is a form of malnutrition. Malnutrition also occurs when adequate nutrients are consumed in the diet, but one or more nutrients are not digested or absorbed properly.

Malnutrition may be mild enough to show no symptoms. However, in some cases it may be so severe that the damage done is irreversible, even though the individual survives.

Symptoms of malnutrition may include dizziness, fatigue, loss of weight and metabolic imbalances. Treating malnutrition usually involves means to replace the missing nutrients back into the body.

Worldwide, malnutrition continues to be a significant problem, especially among children who cannot fend adequately for themselves. Poverty, natural disasters, political problems, and war all contribute to conditions – even epidemics – of malnutrition and starvation, and not just in developing countries.

According to the Lancet, Malnutrition, in the form of iodine deficiency, is "the most common preventable cause of mental impairment worldwide." Even moderate iodine deficiency, especially in pregnant women and infants, lowers intelligence by 10 to 15 I.Q. points, shaving incalculable potential off a nation's development.

Maslow's Hierarchy of Needs

Michael Block
Azusa Pacific University, Azusa, CA, USA

Definition

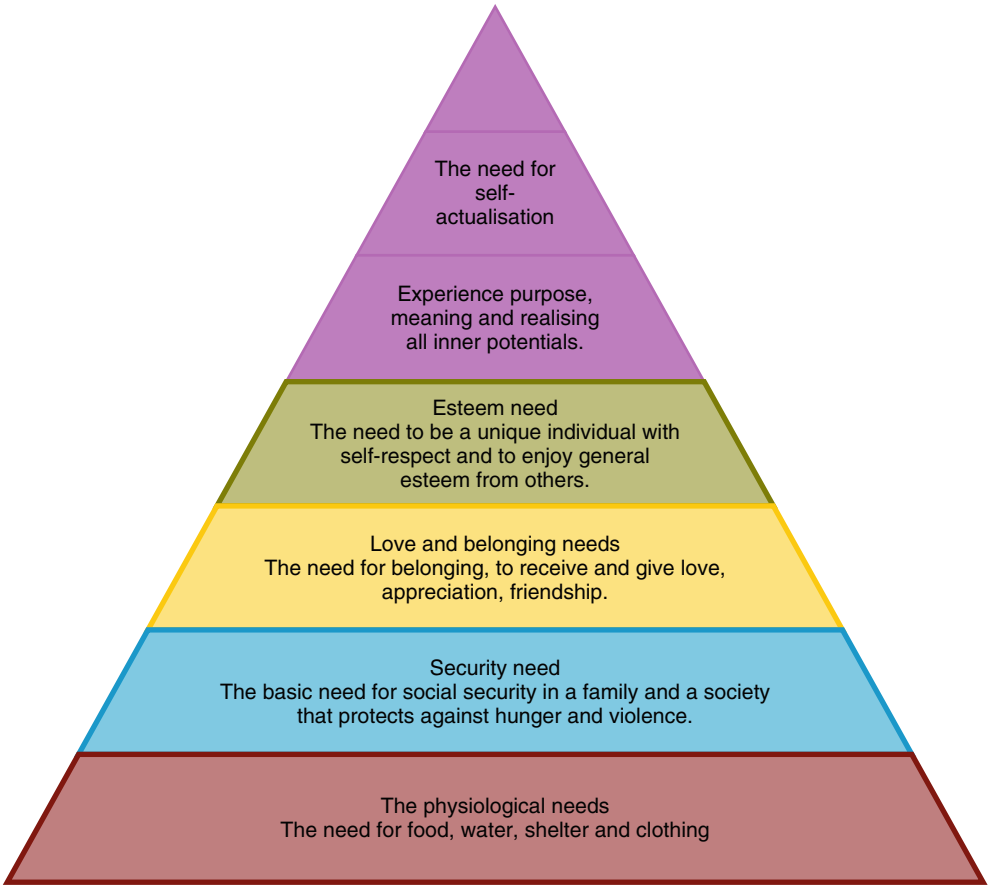
Maslow's hierarchy of needs is a theory in psychology, proposed by Abraham Maslow in his 1943 paper *A Theory of Human Motivation*, which he subsequently extended to include his observations of humans' innate curiosity [2].

Description

Abraham Maslow is a humanistic psychologist who developed a theory of personality that has influenced a number of different fields, including education. This wide influence is due in part to the high level of practicality of Maslow's theory. This theory accurately describes many realities of personal experiences.

Humanists do not believe that human beings are pushed and pulled by mechanical forces, either of stimuli and reinforcements (behaviorism) or of unconscious instinctual impulses (psychoanalysis). Humanists focus upon potentials. They believe that humans strive for an upper level of capabilities. Humans seek the frontiers of creativity, the highest reaches of consciousness and wisdom. This has been labeled "fully functioning person," "healthy personality," or as Maslow calls this level, "self-actualizing person."

Maslow has set up a hierarchic theory of needs often depicted as a pyramid consisting of five levels: the four lower levels are grouped together as being associated with physiological needs, while the top level is termed growth needs associated with psychological needs (Fig. 1). Deficiency needs must be met first. Once these are met, seeking to satisfy growth needs drives personal growth. The higher needs in this hierarchy only come into focus when the lower needs in the pyramid are satisfied. Once an individual has moved upwards to the next level, needs in the lower level will no longer be prioritized. If a lower set of needs is no longer being met, the individual will temporarily re-prioritize those needs by focusing attention on the unfulfilled needs, but will not permanently regress to the lower level. For instance, a businessman at the esteem level who is diagnosed with cancer will spend a great deal of time concentrating on his health (physiological needs), but will continue to value his work performance (esteem needs) and will likely return to work during periods of remission.



Maslow's Hierarchy of Needs. Fig. 1

Maslow's basic needs are as follows:

- Physiological needs

These are biological needs. They consist of needs for oxygen, food, water, and a relatively constant body temperature. They are the strongest needs because if a person were deprived of all needs, the physiological ones would come first in the person's search for satisfaction.

- Safety needs

When all physiological needs are satisfied and are no longer controlling thoughts and behaviors, the needs for security can become active. Adults have little awareness of their security needs except in times of emergency or periods of disorganization in the social structure (such as widespread rioting). Children often display the signs of insecurity and the need to be safe.

- Needs of love, affection and belongingness

When the needs for safety and for physiological well-being are satisfied, the next class of needs for love, affection and belongingness can emerge. Maslow states that people seek to overcome feelings of loneliness and alienation. This involves both giving and receiving love, affection and the sense of belonging.

- Needs for esteem

When the first three classes of needs are satisfied, the needs for esteem can become dominant. These involve needs for both self-esteem and for the esteem a person gets from others. Humans have a need for a stable, firmly based, high level of self-respect, and respect from others. When these needs are satisfied, the person feels self-confident and valuable as a person in the world. When these needs are frustrated, the person feels inferior, weak, helpless and worthless.

- Needs for self-actualization

When all of the foregoing needs are satisfied, then and only then are the needs for self-actualization activated. Maslow describes self-actualization as a person's need to be and do that which the person was "born to do." "A musician must make music, an artist must paint, and a poet must write." These needs make themselves felt in signs of restlessness. The person feels on edge, tense, lacking something, in short, restless. If a person is hungry, unsafe, not loved or accepted, or lacking self-esteem, it is very easy to know what the person is restless about. It is not always clear what a person wants when there is a need for self-actualization.

The hierarchic theory is often represented as a pyramid, with the larger, lower levels representing the lower needs, and the upper point representing the need for self-actualization. Maslow believes that the only reason that people would not move well in direction of self-actualization is because of hindrances placed in their way by society. He states that education is one of these hindrances. He recommends ways education can switch from its usual person-stunting tactics to person-growing approaches. Maslow states that educators should respond to the potential an individual has for growing into a self-actualizing person of his/her own kind. Ten points that educators should address are listed:

1. We should teach people to be *authentic,* to be aware of their inner selves and to hear their inner-feeling voices.
2. We should teach people to *transcend their cultural conditioning* and become world citizens.
3. We should help people *discover their vocation in life,* their calling, fate or destiny. This is especially focused on finding the right career and the right mate.
4. We should teach people that *life is precious,* that there is joy to be experienced in life, and if people are open to seeing the good and joyous in all kinds of situations, it makes life worth living.
5. We must *accept the person* as he or she is and help the person learn their inner nature. From real knowledge of aptitudes and limitations we can know what to build upon, what potentials are really there.
6. We must see that the person's *basic needs are satisfied.* This includes safety, belongingness, and esteem needs.
7. We should *refreshen consciousness,* teaching the person to appreciate beauty and the other good things in nature and in living.
8. We should teach people that *controls are good,* and complete abandon is bad. It takes control to improve the quality of life in all areas.
9. We should teach people to transcend the trifling problems and *grapple with the serious problems in life.* These include the problems of injustice, of pain, suffering, and death.
10. We must teach people to be *good choosers.* They must be given practice in making good choices.

Mastery Orientation

Pei-Hsuan Hsieh
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Learning goals; Task goals; Task involvement; Task orientation

Definition

Mastery orientation is defined as having the goal of learning and mastering the task according to self-set standards. Learner is focused on developing new skills, improving, and acquiring additional knowledge.

Description

Detailed in the literature are two types of goal orientations. The first is a mastery goal, where students focus

on mastery of a task and have the desire to acquire new skills. The second is a performance goal, where learners' main concern is demonstrating competence and focus on receiving favorable judgments of ability from others.

Mastery orientated students find satisfaction with the work and are not influenced by external performance indicators such as grades. Students who have mastery goals tend to engage in activities that will increase their knowledge. They pay more attention, are more likely to process information at a higher level, and are not afraid to ask for help.

Relevance to Childhood Development

Learners are likely to have both mastery and performance orientation. However, research shows a comparative prevalence of the two types of goals between learners of different age groups. Young children are typically more mastery oriented. By second grade, they begin to focus on performance. Adopting performance goals become more apparent as they move into adolescence. This shift in goal orientation may be due to both children's increasing awareness social comparison and teachers' emphases on grades and other forms of formal assessments.

Masturbation

Steuart T. Watson, Christine Griffes
Miami University (OH), Oxford, OH, USA

Synonyms

Autoeroticism; Jacking off; Pleasuring oneself; Servicing oneself; Whacking off

Definition

Self-stimulation of the genitals to achieve sexual arousal and pleasure, generally to the point of orgasm.

Description

Masturbation is achieved via touching, stroking or massaging the penis, vagina, or clitoris until orgasm is reached. Approximately 95% of males and 89% of females masturbate on a regular basis. Masturbation is a normal, healthy activity that generally begins in adolescence, although it is not uncommon for young children to masturbate as they grow and begin to explore their bodies [2]. Masturbation can serve many purposes including relieving sexual tension, stress, and inducing a state of general relaxation [2]. Although masturbation is a normal, healthy activity when it occurs at the appropriate times and places, it becomes problematic when people choose to masturbate in public places or at such a high frequency that it disrupts other behaviors, such as going to work, completing homework assignments, and/or socializing [2].

It is very common for people with cognitive impairments and pervasive developmental disabilities to masturbate. It is estimated that as many as 60–75% of people with Autism and cognitive impairments masturbate on a regular basis [1]. It is suggested that this behavior be considered normal and to not be concerned unless it is occurring too frequently (i.e., every time the student uses the restroom) or in inappropriate places (i.e., the hallway or classroom). If these concerns arise, an intervention may need to be put into place to reduce the frequency and environment in which the behavior occurs [1].

Relevance for Childhood Development

Although masturbation among both males and females is a normal aspect of growth and development, many parents believe that it is harmful or indicates some type of psychological problem with their child. Culturally, there may be taboos against masturbation. Some use religious teachings to discourage masturbation. There is no evidence that children and adolescents who masturbate are experiencing any kind of distress because of their masturbating. The primary problems surface when the child fails to discriminate when it is appropriate to masturbate (e.g., alone in their room) and when it is not (i.e., in the living room during a large family gathering). In such cases, masturbation should not necessarily be discouraged; rather the child should be taught the appropriate time and place for masturbation.

Maternal Alcohol Consumption

Rania D. Hadjicosta, Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Definition

The term "maternal alcohol consumption" refers to the adverse behavior of women who tend to use or abuse alcohol (Alcohol is defined as "a colorless volatile flammable liquid, C_2H_5OH, synthesized or obtained by fermentation of sugars and starches and widely used, either pure or denatured, as a solvent and in drugs, cleaning solutions, explosives, and intoxicating beverages" (http://www.thefreedictionary.com/alcohol).) before, during, or after the gestation of a child. Alcohol consumption may range between light to heavy/alcoholic drinking; however, there is no universal consensus as to how much quantity of alcohol denotes light, moderate, or heavy drinking/alcoholism (World Health Organization (WHO) defines alcoholism as "chronic continual drinking or periodic consumption of alcohol which is characterized by impaired control over drinking, frequent episodes of intoxication, and preoccupation with alcohol and the use of alcohol despite adverse consequences" (http://www.who.int/substance_abuse/terminology/who_lexicon/en/index.html)).

Description

During the 1970s national estimations of alcohol use and abuse in the United States indicated that about 18 million Americans were heavy consumers of alcohol, consuming about 5–6 drinks per day, every day. Within these estimations it was obvious that the majority of heavy drinkers were male, however, sex differences in the amount and frequency of alcohol consumption seemed to gradually disappear since female rates of drinking began to rise rabidly; so did the drinking rates among pregnant women [2].

More recent estimations of the phenomenon indicate that rates of alcohol use during pregnancy tend to decrease, with estimates for 2001 ranging between 15 and 20% while in 2005 the rates for using some alcohol ranged between 12 and 15% [6]. The decreasing tendency of women to reduce alcohol use during pregnancy is also documented by Grant and colleagues [13]. These researchers found that between 1989 and 2004 alcohol use during pregnancy decreased from 30 to 12% in all demographic categories [13].

Estimates for binge drinking (using >3 drinks at one occasion) showed that 3–4% of pregnant women continue to consume alcohol, despite the fact that its detrimental effects on the fetus have been established since the eighteenth century [6]. Furthermore, Grant and colleagues [13] also noted that binge drinking in the month before pregnancy increased across all demographic categories, except Native Americans, a pattern which can predict alcohol use during early gestation too.

Generally, the scientific community is most concerned with maternal alcohol consumption exhibited shortly before and during pregnancy, especially due to the teratogenic effects that such behaviors can have on the fetus. Even though it seems that the severity of deficiency on the child depends on the amount of alcohol consumed [2, 15, 26], the period of gestation during which exposure occurred [2, 15, 26], and the pattern of consumption (binge or steady) [15, 26] these difficulties may manifest themselves even when alcohol consumption occurs at the level of social drinking (1 or 2 drinks, two times weekly) [26].

Regarding the period of gestation during which exposure occurs, four mechanisms by which ethanol can affect the central nervous system (CNS) of the developing fetus

have been suggested. At the time of conception and during the first weeks of development ethanol may act cytotoxically or as a mutagenic agent and cause cell death or lethal chromosomal aberration, resulting to spontaneous abortion. During the following 4–10 weeks of gestation ethanol may cause excessive cell death in the CNS as well as abnormalities in nerve cell migration from cell damage, leading to disorganization of tissue structure and microcephaly. From the eighth to tenth weeks onwards, ethanol continues to cause disorganization or delays in cell migration and development, leading to abnormal synaptic formations [25, 26]. In the third trimester, alcohol exposure has been associated with damage in the cerebellum, hippocampus, and prefrontal cortex [25]. Additionally, ethanol can interfere with neurotransmitter production in the CNS causing neuroendocrine abnormalities and especially growth deficiencies [25, 26].

These effects are caused to the fetus mainly because ethanol can freely cross the placenta, thus the concentration of ethanol in the fetus is equal or even higher than in the maternal blood. However, ethanol remains in the amnionic fluid for a relatively longer period of time making it possible for the fetus to be exposed to it even if there is no ethanol concentration in maternal blood [26]. That is due to the fetus's decreased ability to metabolize ethanol compared to the mother [6].

Risk Factors Associated with Maternal Alcohol Consumption

Several epidemiological studies throughout the years have identified a number of risk factors that are associated with higher maternal alcohol consumption rates and the resulting alcohol related birth disorders. These factors can be collectively divided into four major categories: those that are more likely to increase the risk for heavy maternal drinking (e.g., family traits and early onset of drinking); those that could be the consequence of alcohol abuse (e.g., unemployment and premature mortality); those that are more biologically based (e.g., advanced maternal age, previous pregnancies); and those that represent behavioral patterns of the mother (e.g., smoking) or psychological difficulties (e.g., stress and depression) [22].

The National Pregnancy Risk Assessment Monitoring System, during 2000–2001, identified two different groups of women at risk [6]. The first group has 6–15% probabilities of using alcohol during pregnancy and refers to women above the age of 35, with high socioeconomic status and educational level, not being users of any other illicit drug, and being non-Hispanic, white and married. The second group has 1–3% probabilities of using alcohol during pregnancy and refers to women below the age of 30, single, smoking cigarettes, using other substances (including marijuana, cocaine and opiates), and binge drinking [6].

More recently, Grant and colleagues [13], examining the tendency for alcohol use before pregnancy, reported that women in their study who were more likely to drink in the month before pregnancy were 31–35 years old, had at least 16 years of education, and were smokers. On the other hand, women who were less likely to drink in the month before pregnancy were younger than 21 years old, had less than 12 years of education, were Asian, and had more than one child. In addition, they found that women who were more likely to binge drink in the month before pregnancy, were 21–25 years old, Native American or black race, unmarried, and smokers [13].

Related to heavy and binge drinking is the assumption that heavy and binge drinkers are also more likely to have multiple unprotected sexual encounters resulting in unexpected and unwanted pregnancies. Heavy and binge drinking women also seem to fail to recognize that they have conceived in the early stages of gestation, thus exposing the child to the detrimental effects of alcohol from very early in development without even being aware of it [13].

In all, the risk factors identified to be associated with elevated levels of maternal alcohol consumption include: advanced maternal age, having three or more children, smoking, use of other drugs, low socioeconomic status, transience and low employment, frequent binge drinking, living in a social environment which tolerates or promotes drinking [6, 22] and having personal history of physical or sexual abuse [6]. Poor nutrition, environmental deprivation, poverty and homelessness [6, 22], physical stress, obstetric complications, fetal tissue sensitivity, and genetic susceptibility are also reported as risk factors for increasing maternal alcohol consumption [26].

Relevance to Childhood Development

Concern over the deleterious effects of alcohol on the developing fetus can be traced back to the Old Testament when Judges warned women to "Beware, and drink no wine or strong drink. . . .for lo, you shall conceive and bear a son" [25, 26] and during the time of Aristotle as well, who observed that alcoholic women often bore feebleminded children [2, 29]. Similar observations have been noted several times in the literature since then, especially during the England gin epidemic of the eighteenth century (between 1720 and 1750), relating maternal alcohol consumption with high rates of fetal and neonatal mortality, low birth weight and an array of other deleterious effects [29, 33]. However, it was not until the early 1970s that the association between prenatal alcohol exposure and birth

defects became the object of serious scientific and medical interest [2] and awareness of the teratogenic effects of alcohol was raised [26].

The first scientific study regarding the potentially deleterious effects of prenatal exposure to alcohol was reported from Sullivan in 1899, who reported an increased rate of stillbirths and infant deaths in children of alcoholic mothers [26]. However, for the following decades scientists assumed that the abnormalities exhibited by children of alcoholic mothers were secondary to environmental challenges and interest in the relationship between prenatal alcohol exposure and birth defects was silenced until the early 1970s [26]. Nowadays, and despite the above mentioned vagueness, it is consensually admitted that exposing a child to alcohol while still in the uterus has aversive effects on its physical and mental development, leading to childhood growth deficiency, IQ, motor skills, attention, and school performance difficulties.

In 1972, Ulleland [32] demonstrated that a group of children born to alcoholic mothers were typically underweight at birth, had small head circumference, and exhibited delayed growth and development. Shortly after this report, in 1973, Jones and his colleagues [18, 19] identified and described in more details a pattern of anomalies in a number of children born to alcoholic mothers. Jones and colleagues were the first to recognize these malformations as a distinct clinical entity and this distinct pattern of congenital malformations of altered growth and dysmorphogenesis associated with prenatal exposure to alcohol was subsequently termed the *fetal alcohol syndrome* (FAS).

Based on Jones and colleagues' observations, escorted by subsequent scientific studies in human and animals, FAS is characterized by three main clusters of symptoms. These clusters are: (1) prenatal and/or postnatal growth deficiency, (2) CNS dysfunction reflected in mental deficit, and (3) a distinctive pattern of facial dysmorphology [1].

Pre and postnatal growth deficiency is evidenced in the birth weight and height of the child being below the tenth percentile for age or gestational age [26, 33], while head circumference is characteristically below the third percentile [26]; and these features seem to be consistent even at the age of 14 [10]. CNS dysfunction becomes obvious through behavioral/cognitive impairment including fine motor dysfunction and mental retardation, which is the most detrimental effect of prenatal alcohol exposure [26]. The distinctive pattern of facial and physical malformations include microcephaly [2], short eye lip openings (short palpebral fissures), flat midface, thin upper lip, a flat or absent groove between the nose and the upper lip (philtrum) [16], a short upturned nose [2], flat cheeks (maxilla), and flattened nasal bridge [26]; small teeth with defective enamel is an additional possible defect [15].

This clusters of deficiencies must occur together in order to allow for the diagnosis of FAS. In fact, each component alone is nonspecific and only the amalgamation of these allows for the diagnosis of FAS [1, 14]. Hence, experts in the field soon realized that some children exhibited some but not all the features of FAS or the same symptoms in various degrees of severity. For example, some children even thought they were exposed to alcohol prenatally and showed developmental delay along with behavioral abnormalities they did not have signs of facial dysmorphology.

In the face of the need for a new terminology, then, which would be able to describe these differentiations and denote that these abnormalities were congruent with prenatal alcohol exposure but not sufficient to permit the diagnosis of FAS, the term suspected *fetal alcohol effects* (FAE) was adopted [1, 14]. Subsequently, the Institute of Medicine suggested the distinction between three forms of FAE [16]. Thus, the terms *partial fetal alcohol syndrome* (partial FAS), *alcohol related birth defects* (ARBD), and *alcohol related neurodevelopmental disorder* (ARND) were introduced [16].

Partial FAS refers to children who have confirmed history of heavy prenatal alcohol exposure and show some components of the characteristic alcohol related facial dysmorphology, as well as physical growth and neurodevelopmental deficiencies [16]. ARBD applies to children with confirmed heavy prenatal alcohol exposure accompanied by one or more congenital defects, typically cardiac, skeletal, renal, ocular, or auditory [16] without having the characteristic facial features of FAS though [22]. Finally, ARND refers to children with confirmed heavy prenatal alcohol exposure who also exhibit measurable but milder neurobehavioral deficits than those seen in children with FAS [16], there is, however, lack of the characteristic facial defects and the growth deficiency associated with FAS [22].

Nowadays, the term *fetal alcohol spectrum disorders* (FASD) has been employed as an umbrella term describing the wide range of effects that can occur in an individual whose mother drank alcohol during pregnancy, but this term cannot be applied as a clinical diagnosis [7, 30]. The effects encompassed in FASD generally include physical, mental, behavioral and learning disabilities associated with prenatal alcohol exposure with lifelong implications [7].

Prevalence

Generally, it is estimated that 40% of children born to alcoholic mothers and 11% of children born to moderately drinking, but not alcoholic, mothers exhibit some difficulties related to FASD [17]. Prevalence estimates for FAS range from 1 to 3 per 1,000 live births, but rates may vary between populations. Estimates of the prevalence of FAS among chronically alcoholic women are 25 per 1,000. FAE is more prevalent than FAS, occurring at rates 3–4 times higher [26]. Finally, all the FASD together are 10 times more prevalent than FAS alone [6].

In one meta-analytic study contacted by May and colleagues [22], the overall rates of prevalence for FAS were estimated between 0.5 and 2 per 1,000 live births and for FAS and ARBD combined 10 per 1,000 live births in the United States during the 1980s and 1990s. It is also reported that in families where there is one child diagnosed with FAS, the incidence rate can be even 405-fold higher compared to the worldwide average [33]. Finally, the prevalence of FASD in the United States has been reported as 9.1 per 1,000 live births [7]. Nonetheless, these estimates are tentative since the diagnosis of any of these conditions is very difficult and thus may often be delayed or missed entirely [7].

Physiological Problems Evident in Affected Children

Physiological conditions experienced by children prenatally exposed to alcohol include cleft palate heart, kidney, visual [26, 29], renal and orthopedic defects [20]. Cardiovascular defects include septal anomalies and hypoplastic pulmonary arteries; renal defects may include pyelonephritis, painless hematuria, and hydronephrosis; and orthopedic anomalies may be manifested in radioulnar synostosis, camptodactyly of the fingers, and brachydactyly and clinodactyly of the toes [20]. Additionally, dental and ocular anomalies, accompanied by otitis mefia may be present [26], as well as hemangiomas, micrognathia, and eye and ear abnormalities [8].

Furthermore, sensory problems involving ocular, auditory, and vestibular problems caused by abnormal development of the CNS due to early alcohol exposure have also been reported. These sensory difficulties can consequently lead to permanent speech, language, and cognitive deficits, as well as impaired academic performance [2]. Further physiological problems, which have not been widely studied, include childhood leukemia [24] and cryptorchidism in boys [9].

High risks for premature placenta separation [29], spontaneous abortion [3, 15, 29] and stillbirth [2, 3, 29] have also been documented. In a retrospective study contacted by Abel [3], estimates for spontaneous abortion ranged, according to ethic groups and geographic places, between 18.8 and 81%. It has been also proposed that in the United States women diagnosed with alcohol abuse disorders are two times more likely to have experienced more than three spontaneous abortions [3]. Finally, maternal alcohol consumption poses an increased risk for sudden infant death syndrome, which is increased even more when combined with additional risk conditions, such as smoking [12].

Neurological, Cognitive and Behavioral Problems

Early post-mortem autopsy investigations on individuals prenatally exposed to alcohol have reported a wide range of neuroanatomical abnormalities. These abnormalities include: hydrancephaly, anencephaly, hydroncephale, microcephaly, cerebral dysgenesis, abnormal neural migration, and severe CNS disorganization. Additional abnormalities of the basal ganglia, the cerebellum, and the hippocampus were also noted [30].

Contemporary neuroimaging studies have demonstrated specific neuroanatomical defects. For example, using magnetic resonance imaging (MRI) techniques researchers have identified reductions in the cranial, cerebral, and cerebellar vaults in individuals diagnosed with an alcohol related disorder. In addition, others have reported hypoplasia in the temporal, frontal and especially in the parietal lobes. These abnormalities are thought to be related to executive functioning problems, such as poor planning, cognitive inflexibility, reduced response inhibition, and special memory problem [30].

White matter hypoplasia and increased gray matter density in inferior parietal regions and superior temporal lobes were also evident in the brains of affects children. White matter hypoplasia and increased gray matter in the brain have been associated with deficits in language processing and object recognition. Moreover, reduced surface area and volume of the cerebellum, as well as damage localized to particular areas of the cerebellum, which are consistent with difficulties in balance, bimanual coordination, verbal learning and memory, have also been reported [30].

Finally, studies investigating the corpus callosum have identified hypoplasia of this structure, as well as changes in its shape, a finding which is related to bimanual coordination, attention, executive functioning, and verbal learning deficits. Studies referring to the basal ganglia have reported reduced volume of this structure in affected individuals, and this is associated with problems in movement, procedural learning, and cognitive, affective and

motivational functioning, while others have reported asymmetrical hippocampal formations, which are linked to memory deficiencies [30].

Developmentally, neurological deficit manifestations vary according to the age of the child and the circumstances activated in one's environment. Generally, however, evidence suggest that during the neonatal period these neurological deficits manifest in poor sucking, disturbed sleep states, low levels of arousal, tremulousness, unusual body orientation, excessive mouthing, abnormal reflexes, hypertonia, and poor habituation [33]. Newborns have also been described as difficult to feed and soothe as well as irritable. They may also experience withdrawal symptoms and delays in achieving speech and motor milestones [26]. In older infancy, difficulties are evident in disturbed sleep-wake patterns [31], poor visual recognition, and delays in mental and motor development, spoken language, and verbal comprehension [33]. During the pre-school years, children display attention deficits, delayed reaction times, and problems in fine and gross motor performance. In adolescence, affected children tend to portray more overt psychological problems, while in adulthood they fail to achieve adaptive living and self-sufficiency [33].

More specifically, one of the most detrimental effects of prenatal exposure to alcohol and FAS is mental deficit, ranging from borderline to severe mental retardation [2], with children diagnosed with FAS usually demonstrating an average IQ between 60 and 65, even though there is a wide range of individual IQ scores [25, 26].

Furthermore, it has been generally suggested that maternal alcohol consumption during pregnancy may lead to an array of further cognitive effects in the exposed child. Such effects include hyperactivity and attention problems, learning and memory difficulties, as well as challenges referring to social and emotional development [16].

Attentional difficulties are more evident in certain aspects of attention, such as executive functioning [27], cognitive flexibility, planning, strategy use, verbal reasoning, inhibition, set shifting, fluency, working memory, emotion-related learning [25], and focused attention [16] which seems to be more pervasive in deficits in the ability to focus and sustain attention to visual stimuli and deficits in the ability to sustain attention to auditory stimuli over long intervals [21].

Deficits in language are, on the other hand, found to be specific to production and pragmatics, resulting in defects in the comprehension and use of grammatical markers and in the processing and memorizing linguistic elements [26] as well as in both receptive and expressive language abilities [23]. These language and speech problems appear to be independent of the individual's mental ability [15, 23] and are more likely to impact children's social interactions and behavioral adjustment [23].

As far as social and adaptive behavior is concerned, children with FAS appear outgoing, socially engaging, affectionate, excessively friendly, and they enjoy bodily contact. FAS children also seem not to be able to discriminate between familiar and unfamiliar people, a behavior that raises concerns regarding their safety [25, 26]. These children, additionally, appear to have difficulties with the "theory of mind" (i.e., not being able to infer another's perspective) [25]; and have been found to exhibit poor socioemotional development, which cannot be attributed to their IQ scores [16].

Generally, the cognitive and behavioral profile of children prenatally exposed to alcohol include: communication and speech difficulties, such as speaking too much and/or too fast, and interrupting others; problems with personal manners, such as clumsiness, disorganization, and loosing things; emotional lability, such as rapid mood changes and overreacting; motor defects; poor academic performance caused by their short attention span and their difficulty completing tasks; impaired social interactions, including their lack for awareness of consequences of one's actions and their poor judgment; and unusual physiological responses, such as hyperactivity and sleep difficulties [7, 25].

Comorbid Psychopathology

The most frequently reported behavioral disorder associated with FAS is attention deficit hyperactivity disorder (ADHD) affecting approximately 85% of preschool FAS children [25, 26]. On the other hand, research suggests that hyperactive children often come from homes where one or both parents are alcoholics, thus FAS children are more likely to be raised in unstable home settings. Furthermore, it seems that mothers who have problems related to alcohol consumption were drinking before their pregnancies and are more likely to continue drinking during as well as after that, thus posing the question of whether the difficulties experienced by affected children are due to the combination of pre-, peri- and post-natal maternal alcohol consumption [2] or due to the combination of these.

Other psychological difficulties that have been associated with FAS include: eating problems resulting in failure to thrive, something which can also be associated with the inhibition of the milk ejection reflex in the mother due to alcohol consumption and thus the inability of the mother to feed the child adequately [2]. Moreover, sleeping

disturbances, ticks, phobias, temper tantrums, enuresis and encopresis, and psychosocial difficulties [25, 26], as well as fetal distress and neonatal depression are also common outcomes related to prenatal alcohol exposure [29].

There has also been noted that maternal alcoholism affects the parent-child relationship, since withdrawal symptoms in the mother may affect her behavior toward the child [2] and since alcoholic mothers often fail to assume maternal responsibilities [26]. For example, children prenatally exposed to alcohol appear to be irritable during infancy, which is a temperamental variable, acknowledged to be involved into poorer mother-child attachment and more behavioral problems in childhood [16].

It is well documented that the early attachment relationship is the basis upon which the child develops representations of the self and others and determines the ways a child relates to others and resolves interpersonal issues later in life [28]. Thus, problematic early attachment relationships can have detrimental effects in the child's interpersonal development. Research contacted with children of alcoholic mothers indicated that children of mothers who admitted drinking more before and during pregnancy were judged to be insecure [28]. These children also appear to be less socially competent and more aggressive in the classroom and during adolescence they fail to consider the consequences of one's actions, they are unable to respond appropriately to social cues, and have poor interpersonal relations [16].

It is also very common that children born by alcoholic mothers to be raised in foster homes or adoptive placements, not only because their mothers are unable to care for them adequately but also because these mothers are at increased risk for premature mortality due to their drinking habits [22], thus posing additional risk factors to their development [26].

Nevertheless, the structural abnormalities observed in the brains of children with FASD cannot be attributed to any of the adverse environmental factors described above. Therefore, even though the environment may be a factor of blocking cognitive development, environment alone cannot be held responsible for the deficits exhibited by affected individuals [2].

FASD in Adulthood

The defects delineated above, unfortunately, continue into adulthood, pinpointing the profound, pervasive, and persistent nature of these disorders. Is has been reported that affected individuals continue to experience cognitive functioning deficiencies, especially with mathematics, abstract reasoning, generalization, attention, concentration, memory, judgment, and comprehension [8]. Behaviorally, they exhibit hyperactivity, impulsivity, stubbornness, and oppositional behavior. Most cases also fail to achieve age-appropriate social and communication skills, resulting to maladaptive social functioning as evidenced in failure to consider consequences for their actions, failure to respond to appropriate social cues, lack of reciprocal friendships, mood lability, and bullying [8]. Moreover, these individuals are more likely to experience psychological difficulties related to substance dependency, inability to develop appropriate sexual behavior and they are also more likely to have related legal problems [8].

More specifically, Famy and colleagues [11] have reported that from a sample of 25 individuals diagnosed with FAS and FAE, who were older than 18 years old, 15 had a diagnosis of alcohol or drug dependence, 11 had major depressive disorder, 10 had diagnoses of a psychotic disorder, 5 had bipolar I disorder, 5 had anxiety disorders, and 4 had eating disorders. Famy and colleagues also reported that a substantial percentage of the individuals also had an Axis II diagnosis; 6 had avoidant personality disorder, 4 had antisocial personality disorder, and 3 had dependent personality disorder.

Assessment, Diagnosis and Management

So far, it has become apparent that the adverse effects related to maternal alcohol consumption are neither rare nor simple and that FAS is only a restricted representative of these effects [4]. Since FAS was first described in 1973, it has become obvious that this spectrum of disorders is multifaceted. Affected individuals demonstrate a wide spectrum of symptoms, ranging from severe growth restriction, intellectual disability, birth defects and characteristic dysmorphic facial features to normal growth, facial features and intellectual abilities but with lifelong deficits in several domains of brain function [7]. Moreover, FASD is a condition that has implications for everyone; the affected person, the mother, the family and the community.

FASD is the most prevalent cause of non-genetically based mental retardation and is the only completely preventable and avoidable form of mental defects [33]. In addition, research has indicated that the difficulties evidenced in alcohol exposed children are long-lasting [26] and that these children remain handicapped for the duration of their lives [15]. Thus, an early diagnosis, based on sound assessment, is essential since this is the only vehicle that can allow access to interventions and resources that may alleviate the development of subsequent

"secondary disabilities" (such as unemployment, mental health problems, trouble with the law, inappropriate sexual behavior) among affected individuals.

Furthermore, an early diagnosis will also allow suitable intervention, counseling and treatment for the mother and may prevent prospective births of more children with the same difficulties [7]. Most importantly, accurate and timely diagnosis is essential to improve outcome, as misdiagnoses result in unsuitable interventions, high risk for the development of secondary disabilities, failure to provide prevention and finally inaccurate estimates of incidence and prevalence.

In addition, it is well documented that FAS is difficult to identify, especially at birth, because the signs and symptoms of the syndrome are milder and undifferentiated. Furthermore, the expressed signs of FAS may resemble the patterns of deficiency evident in other conditions such as the DeLange syndrome, Williams syndrome, Dubowitz syndrome, Stickler syndrome, X-linked mental retardation [20, 26], Aarskog syndrome, maternal PKU effects, Noonan syndrome, and Toluene embryopathy [20]. Therefore, differential diagnosis between conditions is of utmost importance. Differential diagnosis however requires a clinical assessment contacted by multidisciplinary teams experienced in the field.

Contemporary knowledge of the complexity of the difficulties associated with prenatal alcohol exposure impose that a comprehensive, multidisciplinary assessment is necessary to make an accurate diagnosis and provide sensible advice for management [7]. The special physical, emotional, and mental needs [15] of children pre- and postnataly exposed to the detrimental effects of alcohol must be adequately assessed and recognized within the context of a multidisciplinary approach so that appropriate residential, educational, mental health, and vocational rehabilitation management programs be developed to facilitate individuals' development to the degree possible [26].

Thus, the core team for such a multidisciplinary assessment ideally should consist of: the coordinator for case management (e.g., nurse, social worker), a physician specifically trained in FASD diagnosis, a clinical psychologist, an occupational therapist, and a speech-language pathologist. Supplementary members, such as addiction counselors, childcare workers, cultural interpreters, mental health workers, parents or caregivers, probation officers, psychiatrists, teachers, vocational counselors, nurses, geneticists or dysmorphologists, neuropsychologists, family therapists can also be included [7].

Following sound assessment accurate diagnosis should be made. The complex and wide variety of the symptoms experienced by children prenatally exposed to alcohol poses great challenge in the development of adequate diagnostic and classification systems. Since alcohol-related abnormalities gained recognition several schemes of diagnosis and classification have been presented. Some of these classification schemes are the one proposed by Majewski and colleagues in 1976 [26] and that proposed by Burd and Martsolf in 1989 [26]. More recent efforts have led to the development of the Institute of Medicine Guidelines [14], the 4-Digit Diagnostic Coding System [4, 5], the Centers for Disease Control Guidelines [20], and the Canadian Guidelines for diagnosis [7]. The decision of which of these systems should be applied can be made only by the clinician since debate upon the qualities of the schemes is still in progress and there is no consensus reached yet as to which is the most appropriate.

Finally, prevention is the only protective measure against FASD and this can be accomplished only by abstinence during pregnancy, since a "safe" limit of alcohol consumption during pregnancy has not been defined [8, 17, 33]. Therefore, policy makers as well as communities should focus on prevention programs such as public health education and public health campaigns advising women to abstain from alcohol use during pregnancy or even while considering pregnancy [13]. Such educational programs should also be applied into school settings [8]. Moreover, prenatal counseling is a strategy widely used in several prevention programs along with screening tools in prenatal clinics for early identification of alcohol use with women at risk, which should also be followed by providing preventive and supportive counseling [8, 13] to identified women.

Maternal Smoking

Louiza Michael Christodoulou, Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Definition

The term "maternal smoking" refers to the adverse behavior of women who tend to smoke (Smoke refers to inhaling of burned tobacco) before, during, or after the gestation of a child.

Description

Maternal smoking has detrimental effects on both the mother and the offspring. Inevitably, the offspring of a mother who is a smoker is exposed to the damaging effects of smoking. Therefore, maternal smoking constitutes a significant risk for the development of children from the time they are a fetus [7] since women that smoke are at risk for ectopic (Ectopic pregnancy occurs when the fertilized egg grows outside the uterus) pregnancies and spontaneous abortions [9]. More specifically, although in the uterus, the fetus is still affected by the smoking mother. Studies have suggested that maternal smoking has a detrimental impact on fetal development and is related to increase in perinatal morbidity and mortality [4, 9]. Furthermore, many studies have provided corroborative evidence that maternal smoking is associated with preterm delivery (i.e., delivery before 37th week) and with Smallness-for Gestational-Age (SGA), a condition where "the birth weight is below tenth centile for

gestational age at deliver" [3, 13]. In addition smoking during pregnancy and low birth weight have been indicated as risk factors for sudden infant death syndrome (SIDS) (Sudden infant death syndrome refers to the unexpected death of an infant during the first year of life) [10].

Opportunities for breastfeeding are diminished in children of mothers who smoke relative to those who do not. It has been reported that smoking mothers are less likely to breastfeed their infants or breastfeed for a shorter period of time than nonsmoking mothers [5]. Breastfeeding has well documented beneficial effects not only on the physical health of the developing infant but also on his/her cognitive development and psychological well being. Consequently the diminished opportunity for breastfeeding places the children of mothers who smoke in a more disadvantageous position.

Harmful outcomes of being exposed to smoking while in the uterus may become evident much later in a child's life. Maternal smoking has been shown to have an impact on many aspects of the developing child, such as his/her mental and physical health and behavior. More specifically, maternal smoking has been implicated in attention deficit hyperactivity disorder [11], in the development of cognitive and behavioral problems in offspring [2, 12], as well as in pediatric obesity [1, 6]. Furthermore, exposure to maternal smoking is associated with immune system dysfunction, increasing the risk for childhood cancers, asthma [8] and the development of acute lower respiratory infections, such as bronchitis and pneumonia [8].

Contemporary research started to explore the risk that being exposed to "thirdhand smoke" (residual tobacco smoke contamination that remains after the cigarette is extinguished) [14] places on the developing child. That is, children may be exposed to "thirdhand smoke," even when they are not directly present when their mother smokes. Therefore, old beliefs about smoking being harmless to the children if they are not present are now being challenged.

Educating women on the risks that smoking imposes on the health of their children, is a promising way for limiting maternal smoking. In addition, stricter smoking bans are required for better protection of children.

Mather, Nancy

Sherry Mee Bell
University of Tennessee, Knoxville, TN, USA

Life Dates

February 4, 1950–Present

Educational Information

Nancy Mather is a renowned expert in the field of learning disabilities. Dr. Mather earned a Bachelor's degree in English in 1972 and a teaching certificate in 1974 from the University of Colorado, Boulder. In 1976, she earned a Master of Arts degree in special education from the University of Northern Arizona. Following 3 years of teaching students with learning disabilities in Santa Cruz, CA, Dr. Mather earned the Ph.D. from the University of Arizona in 1984 with a major in special education and minors in school psychology and reading. Following graduation, she completed a postdoctoral fellowship at the University of Arizona. Dr. Mather was mentored by and completed her dissertation under the direction of Dr. Samuel Kirk, pioneer in the field of learning disabilities, attributed with coining the term *learning disabilities.*

Accomplishments

Author or coauthor of over a dozen books and over a dozen book chapters, Dr. Mather is perhaps best known for her works on interpretation and educational implications of the Woodcock–Johnson cognitive and achievement tests (e.g., *Woodcock–Johnson III: Recommendations, Reports, and Strategies* [10]). In addition to several works on use of the Woodcock–Johnson instruments, Dr. Mather has coauthored several tests including the *Woodcock–Johnson Tests of Cognitive Ability and Achievement* (3rd ed.). [9], the *Woodcock–Johnson Diagnostic Reading Battery* [8], and the *Woodcock–Munoz Bateria III* [4]. An expert in reading and writing learning disabilities, she has also coauthored tests focusing specifically on reading fluency (*Test of Silent Word Reading Fluency* [3]) and orthographic skills (*Test of Orthographic Competence* [5]).

A respected scholar, Dr. Mather has conducted research on topics including teachers' knowledge of literacy instruction, effective strategies for literacy instruction, test accommodations for students with learning disabilities, and other issues related to effective teaching of students with learning disabilities. Recent endeavors include coauthoring reading programs including *Phonics Reading Lessons: Skills* [1] and *Phonics Reading Lessons: Practice* [7]).

Contribution

Drawing on her early work as a teacher of students with learning disabilities, Dr. Mather has made major contributions to the field of learning disabilities. Dr. Mather's professional contributions include service on editorial boards of numerous professional journals including *Journal of Learning Disabilities*, *Learning Disabilities Research and Practice*, *Learning Disabilities Quarterly*, and *Learning Disabilities: A Multidisciplinary Journal.*

In-depth knowledge, an effective communication style, and passion for the field have made Dr. Mather a sought-after speaker at professional conferences, Dr. Mather has served as keynote or highlighted speaker at numerous international, national and regional professional conferences, including Learning Disabilities Association International, National Association of School Psychologists, and International Dyslexia Association.

Current Involvement

In 2003, Dr. Mather earned full professor status at the University of Arizona where she continues to teach and serve on faculty in the Department of Special Education, Rehabilitation, and School Psychology. In addition, she has a long history of service to individuals with learning disabilities, as a learning disabilities teacher, as a diagnostician, and educational consultant. Two of her most recent scholarly texts include *Learning Disabilities and Challenging Behaviors: A Guide to Intervention and Classroom Management* (2nd ed.). [2] and *Evidence-Based Interventions for Students with Learning and Behavioral Challenges* [6].

Maturation

Pamelyn M. MacDonald
Emporia State University, Emporia, KS, USA

Synonyms

Genetic blueprint; Growth

Definition

Maturation is the predetermined unfolding of genetic information.

Description

The concept of maturation was pioneered by the American psychologist *Arnold Gesell* [3]. Maturation stresses the importance of *nature* or *genetics* in human development, as opposed to *nurture* or environment. Maturational development occurs in fixed sequences or stages that are governed by genes. This "genetic blueprint" for development determines the sequence, timing and form of emerging action-patterns [4].

Relevance to Childhood Development

Gesell observed that the motor skills of children developed in a fixed, or stage-like, pattern that were mostly unaffected by external influences. He called this process maturation. Maturation can first be seen in the developing *embryo*, where development occurs in the same pattern for every human without variation. In the embryo, the heart and cardiovascular system develop first, quickly followed by the central nervous system (brain and spinal cord), with the extremities, such as arms and legs, developing last [2, 5].

Sequential development continues after birth in a *cephalocaudal* (head-to-foot) pattern. Infants first control their mouths, then eye movements, followed by control over the neck, shoulders, arms, hands, fingers, trunk, legs and feet. As infants continue to grow into toddlers, they learn to sit up, stand, cruise, walk and then run, with all of these developing in a specific order that emerge with the maturational growth of the nervous system. Rates of development vary from child to child, but all children proceed through the same sequence [6].

Gesell's main scientific focus was maturational growth with regards to early motor behavior. However, Gesell believed that maturation governed growth in all areas of development:

> [The child's] nervous system matures by stages and natural sequences. He sits before he stands; he babbles before he talks; he fabricates before he tells the truth; he draws a circle before he draws a square; he is selfish before he is altruistic; he is dependent on others before he achieves dependence on the self. All his capacities, including his morals, are subject to the laws of growth [3].

Gesell did not completely discount the contribution of nurture or the environment in child development, but he believed that socializing forces worked best when they were in tune with inner maturational principles [1]. For example, Gesell was strongly opposed to trying to induce early walking in a child. He believed that children would walk when they were maturationally prepared to do so and efforts to speed the process could be harmful or create tension between caregivers and children. In addition, research has shown that efforts to speed up motor development produce only small and temporary effects.

May Institute

Fatima Watt
Argosy University, Atlanta, GA, USA

Definition

The May Institute provides research-validated services to children and adults with autism, brain injuries, mental retardation, pervasive developmental disorders (PDD), and behavioral healthcare needs [1].

Description

The May Institute is a network of educational, behavioral, and rehabilitative programs offering a broad range of services in more than 200 sites throughout the country. Its programs blend science and practice, with a core focus on research and training. The May Institute maintains affiliations with more than forty hospitals, universities, and human service agencies worldwide.

The May Institute was founded in Chatham, MA, by Dr. Jacques M. May and his wife, Marie Anne, in 1955. The Institute's first school was created in order to provide treatment and a supportive environment for the couple's twin boys with autism. Dr. May and his wife envisioned a program that would allow children with disabilities to lead the fullest lives possible. Today, the May Institute is among the largest, most respected, and innovative behavioral healthcare organizations in the country.

May provides comprehensive services to children and adolescents with autism, brain injury, developmental disabilities, and behavioral disorders. They have various programs ranging from research-based services for children with autism, to behavioral therapy techniques, and home-based and school consultation services. The Institute maintains four schools for children and adolescents with autism, PDD, and other developmental disabilities located in: Randolph, West Springfield, and Woburn, MA; and Santa Cruz, CA. A supplementary school serves children and adolescents with brain injuries. In addition, the May Institute has developed a unique program that combines behavior support techniques and instructional practices to reduce discipline problems and enhance academic commitment in schools throughout the country. A child abuse prevention program, Safety Protection Education and Assertiveness for Kids (SPEAK), was also developed in order to educate youth about the topic of abuse.

The May Institute offers day program services to adults with autism, mental retardation, developmental disabilities, and behavioral disorders. The Institute also provides community living services including: supported employment environments, employment training, behavioral therapies to assist with daily routines, and 24-h-a-day supervision. For adults with behavioral health concerns ranging from anxiety, eating disorders, and marriage problems to acute psychiatric illnesses, the May Institute offers a full range of mental health services.

The Institute has an empirically based orientation with training and research as a major component. Since 1978, professionals at the May Institute have collectively authored hundreds of articles and book chapters in the following domains: autism, behavioral medicine, behavioral healthcare, brain injury, severe behavioral disorders including conduct disorder, child development, developmental disabilities, eating disorders, forensic psychology, mental illness, mental retardation, organizational behavior management, public schools, quality management, rehabilitative services, self-injurious behavior including suicide, special education litigation, staff training and supervision, and violence prevention. The May Center for Applied Research was created in 1997 to supervise and coordinate research activity at the May Institute. The Center directs and supports research initiatives within the educational and healthcare services. Current research initiatives at the May Institute focus on evaluations of instructional and treatment methods, systems analyzes, comparative outcome assessments, clinical efficacy studies, documentation of large-scale program design, and behavior support and preventive interventions within public schools.

McCarthy Scales of Children's Abilities

Elizabeth Levin
Laurentian University, Sudbury, ON, Canada

Definition

The McCarthy Scales of Children's Abilities refer to a standardized psychological test that assesses a young child's general cognitive abilities.

Description

The McCarthy [3] Scales of Children's Abilities developed by Dorothea McCarthy debuted in 1972. The test was developed based on McCarthy's teaching and clinical experience and took into account what she called functional considerations. The McCarthy was one of the first assessment tools to be developed as an alternative to the better known Wechsler scales, the Wechsler Preschool and Primary Scale of Intelligence and the Wechsler Intelligence Scale for Children, and the Stanford-Binet. For its time, the McCarthy was considered to be a psychometrically sound instrument; while it maintained its popularity through the 1990s, because it has never been re-normed it has fallen out of favor in recent years [2].

The McCarthy Scales of Children's Abilities are designed as an individually administered test of intelligence for children between the ages of 2½–8½ years of age. Test administration time ranges between 45 min and 1 h depending on the age and ability of the child. In lieu of yielding an IQ score as the measure of intellectual functioning, the McCarthy provides a general cognitive index (GCI). This was designed to avoid the misleading connotations that have been attributed to IQ scores [1]. The GCI provides an index of current functioning that does not mark anything as permanent about the child or indicate causal factors. In addition, information is provided on the child's verbal and nonverbal ability, numerical aptitude, short-term memory and coordination.

The McCarthy Scales contain 18 subtests that compose six scales. The Verbal Scale measures maturity of verbal concepts and includes tests of Pictorial Memory, Word Knowledge, Verbal Memory, Verbal Fluency and Opposite Analogies. Taken together, the scale is thought to measure the ability to comprehend verbal information and to express oneself through language. The Perceptual-Performance Scale measures nonverbal reasoning ability and visual-motor coordination. Its seven subtests include Block Building, Puzzle Solving, Tapping Sequence, Right-Left Orientation, Draw-A-Design, Draw-A-Child and Conceptual Grouping. The Quantitative Scale provides information on the child's ability to use and understand number concepts using the three subtests of Number Questions, Numerical Memory, and Counting and Sorting. The total score based on these 15 subtests yields the GCI or overall assessment of the child's cognitive abilities. The fifth scale, the Memory Scale is based on the four subtests which focus on auditory and visual short-term memory. These are the Pictorial Memory, Tapping Sequence, Verbal Memory and Numerical Memory subtests. The sixth scale, the Motor Scale provides an estimate of the child's gross and fine motor coordination. It includes the Draw-A-Design and Draw-A-Child subtests as well as measures of Leg Coordination, Arm Coordination and Imitative Action.

Raw scores on all scales are converted into standard scores so that the scale scores have means of 50 and standard deviations of 10. The GCI has a mean of 100 with a standard deviation of 16.

The McCarthy was considered to be a well standardized test when it was published [4]. Its norms mirrored the 1970 US census data and 1,032 children were tested. The sample was stratified by gender, color (white/nonwhite), geographic region and father's occupation. The test was determined to be reliable both over 1 month and 1 year intervals. Reliability coefficients for the GCI ranged from 0.90 to 0.85, respectively, although individual tests were not as reliable. The McCarthy was also considered valid when compared to other intelligence and achievement tests; however individual children sometimes showed discrepant scores and thus GCI scores may not be equivalent to IQ scores as found on either the Stanford-Binet or Wechsler tests [2].

When it was published in 1972 the McCarthy was a welcome addition to the field. It provided a test that could be used with children as young as 2½ years and its play like qualities made it an attractive test to use with such young children. The manual was considered thorough, the instructions for administration were clear and the test contents were not only well constructed they were easy for examiners to use and fostered interaction with the child. The test was especially suitable for assessing young children with learning problems or other delays. The McCarthy appeared to be a leading contender in the burgeoning field of child assessment, however, because the McCarthy has never been re-normed it has become outdated. Furthermore because the GCI was not equivalent to similar IQs its use for placement decisions has always been questionable. Had the McCarthy been re-normed its limitations could have been addressed. These include the lack of any measures of social judgment or abstract reasoning, weak reliability of individual subtests and weak support for the scales as independent factors.

Advertising; Announcement; Billboards; Books; Broadcast; Cable; Commercials; Communication; Correspondence; Intelligence; Magazines; Mass media; Medium; Music; News; Press; Print; Publishing; Radio; Television

Definition

Media is a form of communicating a message or information to the public that comes in a variety of forms.

Description

Media is the plural form of the word medium. Media also refers to the term mass media commonly utilized to describe an outlet for the means of communication; thus is associated with the press and news reporting agencies. The media is one of the greatest driving forces in society. We are all products and producers of our environment which is greatly shaped and molded by the information we receive from the press. Once this information is disseminated it is then interpreted based on one's sensory perception (i.e. five senses sight, taste, touch, sound, and smell), and worldview of the messages sent. We must also take into account that 'one's perception is their reality' which is intertwined with how an individual interprets and understands the barrage of messages sent out by the media. In addition, once an individual deciphers the data it has the potential to shape and mold individual's thoughts, actions, behaviors, emotions, and ideals.

This multi-billion dollar a year powerhouse is responsible for delivering information through a variety of avenues such as: television, Internet, mail, telephone, radio, news, magazines, books, billboards, and music etc. Advertisements alone which in fact is "the most important aspect of mass media" produces over $40 billion a year in revenue through the mode of television and radio, and an estimated $30 billion a year in revenue from newspapers and magazines [3, p. 35]. The advertising industry can create a false sense of security and hope by marketing a product or concept that is disguised as something that will meet our basic human instinctual needs and desires. Kilbourne [2] stated that "advertisers know us better than we know ourselves, and they use this knowledge to take advantage of us" (p. 77). On the other hand these public institutions collectively deliver news that without this source of communication would leave people less informed. Media involves not just different methods to relay the information, but also key counterparts for example: broadcasters, entertainers, journalists, the paparazzi, newscasters, movie stars and celebrities, photojournalists, marketing and advertisement executives, photographers, news crews, and radio deejays just to name a few.

Relevance to Childhood Development

Children are like sponges absorbing information they encounter in their environment from a variety of sources which includes the media to make sense of the world around them. Media exposure is something that begins in childhood, and continues as one advances through the lifespan. With this young innocence comes the ability to be easily influenced. The media not only targets adults as consumers, but children as well. Kilbourne [3] reported that these young consumers spend "$130 billion dollars a year of their parents spending to $8 billion dollars of their own money annually" (p. 44). With children's spending habits reaching into the billions a year it is creating a market where companies and organizations customize their messages through various outlets of the media to reach their little consumers. The information broadcasts according to age-related interests such as toys, clothing, junk food, music, video games, and movies. As a child is moving through the different stages of development he or she can interpret these messages and the abundance of information as an integral part of their self identity on cognitive, emotional, and social levels with a particular focus on the ability to relate to others.

Ward [5] discussed how media not only affects one's beliefs about themselves, aggression, sexuality, and weight, but that television exposure also impacts the structure and functioning of the brain; thus providing a link between excessive television viewing and attention deficit hyperactivity disorder (e.g., ADHD). Media use contributes to the modeling and the shaping of behaviors particularly

surrounding those related to the defining characteristics of what is considered feminine or masculine. Society defines what is acceptable for one to be considered 'feminine or masculine' based on the images portrayed by the media. If a child or adolescent deviates from what is socially acceptable this can increase the odd for social isolation and exclusion early on in childhood because of not "fitting in" to these specific molds outlined by societal standards of what is acceptable. Ward [5] further posits that

> Nearly every media portrayal, scene, and storyline conveys a message about normative and expected behaviors of women and men. From these portrayals, much can be learned about what types of women are considered attractive, which male behaviors draw scorn, and which life choices are rewarded. (p. 65)

Almost every home household at least in the United States has at least one television set in the home and children from lower income families where the parents have less education levels are more likely to watch more television than children from middle to upper socioeconomic status. The repeated television exposure can result in these children being exposed to the messages brought about by the media as the primary source of education both inside and outside the home. On the other hand, Linebarger and Piotrowski [4] found that since television is a popular and easily accessible medium it can assist children from lower socioeconomic backgrounds with parents with lower levels of education related to the processing of literacy skills, conceptual knowledge, vocabulary development, and even the early development of social skills by watching and listening to narrative-based television stories. This is particularly important when the parents of these children are unable to assist in the education preparation and school readiness due to a lack of financial resources and education.

Fouts et al. [1] reviewed several television cartoons and *Disney* films to assess the use of the word "evil" when referring to a character and reported that 74% of the Disney animated movies and 44% of the television cartoons "indicated the modeling of demonizing for young viewers" (e.g., a person engaging in hurting someone else or to be considered as an evil person, monster, devil, demon, or wicked) (pp. 15–23). Fouts et al. [1] suggests that "watching Disney animated movies may influence children's acquisition of demonizing labels and stereotypes as well as subsequent imitation of the use of such labeling behavior" (p. 20). The findings presented by Fouts et al. have a variety of implications not only for parents, but professionals working with children such as (a) the importance of parents and professionals being critics of children's media, (b) educate children how to be savvy consumers, (c) professionals need to address the stereotypes highlighted in these different types of children's media, and (d) both parents and professional need to take into consideration the beliefs children may adopt around "perceived wrong-doing may be influenced by observing demonizing in the media" (p. 21).

Research findings show inconsistent data related to the usefulness or harm in using the media as an educational outlet for both children and adolescents. The first step begins with parents and professionals taking on active roles as critical consumers of media by monitoring the programs youth frequently view today. It is also important to take on active roles by creating media literacy programs to increase insight and create dialogue with children on these different messages, labels, or stereotypes that may be presented in different forms of media. By creating these types of programs can create a generation of young consumers who are able to "analyze and evaluate the media so that they may less vulnerable to the impact of media's messages" as an integral part of understanding their place in the world, self-worth, and how to relate to others ([1], p. 21).

Medulla

Chad A. Noggle
SIU School of Medicine, Springfield, IL, USA

Synonyms

Medulla oblongata

Definition

The Medulla represents the lowest portion of the brainstem and plays a vital role in the regulation of functions such as breathing, heart rate, and blood pressure.

Description

The Medulla represents the lowest structure of the brainstem. It lies just below the Pons and just above the Spinal cord. The Medulla is the site at which the Vagus, Hypoglossal and Glossopharyngeal cranial nerves arise [1]. Functionally, the Vagus nerve controls the transmission of impulses to and from the CNS from and to the body [2]. In comparison, the Hypoglossal nerve corresponds functionally with the control of the tongue muscles while the Glossopharyngeal nerve corresponds with aspects of taste on the posterior portion of the tongue, tongue control and swallowing [2]. It is also the case that where the Medulla and Spinal Cord a structural region known as the Pyramidal Decussation originates. It is at this point that the majority of the fibers in the Corticospinal tract, which is an essential sensory and motor pathway, cross over to the other side [1]. The functional impact of this is seen in the strong contralateral (i.e., opposite side) presentation of the sensory and motor systems. Specifically, due to this crossing over, sensory and motor functioning of one side of the body is controlled by the opposing side of the brain. As such, lesions above the Pyramidal Decussation (i.e., within the brain) produce contralateral (i.e., opposite-side) impairments [1]. For example, infarction (i.e., stroke) in the region of the right Middle Cerebral Artery may well produce paresis (i.e., weakness) of the left arm. However, lesions (i.e., injuries) below the Pyramidal Decussation will produce ipsilateral (same-side) impairment, as the tracts have yet to cross over [1]. For example, a right-sided lesion below the Pyramidal Decussation (within the spinal cord or peripheral limbs) would produce right-sided impairment in lieu of left, as would occur if the lesion was above the Pyramidal Decussation. Given it houses the Pyramidal Decussation, which is the site at which the brain and spinal cord truly join one another, the Medulla can be conceptualized as the point at which the back-and-forth communication between these two main components of the CNS (i.e., brain and spine) really takes place [4].

Aside from being the origin site of the aforementioned cranial nerves and the Pyramidal Decussation, the Medulla itself, often referred to as the Medulla Oblongata, is charged with the functional duty of regulating vital functions such as respiration, blood pressure and heart rate, and basic muscle tone [4]. Given the Medulla's role in these functions, in combination with its' aforementioned relationship with key sensory and motor pathways, the types of outcomes following lesions (i.e., injuries) of the Medulla may range from subtle deficits of sensory and/or motor functioning to death [2].

In regards to its relationship to child development, the Medulla is one of the first areas of the CNS to develop, becoming functional in the early portions of the second trimester and is generally fully developed by the end of the second trimester [3]. This is essential given the vital functions the Medulla controls. As the Medulla activates in the early weeks of the second trimester, the fetus will begin to display critical reflexes such as continuous breathing movements that involves contractions of the diaphragm and chest muscles as well as sucking and swallowing reflexes. As the Medulla continues to develop over the course of the second trimester these reflexes become stronger and stronger. By the time the infant is born, these reflexes are now strong enough to allow them to breathe and feed outside of the womb.

Medulla Oblongata

Chad A. Noggle
SIU School of Medicine, Springfield, IL, USA

Synonyms

Medulla

Definition

The Medulla Oblongata is one portion of the brain stem which regulates life sustaining functions such as breathing, heart rate and blood pressure.

Description

The Medulla Oblongata constitutes one of the four parts of the brainstem that also includes the Pons, structures of the Midbrain (i.e., Tectum and Tegmentum), and structures of the Diencephalon (i.e., Thalamus and Hypothalamus) [3]. It is part of the Hindbrain, which is the point at which the brain and Spinal Cord join together [1]. Functionally, it represents the area where communication between the brain and spinal cord takes place [3]. Through this line of communication, the Medulla's pathways carry motor (i.e., movement and tone) and sensory (i.e., perception) information back-and-forth between the brain and Spinal Cord [1].

In addition to it being the juncture between the brain and spinal cord, the Medulla Oblongata can likely be called the most essential anatomical structure of the entire Central Nervous System as it plays a crucial role in life sustainment. Specifically, the Medulla Oblongata controls vital functions such as respiration, blood pressure and heart rate, and basic muscle tone [3]. Although minor damage to the Medulla Oblongata may only produce impairments of sensory and/or motor functioning, by disrupting the lines of communication between the brain and the Spinal Cord, at times damage to the Medulla Oblongata may actually lead to death due to disruption of those life sustaining functions previously noted [1].

Developmentally, the Medulla is one of the most developed areas of the brain at birth and is important to the breathing and feeding capabilities of infants. The Medulla begins to develop towards the end of the first trimester, becoming functional by the beginning of the second trimester [2]. As neurons begin to activate in the Medulla, the fetus will begin to engage in critical reflexes including continuous breathing that involves contraction of the diaphragm and chest muscles as well as sucking and swallowing reflexes. These reflexes continue to strengthen throughout the second and, subsequently, the third trimester. As a result, when an infant is born most are capable of breathing and feeding because of the reflexive strengthening brought about by the development of the Medulla. This is in addition to the important role the Medulla plays in the control of blood pressure and heart rate, as well as basic muscle tone [3].

Meehl, Paul Everett

Michael C. Cassano[1], Douglas W. Nangle[2]
[1]The Children's Hospital of Philadelphia, Philadelphia, PA, USA
[2]University of Maine, ME, USA

Life Dates

1920–2003

Introduction

Dr. Meehl was a leading psychologist whose work profoundly influenced methods of psychological inquiry and the understanding of psychopathology and personality. A true philosopher of science, he addressed wide ranging issues including the identification of symptom categories, the validation of test procedures, statistical significance testing, the analysis of cause, the mind-body problem, and applications of metascience, and is credited with inducing actual paradigm shifts in several of these areas. He is widely regarded as one of the most influential psychologists of the twentieth century [6]. It has been written that "Meehl's contributions to psychopathology and personality research are without parallel" [1].

Educational Information

Meehl was born and raised in Minneapolis, Minnesota where he remained to attend the University of Minnesota, completing his bachelor's degree (1941) and doctorate of philosophy (1945). Among several prestigious faculty and applied positions, Meehl spent his career as Regents' Professor of Psychology at the University of Minnesota.

Accomplishments

Suggestive of the breadth of his expertise and influence, Meehl served in faculty positions at the University of Minnesota in the departments of psychology, psychiatry, philosophy, neurology, and law. His corpus of published works has been praised for both its quantity and quality. Many of his almost 200 articles and books continue to rank amongst the most frequently cited publications. He has received countless honors and awards, including lifetime achievement awards from the American Psychological Association, American Psychological Foundation, and the American Association of Applied and Preventative Psychology, and served as the President of the American Psychological Association in 1962. An active clinician as well as researcher, he maintained his professional psychology license and was a Diplomate and Board Member of the American Board of Professional Psychology [9].

Contributions

Meehl's work was not just ahead of his time. Rather, in multiple areas of inquiry, he set standards for the profession that are still being strived for some 50 or more years later and thus remain at the cutting edge of the field today. For instance, in 1962 when environmental explanations for the etiology of schizophrenia were predominate, he took the stage at the annual American Psychological Association meeting and offered a presidential address positing that symptoms of schizophrenia result from an underlying neurological condition with a genetic basis [10]. In doing so, he predated current gene-environment paradigms by decades. In 1955, along with Lee Cronbach, he outlined a procedure for measuring psychological constructs that has been largely unmodified since its inception and remains a benchmark lesson for doctoral students in the field [3]. Similarly, his work in the areas of taxonomy, clinical versus statistical prediction, and significance testing are as relevant today as ever, if not more so given the expansion of applied psychology in recent decades [4, 5, 10].

His identification of "schizotaxia" or a schizoid taxon revolutionized the field of psychopathology. Puzzled by the great phenotypic diversity exhibited by patients diagnosed with schizophrenia, Meehl proposed that the seeming heterogeneity of symptoms was actually consistent with a taxonomic model and followed an identifiable and distinct pattern [8]. Demonstrating the existence of such a "taxon" is critical because it supports categorical rather than dimensional distinctions between various diagnoses and thereby sets the stage for positing specific causes, most often biological in nature. For instance, unearthing the schizoid taxon allowed Meehl to propose that schizophrenia had a basis in genetics and that the phenotype was multidetermined, being influenced by genes, nonshared environmental influences, etc. [1]. In doing this work, Meehl developed taxometric procedures that questioned the precision of current diagnostic classifications and offered alternatives to the existing body of statistical procedures used to identify symptom clusters. Taxometrics involve complex mathematical procedures and algorithmic tests and reveal that, in addition to being a psychologist and philosopher of science, Meehl was also a very talented mathematician. The procedures and associated consistency tests developed by Meehl are now widely applied in the study of psychopathology [2, 10].

Along with colleague Lee Cronbach, Meehl helped to set the standards by which we measure and validate measures of hypothetical constructs [3]. In psychology, the focus of study is most typically phenomena that cannot be directly measured or verified, such as intelligence, creativity, personality, and the like. Objective measures like those used in other branches of science (e.g., thermometers, scales, and rulers) do not exist. This hampers progress in the field and has led to questions about whether psychology is indeed a "hard" science. In response, Cronbach and Meehl outlined a systematic process for establishing "construct validity" or the extent to which an instrument actually measures what it claims to measure. Central to this process was the establishment of a "nomological network." That is, to establish that a given measure has construct validity, one would have to propose a theoretical framework for the construct behind the measure, an empirical basis for how it is to be measured, and specific links between the theoretical framework and any empirical findings. Though extraordinarily useful as a heuristic for guiding assessment, Meehl realized that ultimately the process of "evaluating" the extent to which a given measure exhibited construct validity was left to subjective analysis and statistical significance testing. As part of his broader work in metascience, Meehl described the many limitations of traditional null-hypothesis significance testing and offered alternative quantitative models for theory evaluation. For example, he described how various indexes, such as predictive

accuracy, novelty, and reducibility, could be developed and used to compare theories in a more objective, actuarial manner [4]. Questions about traditional significance testing continue to pose major challenges to the field and Meehl's contributions in this area have been credited with perhaps inspiring, and increasing receptivity to, recent developments such as effect size estimates, goodness-of-fit estimates, and investigation of structural models [1].

Not afraid of stirring controversy, Meehl also questioned the subjective nature of clinical decision making [7]. He reasoned that the majority of clinical decisions, such as prognosis and treatment selection, are based on predictions that are made by considering data from various sources, including interviews, tests, and observations. This consideration most often entails "clinical" combinations of the data that are informal, inferential, and subjective. In contrast, he described a "statistical" approach to data combination relying on more formal, mechanical, and algorithmic methods. Partly because of their consistent application of the data combination rules, Meehl argued that the statistical approaches would outperform the clinical approaches in making predictions and he provided supportive evidence in a review of the empirical literature. His conclusion that "heads" were outdone by "formulas" in the vast majority of cases still stands largely unchallenged and his book on the subject [7] has become a citation classic [5].

Mellaril Concentrate®

►Mellaril®

Mellaril®

Anisa Fornoff
Drake University, Ankeny, IA, USA

Synonyms

Mellaril concentrate®; Mellaril-S®; Thioridazine

Definition

A prescription medication FDA approved for the management of schizophrenia.

Description

This medication is a typical antipsychotic available in an oral tablet, oral solution, or oral suspension.

The recommended starting dose for adults and teenagers is 50–100 mg given one to three times a day. The recommended maximum daily dose is 800 mg. For children 6–12 years of age the recommended starting dose is 10–25 mg given two or three times a day. Dosages for children may be based on body weight and size.

This medication may be taken with or without food. Avoid drinking alcohol and taking antacids within 2 h of taking this medication. Inform your doctor if you have kidney disease, heart disease, history of seizure disorder, or other medical conditions. Mellaril® may cause QTc prolongation, a potentially serious heart problem.

Some side effects are listed here: twitching or muscle movements you cannot control, muscle spasms, increased blinking, sleepiness, blurred vision, dizziness, dry mouth, constipation, and dark urine. Tell your doctor immediately if you notice the following: fainting, loss of balance control, trembling of hands and fingers, or stiffness. This medication may cause lightheadedness when going from a lying or sitting position, so it is recommended to get up slowly. This medication may make you more sun sensitive. Your doctor

may monitor your cholesterol, weight, blood sugar level, heart, mental status, and potassium level.

This medication should be stored out of reach of children and pets and away from light, heat, and moisture.

Relevance to Childhood Development

Mellaril® is FDA approved for use in children older than 2 years of age. Children and adolescents will be monitored closely.

Women should let their doctor know if they are pregnant or planning to become pregnant. Talk with your doctor before breastfeeding.

Memorization

Stephanie A. Grote-Garcia[1], Douglas J. Loveless[2]
[1]University of the Incarnate Word College of Education, Texas A&M University-Corpus Christi, Corpus Christi, TX, USA
[2]Texas A&M University, Corpus Christi, TX, USA

Synonyms

Cognitive structure; Remembrance; Reminiscence; Retention

Definition

Memorization is a mental process that is used to deliberately store items in memory for later recall. Individuals may memorize items such as experiences, names, addresses, and grocery lists for later use.

Description

Memorization does not merely mean creating an accumulation of facts or vocabulary words to be carried in the mind. This stereotype is too simplistic. The knowledge possessed by a reader that facilitates comprehension of written language is a part of long-term memory. It is a remembrance of the sense of past experiences that constructs the foundation of new understandings of texts. Memories are linked in a vast hypertext held within the mind, organized into an intricate and internally consistent working model of the world.

Memorization creates summaries of experiences so that not only is each fact, word, or experience remembered, but they are also categorized within the mind and integrated into a coherent whole allowing new facts, words, and experiences to be ascertained. Chunking information into groups capitalizes on connecting prior knowledge to new knowledge, which enhances learning. Therefore, memorization is a constructive process justifying the summaries of past experiences.

Memorization is aided by discrepant events or emotional connection. Integrating and accessing emotional memory through music, art, and drama creates more links in the mental hypertext and increases the accessibility of information. Memorization must combine information with conceptualization and meaningful practice otherwise it is insufficient.

Principles and techniques used to assist in memorization include:

- Rote learning
- Mnemonic
- Mnemonic link system
- Peg system
- Major system
- Method loci
- Art of memory

Memory Strategies

Russell N. Carney
Missouri State University, Springfield, MO, USA

Synonyms

Cognitive strategies; Learning strategies; Memory techniques; Mnemonic devices

Definition

Memory strategies refer to any of a broad set of techniques that are designed to help one remember. Such strategies range from everyday, external aids (e.g., using a planner) to internal memory strategies (e.g., mnemonic devices) that facilitate storage and retrieval from long-term memory.

Description

External Memory Strategies

Memory strategies can be divided into two main categories: *external* and *internal*. External memory strategies tend to be everyday things we do that cue us to remember things [4]. McPherson [9] lists several common ones, including: using a calendar or blackberry, placing things in conspicuous places, jotting down reminder notes, making a shopping list, asking someone to help you remember, and setting a timer.

Internal Memory Strategies

Simple techniques: Internal memory strategies take place mentally. Perhaps the most familiar of these techniques is *rehearsal*. Repeating something over and over in working memory is one way to retain information and to facilitate its storage in long-term memory. While rote rehearsal is often discounted in favor of other memory techniques involving elaboration, rehearsal is none-the-less a natural way for us to store information in memory. Further, rehearsing something beyond initial acquisition (i.e., *overlearning*) helps to stamp in the information. In this vein, testing oneself (i.e., *retrieval practice*) seems to be an especially effective technique, with *expanding retrieval practice* being an even better approach [2]. Expanding retrieval practice means testing oneself at ever-increasing intervals.

Another common internal technique for, say, trying to recall someone's name, is going down the alphabet to see if a letter "strikes a chord." While this approach provides a degree of cuing, simply saying the letters verbatim may not be enough of a clue to recover the name from long-term memory storage.

Mnemonic devices: Mnemonic devices are specific, cognitive cuing strategies designed to aid memory. They change difficult material into more easily remembered material [11]. Bellezza [1] divided mnemonic devices into two general categories: *encoding mnemonics* and *organizational mnemonics*. Encoding mnemonics facilitate paired-associate learning, such as associating unfamiliar terms with their definitions, or associating names with faces. In this regard, popular encoding mnemonics are the *keyword method* and the *face-name mnemonic*, respectively. In particular, the keyword method has proven to be a versatile and effective technique in a variety of school-related memory tasks, including the learning of states and their capitals (e.g., [5]).

Organizational mnemonics tie together several bits of information in an ordered manner to facilitate serial learning. A simple example of an organizational mnemonic is the popular *first-letter mnemonic*. Students often learn the order of the colors in the spectrum by remembering ROY G. BIV (i.e., red, orange, yellow, etc.). Additional organizational mnemonics include the *pegword method* and the *method of loci*. These systematic techniques provide a set of visualizable "pegs" or "locations," respectively, wherein to store a list of ordered information by way of interactive images. Mental imagery serves as the "glue" in many mnemonic techniques to hold things together (e.g., [8]).

Relevance to Childhood Development

As Thorne [13] has observed, the "memory demands for school-age children are much greater than they are for adults." Thorne goes on to say that "an effective and efficient memory is critical for school success." Indeed, research has shown that more successful students tend to make use of learning and memory strategies. And, knowledge and use of such strategies is closely tied to whether parents and educators have encouraged strategy use. For this reason, Pressley and McCormick [12] propose that memory strategies be taught directly in schools.

A particular limitation of children in using imagery-based memory strategies is that, through the age of 8, children have difficulty in generating images linking two things together [10]. Additional difficulties have to do with *maintenance* and *transfer*. Difficulty in maintenance means that children may not continue to use a particular strategy, even after experiencing first-hand how useful it is. Transfer has to do with using a previously acquired

memory strategy in a situation somewhat different from the original one in which the strategy was applied. Children (and even college students) have difficulty in this regard. Despite these difficulties, encouraging the use of memory strategies in the classroom has much to recommend it (e.g., [5]).

A variety of memory improvement books are available, including Lorayne and Lucas' [6] classic, *The Memory Book*, Higbee's [3] *Your Memory: How It Works and How to Improve It*, and McPherson's [9] *The Memory Key: Unlock the Secrets to Remembering*. McPherson also has a helpful website on memory at www.memory-key.com/index.htm. In terms of special education applications, Mastropieri and Scruggs [7] have written a guide titled *Teaching Students Ways to Remember: Strategies for Learning Mnemonically*.

Mendelian Genetics

Daniel Patanella
New York City Department of Education, New York, NY, USA

Synonyms

Law of independent assortment; Law of segregation; Mendelian inheritance

Definition

Mendelian inheritance refers to the properties of inherited single traits, as described by the law of segregation and the law of independent assortment.

Description

Gregor Johann Mendel (1822–1884) was an Austrian monk who conducted botanical experiments in plant hybridization in the garden of his monastery. Although a contemporary of Charles Darwin (1809–1882), Mendel's [2] published work *Experiments in Plant Hybridization* (1865) failed to attract scientific notice until 1900, when it then became apparent that Mendel's genetic discoveries helped to explain the mechanisms of inheritance necessary for Darwin's Theory of Natural Selection.

Mendel experimented with seven easily identifiable traits of common flowering pea plants. His logic and methodology are elegant. First, he bred several consecutive generations of pea plants via self-fertilization to ensure that the observed traits were constant and the respective plants were pure strains. Then, he would cross-fertilize the plants and record the appearances of the offspring. This first generation of offspring was referred to as the first filial or F_1 generation. He would cross-fertilize examples of the F_1 generation and record the appearance of the new offspring once more. This second generation of offspring was referred to as the second filial or F_2 generation. Mendel would then breed several subsequent generations of pea plants using self-fertilization, repeating the process for all seven traits he studied. While other researchers had attempted the study of plant hybridization before, Mendel

was the first to quantify his results, thereby discovering a constant rate of segregation in the F_2 generation later known as the Mendelian ratio.

As an example, consider that Mendel cross-bred pea plants with purple and white flowers. In the F_1 generation, all the flowers appeared purple (and not pink as other researchers might have predicted). In the F_2 generation, three out of four of the plants had purple flowers, and one out of four had white flowers. The white flower trait appeared to vanish entirely in the F_1 generation, only to reappear in a predictable ratio in the F_2 generation. From this, Mendel inferred that the trait never truly vanished, but was present and not expressed in the F_1 generation. This inference was an important scientific step, because in Mendel's time chromosomes were not understood and DNA had not yet been discovered. Mendel made his breakthrough by studying the careful tabulation of his data, making logical inferences, and replicating his results.

Mendel discovered that genes possess alternate forms known as alleles. Some alleles will be displayed in an organism whenever they are present; these are referred to as "dominant." Some alleles will only be displayed in an organism when both copies of the gene are present; these are referred to as "recessive." Thus, Mendel made an important distinction between genotype (the genetic makeup of a living thing) and phenotype (the appearance of a living thing). Just because an organism displays a trait does not mean that it is pure; living things whose alleles match are called "homozygous" and living things with different alleles are called "heterozygous." According to the Mendelian ratio, in the F_2 generation three out of four offspring will display the dominant phenotype and is referred to as the law of segregation.

Furthermore, Mendel experimented with combining the seven different traits. He learned that the inheritance of each trait was independent of the inheritance of other traits. In other words, possessing a dominant genotype for one trait does not influence the probability of possessing a dominant genotype for a different trait. This is referred to as the law of independent assortment.

Not all traits can be understood within the framework of Mendelian inheritance. The traits Mendel studied were all single-factored, whereas most traits in most organisms are multi-factored and subject to the influence of multiple gene interactions. Furthermore, a variety of traits are sex-linked. In humans, this means that the trait occurs on the X version of the sex chromosome and will be displayed either if it is present on both members of the X chromosome pair (if the organism is female, possessing an XX pair) or if the organism is male (thereby possessing an XY chromosome pair by definition).

Relevance to Childhood Development

The study of Mendelian inheritance is important for students of childhood development because it provides the essential building blocks for understanding more complex patterns of inheritance. While most human traits cannot be reduced to a single gene, several childhood diseases (such as Tay-Sachs disease and cystic fibrosis) are recessive and inherited via Mendelian genetics.

Mental Age

Audrey McKinlay
University of Canterbury, Christchurch, Canterbury, New Zealand

Synonyms

Academic ability; Intellectual ability; IQ; Mental ability

Definition

Mental age, often abbreviated MA, is a measure of mental ability as determined by intelligence tests.

Description

Mental age (mental level) was developed as a means of measuring a child's mental ability using intelligence tests. The concept was devised by Alfred Binet and his colleague Theodore Simeon, who had been commission by the French government to investigate education for children with mental disability and specifically, to develop a method of distinguishing the normal child from the child with intellectual disability whom would not benefit from normal schooling [3].

The subsequent scales that were developed by Binet and Simeon used a variety of tests items that they selected as being suitable to assess a particular ability. The test performance of 300 normally functioning French children between 3 and 13 years was used to determine the age at which a child could be expected to pass a particular test item [4]. The test levels were determined by whether 80–90% of normal children of this age could pass the test items [4]. For example, items passed by the majority of 4 year olds were placed on a 4 year level, whereas those items passed by the majority of 5 year olds were placed on a 5 year old level. Using the different levels of test items that they had developed, a child's mental level could then be determined as the highest mental level achieved.

However, children more often had a scatter of scores. Therefore the concept of basal was often used, and was the highest level at which all tests were passed (basal level), with months of credit added for areas of where the child had passed at a higher age level [2]. The term mental age was substituted for mental level, as it was considered an easier concept [2].

The first major revision of the testing developed by Binet and Simeon was conducted by Lewis Terman [5] who translated the test into English, and developed the test items for American use, renaming it the Stanford – Binet. At this point the concept of an Intelligence Quotient (IQ) was developed [3]. An IQ could be generated by dividing the mental age of the child by the child's actual age and multiply the result by 100. The concept of IQ is now most commonly used to identify the level of intellectual functioning of a child [3].

Relevance to Childhood Development

The development of the concept of mental age and IQ has had a significant impact on educational methods used, and also on how many of the existing childhood psychiatric disorders are conceptualized. In terms of benefits, the evaluation of mental age and IQ provides an objective and standardized way to assess a child's overall intellectual ability. Further, it enables a child's strengths and weaknesses to be identified, and thereby providing a means to target appropriate intervention and or extension. The identification of a child's IQ or mental age provides a common language for professionals and is a core diagnostic feature of a many of psychiatric disorders that occur in childhood. That is, for example, diagnosis of attention deficit hyperactivity disorder requires that the child's behavior be more excessive than would be expected for their mental age. Moreover IQ is also used to determine whether a child's intellectual deficits are of sufficient severity to warrant a diagnosis of mental retardation [1]. However, there are also a number of disadvantages associated with the concept of mental age and IQ. Many tests contained in these batteries have been criticized as culturally insensitive [4]. This is an extremely important issue when one considers the impact that an IQ score can have on a child's educational opportunities. Further, as has been pointed out previously, intelligence testing provides a "snap shot" of an individuals functioning, which may be affected by other factors such as mood and motivation.

Mental Retardation

Sara E. Hoffenberg
Children's Healthcare of Atlanta, Atlanta, GA, USA

Synonyms

Cognitive impairment; Developmental disabilities; Intellectual disability; Mental deficiency

Definition

Mental retardation is defined as significantly subaverage ►intellectual ability and concurrent delays in ►adaptive functioning which present prior to the age of 18.

Description

The term "Mental Retardation" has come to be associated with a negative stigma; therefore, it is now commonly referred to as an "intellectual disability." Mental retardation (MR) or intellectual disability is characterized by both the American Association for Mental Disorders (AAMR) and the Diagnostic and Statistical Manual-Fourth Edition-Text Revision (DSM-IV-TR) as significantly subaverage intellectual ability and concurrent delays in adaptive functioning, which present prior to the age of 18 [1, 2, 3]. Adaptive functioning is generally defined as one's general independence level (i.e., independent self care, communication, socialization, coping, academic functioning, work functioning, etc.) given age expected developmental population norms, which should be based on the individual's sociocultural and community background [8, 9]. Standardized measures of adaptive behavior, such as the Vineland Adaptive Behavior Scales-Second Edition and Scales of Independent Behavior – Revised, are often used to assess adaptive behavior through caregiver report or interview. The DSM-IV discusses five categories or degrees of severity that describe the individual's level of intellectual impairment. The appropriate category for an individual is based upon his or her performance on one of several intelligence measures, such as the Wechsler Intelligence Scale for Children-Fourth Edition (WISC-IV) or Stanford Binet Intelligence Scales – Fifth Edition. Significantly subaverage intellectual functioning

is defined as an IQ score below 70, which corresponds to approximately two standard deviations below the population mean. These categories include: mild mental retardation (IQ score: 50–55 to 70), moderate mental retardation (IQ score: 35–40 to 50–55), severe mental retardation (IQ score: 20–25 to 35–40, profound mental retardation (IQ score: below 20–25), and severity unspecified (strong belief of intellectual impairment, although the person cannot be assessed through standard intelligence testing) [2]. The AAMR definition is similar; however, it places further emphasis on examining each individual's limitations and conducting a valid assessment that considers the individual's context (i.e., age, peers, cultural background, communication abilities, sensory skills, motor skills, and behavioral factors). It also places emphasis on examining the individual's strengths, level of needed support, and the importance of recognizing that with intervention/support the individual's overall functioning will improve [1].

Prevalence

The prevalence of MR is thought to range between 1 and 3% of the general population. Approximately 85% of those with MR fall within the mild range, 10% fall within the moderate range, 3–4% fall within the severe range, and 1–2% fall within the profound range. MR is more prevalent in males. The male to female ratio is approximately 1.5:1 [2]. There is no known difference in prevalence of MR due to genetic factors in the different socioeconomic statuses. However, MR due to environmental factors, such as malnutrition or premature birth is more common among individuals in the lower socioeconomic range [2].

Etiology

MR has been linked to many known etiologies while many continue to be unknown. It is linked to several genetic disorders, including Tay-Sachs Disease, Tuberous Sclerosis, Fragile X Syndrome, and Down's Syndrome. It is also associated with ▶pervasive developmental disorders, including, Autistic Disorder, Rett's Disorder, and Childhood Disintegrative Disorder [8, 9]. A combination of genetic and nutritional factors during the prenatal period or in early childhood is also linked to the development of MR [6]. Problems during the prenatal period include, but are not limited to, hypoxia, fetal malnutrition, maternal drug use, untreated maternal phenylketonuria, fetal stroke, chemical exposure, prematurity, low birth weight, viral infections, and trauma [4, 8]. Problems during early childhood include, but are not limited to, infection, toxic exposure, injury, and neglect/deprivation. The most common causes of MR are Down's Syndrome, Fetal Alcohol Syndrome, Fragile X Syndrome, and Velocariofacial syndrome [4, 8]. While there are numerous known etiologies of MR, no definitive etiology can be determined in approximately 30–40% of individuals with MR [2].

Associated Features

The behavior patterns and personality characteristics of those with MR are not consistently different from the behavior and personality of those with average cognitive ability. However, often times the behavior and personality characteristics of individual's with MR more closely match the characteristics of those with a younger chronological age [9]. For instance, those without functional communication may display aggressive behavior in an attempt to communicate, which is often seen in children who have not yet developed language [2]. The specific behavioral and cognitive patterns seen in individuals with MR often correlate more highly with the specific etiology, rather than the general diagnosis of MR [5]. However, various life experiences that decrease one's motivation and self esteem may be more likely for those with MR, which in turn may lead to a number of negative outcomes affecting many areas of one's personality, behavioral style, and subsequent life experiences [9]. The prevalence of comorbid disorder is significantly higher than within the general population. This may be due in part to a common etiology, although this varies case by case. The most common comorbid disorders are Attention-Deficit/Hyperactivity Disorder, Mood Disorders, Pervasive Developmental Disorders, Stereotypic Movement Disorder, and Mental Disorders Due to a General Medical Condition [2].

Relevance to Childhood Development

Children with MR typically show global delays in most areas of development; including communication, gross and fine motor, self-care, socialization, academic, and coping skills. The level of delay typically correlates with the severity of the child's cognitive impairment and subsequent age at diagnosis. An appropriate assessment of cognitive functioning, needs assessment for treatment, and subsequent intervention are vital to assist the child in meeting his or her optimum potential. The Individuals with Disabilities Act (IDEA, 1997) continues to improve the educational opportunities for children with MR and other disabilities. It requires that each child receive an appropriate education/curriculum with support in the least restrictive environment.

During early childhood, prior to age 3, each state is required to provide intervention. This begins by developing an individualized family service plan (IFSP), which outlines specific goals and interventions for a given child [7].

Once the child reaches the age of 3, the public school system staff and parents will develop an individualized education plan (IEP), which outlines goals (i.e., academic, social, vocational, etc.) and interventions to assist the child in reaching those goals [7]. The type of environment depends on the needs of the child. For many children with mild MR this environment may be one of full inclusion or partial inclusion with their typical peers, while children with more significant impairments may participate in a self-contained classroom. It is always necessary to consider the benefits and costs of each child's educational plan for their learning [8].

Mercury

Madeline Gross
Fordham University, Mount Vernon, NY, USA

Synonyms

Hydrargyrum; Quicksilver

Definition

Mercury is a chemical element with the symbol Hg, named for the Latin *Hydrargyrum*, meaning watery or liquid silver. Mercury, with an atomic number 80, is a heavy, d-block metal, and is the only metal liquid at standard conditions for temperature and pressure. Though used for the manufacture of industrial chemicals, electrical and electronic applications, and thermometers, mercury is now recognized as a neurotoxin and has been slowly fazed out of use by changes to health and safety regulations noticeable hazard to human health and the environment.

Description

Mercury has an atomic number of 80, indicating the presence of 80 protons and 80 electrons in a neutral atom, and an atomic weight of 200.59 g/mol. Mercury is located in period number 6, group number 12, and is a d-block transitional metal with an Electron configuration [Xe] 4f14 5d10 6s2 and two valence electrons. Mercury is a liquid at room temperature, with a melting point of 234.32 K (−38.83°C or −37.89°F) and a boiling point of 629.88 K (356.73°C or 674.11°F). The element has a density of 13.534 g/cm^3, a Heat of fusion of 2.29 kJ/mol, a Heat of vaporization of 59.11 kJ/mol, and a Specific heat capacity (at 25°C) of 27.983 J/mol·K.

There are seven stable isotopes of mercury with Hg-202 being the most abundant (29.86%). The longest-lived radioisotopes are ^{194}Hg with a half-life of 444 years, and ^{203}Hg with a half-life of 46.612 days. Most of the remaining radioisotopes have half-lives that are less than a day. Mercury dissolves to form amalgams (compounds containing mercury) with gold, zinc and many metals. When heated, mercury also reacts with oxygen in air to form mercury oxide, which then can be decomposed by

further heating to higher temperatures, and reacts with atmospheric hydrogen sulfide. Mercury does not react with most acids, such as dilute sulfuric acid, though it does react with strong oxidizing acids such as concentrated sulfuric acid and nitric acid. Mercury reacts with solid sulfur flakes, which may be used in mercury spill kits to absorb mercury vapors (spill kits also use activated charcoal and powdered zinc).

Prevalence

Mercury is an extremely rare element in the Earth's crust, having an average crustal abundance by mass of only 0.08 ppm. Mercury ores, however, can be extraordinarily concentrated considering the element's abundance in ordinary rock, with the richest mercury ores contain up to 2.5% mercury by mass, and even the leanest concentrated deposits are at least 0.1% mercury (12,000 times average crustal abundance). Natural sources such as volcanoes are responsible for approximately half of atmospheric mercury emissions. The human-generated half comes primarily from stationary combustion due to coal-fired power plants (65%). 11% of the mercury emissions are due to gold production, and 3% is a result of waste-disposal and incineration.

Uses

Mercury is most well known for its use in thermometers, though it is also used in other types of scientific apparatuses. Mercury-vapor lamps have been used as a source of ultraviolet light and for sterilizing water. Mercury combines with all the common metals except iron and platinum to form alloys that are called amalgams, often used in dentistry. This element is also used commercially for the creation of disinfectants and germicides, the pigment vermillion, and electrodes and electrical systems.

Because of the extremely toxic effects of mercury, the use of the metal and its compounds has been reduced in several industries, including pharmaceuticals, dentistry, and agriculture.

Toxicity

Mercury is a toxic and hazardous substance that can be inhaled and absorbed through the skin and mucous membranes, or through direct ingestion. Short-term, limited contact with mercury can cause acute symptoms such as bleeding gums, vomiting, and stomach pain. Mercury poisoning, due to prolonged and severe mercury exposure, is potentially fatal and can cause irreversible brain, liver, and kidney damage. Research has demonstrated that unsafe levels of mercury can cause neurological damage, particularly in young children and fetuses. Repeated exposure to small amounts mercury can also result in later mercury poisoning due to the ability for the element to accumulate in the cells of the body.

Ingestion can occur through contamination of the food sources. Concern over the potential health hazards of mercury levels in the environment led the United States Food and Drug Administration (FDA) and the Environmental Protection Agency (EPA) to issue consumption guidelines in March 2004, indicating notice that pregnant women, children, nursing mothers, and women who may become pregnant should not eat certain foods known to contain some levels of mercury, including shark, swordfish, king mackerel, or tilefish.

Relevance to Childhood Development

Studies have demonstrated that exposure to mercury during fetal development can have serious effects on brain and body development. In a study of a widespread mercury exposure in Minamata, Japan, pregnant women who consumed the contaminated fish manifested mild or no symptoms but gave birth to infants with severe developmental disabilities, including cerebral palsy, mental retardation, and seizures.

Mercury exposure may be more commonplace than assumed. Neonates and infants may be particularly sensitive to exposure. Toddlers may come in contact with or ingest mercury from spills (such as from thermometer breakage) that collect on the floor after inappropriate cleaning. The Food and Drug Administration has also indicated that on the basis of current fish consumption patterns among pregnant women of childbearing age in the United States, over 60,000 children are born each year at risk for adverse neurodevelopmental effects due to mercury exposure.

While there is negligible evidence that the low-level mercury in some vaccinations can lead to later brain damage, some members of the global community are forgoing having their children immunized fearing exposure to mercury from the vaccines. Such practices occurring on a large enough scale, however, could seriously compromise disease control, leading to a greater risk to child health and development than mercury might present.

Messenger RNA

Messenger RNA or ribonucleic acid is a molecule of RNA encoding a chemical blueprint for protein products. Messenger RNA is transcribed from a DNA template and carries coding information to the sites of protein synthesis known as ribosomes. In messenger RNA as in DNA, genetic information is encoded in the sequence of nucleotides arranged into codons consisting of three bases each. Each codon encodes for a specific amino acid. This process also requires transfer RNA which mediates recognition of the codon, provides the corresponding amino acid and ribosomal DNA which is the central component of the ribosomes protein manufacturing machinery.

Meta-Analysis

Synonyms

Meta-analytic review

Definition

In statistics, a meta-analysis or meta-analytic review synthesizes and describes the results from a large number of studies on a common topic. It provides a summary of the existing research literature in a non-biased manner by using a quantitative approach.

Description

Meta-analysis was first employed by the field of psychology to assist in determining the effectiveness of interventions, but has been widely applied in the fields of medicine and education.

To conduct a meta-analysis the investigator must:

- define the range of years from which to draw studies, typically a 10–20 year time period
- define the problem to investigate
- define the participants, (i.e., age, diagnoses, geographical region)
- specify the treatment or intervention to evaluate
- collect all the published articles that meet the criteria through rigorous research
- conduct a statistical analysis

The statistical analysis compares the pre-treatment or baseline data to the post-treatment data. This requires the use of z-score transformations of the data which set the baseline data points to zero. This procedure allows for comparisons between baseline and post-treatment data from various dependent measures. The transformations also allow the researcher to compare treatments by effect size, a measure of the strength or magnitude of the independent variable on the dependent variable. More simply, an effect size assigns a numerical value that describes how effective a treatment is.

Meta-analytic results are typically reported in effect sizes. There are several statistical methods used to report effect sizes. The most common is *Cohen's d*, which compares the baseline phase and treatment phase means. It is calculated by subtracting the mean of the treatment phase from the mean of baseline phase and dividing this value by the standard deviation at baseline. Values close to zero suggest that the intervention or independent variable had little effect on the dependent variable, whereas values closer to 1.0 describe very large changes possibly attributable to the independent variable or intervention. Other statistical methods for calculating effect sizes include Percentage of Non-Overlapping Data Points (PND), Busk and Serlin's No Assumptions Method, and Hierarchical Linear Modeling. Each approach has strengths and weaknesses; some are known to be more strict and thus produce conservative estimates while others may overestimate effects. This is a common criticism of analyzing effect sizes.

Another problem with meta-analyses is the "file drawer problem". This refers to the fact that most

published research papers only report positive intervention findings, leaving studies with null findings unpublished. Therefore, when one goes to conduct a meta-analysis the results may reflect only positive intervention results, failing to account for an unknown number of studies suggesting less favorable results. Nevertheless, meta-analysis is a powerful tool for summarizing results across studies.

Meta-Analytic Review

►Meta-Analysis

Metacognition

Synonyms

Critical thinking; Metacognitive awareness; Metacognitive strategies

Definition

Simply defined, metacognition is thinking about one's own thinking. More technically, metacognition involves the ability to evaluate one's own comprehension of subject matter and use that evaluation to predict how well one might perform a task. It refers to our understanding and control over our own thinking processes including awareness, control, and regulation.

Description

Considered a subcomponent of metacognition, metamemory involves reflecting on our own memory processes with the goal of improving our memory. Metacognitive abilities appear to increase with age through early adulthood and are associated with improvements in encoding and retrieving memories and processing speed. The allocation of attention and ability to hold and manipulate information in one's working memory are also heavily dependent on metacognitive thinking strategies. For example, these strategies include mnemonic devices, rehearsal, and response inhibition. In the domain of cognitive neuroscience, metacognitive monitoring and control has been viewed as a function of the prefrontal cortex, which receives and monitors sensory signals from other cortical regions and implements control.

Metadate CD (Methylphenidate)

Anna L. Lopez
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Metadate CD®; Metadate ER®; Methylphenidate

Definition

Metadate® is a stimulant medication FDA approved for children 6 and older for the treatment of ADHD.

Description

This medication is a psychostimulant. Similar to most other stimulant medications, the active ingredient in Metadate® is methylphenidate. The medication is available in two forms of extended release capsules. Metadate CD® provides 30% of the methylphenidate dose by immediate release beads and 70% by extended-release beads and is reported to have an 8 h duration of action. Metadate CD® (available in 10, 20, and 30 mg) capsules can be opened and the medication spheres can be sprinkled into applesauce. Metadate® is also available in a slowly absorbed tablet (Metadate ER®) with methylphenidate incorporated in a wax matrix tablet, allowing gradual diffusion reported to have a 6–8 h duration of action. Metadate ER® (available in 10 and 20 mg) is usually administered twice daily and must be taken whole.

There is no universally agreed-upon method for dosing with stimulants; doses are individualized according to the child's clinical response. Some clinicians utilize the

child's weight as a guideline and others begin at the approved dose range until a clinical response occurs. The approved dosage starts at 20 mg and increases by 10–20 mg/day at weekly intervals as needed. The maximum daily dose of Metadate® is 60 mg.

Possible side effects include insomnia, appetite loss, weight loss, rebound hyperactivity, headache, tachycardia, precipitation or exacerbation of tic disorders, and possibly growth delay.

Relevance to Childhood Development

Methylphenidate, the active ingredient in Metadate®, is the most commonly used stimulant prescribed for children with ADHD. Beneficial effects of psychostimulants may include reduced hyperarousal, reduced motor restlessness, enhanced concentration, and less aggressive and antisocial behavior. Metadate® is not FDA approved for children under the age of 6.

Microcephaly

Brady I. Phelps
South Dakota State University, Brookings, SD, USA

Definition

Microcephaly is a cephalic disorder, or a disorder resulting from damage or abnormal development of the developing nervous system [6]; it is a clinically diagnostic term assigned to a head circumference significantly smaller then what is considered normal or average for a given individual's sex and age [11]. There is some disagreement as to the defining features of a diagnosis of microcephaly. Abuelo [1] stated most researchers consider microcephaly to be present when person's head circumference is two

standard deviations (−2 SD) below normal for a given age and sex. Others argue that a head circumference of three standard deviations (−3 SD) below the age and sex appropriate norm is the cut-off point for defining microcephaly [3, 10, 11]. The disagreement about diagnostic criteria also leads to differences in the estimates of its incidence. If the criterion of −2 SD is adopted, then roughly 2% of the population has microcephaly; adhering to the −3 SD criteria means that only about 0.1% of the population display microcephaly [1].

Deficits of Brain Development

Individuals born with this cephalic disorder display a significantly smaller ►brain; head circumference is a useful but indirect measure of the size of the brain [3]. The brain that is present is missing the ►cerebral cortex (the neocortex) of the cerebral hemispheres, the greatest share of the mass of the cerebral hemispheres [2]. Microcephaly can be separated into primary microcephaly in which the brain fails to reach expected correct size in prenatal development and secondary microcephaly in which the brain does attain an expected normal size at birth but fails to subsequently undergo normal postnatal brain development and growth [10]. Primary microcephaly is thought to be due to insufficient cellular division to produce the appropriate number of brain neurons during prenatal neurogenesis and secondary microcephaly is the result of a significantly reduced growth and branching of neuronal fibers, primarily the dendrites and a reduction in the number of synaptic connections amongst the neurons [10]. Hence, primary microcephaly is considered to be present at birth or ►congenital and secondary microcephaly has a later onset [1]. Some researchers have proposed that the descriptive term "primary" should be used to imply a genetic causation while the term "secondary" should be reserved for cases where the etiology is environmental [7]. This distinction, however, cannot always be maintained so others have concluded that these terms should not be used and instead the microcephaly be classified in terms of its onset (present at birth or postnatal) and its presumed etiology (genetic or environmental [1]. There are multiple possible genetic conditions as well as environmental variables that can lead to microcephaly [1, 10].

The clinical significance of the reduced brain size is that microcephaly is highly correlated with mental retardation [3], however individuals with a head circumference of −3 SD and normal intelligence have been occasionally reported [11] but individuals with a head circumference of −4 SD (or less) and normal intellectual ability are exceedingly rare [9, 11].

A website maintained by the National Institute of Neurological Disorders and Stroke (the NINDS) describes anencephaly in the following:

Etiology

Microcephaly is a medical condition in which the circumference of the head is smaller than normal because the brain has not developed properly or has stopped growing. Microcephaly can be present at birth or it may develop in the first few years of life. It is most often caused by genetic abnormalities that interfere with the growth of the cerebral cortex during the early months of fetal development. It is associated with Down's syndrome, chromosomal syndromes, and neurometabolic syndromes. Babies may also be born with microcephaly if, during pregnancy, their mother abused drugs or alcohol, became infected with cytomegalovirus, rubella (German measles), or varicella (chicken pox) virus, was exposed to certain toxic chemicals, or had untreated phenylketonuria (PKU). Babies born with microcephaly will have a smaller than normal head that will fail to grow as they progress through infancy. Depending on the severity of the accompanying syndrome, children with microcephaly may have mental retardation, delayed motor functions and speech, facial distortions, dwarfism or short stature, hyperactivity, seizures, difficulties with coordination and balance, and other brain or neurological abnormalities. Some children with microcephaly will have normal intelligence and a head that will grow bigger, but they will track below the normal growth curves for head circumference [5].

A website maintained by the Centers for Disease Control provide standardized growth curves of head circumference for infants from birth up to age 3 at http://www.cdc.gov/growthcharts. As stated above, the clinical significance of microcephaly is that the reduced head circumference is likely accompanied by mental retardation, with more severe retardation being the product of more significant reduction in brain size [6]; there are however rare cases of individuals with greatly reduced brain size not only being spared retardation but having normal intelligence [9]. While no treatment can restore brain size [5] the symptoms of mental retardation, hyperactivity and other behavior problems can be remediated with applied behavior analytic interventions [4, 8].

Midbrain

Chad A. Noggle
SIU School of Medicine, Springfield, IL, USA

Synonyms

Brain stem

Definition

The Midbrain is one portion of the brainstem that contains the Tectum and Tegmentum, which together coordinate visual and auditory information to assist in the regulation of spontaneous movement.

Description

The Midbrain represents one of three divisions of the brain, in addition to the Hindbrain and Forebrain. Anatomically, it lies just above the brainstem and just below the Diencephalon, which contains the Hypothalamus and Thalamus [6]. From a functional standpoint, the midbrain has been linked to spontaneous movement in response to visual and auditory stimuli as well as aspects of other automatic and voluntary movements ranging from grooming to behaviors such as standing, walking, turning, jumping, climbing [4].

The Midbrain is made up of two structures called the Tectum and Tegmentum [6]. The tectum is also made up of two structures known as the Inferior and Superior Colliculi. Whereas the Inferior Colliculi coordinates aspects of hearing, the Superior Colliculi is more prominently involved in the coordination of vision [4]. The two colliculi also influence reflexive actions. Specifically, the Inferior Colliculi corresponds with auditory reflexes such as orienting oneself to a loud noise, whereas the Superior Colliculi corresponds with visual reflexes such as blinking [2].

The Tegmentum is also made up of two structures called the Substantia Nigra and Red nucleus, which are both crucial motor nuclei [2]. While the Substantia Nigra is part of the Tegmentum, it is often viewed as part of the Basal Ganglia due to its' close ties with the functioning of this region. Please see Basal Ganglia for more in-depth description. Specifically, the Substantia Nigra is crucial to motor activity as it represents a site of origin of the vast majority of Dopamine-containing neurons within the system which help initiate movement [1]. As a result, depletion of the Substantia Nigra leads to a corresponding deficit in Dopamine which, in turn, leads to a lack of excitatory action and thus a lack of motor initiation. This is best exemplified in Parkinson's disease. In this disease, the Substantia Nigra deteriorates. As this occurs, there is a lack of movement initiation because of low Dopamine levels. In which degradation of the Substantia Nigra leads to a paucity of movement due to diminished excitation and thus greater inhibition, in turn corresponding with the diseases bradykinetic (slowed motor movement) manifestations.

Developmentally, the midbrain begins to grow around the 27th week of the fetal development. As this area begins to activate, the fetus will demonstrate reflexive responsiveness to vibration and acoustics. While the process begins at the 27th week, the colliculi continue to develop up until the 36th week. This allows the infant to more easily make auditory discriminations and react to sound. This has been demonstrated in infants' heart rates differing in

response to their mother's voice over other voices (i.e., auditory discrimination) as well as in reflexive head turning to sound heard in the womb [5]. While these reflexes remain throughout childhood, in some instances they weaken as purposeful movement predominates, although some, such as reflexive blinking, remain a strong reflex throughout the lifespan.

Mild Mental Retardation

Sara E. Hoffenberg
Children's Healthcare of Atlanta, Atlanta, GA, USA

Synonyms

Cognitive impairment; Developmental disabilities; Intellectual disability; Mental deficiency

Definition

Mild mental retardation is defined as significantly subaverage ►intellectual ability, which ranges between 50–55 and 70, and concurrent delays in ►adaptive functioning that present prior to the age of 18.

Description

According to the *Diagnostic and Statistical Manual- fourth edition-text revision* [2], mild mental retardation (MR) is characterized by individuals with cognitive impairments that correspond to an IQ score between 50–55 and 70 and deficits in adaptive functioning that present before the age of 18. Mild MR is the most common type of MR; approximately 3% of the general population has mild MR [5]. Approximately 85% of individuals with MR fall within this range.

Relevance to childhood development

Children with mild MR often are not diagnosed until later childhood, as they typically develop minimal impairments in communication, social skills, and motor skills during early childhood [1, 2, 6]. However, they may have mild developmental delays in the areas of language development, motor development, self-care skills, early academic skills, social skills, and coping skills during early childhood [1, 3, 4]. Children with mild MR often are able to participate in an inclusion classroom with their typical peers [6]. By late adolescence most teens with mild MR are able to acquire academic skills up to a sixth grade level; however, they are usually not able to acquire high school level material and need special education which focuses on vocational training [2, 6].

During adulthood, individuals with mild MR are often capable of living independently or in supervised settings. With appropriate vocational training, individuals with mild MR typically only need intermittent to limited support in the employment setting. They may need supervision, guidance, and assistance particularly during times of stress [2]. Employment opportunities have significantly increased for individuals with mild MR during the past several decades due to increased awareness within the general community and federal policies, such as the Americans with Disabilities Act (ADA), which promotes employment for those with disabilities. [5].

Milgram, Stanley

Daniel Patanella
New York City Department of Education, New York, NY, USA

Life Dates

1933–1984

Educational Information

Milgram attended Queens College as an undergraduate and earned his Ph.D. at Harvard.

Accomplishments

Milgram was a professor at Yale, Harvard, and the City University of New York, where he ultimately earned his tenure and spent the bulk of his academic career. Milgram worked within the conceptual social psychology framework of his mentor Solomon Asch (1907–1996), and researched topics such as conformity, factors that influence obedience and disobedience, and the unspoken norms that define city dwelling. Situationism was his primary theoretical influence.

It was at Yale in the early 1960s that Milgram conducted his most famous research, which would later be summarized in his book *Obedience to Authority: An Experimental View* (1974) [11]. Milgram designed an ingenious experiment in which naïve adult male participants recruited from the general community, and each tested individually, believed they were delivering painful and sometimes lethal electrical shocks to a fellow research participant in a memory study. In actuality, the perceived victim in the study was an actor (or confederate) paid by the researcher to feign the effects of electrical shock. As part of the script as reproduced in its entirety in *Obedience to Authority*, the actor informed the research participant near the beginning of the study that he had been diagnosed with a heart condition. All the coercion in the study came from adherence to role playing and norms, yet a surprising number of participants demonstrated behaviors that could have resulted in injury or death had the electric shocks been genuine. In the initial and best known version of this experiment, a lab assistant (yet another of Milgram's confederates) stayed in the same room as the research participant and politely yet firmly reiterated that the experiment must continue; the perceived victim could be heard but not seen by the participant and there was only voice contact between them during the experiment. In this version of the study, 62.5% of Milgram's 40 participants believed they were administering a 450-volt shock to the victim, who by this point had stopped responding and was presumably unconscious [8]. These initial findings were replicated with many variations, including explorations on the effect of having the perceived victim in closer proximity to the research participant and the introduction of dissenting lab assistants. Milgram also documented his findings, which at the time seemed unbelievable to many, in a film called *Obedience* released in 1965 [10].

It is important to note that Milgram's research techniques and theoretical leanings were well within the bounds of contemporary social psychology. The use of deception within a research study was practiced notably by both Asch and Sherif [2, 15] within pseudo-psychophysical context requiring participants to estimate the lengths of lines or the distance a point of light moved in the darkness of a psychology lab. Confederates were used in those studies to deceive the research participant into voicing observations that conformed to a perceived group. Kurt Lewin (1980–1947), one of the earliest social psychologists, helped to pioneer the experimental manipulation of the social situation to elicit differing prosocial and antisocial behaviors; Lewin, Lippit, and White's study on leadership styles in children's clubs (1939) demonstrated the lack of initiative and other negative behaviors resulting from authoritarian-style social structure [7]. Milgram differed from all of these in that the entire social structure of his initial experiment consisted of the participant and the confederates impersonating the experimenter and the learner. Milgram demonstrated participants' compliance to requests from an authority figure (and not an organization or a perceived social group) to do harm to another human being.

Milgram's other work was considerably less controversial by comparison and is not cited as frequently within the literature. Nevertheless, this diverse assortment of city-based studies shares with the obedience research a commitment to the exploration of situationist variables and their relation to rule-based behavior. Among the areas Milgram explored were the formations of crowds of observers and the etiquette of cutting into waiting lines in public places [9, 12]. Milgram also published research on the "Small World" problem based on communication and social networking theory, in which persons were asked to indirectly forward a package to a stranger in a different city by mailing the package to someone they thought

might know the stranger [6]. While the research is inconclusive due to the large number of unsuccessful completions, in successful completions, Milgram found that the average length of a chain consisted of five to six people and in this sense Milgram's results anticipated the "six degrees of separation" theory that is popularly known on the Internet today.

Contributions

While not a prolific publisher, Milgram's body of research on obedience to authority is exceptionally important not only within psychology, but for society in general. Milgram's core research on obedience is almost universally cited within introductory psychology textbooks, making it one of the best-known research studies of all time. Milgram's research, while disquieting, also illuminated issues of conformity, depersonalization, authoritarianism, and willingness to engage in destructive behavior as a function of the situation. Milgram himself publicly suggested the obedience studies helped explain institutional atrocities of the twentieth century, especially the extermination programs of Nazi Germany.

Although Milgram almost certainly did not intend it, the obedience studies also drew necessary attention to research ethics of psychologists. Although no participants were physically harmed, and Milgram maintained that none experienced psychological trauma, the psychological research community at large reassessed the appropriateness of deception as a methodological tool and the importance of written informed consent and debriefing. This began as early as 1964, when developmental psychologist Diana Baumrind (born 1927) published her critique of Milgram's initial obedience study [3]. Rather than focus on Milgram's reassurance that no harm had been done, Baumrind concentrated on the potential harm that might have occurred; her concerns are echoed in contemporary guidelines for Institutional Review Boards who must consider and heavily weigh the potential for harm and protection of human subjects in research studies in deciding if the research should be approved or denied (*Belmont report*, 1978). The American Psychological Association's ethics code (2002) is another post-*Obedience* document that not only shares the *Belmont Report*'s position on the prevention of possible harm but also strongly discourages the use of any experimental deception in modern research [1].

Millon Adolescent Clinical Inventory

Jessica R. Gurley
Argosy University, Arlington, VA, USA

Synonyms

Millon adolescent personality inventory; Personality testing

Definition

The Millon Adolescent Clinical Inventory (MACI) is a personality inventory for adolescents between the ages of 13 and 19.

Description

The MACI is a 160 question self report personality inventory (self-report personality test) that assess personality styles based on Millon's theory of personality styles. It was designed to supplement the Millon Adolescent Personality Inventory (MAPI). The MACI was initially published in 1993 and is appropriate for adolescents between the ages of 13 and 19. The test items were written at a sixth grade reading level and the instrument can be completed in 25–30 minutes [1]. The MACI was specifically designed for use with adolescents in clinical settings only and should not be used with nonclinical adolescents [3, 4, 5].

The MACI was developed to correlate with diagnostic criteria in the DSM-IV. It is available in both English and Spanish [3, 4].

Scales

The MACI has a variety of scales, including three modifying indices, 12 Personality Patterns Scales, eight Expressed Concern Scales, and seven Clinical Syndromes scales. In addition to these 30 indices and scales, the MACI contains two validity questions designed to assess the adolescent's attention to the test items. The three modifying indices – Disclosure, Desirability, and Debasement – were designed to assess the adolescent's attitude towards the test [3]. The 12 Personality Patterns Scales – Introversive, Inhibited, Doleful, Submissive, Dramatizing, Egotistic, Unruly, Forceful, Conforming, Oppositional, Self-Demeaning, and Borderline Tendency – were based on Millon's theory of personality structure [2–4]. The eight Expressed Concerns scales – Identity Diffusion, Self-Devaluation, Body Disapproval, Sexual Discomfort, Peer Insecurity, Social Insensitivity, Family Discord, and Childhood Abuse – were meant to focus on attitudes and feelings that are common among adolescents involved in mental health treatment. The remaining seven indices – Eating Dysfunctions, Substance-Abuse Proneness, Delinquent Predisposition, Impulsive Propensity, Anxious Feelings, Depressive Affect, and Suicidal Tendency – form the Clinical Syndromes scales. The Clinical Syndromes scales each assess a different specific clinical syndrome, such as anxiety (Anxious Feelings) [3, 4].

In addition to these scales, the MACI software now provides Grossman Facet Scales for each of the 12 Personality Patterns Scale. Each Personality Pattern Scale has three Grossman Facet Scale intended to help to identify specific personality processes. For example, the three Grossman Facet Scales for Borderline Tendency scale are Temperamentally Labile, Cognitively Capricious, and Uncertain Self Image. Each of these is an individual personality characteristic associated with Borderline Tendencies [2].

Scoring

The MACI can be scored by hand, by computer using the Q local software, by mailing the forms in, or by scanning. The manual advises against hand scoring; however, describing the procedure as "complex." The MACI does not use *t* scores, like the MMPI-A. Instead, the MACI relies on base rates that are adjusted based on how the adolescent responds to the items on the test. The base rate adjustments are described in the manual and are a complex series of calculations [3, 4].

Psychometric Properties

The MACI was standardized on 1,017 individuals between the ages of 13 and 19. The standardization sample was over 50% male. The base rates were developed on 579 adolescents. Additionally, 333 adolescents participated in cross validation studies with the Beck Depression Inventory, Beck Hopelessness Scale, the Beck Anxiety Inventory, the Eating Disorder Inventory-3, and the Problem Oriented Screening Instrument for Teenagers [3, 8].

The internal consistency of the various scales is good, ranging from 0.73 (Expressed Concerns – Sexual Discomfort) to 0.91 (Expressed Concerns – Self Devaluation). Test-retest reliability was based on 47 protocols and ranged from 0.57 (peer insecurity) to 0.92 (borderline tendencies) [3, 8].

Relevance to Childhood Development

The MACI is a personality instrument that can be used with adolescents involved in mental health settings to help guide treatment [5–8].

Millon Adolescent Personality Inventory

Jessica R. Gurley
Argosy University, Arlington, VA, USA

Synonyms

Millon adolescent clinical inventory; Personality testing

Definition

The Millon Adolescent Personality Inventory (MAPI) is a personality inventory for adolescents between the ages of 13 and 18.

Description

The MAPI is a 150 question self-report personality inventory that assesses personality styles based on Millon's theory of personality types. It was initially published in 1982, designed to correlate with DSM-III-R diagnostic criteria, and is appropriate for adolescents between the ages of 13 and 18. The test items were written at a 6th grade reading level and a typical adolescent can complete the instrument in less than 30 minutes. Unlike the other Millon personality test designed for adolescents, the Millon Adolescent Clinical Inventory (MACI), the MAPI was designed for use with both "normal" adolescents and adolescents involved in clinical settings [2, 4–6].

The MAPI is an update to the Millon Adolescent Inventory (MAI). It has two forms: the Clinical Form (MAPI-C) and the Guidance Form (MAPI-G). The MAPI-C was developed in order to serve as an aid to mental health professionals who work with adolescents in a clinical setting. The MAPI-G was developed to help school professionals identify students who may benefit from additional mental health services [4].

Scales

The 150 true/false items on the MAPI yield 20 different scales and two validity indices. The validity indices, Reliability and Validity, each contain three items. The Validity index assesses for random responding while the Reliability index assesses the adolescent's honesty in responding to the items. In addition to these two indices, the MAPI has a mechanism similar to the K correction on the MMPI-2 and the MMPI-A. This method of response bias incorporates the response bias (e.g. presenting self in an overly positive manner) directly into the 20 scales of the MAPI [1].

The 20 scales are subdivided into eight Personality Styles scales, eight Expressed Concerns scales, and four Behavioral Correlates scales. The Personality Styles scales assess eight different personality characteristics based on Millon's schema of personality: Introversive, Inhibited, Cooperative, Sociable, Confident, Forceful, Respectful, and Sensitive. The Expressed Concern scales assesses eight areas that adolescents typically have some level of personal concern about, including Self-Concept, Personal Esteem, Body Comfort, Sexual Acceptance, Peer Security, Social Tolerance, Family Rapport, and Academic Confidence. Finally, the Behavioral Correlates scales evaluate that adolescent's actual behavior in four areas: Impulse Control, Social Conformity, Scholastic Achievement, and Attendance Consistency [1, 4, 6].

Scoring

The MAPI cannot be hand-scored. Instead, users can choose between three different scoring methods: Mail In, Computer Scoring, and Scan Scoring. Each method of scoring provides a computer printout that includes the raw scores, the base rates, and an interpretation for each of the 20 scales. The response bias (e.g., presenting self in an overly positive manner) is incorporated into the base rates; however, the computer print out does not include what portion of the base rate is due to the response bias correction [1, 4].

Psychometric Properties

The MAPI was standardized on 2,157 normal adolescents (1,071 males and 1,086 females), representative of various socioeconomic statuses. It is not clear in the manual whether the normative sample was representative of race/ethnicity. The clinical sample consisted of 430 additional adolescents who were receiving either outpatient or inpatient mental health treatment [4].

The internal consistency of the items on the MAPI is adequate, ranging from 0.45 to 0.84. The manual reports correlations between the MAPI and other personality measures, including the California Personality Inventory [4]. Studies examining the relationship between the MAPI and the MMPI have shown low rates of diagnostic agreement [3].

Relevance to Childhood Development

The MAPI can be used by mental health professionals for use in treatment planning with adolescents. It can help to identify areas of concern for the adolescent and areas that could be addressed in therapy.

Mindblindness

Lee A. Wilkinson
Nova Southeastern University, Fort Lauderdale, FL, USA

Synonyms

Empathizing; Mentalizing; Mindreading; Perspective taking; Theory of mind

Definition

The inability to attribute mental states such as thoughts, desires, knowledge, and intentions to self and others, and to make sense of and predict another person's behavior.

Description

Mindblindness theory proposes that children and adults with autism spectrum disorders are delayed in the development of what Premack and Woodruff [19] termed "theory of mind" (ToM). ToM is a cognitive (attribution) component of empathy; the ability to identify cues that indicate the thoughts and feelings of others and "to put oneself into another person's shoes" [1]. It is also referred to as "mentalizing," "mindreading," and "perspective taking." According to Baron-Cohen [2], the ability to reflect on one's own and other people's minds (beliefs, desires, intentions, imagination and emotions) allows us to interact effectively with others in the social world. Typical individuals are able to mindread relatively easily and intuitively. For example, we can read a person's facial expression and body language, and tone of voice and recognize his or her thoughts and feelings, and the likely course of behavior. In other words, we interpret, predict, and participate in social interaction automatically, and for the most part, instinctively. This attribution of mental states is a fundamental component of social interaction and communication. An impairment in ToM results in an inability to appreciate other people's emotions and thoughts, and to make sense of or predict another's actions. As a consequence, the person with impaired ToM is said to have a form of "mindblindness" or a deficit in "empathizing" ability [3].

Relevance to Childhood Development

The concept of ToM and mindblindness has been widely studied over the past two decades and used to explain the development of social cognition and the core social deficits of developmental disorders such as autism [6, 16]. The understanding of other people's mental states develops early in life and becomes more complex with advancing age [7, 8]. Research suggests that typically developing children, in contrast to those with autism, are born with a set of skills which enable them to comprehend and respond to other people's mental states and feelings [3]. For example, children can understand relationships between mental states by 3 years of age. By age four, they can understand that people can hold false beliefs (deception). Typical children at age seven begin to understand what not to say to avoid offending others. A typical 9 year-old can interpret another person's facial expressions and figure out what they are thinking or feeling [3]. It is a deficit in this normal process of ToM or empathizing that has the potential to explain the lack of pretend play and the core social and communication problems diagnostic of children with autism [6, 15]. Children with autism are said to lack an effective ToM and thus, have a form of mindblindness. Baron-Cohen [3] has broadened the mindblindness theory to include an affective component (emotional reactivity) and a second factor termed systemizing to explain the non-social areas of strength often demonstrated by individuals with autism spectrum conditions.

Children with ToM impairment frequently experience academic, behavioral, and emotional problems related to their social skills deficits. Indeed, impairments in social reciprocity are one of the defining characteristics of autism spectrum disorders [3, 18]. Consequently, interventions focusing on social adaptive skills are critically important to the treatment of this group of children [17]. While the research on the effectives of social skills

intervention is still in the formative stage, several programs have been developed to promote prosocial behavior and expand ToM abilities among children with autism spectrum disorders [10]. They include: social stories [12], computer programs such as Mind Reading: The Interactive Guide to Emotions [5] and The Transporters [4]; ToM teaching programs [13, 18] and social skills programming [9, 11, 14, 20].

Minnesota Multiphasic Personality Inventory

►MMPI

Minnesota Multiphasic Personality Inventory-Adolescent (MMPI-A)

Chris Leeth
University of Texas at San Antonio, San Antonio, TX, USA

Definition

The MMPI-A is a structured personality inventory based on the MMPI-2. However, the MMPI-A is designed to be used with adolescents ages 14–18.

Characteristics

The MMPI-A is designed to measure characteristics of personality and psychopathology among adolescents. The test was published in 1992 and consists of 478 true/false items. The person being tested can complete the test individually; it is self-administered. Scoring of the MMPI-A can be done by the administrator, by hand, or with the use of a computer program. The MMPI-A has several validity scales to detect response patterns such as defensiveness or inconsistent responding. The primary clinical scales are the same as those on the original MMPI and MMPI-2, and thus include: Hypochondriasis, Depression, Hysteria, Psychopathic Deviate, Masculinity-Femininity, Paranoia, Psychasthenia, Schizophrenia, Hypomania, and Social Introversion. There is much research on the reliability and validity of each of these scales. Since the publication of the MMPI-A, several other scales (e.g., content scales, supplementary scales) have been created to assess other components of an adolescent's personality. As with the MMPI and MMPI-2, valid interpretation of MMPI-A scores requires a high degree of experience and expertise.

Mirror Neurons

Robert Walrath
Rivier College, Nashua, NH, USA

Definition

Nerve cells, first discovered in monkeys, located in the ventral premotor cortex (F5) of the macaque. These cells fire both when the animal engages in goal directed behavior and also when it observes the same behaviors performed by others. A similar system of neurons has been identified in the right inferior parietal lobe of the brain in humans using fMRI techniques, and mirror neurons are hypothesized to exist in other regions of the brain.

Description

The mirror neuron system is considered to be an "observation-execution" or "self-other" matching system within the nervous system that converts sensory information to a motor format. This system has been hypothesized as a neural substrate for processing motor, linguistic, emotional and other higher cortical functions [6]. Mirror neurons are believed to account for aspects of empathy and ability to "read" the thoughts of others (theory of mind), social learning and understanding or inferring intention, as well as learning motor skills through imitation. They are believed to serve the adaptive function of allowing "access" to the thoughts of others, thereby promoting socialization and social behavior.

Damage or deficits in this system are hypothesized to explain the absence of social behaviors in autism, as well as some symptoms of schizophrenia. There are implications for the mirror neuron system in the development of language (by processing prosody via the limbic system) and processing emotion as well.

The mirror neuron construct has become less controversial over time as numerous studies, including more recent neuroimaging and neurophysiological research, have demonstrated more conclusive findings regarding the existence of these systems in the human brain.

MMPI

Christopher Leeth
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Minnesota multiphasic personality inventory; MMPI-2

Definition

The MMPI (and the revised version, the MMPI-2) is a structured personality inventory that includes multiple validity and clinical scales in order to measure personality across numerous dimensions. It also has content scales that can be used to measure different aspects of an individual's personality, and research continues to examine the creation and psychometric properties of additional scales. The MMPI-2 was published in 1989 [1], and this updated version capitalized on what was learned from the years of research and clinical use of the original MMPI.

Description

The MMPI-2 is used as a measure of personality characteristics and psychopathology among adults ages 18 and older. The test consists of 567 true/false items. The person being tested can complete the test individually; it is self-administered.

Scoring of the MMPI-2 can be done by the administrator, by hand, or with the use of a computer program. The MMPI-2 has several validity scales that are designed to detect response patterns, such as inconsistent responding, defensiveness, or reporting extremely rare or severe collections of symptoms. The primary clinical scales are consistent across the MMPI and MMPI-2 and include: Hypochondriasis, Depression, Hysteria, Psychopathic Deviate, Masculinity-Femininity, Paranoia, Psychasthenia, Schizophrenia, Hypomania, and Social Introversion. There is much research on the reliability and validity of each of these scales, and on using the combination of different scale elevations to make predictions about personality and behavior. Since the publication of the MMPI-2, several additional scales have been created to assess other (i.e., more precise or narrowly-defined) components of a person's personality.

Mnemonic Device

Russell N. Carney
Missouri State University, Springfield, MO, USA

Synonyms

Cognitive strategies; Memory strategies; Memory technique; Mnemonic; Mnemonic strategy; Mnemonic technique

Definition

A mnemonic device is a specific, cognitive cuing strategy designed to aid memory.

Description

Mnemonic devices are memory techniques that systematically change difficult to remember material into more easily remembered material [16]. Such devices provide a cognitive cuing structure [2] by which to bring back to-be-recalled information. As a simple example, the *first-letter mnemonic* is a device familiar to most individuals. Many students learned to remember the names of the great lakes by remembering *HOMES* (i.e., Huron, Ontario, Michigan, Erie, and Superior). Another example is using *ROY G BIV* to prompt recall of the colors of the spectrum (i.e., red, orange, yellow, etc.). Notably, here, the colors of the spectrum are cued *in order*. The downside to this simple device is that single letters serve as rather meager retrieval cues. Mnemonic devices have been around for many years, and some, like the *method of loci*, date back to ancient times [19]. Much of the empirical research regarding such techniques began in the mid-1970s and continued through the 1990s.

Encoding Versus Organizational Mnemonics

Bellezza [2] proposed two general categories of mnemonic devices: *encoding mnemonics* and *organizational mnemonics*. Encoding mnemonics essentially facilitate paired-associate learning, such as associating words and their meanings, states and their capitals, names and faces, and so on. Examples of encoding mnemonics include the *keyword method* and the *face-name mnemonic*. In contrast, organizational mnemonics associate several pieces of information, such as remembering the names of all the great lakes, or the order of the colors in the spectrum. Examples of organizational mnemonics include the *first-letter mnemonic*, the *method of loci*, the *pegword method*, and the *story* and *link mnemonics*. Organizational mnemonics are particularly useful for serial or free recall of ordered information, as in the ROY G BIV example.

Encoding Mnemonics

The keyword method: Of the various encoding mnemonics, perhaps the most versatile (and most researched) is the keyword method (e.g., [1]). The technique can be described in terms of Levin's [7] *three R's* of associative mnemonic recall: *recoding*, *relating*, and *retrieving*. Say that one wanted to remember that the word *loquacious* means overly *talkative*. First, the word *loquacious* is *recoded* as an acoustically or orthographically similar keyword, such as *liquor*. Next, the keyword, *liquor*, is *related* to the meaning by way of an interactive visual image (e.g., imagine someone drinking *liquor* and becoming very *talkative*). So encoded, *retrieval* proceeds as follows: *loquacious* -> *liquor* -> the image involving liquor and talkativeness -> *talkative*. Visual imagery (e.g., [12]) is often called upon in mnemonic techniques to serve as the "glue" to hold things together. Extensive research has validated the keyword method as a useful device for facilitating paired-associate learning in a variety of situations, such as foreign words and their meanings, science terms and their definitions, and, using a dual-keyword approach, states and their capitals (e.g., [8, 16]). A fourth important *R* is *rehearsal*. As in learning anything, acquiring information by way of a mnemonic device benefits from overlearning.

The face-name mnemonic: Another potentially useful encoding mnemonic is the *face-name mnemonic*. A close cousin to the keyword method, the face-name mnemonic associates a pictorial stimulus (i.e., a person's face) with a verbal response (i.e., the person's name). For example, imagine someone named Komer who has a prominent feature: a thick mustache. One first recodes the name *Komer* as a more concrete name clue (or keyword), such as *comb*. Then, the name clue, *comb*, is related to his face by interacting the comb with his mustache (e.g., imagine a comb stuck in his thick mustache). Then, upon next seeing Mr. Komer, retrieval proceeds as follows: face -> thick mustache -> image of comb stuck in mustache -> *comb* -> *Komer*. Research has provided some support for the face-name mnemonic (e.g., [14]). It can also be applied to other learning tasks where a pictorial stimulus (e.g., a painting) prompts a verbal response (e.g., an artist's name), such as in learning to associate artists' names and their paintings in art appreciation and art history classes (e.g., [4]).

Organizational Mnemonics

The pegword method: Two of the most researched organizational mnemonics are the pegword method and the method of loci. These two strategies are quite similar in that each has a fixed set of "hooks" (i.e., either pegwords or locations) with which to interact to-be-remembered items through visual imagery. To use the pegword method, one first learns a set of easily-remembered pegwords that rhyme with numbers (e.g., 1–10). It is easy to remember that *one* is a *bun*, *two* is a *shoe*, *three* is a *tree*, and so forth up to *ten* is a *hen*. Then, to mentally store a list of things (e.g., groceries, such as milk, bread, bananas, ketchup, etc.), one simply interacts each to-be-remembered item with each of the pegwords (e.g., imagine *milk* being poured on a *bun*, a *shoe* squashing a loaf of *bread*, *bananas*

hanging in a *tree*, *ketchup* splattered on a *door*, etc.). Remembering, then, is prompted by simply going down the list of numbers (1, 2, 3, 4 and so on). For example, saying "one" cues *bun*, *bun* cues the image involving the *milk*, and this, in turn, yields *milk* – the first item on your grocery list. The remaining items are easily recalled via this cognitive cuing structure. On a more school-related note, more abstract, ordered lists encountered in academic settings (e.g., hardness levels of minerals, the ten highest mountains, the order of events in an historical account) can also be stored this way. However, less-than-concrete to-be-learned items (e.g., minerals: *talc*, *crocoite*, *antimony*, *wolframite*, etc.) may need to be recoded as keywords (e.g., *tail*, *crocodile*, *ant*, and *wolf*) before interacting them with the pegwords. With this added step, remembering is as described previously, except that recall of the image yields the keyword, which in turn yields the actual item (e.g., *wolf* prompts *wolframite*). As with other strategies, research as generally supported use of the pegword mnemonic (e.g., [6]).

The method of loci: Instead of pegwords, the method of loci uses a fixed set of locations to serve as the cognitive cuing structure. The locations might be places or things one might encounter in walking across campus or through ones home. For example, upon arriving home, one might encounter the driveway, the garage, the front door, the closet, and so forth, in that order. To-be-remembered items, such as the grocery list items mentioned earlier, can be interacted with each of the locations in a visual image. For example, one might imagine *milk* running down the *driveway*, loaves of *bread* stacked neatly in the garage, a *banana* squashed against the front *door*, and so forth. Then, to remember the items, one simply takes a mental walk through the locations (in order). Each location should bring back the visual image, which in turn yields the grocery item. As described above, keywords can be used in place of less than concrete to-be-learned items, such as the list of minerals. As with other mnemonic devices, research regarding the method of loci has generally supported its use (e.g., [3, 10]).

Why Mnemonic Devices Work

While mnemonic strategies are sometimes discounted as mere tricks or gimmicks, they work because they are based on sound memory principles, such as rhyming, recoding, and relating. All mnemonic devices involve some form of elaboration (e.g., [18]). And, although most of the examples included here suggest visual imagery, verbal elaboration can be used as well, as in the rhyme "i before e, except after c." Indeed, the various descriptions of images were presented verbally, and hence may be especially memorable because of their dual representation in memory (i.e., they are encoded in memory as both imaginal *and* verbal units). See Paivio's [15] *dual-coding hypothesis* for more on this theoretical explanation.

Relevance to Childhood Development

Even in this age of instant facts via the Internet, school children are still called upon to learn and remember much information. Further, higher-order thinking is often built upon "facts" that are stored in and available from memory. While some students are blessed with good memories, others struggle with tasks that require memorization. In this regard, mnemonic strategies come highly recommended. Extensive research, particularly with the versatile keyword method, has supported the use of such techniques with children in a variety of content areas.

However, the extant research does not represent a blanket endorsement. In his "twenty-year report card" based on mnemonic strategy research findings, Levin [8] assigned A's to the use of mnemonics when applied to factual content (e.g., using the keyword method to associate a term and its definition), and to their use in special education. Next, a B was awarded when it came time for students to generate their own mnemonics (following instruction and practice). Graded a bit lower, C's were awarded when the particular mnemonic strategy was overly complex (e.g., the *digit-consonant mnemonic* for remembering numbers or dates), and when different mnemonic devices were combined (again, yielding a more complex approach). Finally, a D was assigned when it came to *transfer*. That is, just because students learned to use a mnemonic in one situation did not mean that they would apply it in a new, slightly different situation. A final caveat is that, below the age of nine, children tend to have difficulty when directed to use mental imagery. Hence, providing pictures illustrating mnemonic interactions is preferred in working with young children.

As indicated by Levin's "A" award, mnemonic strategies have been used quite effectively with children in special education settings. Based on their research, Mastropieri and Scruggs [11] have written a guide describing the use of mnemonic techniques with such students. More generally, practical, memory improvement and memory strategy books abound (e.g., [5, 9, 13, 17]).

Modeling

Elaine A. Thomas
Argosy University, Atlanta, GA, USA

Synonyms

Observational learning; Social learning theory

Definition

Modeling is the process through which children learn a large number of behaviors, skills and, ways of thinking and feeling without direct experience. The phenomenon of modeling, proposed by Albert Bandura recognizes that learning can take place through observation and that this learning involves cognitive processes. The term is also used to refer to techniques in cognitive behavior therapy where the therapist enacts a skill or behavior that the client will learn through observation and imitation of the therapist or where the therapist presents information in symbolic form to the child that the child may use to modify behavior.

Description

Theory

The process of modeling acknowledges the social cognitive aspects of learning. It goes beyond description of learning thorough operant principles to describe how children and others can learn without direct experience of consequences for their responses. Considerable learning is purported to take place through the child's watching and listening to others' behaviors, speech, and actions. This learning can occur through either live or symbolic models. Live models are typically parents, teachers, other adults or peers. Symbolic models include books, videotapes, films, or other media. Live modeling then describes learning by direct observation of a model or exemplar while symbolic modeling describes learning by presentation of a model or exemplar indirectly. Not only do children learn actual behaviors but also they learn the probable consequences of behaviors through vicarious reinforcement. Thus imitation, the matching of the model's behavior, may be described separately from vicarious learning which is the increase or decrease in the observer's behavior that is similar to that of the model whose behavior was reinforced or punished [1]. Imitation and observational learning are notably not the same according to Bandura's conceptualization.

According to Bandura, observers acquire symbolic representations of the observed behavior which is later used to guide the observer's performance. He specifies

the component processes involved in this process of observational learning: attention, retention, motor reproduction, and motivation [2]. All four are necessary for observational learning to occur. Attention is key due to important features of both the observed or modeled events and the observer. First, the event must attract the attention of the observer. Important features of the modeled events related to the attention they will attract include salience, affective valence, complexity, prevalence, accessibility, and functional value. Similarly, important observer characteristics determine what will be attended to and those include cognitive capabilities, cognitive preconceptions, arousal level, and acquired preferences. Retention processes refer to the processes involved in remembering or acquiring a symbolic representation of the event so that they may be recalled at a later date. These include symbolic coding, cognitive organization, cognitive rehearsal, enactive rehearsal, cognitive skills, and cognitive structure. Motor reproduction features describe the features in the observer that are necessary for recreation after they have been attended to and retained. In sum, the observer must be able to retrieve the information from memory, organize it, engage in a reproduction of it, compare the reproduction to the conceptual model and adjust the response accordingly. Thus, important characteristics in this step include the availability of component responses, physical capabilities, self-observation and monitoring of reproduction and, accuracy of feedback. Last, motivational processes determine whether a behavior that is attended to, retained, that the observer has the capability to reproduce will in fact be performed. Performance of behavior will depend on external reinforcement, vicarious reinforcement and, self-reinforcement and self-evaluation. That is on the extent to which the observer is likely to obtain direct reinforcement for the behavior, the extent to which the observer was influenced by the reinforcement received by the model, the observer's capacity to reinforce himself and other observer attributes such as internal standards, reinforcement preferences and social comparison bias.

In later conceptualizations [4], Bandura used the concept of self-efficacy to describe an important observer characteristic influencing both learning and production of behavior. Self-efficacy, the belief that one can cause some effect in the environment, guides what behaviors are attempted and what further behaviors develop. It is a concept describing the individual's expectation he or she will likely be successful in performing a behavior in a particular situation or context. Self-efficacy develops through a history of successes, observational learning, what others tell us about our abilities and the emotional state experienced when performing the behavior.

Applications to Child Psychotherapy

Modeling is often used in child psychotherapy. Indeed, it is a technique that often appears in evidence-based child treatments and is designated as one of twenty six effective interventions known as "practice elements" by Chorpita, Daleiden and Weisz appearing in evidence-based treatment approaches [7]. Therapists demonstrate adaptive behaviors, ways of thinking etc. with the expectation that they child will learn new ways of behaving, thinking and feeling. Therapists typically provide: a live demonstration (live modeling); a video, pictorial or story demonstration (symbolic modeling,) or; an adaptation that involves asking the child to imagine a model engaging in behaviors and activities related to the target adaptive behavior (covert modeling) [7]. Additional variations include: graduated modeling (presentation of successively more difficult behaviors); guided modeling (use of physical prompting); guided modeling with reinforcement, and; participant modeling (use of contact with the therapist to guide performance) [7].

Relevance to Childhood Development

Modeling is one of the fundamental mechanisms through which learning and development take place in children according to social learning and social cognitive theory. Children learn a wide variety of adaptive and maladaptive behaviors through modeling. Social skills, language, moral reasoning, and gender roles are acquired primarily through observational learning. Similarly, children's fears can be acquired without exposure to the feared stimulus through observational learning and aggressive behaviors can be acquired through observational learning.

Cognitive impairment; Developmental disabilities; Intellectual disability; Mental deficiency

Definitions

Moderate mental retardation is defined as significantly sub average intellectual ability, which ranges between 35–40 and 50–55 and concurrent delays in adaptive functioning that present prior to the age of 18.

Description

According to the Diagnostic and Statistical Manual-Fourth Edition-Text Revision (2000), Moderate Mental Retardation (MR) is characterized by individuals with cognitive impairments that correspond to an IQ score between 35–40 and 50–55 and deficits in adaptive functioning that present before the age of 18. Individuals with moderate MR constitute 10% of the mentally retarded population 1–3).

Relevance to Childhood Development

During the preschool years (between birth and age five), children with moderate MR can learn to speak and communicate; however, these children will often have poor social awareness and fair motor development [1, 2]. In addition, these children may profit from training in self-help skills, although moderate levels of supervision are frequently required [1, 2].

Children with moderate MR also benefit from social and occupational training; however, these children are unlikely to progress beyond the second grade level in academic subjects. Due to legislative polices, such as the Individual with Disabilities Act (IDEA, 1997), which stipulates that children with disabilities receive appropriate education within the least restrictive environment, children with moderate MR are now remaining in school for longer durations than before [3].

In familiar places, children with moderate MR can learn to travel independently. Throughout adolescence, difficulties in recognizing social conventions may interfere with peer relationships. As adults, a majority of individuals with moderate MR are able to perform unskilled or semi-skilled work under supervision. This can occur in sheltered workshops or within the general workplace. Adults with moderate MR can adapt to life in the community, typically in supervised settings [1, 4].

Monozygotic (MZ) Twins

Mysti S. Frazier
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Identical twins; True twins

Definition

Monozygotic twins are formed from the fertilization of one egg from one sperm. A split in the fertilized egg (zygote) occurs during the early part of the gestational period, within 15 days when there are just a few cells. This causes two separate but genetically equal embryos to form, which accounts for their physical, mental, and sometimes emotional similarities.

Description

In the last century it was estimated that 3.5 of every 1,000 births were twins [3]. However, today it is estimated that about 1 of every 70 births are twins [1]. This rise is likely a result of scientific advancement in artificial fertilization and multiple egg fertilization for women who are unable to conceive otherwise.

Monozygotic twins share a placenta but have different amniotic sacs in 70% of the cases. This means that separate placentas and sacs can form, but this is more common in dizygotic twins [1]. Twins who share a placenta and sac rarely survive to birth because of the struggle for nutrients.

The pioneer in twin studies is Sir Francis Galton, who accurately proposed that similar genetic makeup was the reason twins looked alike [3]. In the 1930s, Josef Mengele, a young doctor from Germany began researching similarities in twins. His research and obsession reached its peak in the Nazi concentration camp, Auschwitz, where he experimented on twins. Mengele's research is still unknown because it was destroyed before soviet forces could reach him, though it is assumed that it was probably used to validate the Nazi idealization of the superiority of the Aryan race [3]. In the 1970s twin research focused on similarities between the two individuals. At the University of Minnesota, Thomas J. Bouchard Jr. began a study of twins who had been reared separately to compare their uncanny similarities in speech, choice of spouse, hobbies, and everyday behavior. Bouchard found that monozygotic twins "reared apart were as much alike as – in some cases more alike than – identicals reared together" [3].

Different cultures view twin births in different, unique ways. Some cultures revere twins as god-like and worthy of praise and admiration, while others see twins as a bad omen and thus discard and disgrace them [1]. In the United States twins are seen as unique oddities and can be singled out throughout their lives [1]. However, twins are fascinating to biologists and many studies have been conducted to find out more about them. As one recent example, a 19-year study of grey and white brain matter development in twins suggested that genetic factors play a role in similarities in brain development among twins; however, as they grow older, environmental factors play a larger role [2].

Mood

Christi Sikora
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Affect; Disposition; Frame of mind; Humor; Inclination; Temper

Definition

A continued emotional state that affects one's outlook on life.

Description

Mood is a nebulous construct but generally refers to an emotional state that influences one's outlook on life. Within the context of child behavior and development, mood is often studied from the perspective of disturbances in mood, and the impact that these disturbances have on social, behavioral, and academic functioning. Three groups of criteria are used to diagnose issues related to mood; these groups include mood episodes, mood disorders, and specifiers that describe the current episode and recurrent course. Mood episodes are important because they describe the range of mood in children and adolescents. Mood episodes include Depressive, Manic, Mixed, and Hypomanic. A Major Depressive Episode

can be described as depressed, sad, down in the dumps, discouraged, and/or hopeless. Children and adolescents may exhibit an irritable or cranky mood during a Major Depressive Episode as opposed to sadness. This must be distinguished from irritability due to frustration. Manic Episodes are identified by an interval of time with a euphoric, expansive, or irritable mood that lasts at least one week. A Mixed Episode includes both a Major Depressive Episode and a Manic Episode. A Hypomanic Episode has the same criteria as a Manic Episode; however, criteria for this episode are met after only four days. Depending on the characteristics of the mood and the duration, a child may be diagnosed with a mood disorder; these diagnoses have very specific criteria in order to facilitate diagnostic precision.

Mood Disorders

Christi Sikora
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Affective disorders

Definition

Refers to a group of psychological disorders identified by a disturbance in mood.

Description

Mood disorders represent a major category of the DSM-IV-TR diagnostic classification system. Mood disorders include many diagnoses, specifiers that describe the current and recurrent episodes, and qualifiers for levels of severity. Mood episodes do not have their own diagnostic code; however, they are the building blocks for the diagnosis of mood disorders. Mood disorders are separated into four categories: Depressive Disorders, Bipolar Disorders, Mood Disorder Due to a General Medical Condition, and Substance-Induced Mood Disorder. Depressive Disorders include Major Depressive Disorder, Dysthymic Disorder, and Depressive Disorder Not Otherwise Specified. These disorders are differentiated from Bipolar Disorders based on the absence of a Manic, Mixed, or Hypomanic Episode. Bipolar Disorders include Bipolar I Disorder, Bipolar II Disorder, Cyclothymic Disorder, and Bipolar Disorder Not Otherwise Specified and normally include Manic Episodes, Mixed Episodes, or Hypomanic Episodes together with current or past Major Depressive Episodes.

Historically, research on mood disorders among youth was neglected in comparison to the large amount of such research among adults. Recently, the study of mood disorders in children and adolescents has increased significantly, with particular attention given to developmental differences in the manifestation of mood disorders and whether the diagnostic criteria for mood disorders used with adults can also be applied to youth. The depressive disorders often have onset in childhood or adolescence and often have a chronic or recurrent course. Research continues to look at familial and interpersonal aspects in addition to genetic and neurobiological factors.

Moral Behavior

Victoria Talwar
McGill University, Montreal, QC, Canada

Definition

To act according to ones moral values and standards. Children demonstrate prosocial and moral behavior when they share, help, co-operate, communicate, sympathize or in otherwise they demonstrate ability to care about others.

Description

A number of elements affect whether an individual will act morally. The ability to reason about moral issues provides a basic level of understanding necessary for moral action. According to Kohlberg's theory of moral development, individuals progress through stages of moral reasoning with higher order reasoning including concepts of fairness, justice and welfare [7]. Through the process of reasoning and judgment, an individual is able evaluate interpret the moral situation, formulate the moral ideal and choose a course of action that corresponds to one's moral values. Thus, higher order moral reasoning may lead to greater likelihood of moral behavior. For instance, research has found that children who cheat have lower levels of moral reasoning than those who do not. Delinquent adolescents have been found to have lower moral reasoning than non-delinquents. Higher levels of moral reasoning have also been found to be related to altruism. Matsuba and Walker [8] found adolescent moral exemplars who engaged in a high degree of moral behavior through social organizations they were involved in were more advanced in their moral reasoning [8].

However, moral reasoning does not necessarily predict behavior. There is often a discrepancy between moral judgment (perceiving an act as right or wrong) and moral choice (deciding to act in morally right way). Research has found that while we often espouse certain moral standards and values, we may act in our own self-interests in contradiction to those beliefs. In fact, in real life moral conflict situations, contextual factors may influence our actions more than logical thought and we may not use higher level reasoning abilities [2]. Self-interests may prevail instead. For instance, Hartshorne and May's classic study found that moral behavior does not depend on a child's character but is a function of situational factors [6]. Thus, while a child may act morally in one situation, they may act in their own self-interests in another.

Choosing which action is most moral for the situation, requires interpreting the need for a moral response to the situation at hand. However, social domain theory suggests that while some issues/dilemmas may be considered moral (i.e., related to issues of welfare, justice, rights), others may be viewed as social conventions or personal interests [12]. An individual may judge the issue to be in the moral domain and then act accordingly. However, these judgments may shift depending on the situation. By 3 years of age, most children can distinguish moral rules from social conventions. They evaluate hurting another or taking another's possessions as serious moral transgressions. Children also view lying as wrong and that honesty is the morally right behavior. Nevertheless, they may lie in some contexts to protect their self-interests (i.e., to avoid being punished) [10]. On the other hand, in some contexts children will lie (breach a moral code) in order to protect or help someone else (prosocial behavior). [11] Thus, children's behavior depends on the context and their evaluation of cost-benefit ratio to themselves and others and the resulting moral or prosocial behavior may be motivated by self-interests as well as adherence to moral codes or concern for others.

One of first steps toward moral behavior is the development of self-control, the ability to inhibit impulses. Preschoolers start to develop self-control and attempt to restrain their behavior to avoid temptation by distracting themselves or repeating the rules (i.e., I have to wait to play with the toy). Children's abilities to exercise self-control and to restrain unacceptable behavior gradually increases through elementary school years. An important motivating factor for moral behavior is empathy which involves being able to identify with another as well as understanding the effect of various possible actions on others. Empathy motivates individuals to become involved and provides information about another's distress and how it can be alleviated. As early as the preschool years, children show guilt and distress when they feel they have done something wrong and show empathy towards another when they are in distress. With increasing age, children show more empathy for others in difficulty. As children's ability to understand the perspective of others and reason prosocially increases, so does their prosocial behavior. Children have been found to exhibit more prosocial behaviors from elementary school onwards [5].

During adolescent years, identity development becomes important factor in motivating moral or prosocial behavior. As part of that development, adolescents feel a personal moral responsibility to act prosocially. According to Blasi, judgments of responsibility develop in stages somewhat in parallel to moral judgment stages [3]. Individuals who are at higher stages are more personally responsible for their values, decisions, and actions. For instance, adolescent care "exemplars" have been found to have an understanding of self based upon systematic moral belief systems. As adolescents' self-understanding and self-identity develop, there is an increase in the use of moral concepts to guide conduct.

Children internalize the moral rules and principles by adapting the external standards of the adult authority figures around them which they learn through directing instruction, observation, rewards and punishments [1]. Authoritative, democratic, responsive parenting is associated with higher levels of moral maturity. Children's moral

behavior is developed through warm caring parenting with clear consistent expectations. Adults foster moral behavior through control and communication of values, role modeling, fostering active reflection and the creation of opportunities for child to practice moral reasoning actions.

In addition to the influence of parents and other significant adults, peers can also influence children's moral behavior. Social expectations and norms of the peer group may influence children's behavior. For instance, in high school there is sometimes the perception that cheating is prevalent. Peer norms and attitudes of friends may influence if a child engages in academic dishonesty [9]. Research has found that children's peer debates can generate increased awareness of fairness and rights of others [4]. Other studies based on cognitive theory of moral development have found that discussions led by teacher-facilitators can also promote children's moral maturity. Kohlberg created the Just Community programs in high schools where students developed their own rules of conduct through discussion, reason and argument about fairness. Moral development occurred when students shared in the responsibility of creating a moral environment. Results suggest that students' complex moral reasoning increases while antisocial behavior declines.

M

Synonyms

Development of moral sense; Ethics; Moral growth; Moral maturation

Definition

Moral development refers to the process whereby people form a progressive sense of what is right and wrong, proper and improper. As implied by the term development, human moral sense is commonly seen to involve a movement from simple and finite definitions of right and wrong to more complex ways of distinguishing right from wrong.

Description

Throughout history, the topic of moral development has been taken up by many theologians, scientists, and philosophers. Western philosophy provides three common platforms for thinking about human morality [9]. Christianity provides the doctrine of original sin, which holds that all human beings are born with a proclivity towards concupiscence. That is to say, without salvific intervention, all people will naturally behave selfishly, improperly, without regard for the good of others [5]. The second philosophical platform is that proposed by

Swiss-born French philosopher Jean-Jacques Rousseau, who believed that human beings are born good. Rousseau proposed that moral development required little if any societal or parental intervention, but that people would naturally develop a sense of right and wrong. Believing that societal institutions actually led people astray from naturally occurring moral development, Rousseau proposed the concept of the *noble savage*, a person uncorrupted by society's moral interference [10]. English philosopher John Locke proposed a third moral philosophy – human beings are born amoral and are influenced by experience. Locke proposed the term *tabula rasa*, or blank slate, to convey the idea that morality is completely derived from environmental interaction [10, 17].

More recently, psychologists have proposed several theories of moral development. The two predominant theoretical orientations of moral development that have emerged from psychology are the social learning/social cognition approach, based primarily on the work of Bandura [1–4], and the cognitive structuralism approach, which will be discussed here based primarily on the work of Piaget and Kohlberg [13–15, 18, 19].

From a social learning/social cognition approach, moral development is based upon values, both those of the individual – individual values – and those held by the community or group within which the individual resides – shared values [25]. For example, a value may be "human life is to be defended above all else," or "children should be seen, not heard." These values may then be translated into behaviors. Successful moral development within this theoretical framework occurs when individuals consistently engage in behaviors with positive consequences – that is to say, when an individual behaves according to values, or convictions, that are also shared by the community or group to which the individual belongs. This is learned both by noting the consequences of one's own actions, as well as the consequences of the actions of others, or environmental modeling [1–4]. Moral behavior, what is right and wrong, can be defined only relative to social context.

The cognitive structuralist view conceptualizes moral development as the acquisition via experience of social rules rather than the development and internalization of values. In contrast to the contextual values of social learning/social cognition theory, within the cognitive structuralist framework, rules are not relative, but rather universal, external properties of the world [25]. Piaget describes moral development, therefore, as playing a game, the object being the discovery of these rules [18–20]. As a person plays the game, they begin to pick up on rules, first seeing the rules as basic and finite, and then learning increasingly nuanced rules via social interaction and observation.

A third theory of moral development emerging from psychology, which bears mentioning, comes from the psychoanalytic tradition. According to Freud, moral development is the result of a childhood confrontation between the demands of the id and the desire to avoid punishment and earn desired acceptance [6].

Relevance to Childhood Development

Both social learning/social cognition and cognitive structuralism hold that human beings are innately amoral and stress experience as the key component of moral development. And while both theories hold that moral development occurs over the lifespan, each holds that the most significant moral development is achieved during the first two decades of life, with later development building on earlier foundations.

Social learning/social cognition conceptualizes moral growth as occurring gradually throughout life. That is to say, moral development is seen as a day-to-day accumulation of moral reasoning and understanding throughout life. This stands in contrast to the stage theory approach of cognitive structuralism, which posits sharp developmental trends [9, 18–20].

Both Piaget and Kohlberg, of the cognitive structuralist school of thought, proposed stages of moral growth thought to be observable at predictable ages. These stage theories emphasize increasingly complex internal cognitive processing. As a child's capacity for complex reasoning increases due to maturation in cognitive structures, schemas, and operation mechanisms, their moral worldview also increases in complexity [13–15, 18, 19].

Piaget proposed four stages of cognitive development along with three concurrent stages of moral development. His first stage of moral development, lasting between 4 and 7 years of age, is that of heteronomous morality. Heteronomous morality is characterized by an inflexible system of rules and the absence of questioning of authority. The second stage, lasting from 7 to 10 years of age, is the transitional stage in which a child exhibits moral judgments characteristic of both the first and third stages of moral development. Piaget's third stage is that of autonomous morality, which begins at age 10 and is characterized by a flexible rule system and concepts like equality, reciprocity and justice [18–20].

Kohlberg proposed a more detailed six stage model of moral development. Like Piaget, Kohlberg's first stage, also termed heteronomous morality involves an unquestioning attitude towards authority. His second stage, referred to as individualistic/instrumental morality, involves

maximizing the benefits to oneself while minimizing consequences. Stage three is that of impersonally normative morality, in which one partakes in shared social norms. During stage four, social system morality, one makes moral decisions in pursuit of the greatest common good. Stage five, human rights and social-welfare morality, marks the beginning of the promotion of universal values and rights. Kohlberg's sixth and final stage is that of universalizable, reversible, and prescriptive general ethical principles [13–15].

In psychodynamic theory, moral development is associated with the emergence of the superego during the Oedipal period, which occurs during the ages of 4–6. In essence, the id, the part of the mind that operates on the pleasure instinct, issues a demand that is met with prohibition. This is commonly understood as occurring in strictly Oedipal terms. That is to say, a child desires to replace the same-sex parent and possess the parent of the opposite sex. For a male child, the desire to overthrow father and possess mother results in feelings of being threatened by the same-sex competitor, namely castration anxiety. Frustrated, the child decides to ally himself with his father and begins to adopt his values and behaviors [6]. Because females are not confronted with the fear of castration, having no phallus to lose, psychodynamic theory is associated with the idea that females are weaker morally than men, having less motivation to adopt the values of the same-sex parent. However, the frustration of desire leading to the internalization of societal rules/values can easily be seen in many situations. If the superego does not emerge, and alliance with the same-sex parent does not occur, moral development may be affected throughout life.

Some theorists have taken issue with the above theories of moral development, specifically those of Kohlberg and psychodynamic theory, noting that they are biased towards male-typical moral development and underestimate the moral maturation and reasoning of women [7, 8, 27, 28]. One such theorist is Carol Gilligan, a student of Lawrence Kohlberg. Gilligan proposed that women develop moral systems based upon an ethic of care rather than an ethic of justice [7]. Gilligan proposed an alternative theory of moral development based upon care focused morality. The three stages she proposed are the preconventional stage (in which morality is based upon individual survival), the conventional stage (in which self-sacrifice is seen as goodness), and the postconventional stage (in which people operate using a principle of nonviolence to self and others).

More recent research in the moral development of children suggests that children begin to exhibit the beginnings of moral thinking much earlier than purported by traditional theories. In light of new research regarding the conceptual skills and relational abilities of infants and young children, it is increasingly believed that early childhood experiences experiences provide a foundation for moral thinking and humanistic regard in later life [26]. For instance, several studies provide evidence that, as early as 26 months, young children exhibit normalized standards for appearance and integrity by responding with distress when presented with flawed objects and showing moral emotions of embarrassment or concern in response to their image in the mirror showing a spot of rouge on their noses [12, 16]. Studies also suggest that 3- and 4-years olds distinguish between the domains of moral and socio-conventional standards, and that preschoolers prioritize fairness over convention during peer play [11, 21–24]. These and others studies suggest that the field of childhood moral development is still young and that we still have much to learn about the skills, abilities, and cognition of children [26].

Definition

Moral judgment refers to an evaluative assessment of others' actions based on the agent's motive as well as based on the consequence of the action within the context of societal and cultural values and standards.

Description

Human beings have the unique ability to assess a given situation with possible alternatives and potential consequences before generating an appropriate response. Such evaluations are usually guided by the accepted values and codes of the society, especially the moral values and moral codes. Morality is considered as a set of customs and values accepted by a cultural group or society in order to guide and control social conduct of individual members of that group. The actions of an individual or a group are judged based on such values and customs. Accordingly, certain actions are considered right and certain others as wrong. Such judgments may differ from society to society and culture to culture. Morality is a product of evolutionary forces that have shaped social cognitive and motivational mechanisms, which had already developed in human ancestors, into uniquely human forms of experience and behavior [25]. Moral judgment involves an evaluative assessment of the actions of others based on the agent's intentions and on the impact of the action on another individual or society. Moral judgments are evaluations of the actions or character of a person that are made with respect to a set of virtues held to be obligatory by a culture or subculture [12].

The ability to make moral judgments is thought to develop through several different stages. Psychological research by Piaget [23] and Kohlberg [21] on the development of moral cognition has focused on progressive stages of moral development. Their theories suggest that the progression from one stage to another is determined by experience. It is a progression from egocentric thinking to empathic thinking. It is also a progression from consequence based reasoning to intention based reasoning, where the actions and events are judged based on the consequences rather than the motive behind an agent's actions. For example, John breaks ten cups accidentally, whereas Jim breaks one cup deliberately. Very young children might judge John's action morally more wrong than Jim's. This is because their judgment of these situations is dependent on the consequence of the action rather than the intention behind the action. In order to interpret and judge a moral transgression, some understanding of the transgressor's motive is crucial. Young children's moral judgments are determined by the action's outcome rather than the actor's intention [13, 23, 26, 29, 30]. However, older children develop the ability to integrate the intentionality of the agent with the consequences of the agent's actions in making moral judgment [29, 30]. People's beliefs about an agent's mind serve as an input to the process by which they arrive at moral judgments about that agent's behavior [18]. Such understanding of other people's beliefs, desires and motives (Theory-of-Mind,

ToM) help us not only interpret others' actions but also predict their actions to a certain extent.

Theory of Mind (ToM) and moral judgment: Processing social transgressions has been associated with activation in neural systems involved in the representation of mental states of others [4]. ToM refers to the ability to understand and attribute mental states to oneself and to others, and is critical in social cognition and social interaction. Social interactions involve the reciprocal, interactive game of understanding other minds and modifying our own beliefs and thoughts about other minds based on our understanding. Having a ToM may be related to the ability to make moral judgment. The most important connection is that understanding the intentions of an agent is critical in morally judging the agent's actions. A recent functional MRI study of the interaction between ToM and moral judgment highlighted the importance of belief attribution during moral judgment [28].

As mentioned earlier, successfully interpreting and judging social scenarios also involves understanding a situation from multiple perspectives. Evaluation of the violation of a social norm differs depending on whether one is an agent or witness to a social transgression. Perspective-taking abilities have been found to have significant effect on moral reasoning [16]. According to Kohlberg [20], moral growth is guided not by simple brain maturation but rather by experience in role-taking or looking at a problem from multiple perspectives. Cognitive empathy, which has also been referred to as perspective-taking or role-taking, is the ability to understand the point of view of another person and is considered as an important achievement in cognitive development. Affective empathy, on the other hand, is the emotional response which often results from perspective-taking [24].

Emotion and reason in moral judgment: Moral judgment is an important aspect of human thought that sits at the intersection of cognitive and social domains as it involves the interplay of cognition and emotion. Emotion and reason have been at the center of the debate on moral cognition in philosophy, in psychology, and in neuroscience. In daily life we constantly assess a situation and make rightness or wrongness judgments. Evaluating a moral dilemma and coming up with a possible action plan involves the battle between cognition and emotion. However, the relative roles of emotion and cognition in moral judgment have been debated. Kant [17] believed emotional forces to be sources that tainted the process of moral thought, primarily because they were against the reasoning process. On the other hand, Hume [14, 15] argued that emotion is critical to moral judgment, and reason has no place in moral cognition. He believed that moral judgments are similar to aesthetic judgments and they are derived from sentiment, not reason. Damasio [7], through the somatic-marker hypothesis, emphasized the importance of emotions in decision-making process. He argued that emotions help to accelerate the decision-making process by limiting the number of possible alternatives available to the individual. This is particularly true in moral situations. For instance, an individual may not give second thought when he sees a group of teenagers pushing and shoving a blind man. Here, the immediate empathic arousal leads to a judgment which then prescribes an action. The social intuitionist model [12] proposes that moral reasoning does not cause moral judgment; rather moral reasoning is a posthoc construction, generated after reaching moral judgment. According to this view, moral judgment is caused by quick moral intuitions, as in the earlier example, and is followed by slow moral reasoning. Greene et al. [11] argued that emotions play a larger role in *personal* moral dilemmas than in *impersonal* or abstract ones. In their functional MRI study with typically developing individuals, regions associated with emotional processing were activated (medial frontal cortex, superior temporal sulcus, and posterior cingulate) during personal moral dilemmas, whereas cognitive areas were activated (dorsolateral prefrontal cortex) during impersonal moral dilemmas. On the whole, both emotion and reason play critical roles in moral judgment and their relative role is still a topic of debate. The relative role of emotion and reason may depend on several factors, such as the nature of moral dilemma, and the emotional or cognitive state of the evaluator.

The moral brain: The human brain is best understood as a confederation of mechanisms that usually act together, but at times may compete with one another, favoring different evaluations of similar circumstances [6]. A good example of such a circumstance is evaluating a social action and making moral judgment about it. Evaluating social situations is a daily affair in one's life and such assessments would require the integrative functioning of several processes, such as understanding a given situation, realizing the context, and integrating it with background information. The evolution of the human prefrontal cortex is intimately related to the emergence of human morality [22, 27]. The cortical areas primarily involved in moral judgment are the medial frontal cortex, the orbitofrontal cortex, ventromedial prefrontal cortex, superior temporal sulcus, amygdala, insula, posterior cingulate cortex and precuneus [10, 22]. Patients with lesions in the orbitofrontal and ventromedial prefrontal cortex have long been described as presenting high levels of aggression, lack of concern for social and moral rules

and irresponsibility [5, 7]. Lesions of these same areas during childhood impair the development of moral knowledge and ethical judgment [2]. The evidence converging from lesion studies underscores the role of these regions in moral behavior. Studies of individuals with psychopathy reveal utilitarian moral judgment. Patients with ventromedial prefrontal cortex damage exhibit generally diminished emotional responsivity and markedly reduced social emotions (e.g., embarrassment or guilt) that are closely associated with moral values [2, 3, 8, 9], and also exhibit poorly regulated anger and frustration tolerance in certain circumstances [19, 1]. Assessing a moral scenario involves looking at the agent's actions within the backdrop of a larger societal setting. Therefore, moral judgment may involve the coordinated functioning of several processes, such as reason, emotion, intuition, and intentionality, and may demand flexibility in thinking. In sum, the prefrontal cortex, especially the ventromedial prefrontal cortex may play a crucial role in moral decision-making process.

Moro Reflex

Jordana E. Mortimer, Denise E. Maricle
Texas Woman's University, Denton, TX, USA

Synonyms

Embrace reflex; Startle reflex; Startle response

Definition

The Moro Reflex is one of the infantile reflexes and is also known as the startle reflex. It is an involuntary response that is present prenatally and at birth, which then disappears between the ages of 3 and 6 months. The reflex is elicited when the infant is startled by a loud noise, the sensation of falling or other environmental stimuli. The reflex causes the infant to arch the back, extend the arms, legs and fingers (abduction), and in most cases to cry.

Description

The Moro Reflex is characterized by a two step process in response to startling stimuli. First, the arms and legs extend and move away from the body, the spine extends which causes the head to roll back, and the fingers will fan out while the thumb and index finger form the shape of a "c." During this initial phase, the extension of the spine may be so great that the infant may roll to one side. Next, the legs and arms will be brought back to center as if in the form of an embrace and the hands will become clenched; this physical response is then usually followed by intense crying [1, 11, 12]. The Moro Reflex can be seen as early as nine weeks in utero and a full response will become integrated between two and four months postnatally [4, 6]. As the central nervous system develops, this response should gradually disintegrate until only a simple body jerk is left in adults in response to startling stimuli [12]. Hunt [10] describes deterioration of this response occurring as early as 1 month, Mandleco [11] states that this response should disappear between 3–4 months, Berk [3] states 6 months, and McGraw [12] recommends that if this response occurs after 5–7 months then medical inquiry into development is needed. The Moro Reflex is considered pathological if displayed in older children or adults as it indicates neurological damage. This same concern is applicable if an infant does not exhibit the Moro Reflex completely or partially during the first few months of development.

This innate reflex serves as a survival mechanism for the infant (e.g., in response to a threat such as a fall it helps the infant cling to the mother) and it is thought to be the only unlearned fear response in humans [3, 12]. One of the main purposes of this reflex is the assistance it provides during child birth. The vestibular system becomes functional around 8 months of pregnancy which allows the baby to turn itself into the head-down position. Infants that have a defect in this system are more often born breech, or feet first. This occurs because the infant may have difficulty detecting its position in space [6]. Due to the timeline of the development of the vestibular system, the Moro Reflex is often absent in preterm infants [14].

Ernst Moro (1874–1951), an Austrian pediatrician, first discovered and described this reflex. Because of his contributions to pediatrics, this response was named in his honor [12]. Gordon [8] and Sanford [16] are credited with first using this reflex as a diagnostic tool, suggesting that a continuance of the Moro reflex into childhood was indicative of cerebral or pyramidal injury and an asymmetrical pattern was indicative of injury on that side or motor paralysis. Sanford [16] used this reflex to assess injuries to the clavicle bone. The Moro Reflex is still used in infant assessment today to assess neurological development and physical injuries [8, 9, 15, 17]. Damage to the brain or spinal cord may cause infants to have a complete or partial absence of the Moro Reflex. Other injuries such as a broken shoulder or clavicle bone, cerebral anoxia, Erb's palsy, and Erb-Duchenne paralysis may also result in a defect in the Moro Reflex in infants [14, 15]. A retained Moro Reflex in older childhood and adulthood can be an indicator of a wide range of disease processes including vestibular problems, damage to the brain and spinal cord, neuropathic lesion, maldevelopment of the pallidal area and the pyramidal tracts, and mental retardation. A retained Moro Reflex can also cause biochemical and nutritional imbalances, ear and throat infections, fatigue, and mood swings [4, 5, 12].

In addition to the traditional method of eliciting the Moro reflex by dropping an infant slightly through space, other methods include tapping the abdomen, cold or warm applications to the child's trunk, extending the legs at the hips, blowing on the face, and bumping the

crib where an infant lies [1, 10]. Purposefully eliciting this response should be performed only in infants who are suspected to have serious neurological abnormalities as it can be very distressing to infants [15].

Morpheme

Shelia M. Kennison
Oklahoma State University, Stillwater, OK, USA

Synonyms

Infix; Prefix; Suffix; Word

Definition

A morpheme is a word or part of a word that is the smallest meaningful unit; it cannot be divided into smaller units of meaning (e.g., *hopelessness* contains three morphemes: *hope, -less*, and *–ness*).

Description

A morpheme may be an entire word or a part of a word. When a morpheme is an entire word (e.g., *dog*), it is referred to as a free morpheme. When a morpheme must be added to another morpheme in order to be used, it is referred to as a bound morpheme. Morphemes that can be added to the beginning of words are referred to as prefixes (e.g., *re-* as in *rewrite*). Morphemes that can be added to the end of words are referred to as suffixes (e.g., *-less* as in *childless*). Both prefixes and suffixes are common in English. Other languages also have morphemes that can be added to the middles of words. Such morphemes are referred to as *infixes* [1]. When bound morphemes are added to a word, the resulting word may be the same part of speech (i.e., noun, verb, adjective, etc.) as the word to which the bound morpheme is added. Such bound morphemes are referred to as inflectional morpheme (e.g., *-s* as in *chairs* and *–ing* as in *singing*). When the part of speech of the resulting word is different from the part of speech of the word to which the bound morpheme is added, the bound morpheme is referred to as a derivational morpheme (e.g., *-er* as in *thinker* because *think* is a verb and *thinker* is a noun).

Research on reading comprehension has shown that when readers process words in sentences, they are processing the individual morphemes within the word. Research on reading in English has shown that words containing more than one morpheme take longer to read than words containing one morpheme [2]. Recent research has shown similar results for the reading of Hebrew [3] and Finnish [4]. These results suggest that the processes involved in identifying individual words involve a stage of processing in which the subcomponents of a word (or morphemes) are identified [5].

Languages differ in the average number of morphemes per word. Languages, such as Finnish and Hungarian, have high numbers of morphemes per word [6]. For example, in Finnish, words may contain two or more nouns that are joined together (e.g., *lumi* = snow, *lumlpallo* = snowball, *lumipallosota* = snowball fight, *lumipallosotatantere* = snowball fight field) [4].

Relevance to Childhood Development

As children acquire the grammatical rules of language, they learn how to use morphemes appropriately. For example, the bound morpheme re- can be added only to words that refer to an activity that can be repeated. Children somehow learn that the combinations *resleep* or

reknow are not typical usages. The acquisition of morphemes typically begins during the second year of life [7]. Research by Roger Brown in 1970s showed that morphemes are acquired in a specific order. The present progressive *–ing* and the plural *–s* are acquired first and second, respectively. Contractions (e.g., *he's* for *he is* and *she's* for *she has*) are acquired last [8].

Difficulty in using morphemes appropriately is common in young children. For example, most children produce overregularizations, such as *broked* or *mices*, in which they add a suffix to word that has an irregular form. Overregularizations are normal and cease to occur as the child learns which words are irregular and do not take the suffix and which words are regular as do take the suffix. However, some individuals may have difficulties with morphemes throughout their life. These individuals may have a language disorder referred to as Specific Language Impairment (SLI). Because affected individuals often have family members with similar difficulties, SLI can be inheritable [9].

As children begin to learn to read, their awareness of morphemes may influence their performance. Recent research has shown that children with higher levels of awareness of morphemes (or morphological awareness) had higher levels of reading ability than children with lower levels of morphological awareness. This research also showed that reading ability was related to sensitive to the prosody of words. The children who displayed the highest levels of reading ability scored high on both morphological awareness and prosody [10].

Morphology

Linda R. Sealey
Oklahoma State University, Stillwater, OK, USA

Synonyms

Grammar; Syllable structure; Syntax; Word structure

Definition

Morphology is the study of how words are formed through the combining of minimal, meaningful units of sound (morphemes) according to the word-sound rule system of a given language.

Description

Morphology is the study of the rules that tell how meaningful sounds (morphemes) are combined into words and have meaning in a language. A morpheme is the smallest meaningful unit of a language. Morphemes can be classified as free, bound, inflectional, and derivational. Free morphemes are units that have meaning and can stand alone, such as "is" or "cat." Bound morphemes are minimal units that must be attached to free morphemes to have meaning, such as plural "-s" in "cats." There are two types of bound morphemes, inflectional and derivational. Inflectional morphemes include bound morpheme forms that change the word to which it is attached by plurality, possession, tense, or degree. An example of an inflectional morpheme is the "*-ed*" inflection added to "jump," indicating past tense by forming "jumped." The seven inflectional forms in English are: plural "*-s*," possessive "*-s*," third person singular "*-s*," past tense "*-ed*," past participle "*-en*," present progressive participle "*-ing*," comparative "*-er*," and superlative "*-est*." A derivational morpheme is a bound morpheme form that changes the grammatical class of the word to which it is attached. An example of a derivational morpheme is the "*-er*" inflection added to "jump," changing the verb "jump" to a predicate adjective in "*He is a jumper*." There are 14 morphemes that are *grammatical* morphemes in English. These were identified by Brown [3] as important in language development based on the diary accounts of three young children's spontaneous language production. The 14 grammatical morpheme forms are: present progressive "*-ing*," prepositions "*in*" and "*on*," plural "*-s*," past tense irregular verbs, possessive "*-s*," uncontractible copulas, articles, regular past tense "*-ed*," regular third person singular, irregular third person singular, uncontractible auxiliary, contractible copula, and contractible auxiliary (see Table 1 below).

Morphology. Table 1 Rank order of acquisition of Brown's 14 grammatical morphemes [3, 4]

Rank	Morpheme	Example
1	Present progressive "-ing"	*Jumping*
2	Preposition *in*	*In*
3	Preposition *on*	*On*
4	Regular plural inflection "-s"	*Toys*
5	Past tense irregular	*Was*
6	Possessive inflection	*Mom's*
7	Uncontractible copula	*Is he here?*
8	Articles	*A, the*
9	Regular past tense	*Jumped*
10	Regular third person singular	*She jumps.*
11	Irregular third person singular	*He does.*
12	Uncontractible auxiliary	*Is she jumping?*
13	Contractible copula	*She's pretty.*
14	Contractible auxiliary	*He's tall.*

Development

Tracking children's understanding and use of these grammatical morphemes is a convenient and reliable method for measuring language development. As children learn the morphology of a language, they demonstrate understanding and use of grammatical morphemes. Therefore, the absence or disordered production of grammatical morphemes is often used as a marker for language disorder. In children who are typically developing, other areas of language, such as sentence structure and vocabulary, usually become more complex, or more adult-like, as they incorporate morphological units into the language they use to make their thoughts, ideas, and wants known (expressive language). Morphological development is usually measured by counting the number of morphemes, both words and grammatical morphemes, in each sentence or utterance, and is reported in a calculation of mean length of utterance in morphemes (MLUm). Though recent research has questioned the soundness of MLUm as a measure for development in grammatical morpheme usage [8], it is still commonly used as a measure of how children use language to make their wants and needs known, and continues to be considered a well-known and robust gauge of grammatical development to an MLUm of 4.0 [3, 12].

Morphological development in children who are typically developing appears to be generally predictable [3, 4]. Using language samples gathered repeatedly over time from the same children, Brown [3] documented the approximate order of acquisition of 14 grammatical morphemes, and found that acquisition of these markers mirrored increases in MLUm. A study by DeVilliers and DeVilliers [4] demonstrated a similar order of acquisition of grammatical morphemes (see Table 1). However, recent research has indicated that different children may have a slightly different order in which they develop these markers. Therefore, the child's achieved MLUm should be used only as a general sign of language development [7, 13]. The order and age at which a child begins to use a given grammatical morpheme appear to be influenced by how often the morpheme is used in the language the child hears on a daily basis [6] and the child's cognitive development and emerging world knowledge [1, 5, 9, 11].

Morphological acquisition is not an all or none proposition. Children first say a grammatical morpheme on only some words followed by a "spread" of the grammatical morpheme by attaching it to other words. Further, the correct production of some grammatical morphemes disappears from children's speech only to re-emerge in a later stage. For example, the first past tense grammatical morpheme to develop is the irregular past tense, as in "*went*." Rather than adding a morphological marker to a present tense verb as in regular past tense "*-ed*," irregular past tense verbs are single vocabulary words; each word's internal structure is unique, as in "*drank*," "*ate*," and "*thought*." Young children first produce a relatively small vocabulary of irregular past tense verbs associated with everyday actions they can see or know, as in "*sat, fell,* and *went*." It appears these first examples of irregular past tense verbs are learned as single words and are not associated with the present tense or other tenses of the verb; "*ate*" is not associated with "*eat*." During the developmental language period in which past tense "*-ed*" emerges, children overuse the past tense "*-ed*" by adding it to irregular past tense items previously learned, as in "*wented*." As children learn the rule of past tense "*-ed*" it is supposed that they "break the code" of when to apply the marker and to which forms it is applied [9–11]. Soon after which, they once again produce irregular past tense forms correctly, "*went*."

The order of acquisition, above, is presented as an approximate order of mastery of grammatical morphemes. It is important to know that toddlers can understand what these grammatical morphemes mean before they are able to use them in their speech; understanding precedes use [2, 9–11].

Motivating Operations

James K. Luiselli[1], Derek D. Reed[2]
[1]The May Institute, Inc., Randolph, MA, USA
[2]University of Kansas, Lawrence, KS, USA

Synonyms

Establishing operations; Incentives; Motivational events

Definition

Motivating operations (MOs) refer to a broad class of events that both increase and decrease the probability of behavior. These events function by changing the reinforcing value of stimuli and the behavior that has previously contacted these stimuli.

Description

Learning theory, specifically operant psychology, posits that a person's behavior is influenced by its consequences. Behavior is maintained when it produces pleasurable consequences (*positive reinforcement*) and avoids aversive consequences (*negative reinforcement*). However, the effects of positively reinforcing and negatively reinforcing consequences can change depending on a person's motivational state. Consider, for example, conditions of hunger and thirst. If a person has eaten a full meal, the reinforcing value of food is diminished. Similarly, after drinking a large amount, liquids will be less reinforcing. The converse of these conditions also is true: the reinforcing properties of food and liquid will be potent when a person has not consumed them between meals.

The preceding examples illustrate the concept of MOs. Essentially, a MO is any event, activity, or interaction that increases or decreases the effectiveness of consequences to function as reinforcement and the behavior that has been reinforced by those consequences. Some behavioral theorists have proposed that the term, *establishing operations (EOs)*, be reserved for manipulations that increase the reinforcing value of consequences, and the term, *disestablishing operations (DOs)*, be reserved for manipulations that decrease the reinforcing value of consequences. With this schema, EOs and DOs comprise the superordinate category of MOs.

In function, MOs involve momentary changes in states of deprivation and satiation. Using the example of socially reinforcing consequences, children are more likely to enjoy attention from peers and demonstrate behavior to attract such attention when they have been away from friends and classmates. Concerning parental attention, children may be less inclined to seek contact with their mothers and fathers if they have been with them all day compared to periods of separation such as being at school or summer camp.

Relevance to Childhood Development

Motivation is an essential concept in human psychology and child development. Various theories have been proposed to explain why children behave in different social contexts (family, school, athletic teams) and how to motivate exemplary actions. MOs represent an empirically testable principle to account for, promote, and predict behavior.

Synonyms

Drive; Incentives; Inspiration; Purpose; Reason; Stimulus

Definition

Motivation is defined as the instinctual drive to accomplish a task or goal and is an incredibly important factor in determination of behavior. Such tasks or goals range from satisfying hunger to obtaining a certain job or degree. Within developmental and psychological fields, three leading theorists behind the concept of motivation are David McClelland, Abraham Maslow and J. B. Rotter.

Theories

David McClelland presented a theory of motivation which is directly connected to individuals' needs for power, affiliation and achievement. His theory has become known as acquired-needs or learned needs theory. It is an individual's desire or lack thereof, for these three needs that drives their development and ambition over their entire lifespan [2]. Through his analysis of these three concepts, McClelland was led to develop a well known psychological needs assessment instrument entitled the Thematic Apperception Test. As children develop their need for primarily academic achievement, as well as athletic achievement, accompanied by the concepts of power and affiliation motivate their development in biological, cognitive, and emotional areas.

Abraham Maslow is best known for his concept of Maslow's Hierarchy of Needs. The premise behind the theory is that individuals, regardless of age, are motivated by their instinctual drive to satisfy certain needs and desires [1]. The initial needs individuals are motivated to meet are the basic physiological needs of food, water, shelter and clothing. As the basic physiological needs are met, individuals are motivated to fulfill or meet other needs or desires, in particular, according to Maslow, safety needs, love and belonging needs, esteem needs, and finally the need for self-actualization. It is only after the basic needs are meet that individuals strive for the ultimate goal of self-actualization. Children are no exception to these motivating principles. In order to meet the basic physiological needs, children are motivated to learn how to request or cry for food, water, shelter and clothing. As they grow, they learn to adjust in order to continue to fulfill these needs.

J. B. Rotter examined the ideas of internal and external factors of motivation. According to Rotter, **Intrinsic motivation** consists of internal factors within a person, which are defined as biological drives or instincts [3]. Intrinsic motivation is characterized as an internal desire to obtain the task or goal. The completion of such tasks or goals evokes a sense of satisfaction and accomplishment. For example, when a child is learning to play a new game, intrinsic motivation for doing so would be an internal desire to obtain a goal set before them for their own personal satisfaction or feeling of success. Additionally, accomplishing the task would bring a certain sense of accomplishment, which represents an internal or intrinsic motivating factor.

Extrinsic motivation represents the rewards or pressures found from external factors, such as the recognition received for completing a task or goal or the desire to avoid the disappointment that may surface from important individuals in a person's life should the task not be completed. Extrinsic motivators are thought to be more powerful than intrinsic motivating factors. Continuing with the example of a child learning a new game, parental pride, expectations of peers, or simply having a new game to play with friends would all represent extrinsic or external motivating factors.

Whether the motivation comes from intrinsic or extrinsic factors, a significant component behind the progression of motivation is the expectations of the individual, expectations of what will or will not occur should a task be completed or a goal reached. For example, in taking a standardized test, an individual's expectations for how they will or want to score motivate the level of studying and preparation, as well as the amount of anxiety experienced going into the exam. Motivation is only one factor, but is an incredibly important factor in determining behavior.

Motor Area of the Brain

Chad A. Noggle[1], Andrea R. Moreau[2]
[1]SIU School of Medicine, Springerfield, IL, USA
[2]Indiana Neuroscience Institute/St. Vincent's Hospital, Indianapolis, IN, USA

Synonyms

Primary motor cortex

Definition

The motor area of the brain, also referred to as the Primary Motor cortex, is localized to the Precentral gyrus of the Frontal lobe and is responsible for carrying out.

Description

The motor area of the brain may well be a misnomer, although some use this terminology interchangeably with the Primary Motor cortex. While the latter is localized to the Precentral Gyrus of the Frontal lobe and is seen as the key player in the carrying out of purposeful movement, the full gamut of motor behavior is the end result of the collaboration of this region with an array other structures and neuroanatomical regions [2].

As noted, from a functional standpoint, the primary motor cortex is responsible for modulating the fine details required to carry out purposeful movement [3]. Specific cells in this region are directly linked with specific spinal motor neurons and motor nuclei in the cranial nerves [1]. This connection presents as direct pathways between cells of the primary motor cortex and output of the peripheral system such that lesions of a specific area of the motor cortex will lead to a loss of voluntary control over the specific area of the body with which that area is linked. This is arranged in a contralateral fashion such that motor actions of the right are controlled by left hemisphere functioning and motor actions of the left are controlled by right hemisphere functioning.

Working closely with the primary motor cortex is the Premotor cortex. These regions together may be seen as representing the card catalog of the library of movement. In comparison to one another, the Primary Motor cortex regulates movements that are lower order than those of the Premotor cortex [2]. This is due to the Primary Motor cortex merely housing the movements whereas the Premotor cortex is entrusted with organizing the movement sequences [2]. The contribution of the Premotor cortex to motoric functioning is directly related to its connections with essential subcortical areas and structures, such as the Basal Ganglia, which are crucial to the refinement of motor coordination and organization [1]. Prior to the Primary Motor cortex and Premotor cortex initiating motor activity they receive neuronal instruction from the prefrontal cortex which is charged with the duty of mapping out/planning those movements to be carried out [2]. Throughout the motoric process, the motor areas of the brain and the somatosensory cortex are networked with one another providing a reciprocal line of communication between one another such that feedback from the somatosensory system may be integrated into the process thereby refining the motor action [3].

Motor Learning Difficulties

►Developmental Coordination Disorder

Motor Skills

Definition

A motor skill is a learned sequence of movements that combine to produce a smooth, efficient action in order to master a particular task.

Gross motor skills include lifting one's head, rolling over, sitting up, balancing, crawling, and walking. Gross motor development usually follows a pattern. Generally large muscles develop before smaller ones, thus, gross motor development is the foundation for developing skills in other areas (such as fine motor skills). Development also generally moves from top to bottom. The first thing a baby usually learns to control is its eyes.

Fine motor skills include the ability to manipulate small objects, transfer objects from hand to hand, and various eye–hand coordination tasks. Fine motor skills may involve the use of very precise motor movement in order to achieve an especially delicate task. Some examples of fine motor skills are using the pincer grasp(thumb and forefinger) to pick up small objects, cutting, coloring, writing, or threading beads. Fine motor development refers to the development of skills involving the smaller muscle groups.

Multicultural Education

Teresa Gonzalez
Queens College, City University of New York, Flushing, NY, USA

Synonyms

Cultural diversity; Diversity; Equity

Definition

Multicultural Education

Multicultural education refers to the process of educational reform that assures that students from all groups (e.g., racial, ethnic, socioeconomic, ability, gender) experience educational equality, success, and social mobility.

Description

As the diversity of our country continues to grow so does the number of diverse students entering our elementary and secondary schools. Multicultural education stems from the civil rights movements of the 1960s [2]. It is an educational strategy where students' cultures are used to develop effective classroom instruction and school environments. It supports the concept of culture, diversity, equality, success, and social mobility in the school setting. Sleeter and Grant [7] in their analysis of the phrase "education that is multicultural" stated that the entire education program should be designed to address the needs of diverse groups regardless of race, ethnicity, religion, exceptionality, or gender. This Social Reconstructionist approach strives to provide students with the skills necessary to become socially active ([2], p. 50).

Relevance to Childhood Development

Crushner, McClelland, and Phillip [3] suggest that developmental appropriate practice (DAP) involves providing learning environments, instructional content, and pedagogical practices that are responsive to the major attributes and salient needs and interest, which characterize and facilitate continuing development. This is accomplished through professional practices by educators who make constructive decisions about the education and

well-being of children based on: 1) what is known about child's development and learning. 2) what is known about the strengths, interests, and needs of each individual child in the group. and 3) knowledge of the social and cultural contexts in which children live. Thus, these changing dynamics require that teachers remain as learners throughout their careers.

The word *education* derives from the Latin word educare, meaning "to lead forth." It is important for educators to have a strong philosophy that guides their work in order to meet the challenges that diversity brings to the classroom. Hence, State and school districts expect teachers to have proficiencies or specific knowledge, skills and dispositions related to multicultural education by the time they finish their teacher education program. In working with students who come from different ethnic background, racial language, religious groups than the teacher, the development of dispositions that are supportive of diversity and differences is important. Students quickly become aware of the educators who respect their culture, believe they can learn, and value differences in the classroom [2].

Consequently, culture and language have become one of the most powerful factors in multicultural education. It helps to define who we are and influences our knowledge, beliefs, and values. In order to reach our students and "lead them forth" we must become "culturally sensitive," Giroux and Simon [4] spoke clearly of the importance of teachers understanding their own cultural identities and those of their students:

By ignoring the cultural and social forms that are authorized by youth and simultaneously empower and disempower them, educators risk complicity in silencing and negating their students. This is unwittingly accomplished by refusing to recognize the importance of those sites and social practices outside of the schools that actively shape student experiences and through which students often define and construct their sense of identity, politics, and culture ([2], p. 58).

Jodi Reiss [6] focuses on the importance of Language as a social construct. She states that its purpose is to communicate, in a process closely resembling First Language Acquisition children learning English communicate to make friends, participate in youth culture of sports, games, music etc. The following are some examples of some approaches and/ or strategies teachers may use in a classroom setting with diverse students:

- Through the process known as Natural Acquisition and by being immersed a English-language rich environment, students can develop language skills of everyday activities.
- As part of Stephen Krashen's [5] Five hypotheses, Monitor Model of Second Language Acquisition (SLA), he proposed the existence of an emotional filter, which influences how much actual learning takes place in relation to the comprehensive input. The Affective Filter can be conceived as the emotional wall that blocks input from reaching the brain. He states that the greater the self-confidence, the more motivation to learn. Ultimately; lowering the Affective Filter and allowing for more academic input.

Jim Cummins [1] mentions *scaffolding instruction* as a means of building upon student's prior knowledge. By tapping into a students' prior experiences we contribute to their cognitive demands in and outside of the classroom.

Merrill Swain's [8] concept of meaningful output has direct bearing on learning. The concept highlights the importance of small group interaction in long-term retention of both language and conceptual knowledge. Teachers can promote learning by choosing strategies that encourage students to negotiate meaning through paired or small group discussions.

Lev Vygotsky [9] *Zone of Proximal Development* (ZPD) which he defines as "the distance between" (a student's) actual development level as determined by independent problem solving, and the level of potential development as determined through problem solving under adult guidance or in collaboration with more capable peers. ([6], pp. 4–10).

In conclusion, in order to meet the multicultural educational needs of our diverse student population educators are empowering themselves and actively engaging students in the learning process. This is being accomplished integrating student experiences in and out of the classroom and providing them with the necessary tools to become socially active in a competitive environment.

Multifinality

Tasha R. Howe
Humboldt State University, Arcata, CA, USA

Synonyms

Developmental outcomes; Developmental pathways; Developmental trajectories

Definition

The concept that people can experience the same life events or have similar histories yet their developmental outcomes can vary widely.

Description

Multifinality literally means "many ends." This refers to people having similar histories (e.g., child sexual abuse, death of a parent, or a secure attachment history) yet their developmental outcomes can vary widely. For example, two children who were sexually abused could have very different outcomes despite extremely similar early experiences. One child might be well-adjusted yet another child might develop clinical depression. This concept is important because it encourages clinicians and researchers to examine entire developmental histories instead of only looking at symptom profiles. The field of developmental psychopathology (DP) brought this idea to light in its conceptualization of mental health and illness in children [1]. Researchers from the DP perspective de-emphasize a categorical diagnostic approach such as the traditional use of the DSM-IV. The traditional categorical clinical approach using the DSM-IV would require the child to have a certain number of depressive symptoms with a clear cut-off point for clinical relevance before treatment was warranted. Moreover, the symptoms must be present for a required length of time, in order for a child to be diagnosed with a "disorder" like depression. Using a DP approach, however, attention is focused on normal developmental tasks, such as the status of the child's attachments to caregivers, emotional regulatory abilities, and peer relations. If the child has failed to accomplish these normal developmental skills, prevention efforts might be implemented before a child's sad mood had the chance to develop into a diagnosable disorder. The changeability of symptomatology in children is emphasized from this perspective, and caution is directed at assuming that similar histories or profiles will inevitably result in similar symptoms or disorders later on. Thus, the concept of multifinality allows us to examine individual children's developmental trajectories in order to improve their developmental skills, rather than making generalized assumptions about how a certain type of child might "end up" [2].

Multimodal Therapy

Fatima Watt
Argosy University, Atlanta, GA, USA

Synonyms

Multibehavior therapy; Systematic eclecticism

Definition

Multimodal therapy is a form of psychotherapy developed by Arnold Lazarus. It focuses on reducing psychological suffering and promoting personal growth as rapidly as possible. Multimodal therapy is based on the idea that humans are biological beings that think, feel, act, sense, imagine, and interact. Each of these modalities is thoroughly assessed in therapy in order to achieve a comprehensive and holistic understanding of the client and his or her social environment [2, 3].

Description

Multimodal therapy posits that human personalities are the products of ongoing behaviors, affective processes, sensations, images, cognitions, interpersonal relationships, and biological functions (referred to as drugs/biology). The first letters of each of those modalities form the acronym BASIC I.D. The fundamental assumption is that BASIC I.D. encompasses the entire range of human personality. There is no predicament, affect, accomplishment, dream, or behavior that cannot be understood through BASIC I.D. Multimodal therapy focuses on specific difficulties within a given modality as well as the interaction between the modalities. The multimodal framework identifies individual problems along with factors that may be maintaining those problems. The clinician is then able to identify interventions by examining the interactive aspects of the identified problems [2, 3].

Arnold Lazarus developed multimodal therapy within the context of ►behavior therapy and, later, cognitive behavior therapy. Lazarus recognized that merely addressing behaviors and cognitions in therapy was not sufficient enough to impact the many areas of psychosocial functioning. This led him to expand the traditional models to integrate additional domains for assessment and treatment. This was known as broad-spectrum behavior therapy then multi-behavior therapy prior to being termed multimodal therapy [2, 3].

Theoretically grounded in ►social learning theory, the application of multimodal therapy relies on technical eclecticism, which is the practice of utilizing techniques from various sources without also adhering to the theories or disciplines from which they were created. Multimodal therapists use various techniques in their approach in order to effectively treat a wide range of problems and personalities. Treatment is tailored to the individual client and several methods are utilized in order to identify specific problems within the various BASIC I.D. modalities. Specific therapeutic interventions are created for each identified problem through the processes of tracking and bridging. Tracking allows the therapist to determine the interactive effects across the BASIC I.D. in order to establish the sequential order of the client's cognitions, images, sensations, and behavior. Each client has a different sequential order or "firing order," which will call for a different corresponding set and sequence of treatments. The client is asked to note all stimuli and events that precede and accompany any negative emotional reactions in developing the firing order. In a parallel process, called bridging, the therapist is attuned to the client's primary modality and will access the primary modality to obtain reactions in another modality. Multimodal therapists are expected to consult relevant research and favor research based techniques over non researched based techniques [4].

Multimodal therapy has been applied and adapted to the treatment of children and adolescents. In Keats's adaptation to children [1], the BASIC I.D. acronym shifts to the HELPING acronym. The seven HELPING modes are those of Health, Emotions-feelings, Learning-school, People-personal relationships, Imagination-interest, Need to know-think (Notions), and Guidance of acts, behaviors, and consequences. While the HELPING modes are the same as the BASIC I.D., the HELPING acronym is particularly useful in communicating concepts to parents, teachers, and children. The multimodal approach allows the therapist to systematically assess and formulate the child's problems in order to determine where the child is primarily experiencing his or her difficulties. Using the HELPING acronym as a map, the main therapeutic task is to determine which interventions can be utilized in order to improve the child's difficulties. Common treatment goals, addressing each of the seven HELPING modes, include, but are not limited to: appropriate diet and exercise; expression of feelings, joy attainment, and anxiety management; auditory appreciation, motor coordination, study skills, and sensory awareness; getting along with other children and communicating with adults; developing self-worth, awareness of imagery, and meditation; improving decision making and identifying irrational ideas; and attention-paying and assertiveness training [1].

Multiple Intelligence

Anne Fierro Vanderlaan
Saybrook University, Meridian, ID, USA

Definition

Howard Gardner's theory of multiple intelligences addresses the unique talents and gifts of children.

Understanding multiple intelligences can help clinicians look for and identify strengths, natural pathways for learning, and alternative avenues for working with patients. Through this identification, therapists can encourage greater self-awareness and self-acceptance, and they can open doors to alternative arenas where children can succeed.

Description

Gardner's [2] definition of intelligence comprises emotional, behavioral, and mental information processes put into motion by a cultural environment; in this environment, works are produced that are highly esteemed in culture (p. 33). These intelligences emerge and respond differently than the intelligence quotient as defined by traditional operational statistical classifications. Creative people such as weavers, painters, sculptors, and glass blowers are valued because of the artifacts they produce; performances by dancers, singers, and musicians are also respected. These kinds of intelligence are not recognized in traditional definitions, however. The multiple intelligences theory allows for greater respect of creative individuals and cultures by providing empirical data that validates disciplines previously rejected in individual intelligence assessments [1]. Gardner also examined cognitive profiles of all kinds of people, including those with special needs such as learning disabilities, autism, and savant syndrome. The assessed children had extreme problems living; they might be considered cognitively unstable and possessing low intelligence, yet these children might have other strengths not manifested previously ([1], p. 8). Gardner compared how these same children would be measured using IQ assessments; such children would be considered cognitively jagged. According to Gardner, IQ tests only measure logical or logical-linguistic capacities. In this society, we are nearly "brainwashed" to restrict our notions of intelligence to the capacities used to solve logical and linguistic problems ([1], p. 14).

Howard Gardner's Theory of Multiple Intelligences

Howard Gardner to date suggested that there are eight intelligences; these intelligences are as follows:

1. Musical: Children with musical intelligence often sing or tap out beats. They are more aware of sounds and will notice sounds that most people do not. Musical children are discriminating listeners and hear music in mundane sounds.
2. Linguistic: Children with linguistic intelligence excel at reading, writing, storytelling, and doing word puzzles.
3. Logical-mathematical: Children with this type of intelligence are interested in patterns, categories, and relationships. They are good at solving mathematic problems, conducting science experiments, and playing strategy games.
4. Body-kinesthetic: These children process knowledge through their senses. They usually excel at athletics and dance.
5. Spatial: These children think in images and pictures. They are sometimes good at mazes and jigsaw puzzles. These children spend time drawing, building (with blocks, Legos, or erector sets), and daydreaming. They also like to take things apart and put them back together.
6. Interpersonal: This type of intelligence cultivates children who are leaders among their peers. Communications with others comes easy for these children, and they understand others' feelings. They also understand others' motivations, and they are outgoing.
7. Intrapersonal: These children are introverted. They are aware of their own feelings, take care of themselves, and are self-motivated.
8. Naturalist: This type of intelligence allows children to distinguish categories within, classify, and remain in tune with the environment. These children like outdoor play, and they are likely to make good farmers, gardeners, botanists, geologists, florists, and archeologists.

Parents, friends, and teachers can observe these areas of intelligence. As Gardner [1] explained, "I believe that we should get away altogether from tests and correlations among tests, and look instead at more naturalistic sources of information about how peoples around the world develop skills important to their way of life" (p. 7).

Muscular Dystrophy

Definition

Muscular dystrophy is a group of inherited disorders that involve muscle weaknessmuscle weakness and loss of muscle tissue, which get worse over time.

Description

Muscular dystrophies, or MD, are a group of inherited conditions, which means they are passed down through families. They may occur in childhood or adulthood. There are many different types of muscular dystrophy. They include:

- Becker muscular dystrophyBecker muscular dystrophy
- Duchenne muscular dystrophyDuchenne muscular dystrophy
- Emery-Dreifuss muscular dystrophy

- Myotonic dystrophy

Symptoms

Symptoms vary with the different types of muscular dystrophy.

All of the muscles may be affected. Or, only specific groups of muscles may be affected, such as those around the pelvis, shoulder, or face. Muscular dystrophy can affect adults, but the more severe forms tend to occur in early childhood.

Symptoms include:

- Mental retardation (only present in some types of the condition)
- Muscle weakness that slowly gets worse
- Delayed development of muscle motor skills
- Difficulty using one or more muscle groups
- DroolingDrooling
- Eyelid droopingEyelid drooping (ptosisptosis)
- Frequent falls
- Loss of strength in a muscle or group of muscles as an adult
- Loss in muscle size
- Problems walkingProblems walking (delayed walking)

Mutism

Ivy Chong, Paula Wolfteich
Florida Institute of Technology, Melbourne, FL, USA

Synonyms

Deaf-mutism; Selective mutism

Definition

Mutism is a rare speech disorder in which the individual demonstrates the inability or unwillingness to speak.

Description

The term "mutism" refers to an individual who is mute and cannot or does not talk [1]. It is specifically applied to people who, due to profound congenital (or early) deafness, are unable to use vocal speech and thus, are diagnosed with ►deaf-mutism. The word "mutism" comes from the Latin "mutus" meaning unable to speak. In the Diagnostic and Statistical Manual of Mental Disorders–IV, ►selective mutism is described as a rare psychological disorder in children characterized by a consistent failure to speak in situations where talking is expected [2]. The child has the ability to converse normally, and does so, for example, in the home, but consistently fails to speak in specific situations such as at school or with strangers. The onset of selective mutism is typically before age five but it is often not formerly diagnosed until a child enters the school system. It is estimated that 1 in every 1,000 school-age children are affected by selective mutism.

Relevance to Childhood Development

Affected children are typically shy, particularly when encountering unfamiliar surroundings, situations, or unfamiliar individuals. Particularly in young children, selective mutism can be confused with an autism spectrum disorder [2], especially if the child acts particularly withdrawn around unfamiliar individuals, including clinicians. Unfortunately, this can lead to incorrect diagnosis and consequently, treatment. Individuals with selective mutism can often communicate normally when in familiar situations with familiar individuals or caregivers, as can many individuals on the autism spectrum. If a child is not speaking mainly in social situations (i.e., will speak in the home or with familiar individuals), this is likely not an autism spectrum disorder, but may be selective mutism. Additionally, it is important to note that children with selective mutism typically show normal growth in most developmental domains whereas children on the autism spectrum do not. Finally, nonverbal social engagement typically occurs in children diagnosed with selective mutism but not autism.

Myelin Sheath

Chad A. Noggle
SIU School of Medicine, Springfield, IL, USA

Definition

►Myelin sheath*:* Myelin sheath refers to a lipid-based, protein covering that encases the axons of the brain that helps improve the transmission of neuronal impulses.

Description

The myelin sheath within the central nervous system refers to the lipid-based covering that encases the axons of the brain that serves the primary role of speeding along, and thus improving, the transmission of neuronal impulses. The myelin sheath is to axons of the brain what rubber encasing is to telephone lines. In regards to the latter, the rubber encasing increases the speed of transmission and reduces the presence of static thereby improving overall transmission. Much in the same way, the myelin sheath of the brain speeds up neuronal communication by allowing for more continuous and rapid transmission of impulses [2]. It is this lipid-based covering that gives neurons their characteristic white appearance, thus resulting in the term white matter. The myelin sheath is formed by Oligodendrocytes in the CNS and by Schwann cells in the PNS [1]. This occurs by way of the projections of the surface membrane of both cells fanning out and coiling around the axon of neurons to specifically form the myelin sheath [3]. The process by which axons are encased in myelin is referred to as myelination. This process begins in some areas slightly before birth and continues until early adulthood. The pattern by which myelination of the CNS occurs follows an in-to-out and back-to-front progression. As such, myelination first onsets within the Spinal Cord followed then by myelination of subcortical regions and then on into cortical areas [3]. While white matter/myelin may be negatively impacted by a multitude of presentations, demyelinating diseases such as Multiple Sclerosis are most commonly associated with this occurrence as they lead to degradation of myelin within the system, thus reducing the efficiency of neuronal transmission in those areas and, in turn, leading to symptom manifestation.

Myelination

Chad A. Noggle
SIU School of Medicine, Springfield, IL, USA

Definition

Myelination refers to the process by which axons are enveloped in a myelin sheath, which is lipid-based covering that serves to improve neuronal transmission.

Description

Myelin refers to the lipid-based sheath that encases axons within the nervous system [3]. The relevance of this, from a functional standpoint, corresponds with the fact that this increases the speed and efficiency of neuronal impulse transmission by acting as an electric insulator that increases conduction velocity [4]. Metaphorically speaking, myelin is to axons what the rubber encasing is to telephone wires. It reduces static while increasing speed of transmission. Essentially, it ensures that the impulse gets from the beginning of an axon to the end [1]. The myelin sheath is white appearance which is the basis for the regions and axons that are heavily myelinated being referred to as white matter. Myelination is the process by which the axons are enveloped in this myelin sheath. Within the Central Nervous System Oligodendrocytes are responsible for the formation of Myelin whereas Schwann cells play this role in the Peripheral Nervous System [2]. It is the projections of the surface membrane of each of these cells that fans out and coils around the axons to form the myelin sheath [4]. In comparison to one another, where one Oligodendrocyte can form myelin sheaths around several axons in the CNS, one Schwann cell can only myelinate one peripheral axon [2]. The entire process of myelination takes some time and to some extent corresponds with cognitive maturation. During development of the CNS, as cellular migration is nearly complete, the process of myelination first beings [4]. From this starting point until the process is complete, which may not be until one is well into adolescence and early adulthood, the process of myelination follows a particular pattern. Specifically, myelination first onsets within the Spinal Cord followed then by myelination of subcortical regions and then on into cortical areas [4]. As a whole, the progression of myelination may be depicted as occurring in a back-to-front and in-to-out pattern. Given this it makes complete sense that those skills that are of the highest-order (e.g. abstract reasoning) do not emerge until adolescence and why behaviorally there is staunch differences between the behavioral inhibition abilities of a 10-year old in comparison to a 3-year old as such functional control relies on more anterior systems.

Narcissism

Mae E. Jesneck
Union Institute and University, Cincinnati, OH, USA

Definition

Havelock Ellis (1898; 1933 in Joines & Stewart) was the first person to use the term narcissism in a psychologically significant way, and he conceptualized it as autoeroticism.

Paul [10] used the term narcissism to describe the perversion of being preoccupied with the sight and pleasure of one's own body.

Sigmund [3] described narcissism as a normal phase of development between auto-eroticism and object-love. Later he described narcissistic libidinal type which corresponds to the current DSM description of Narcissistic Personality Disorder.

Description

The Freudian Theory of Narcissism

Freud suggested self-love might be a normal component of the human psyche, and might be the desire and energy that drives our instinct to survive. He called this: Primary Narcissism (Joines & Stewart).

According to Freud we are not born with a sense of ourselves as individuals, or ego. The ego only develops during infancy and the early part of childhood, as the outside world, usually in the form of parental controls and expectations, intrudes upon primary narcissism, teaching the individual about the nature and standards of his social environment from which he can form the ideal ego, an image of the perfect self towards which the ego should aspire (Joines & Stewart).

Freud regarded all libidinous drives as fundamentally sexual and suggested that ego libido (libido directed inwards to the self) cannot always be clearly distinguished from object-libido (libido directed to persons or objects outside of ourselves) (Joines & Stewart).

An aspect frequently associated with Primary Narcissism appears in an earlier essay, "Totem and Taboo" [3], where he describes his observations of children and primitive people, which he called "magical thinking." An example of magical thinking would be believing that you can have an effect on reality by wishing or willpower. This demonstrates a belief in the self as powerful and able to change external realities, which Freud believed was part of normal human development (Joines & Stewart).

Secondary Narcissism

According to Freud, secondary narcissism is a pathological condition which occurs when the libido withdraws from objects outside of the self. Freud further claimed that it is an extreme form of the narcissism that is part of all of us (Joines & Stewart).

Narcissism, Relationships, and Self Worth

According to Freud, to care for someone is to convert ego-libido into object-libido by giving some self-love to another person, which leaves less ego-libido available for primary narcissism and protecting and nurturing the self. When that affection is returned so is the libido, thus restoring primary narcissism and self worth. Any failure to achieve, or disruption of, this balance causes psychological disturbances. In such a case primary narcissism can only be restored by withdrawing object-libido (also called, object-love), to replenish ego-libido (Joines & Stewart).

According to Freud, as a child grows, and his ego develops, he is constantly giving of his self-love to people and objects, the first of which is usually his mother. This diminished self-love should be replenished by the affection and caring returned to him (Joines & Stewart).

Sam Goldstein & Jack A. Naglieri (eds.), *Encyclopedia of Child Behavior and Development*, DOI 10.1007/978-0-387-79061-9,

Relevance to Childhood Development

During the practicing sub-phase of the separation-individuation process [9], the child goes through a normal, healthy period of narcissism. During this time, the child feels he is the center of the universe, the world is constructed to meet his needs, all he has to do is cry, and people take care of him. This period of narcissism is critical for normal development of healthy self esteem [8].

Gradually the child's grandiosity is deflated as he experiences narcissistic wounding. He learns he is not the center of the universe and that he has to get his needs met in cooperation with other people getting their needs met. If this wounding does not happen, the child does not learn to accommodate the needs of others [8].

Narcolepsy

Definition

Narcolepsy is a chronic neurological disorder caused by the brain's inability to regulate sleep-wake cycles normally. At various times throughout the day, people with narcolepsy experience irresistable bouts of sleep. If the urge becomes overwhelming, individuals will fall asleep for periods lasting from a few seconds to several minutes. In rare cases, some people may remain asleep for an hour or longer. In addition to excessive daytime sleepiness (EDS), three other major symptoms frequently characterize narcolepsy: cataplexy, or the sudden loss of voluntary muscle tone; vivid hallucinations during sleep onset or upon awakening; and brief episodes of total paralysis at the beginning or end of sleep. Narcolepsy is not definitively diagnosed in most patients until 10 to 15 years after the first symptoms appear. The cause of narcolepsy remains unknown. It is likely that narcolepsy involves multiple factors interacting to cause neurological dysfunction and sleep disturbances.

Native Language Acquisition

►Language Acquisition

Nativist Theory

Kyle A. Litchfield, Matthew C. Lambert
Texas Tech University, Lubbock, TX, USA

Synonyms

Innate language acquisition; Nature vs Nurture debate

Definition

A set of theories which contend that human abilities and developmental processes are innate and hard-wired at birth. These theories inform beliefs about developmental processes most closely associated with initial language acquisition.

Description

Language acquisition is the study of the processes by which a person learns a language. Nativist theories hypothesize that language is an innate fundamental part of the human genetic make-up and that language acquisition occurs as a natural part of the human experience. Nativist theorists argue that children are born with an innate ability to organize laws of language, which enables children to easily learn a native language. They believe that children have language-specific abilities that assist them as they work towards mastering a language. This notion is often times contrasted to the behavioralist perspectives of Skinner and Watson who argued that language (i.e., verbal behavior) is an operant class of behaviors that are learned through modeling, then shaped and sustained through reinforcement processes. Under a behavioral framework external sources of development are considered most pivotal to language acquisition while a nativist framework holds that the process is much more internally driven.

Perhaps the most well known nativist theorist, Noam Chomsky, hypothesized that children are born with a hard-wired language acquisition device (LAD) in their brain. This idea was later expanded into the concept of "universal grammar," which maintains that most languages have quite similar basic underlying structures, and specific languages have rules that transform these underlying structures into specific patterns found in any given language. As children hear their parents speak they unconsciously recognize and assemble the rules for the particular language being acquired. Under this theory, the presence of "universal grammar" in the minds of children allows them to deduce the structure of their native language simply by being exposed to it.

Relevance to Childhood Development

Nativist theories posit that children are born with the innate ability to acquire language and thus are able to acquire and master the grammar of their native language by the age of three. Researchers who support nativist theories believe in the existence of a critical period of development, specific time frames which environmental exposure is needed to stimulate a congenital trait. Eric Lenneberg, a linguist and neurologist, believed that the critical period for language acquisition ends around the age of 12. Nativist theories support this notion and believe that if a native language is not learned before this age, it can never be learned in a normal, natural manner or to a fully functional state.

In addition, research on brain structure and neurological activity also supports the existence of a critical period, but postulates that the critical period for initial language development is much earlier than age 12 although this period may continue until age 12 simply with less significant neurological foundations. This research suggests that brain growth is rapid and expansive up to the age of two with children of this age possessing up to 50% more synapses than a normally developed adult. Furthermore this research establishes that until the age of seven, the number of neurological synapses in children is greater than that of adults. However, neurological researchers conclude that the period from birth to 2 years is the most critical period for language acquisition associated with brain structure. After this period, researchers suggest that motivation, opportunity, environment, and personality are more salient factors in language acquisition than the role of brain structure similar to the developmental processes associated with second language acquisition.

Natural Observation

Jessica Sparling, Ivy Chong
Florida Institute of Technology, Melbourne, FL, USA

Synonyms

Direct observation; Field observation; Naturalistic observation

Definition

Studying or assessing individuals as they interact in their typical environment.

Description

During an observation, there is no experimental manipulation, and data are recorded under the conditions that occur in the environment. Specifically, natural observation is a technique used in research and assessment, which is similar to direct observation, where information regarding an individual or individuals is gathered immediately while the individual's behavior occurs naturally their everyday environment, rather than a laboratory or clinical setting [1]. Information gathered during observations may be used in order to identify environmental variables necessary to create an artificial laboratory or clinical environment in which to assess or conduct research in, to identify areas which need assessment or research, or may garner the information necessary when research or assessment is being conducted.

While the methods in which information is gathered during observations vary, standardized methods have been developed, such as behavioral checklists. Methods of observations vary as well, sometimes occurring by video-taping an individual and recording data afterwards. However, most observations occur in real-time with the observer in the room, but the observer may be hidden or distanced from the individual(s) being observed in some way.

There are some problems with natural observation. For instance, although an observation may be structured, it is difficult to exert complete control over the environment. This means that the information gathered during an observation must be evaluated carefully, as it may not be possible to identify definitive relationships between an individual's actions and the environment [2]. Further, an individual's behavior may change solely as a factor of being observed, known as reactivity. This is often controlled by the observer being hidden from the individual, such as observing through a two-way window. Observer bias, or that an observer's information is gathered based on what they believe may happen versus what actually occurs, is another threat to the results of a natural observation. This is often controlled by two or more observers independently observing and collecting information. Information is then compared to ensure it is being collected consistently, referred to as inter-observer agreement. Further, the development and use of structured data collection tools, as well as an emphasis on operationally defining what is being observed, has diminished the threat of observer bias greatly in many instances. The

information garnered from an observation of an individual in their natural environment is often greatly useful and important, and oftentimes more valid than information gathered from more indirect measures, such as interviews, where the individual is never observed. As an individual's natural environment encompasses all the variables that may influence or affect an individual's behavior, observation in an individual's specific environment ensures that these variables are present, and important variables are not absent during observation.

Relevance to Childhood Development

Natural observation has become a cornerstone of researching, assessing, and evaluating the treatment of children's behavior. Observations of how children interact with each other and their environment are often conducted in order to gather information for research, whether conducting an experiment directly in the environment, or gathering information to assist in formulating hypotheses, structuring studies in laboratory environments, or validating data that had been gathered in a laboratory setting. Further, children are often assessed in the same way, through use of behavior checklists or similar assessment tools, in order to ensure that all variables that are present when a specific behavior occurs are also present during an assessment. Such assessments are often used in schools, and may be used for diagnostic purposes as well as assessments conducted prior to treatment [3]. The effectiveness of a particular treatment may be evaluated by conducting natural observations, whether treatment occurs in that environment, or evaluating the utility of a treatment to allow for behavior change outside of a clinical or laboratory setting. Natural observation has been used to study various behaviors of preschool children, children's development, and aggression, among many other subjects.

Nature vs Nurture Debate

►Nativist Theory

Nature vs. Nurture

Leah E. Johnson, Kyle A. Litchfield
Texas Tech University, Lubbock, TX, USA

Synonyms

Nature-nurture controversy; Nature-nurture issue

Definition

The debate over the extent to which development is influenced by a person's genetics or a person's environment.

Description

This controversy involves the question whether human behavior is predominately due to nature (heredity) or nurture (environment). Nature includes inborn biological information received from one's parents at the moment of conception. Nurture involves complex factors from the physical and social world that influence before and after birth. Those who stress the importance of nature point to the commonalities in growth and development across cultures. People typically progress through similar stages of development, from infancy to adulthood. Supporters of the nature perspective recognize that extreme environments can retard development, but also contend that basic developmental patterns are genetically programmed into humans. However, there are those who emphasize the importance of nurture in development, including environmental factors such as nutrition, medical care, physical accidents, family, schools, community, and culture.

Despite the age-old debate on this issue, most developmentalists agree that human development and behavior is affected by a combination of nature and nurture. For example, puberty occurs sometime between about age 9 and age 16 in every culture, with the timing being influenced by environmental factors such as diet.

No aspect of development is influenced solely by heredity or environment, but the interaction of the two. The question should not be whether nature or nurture influences development rather how these two influences interact together. Even though agree has been reached about the shared impact of nature and nurture, disparate theories still exist as the relative emphasis on nature or nurture.

Near-Infrared Imaging

►Near-Infrared Spectroscopy (NIRS)

Near-Infrared Spectroscopy (NIRS)

Marie C. McGrath
Immaculata University, Immaculata, PA, USA

Synonyms

Chemometric spectroscopy; Near-infrared imaging; Optical imaging; Optical tomography; Oximetry

Definition

A technique used to monitor changes in blood volume and oxygenation levels in living tissue through analysis of the properties of emitted and reflected light.

Description

The term *spectroscopy* refers to techniques that use light and its properties to analyze the chemical composition of various substances. Near-infrared spectroscopy (NIRS) uses light waves in the red and near-infrared (NIR) ranges of the light spectrum to monitor changes in oxygen and blood volume levels in human tissue. These light waves can harmlessly penetrate several centimeters into tissue prior to being absorbed or reflected; measurement of the wavelengths of the reflected light provides information on the degree to which various *chromophores*, or molecular units that absorb light, are present in the tissue.

NIRS techniques generally involve measurement of the chromophore *hemoglobin*, an iron-containing protein in red blood cells that transports oxygen from the lungs through the bloodstream for use by the body in energy-generating metabolic processes. Hemoglobin molecules that are actively involved in transporting oxygen in the bloodstream are sometimes referred to as *oxyhemoglobin*; non-oxygen-carrying hemoglobin molecules are known as *deoxyhemoglobin*. Oxyhemoglobin molecules in the bloodstream absorb more NIR light, but less red light, than deoxyhemoglobin. Therefore, more red-wavelength than NIR-wavelength light will be reflected by tissue that contains greater concentrations of oxyhemoglobin. These light absorption differences, which also account for the visible difference in color between oxygenated and deoxygenated blood, permit estimation of both oxyhemoglobin and deoxyhemoglobin levels in living tissue.

The pulse oximetry devices traditionally used in medical settings to provide measures of cardiopulmonary function represent a relatively simple use of NIRS technology. Generally affixed to a finger or an earlobe, a pulse oximeter shines light at multiple wavelengths into and through flesh. Detectors positioned on the other side of the finger or earlobe measure the intensity and wavelengths of the light transmitted through the tissue. By providing information on the relative concentrations of oxyhemoglobin and deoxyhemoglobin in the tissue, pulse oximetry indicates whether blood oxygen levels are adequate to support healthy tissue functioning. More recently, NIRS has been used to estimate levels of activity in the frontal regions of the human brain by measuring blood flow and oxygenation patterns in the prefrontal cortex; to

date, however, application of NIRS as a functional neuroimaging technique has occurred mainly in research, rather than clinical, settings. Additionally, a number of small-scale studies have examined whether this technology can be used to differentiate malignant tumors from healthy tissue, since tumors contain different concentrations of chromophores than surrounding tissue. While these studies suggest that tumor-specific NIR light absorption and reflectance patterns can be identified, further research is needed to examine the diagnostic utility of this technology.

NIRS seems to pose few health risks, since it does not involve the use of radioactive materials or cause damage to skin or underlying tissues. It has several practical advantages over more traditional neuroimaging technologies; specifically, it uses relatively inexpensive materials (such as LED light sources), is portable and lightweight, and permits subjects to speak, write, move, and assume a variety of positions while data are being collected. However, current NIRS technology also has several limitations. Data obtained via NIRS represent estimates, rather than absolute measures, of blood volume and oxygenation. Since NIRS measures physiological markers of changes in brain activation patterns, rather than actual neuronal activity, its temporal resolution is not as good as more direct measures of brain functioning, such as electroencephalography (EEG) or magnetoencephalography (MEG). Additionally, while NIRS offers good levels of spatial resolution, the utility of NIRS as a neuroimaging technology has, to date, been somewhat limited by neurophysiological differences among individuals, which make it difficult to reliably establish the precise location(s) in the brain associated with different activation patterns using NIRS alone. Finally, since the red and near-infrared light waves emitted by NIRS devices can penetrate only a few centimeters into brain tissue, the technology does not permit functional imaging of deeper layers of cortical tissue, or of subcortical structures.

Nearsightedness

Synonyms

Myopia

Definition

The inability to see objects at a distance clearly.

In people with myopia, the eyeball is slightly longer than usual from front to back. Light rays which make up the images you see, focus in front of, rather than directly on the retina, the light-sensitive part of the eye. When this happens, objects at a distance seem blurry and unclear.

Progressive myopia or nearsightedness is predominantly caused by genetics. Children inherit a tendency to develop the eye condition from their parents. The manner in which a person uses their eyes, such as often performing detailed or up-close work, may also have an influence on the progression of nearsightedness.

Nearsightedness in children is most commonly treated by corrective eye wear usually with glasses or contact lens. In some cases, depending on the severity of their myopia, when children reach adulthood, surgical procedure such as Lasik surgery can correct the myopia.

Nefazodone

Synonyms

Serzone®

Definition

A prescription medication FDA approved for the treatment of depression.

Description

This medication is a serotonin and norepinephrine reuptake inhibitor available as a tablet. This medication is no longer available as brand name Serzone®.

The recommended starting dose for this medication is 100 mg taken two times a day. Maximum suggested total daily dose is 600 mg. This medication should only be taken as directed by a doctor. This medication may need to be taken for four weeks before improvement in symptoms is seen.

This medication may be taken with or without food. Avoid drinking alcohol. Tell your doctor if you have a history of a seizure disorder or liver disease.

Concomitant use in patients taking monoamine oxidase (MAO) inhibitors is not advised.

Some side effects are listed here: confusion, dizziness, drowsiness, dry mouth, constipation, diarrhea, and trouble sleeping. Certain side effects may go away during treatment. Tell your doctor immediately if you notice the following: blurred vision, unsteadiness, ringing in the ears, skin rash, or itching. This medication may cause serious liver problems. Life-threatening liver failure has been reported in some patients taking this medication. Liver function tests may be required. Contact your doctor if you notice abdominal pain, vomiting, yellowing of eyes or skin, dark urine, or are feeling weak.

If you choose to stop taking nefazodone, you are encouraged to tell your doctor and slowly taper this medication to prevent withdrawal symptoms.

This medication should be stored out of reach of children and pets and away from light, heat, and moisture.

Relevance to Childhood Development

Nefazodone is not FDA approved for use in children.

A medication guide must accompany this medication containing information related to the increased risk of suicidal thinking and behavior in children, adolescents, and young adults compared to those not taking the medication. Doctors will monitor patients closely for worsening of symptoms, change in behavior, and thoughts of suicide. Patients are strongly encouraged to notify their health care provider to report sudden changes in mood, behavior, thoughts, or feelings.

Women should let their doctor know if they are pregnant or planning to become pregnant. It is not recommended to breastfeed while taking this medication.

Negative Academic Self-Evaluation

Timothy J. Cleary
University of Wisconsin-Milwaukee, Milwaukee, WI, USA

Synonyms

Maladaptive self-reflection; Negative self-evaluation standards

Definition

Negative academic self-evaluation is a type of self-reflection process in which students' evaluative judgments about task performance are inaccurate or maladaptive and or promote dysfunctional regulatory or motivation reactions.

Conceptual Framework

Most theories of self-regulation involve a self-evaluative component whereby individuals examine their performance outcomes and or progress towards personal goals [1]. From a social-cognitive perspective, self-evaluation does not occur in isolation but rather within a broader framework of forethought and reflective decision-making. For example, Zimmerman developed a cyclical model of self-regulation whereby regulated thought and action proceeds sequentially across three phases: forethought (i.e., processes that precede efforts to learn or perform; goal setting and strategic planning), performance control (i.e., processes occurring during learning efforts; self-monitoring and self-control), and self-reflection (i.e., processes occurring after learning or performance; self-judgments and self-reactions) [13]. Each of these regulatory phases has been shown to exert independent effects on students' academic achievement and behavior. However, the processes within these phases are interdependent, suggesting that as one process breaks down or becomes maladaptive there is a strong likelihood that others will be adversely affected.

Academic self-evaluation involves a process whereby students compare their current performance on an academic task (e.g., test performance) to some standard or

benchmark [13]. From a self-regulation perspective, engaging in this process is essential because it defines whether a performance was successful or not and thus initiates a more complex set of reflection processes, such as identifying the causes of one's successes or failures as well as the necessary strategic adjustments to improve future performance. It is quite common for most students to encounter situations throughout their academic careers when they determine that they are performing below expectations. Although these experiences are "negative" from a performance standpoint, they do not necessarily imply that students' engagement in self-evaluation is faulty or maladaptive. In other words, there is an important difference between negative performance information generated by the self-evaluation process and the use of negative or ineffective forms of self-evaluation. A primary focus of this paper will be to review the negative forms of self-evaluation and their primary determinants.

Self-evaluation represents the initial component of the self-reflection process. However, it is students' interpretations of and reactions to their perceived performances, and in particular failure, that cultivates adaptive or dysfunctional academic behavior. When students struggle in school, it is important for them to sustain a belief that they can control their learning and performance outcomes. Researchers often point to different motivation and regulatory processes that mediate the relationship between self-evaluation and evaluative reactions, with social-cognitive researchers citing self-efficacy as one of the key variables [7]. In short, when students begin to doubt their capabilities to perform specific tasks or feel incapable of managing the demands of school, they will often disengage from learning and will show decreased levels of interest and persistence. Another factor that links self-evaluation to maladaptive behavioral reactions following failure is causal attributions; the reasons students perceive as the causes of their performances outcomes [12]. For example, if a student fails two consecutive writing assignments in English class, typical attributions include low effort when writing, teacher difficulty, or even poor writing skills. Research has shown that when students are prompted to make attributions to factors that are controllable, such as strategy use and effort, they will exhibit more adaptive motivation beliefs and will have a greater likelihood of adjusting or modifying their learning methods in order to improve future performances; a process called adaptive inferences [2]. However, if students believe that the causes of their failure experiences are outside of their control, then they will have minimal incentive to put forth the necessary effort to improve or adjust how they are learning.

Along a similar vein, Dweck and colleagues present a model of achievement motivation that emphasizes how students' conception of intelligence or ability impact the goals that they select for academic tasks and their reactions to failure and success [4]. From this perspective, students can conceptualize intelligence from an entity or incremental theory perspective. Students who possess an entity perspective of ability view intelligence to be stable in nature and thus perceive mistakes and errors as indicators of poor abilities and competencies. These individuals tend to exhibit a more helpless-oriented response style to failure as they pursue low- difficulty tasks and will withdraw as academic activities become more challenging and intense. Conversely, students who possess an incremental conception of ability perceive intelligence to be a malleable construct that can change through effort and learning. These students tend to be more mastery-oriented as they embrace challenges and view failures as opportunities to grow and improve.

In short, the impact of students' self-evaluations on their motivational and regulatory reactions will often depend on various cognitive beliefs, such as self-efficacy, attributions, and conceptions of intelligence. Of primary concern in this paper, however, are situations when the actual self-evaluation process breaks down and or produces inaccurate or misleading information about one's abilities and skills. When students misinterpret their successes or failures the entire reflective process will invariably be affected.

Determinants of Negative Self-Evaluation

Most students will encounter situations in school when they perform in a negative manner; that is, they do not achieve up their potential or expectations. These situations are not ideal but they do represent important opportunities for students to both reflect on the adequacy of their learning methods and to modify these strategies to improve their achievement. However, one can only learn from self-evaluations when the information that is generated is accurate and valid. Unfortunately, there are a variety of factors that inhibit healthy self-evaluation and or distort the information that individuals self-generate during this evaluative process.

Proactive versus reactive evaluators. The extent to which students proactively set performance standards and monitor their progress towards these standards will greatly influence the nature of their self-evaluative skill. Social-cognitive researchers have differentiated between two types of regulators, proactive and reactive [14]. Proactive regulators naturally engage in forethought processes (e.g., goal-setting, strategic planning) *prior* to a learning

activity and continually monitor their behaviors and outcomes *during* learning. In contrast, reactive learners are much less aware of their personal objectives and their progress towards these ill-defined standards of performance. Teaching students to become more mindful of their objectives and learning behaviors promotes accurate self-evaluation because it establishes clear, identifiable benchmarks through which students can compare their performance outcomes. When students do not establish these criteria in an a priori fashion the process of self-evaluation becomes more variable and reliant on social comparisons. For example, suppose Deangelo, who is a seventh grade student at a middle school, has shown much difficulty passing his math tests for the past few months. He rarely thinks about his standards of performance, aside perhaps from general thoughts such as, "I need to do better." In addition, he is largely unaware of how he should prepare for math tests and thus tends to exhibit an inconsistent array of studying behaviors. Whenever Deangelo receives a test grade back from this teacher he either immediately shoves the test in his math binder or thinks about how incompetent he is compared to his classmates. This scenario illustrates a common theme with reactive regulators; that is, they either avoid engaging in the self-reflection processes needed to improve their skills or lack the structure or foundation from which to adaptively evaluate their math skills and performance.

In addition to developing performance standards in a forethoughtful manner, proactive learners will also frequently engage in *self-observation* during the learning process. In short, this process involves monitoring aspects of one's performance and the conditions that encapsulate it; self-recording is one common example of an overt observation technique [13]. Self-observation or recording is linked to self-evaluation because it provides a learner with detailed performance and process information that is needed to assess one's performance attainments. Research has shown that when elementary school children set performance goals and are taught to self-evaluate their capabilities over repeated sessions, a form of self-monitoring, students exhibited higher math skill and self-efficacy than those who did not engage in repeated self-evaluation [8].

Dimensions of self-evaluative standards. Simply becoming more mindful and proactive in one's approach to learning does not ensure that adaptive self-evaluation will unfold. One must also closely examine the nature of the standards that one uses in the evaluation process. There are several dimensions of performance standards that can adversely impact the accuracy and regulatory consequences of students' evaluative judgments, including: (a) type of evaluative criteria, (b) level of difficulty, (c) level of specificity, and (d) focus.

The performance standards that students select can involve one of several *types of evaluative criteria*, such as mastery, self or prior performance, and normative [13]. Mastery criteria consist of benchmarks that represent a wide range of skills or competencies, typically from a basic to a more advanced level. In contrast, the use of self or prior performance criteria involves using prior academic grades or attainments as the benchmarks to evaluate success or progress. Both of these types of criteria typically facilitate adaptive motivation and self-regulation because they direct students' attention towards personal progress and behaviors and or the essential features of relevant academic tasks. For these reasons, most applied self-regulation training programs emphasize one or both of these types of performance markers [5, 6].

In contrast, normative or social comparisons will often lead to maladaptive self-evaluations and reactions, particularly for children who struggle in school. A key limitation of this type of criteria is that it shifts students' evaluative judgments to factors that are typically not under their control, such as poor ability and peer performance. Social comparisons are also problematic because they can mask or obscure subtle signs of progress that students are making on an academic task. Consider an example of a fifth-grade student, Tony, who has gradually increased his science test scores by 12 points (i.e., from a 72 to an 84) over a two-month period. Despite showing some improvement, if Tony's science grades continued to fall consistently below that of his classmates and if he consistently relied on normative comparisons to evaluate his competencies, it is highly likely that he will not recognize this test grade improvement as progress.

Inaccurate or misleading evaluative information can also result when the *level of standards* that students use are excessively stringent. A rigid application of harsh standards can often be a reflection of metacognitive deficits, personality traits, or the presence of mood disorders. For example, research has shown that children who possess metacognitive deficits, such as those with learning disabilities, are often unaware of the skills and behaviors needed to successfully accomplish various academic tasks [11]. Furthermore, students with learning disabilities typically do not establish clear personal goals or standards of performance and when prompted to estimate task performance they often develop unrealistically high expectations. The development of extremely high standards of performance can also result from personality

characteristics, such as perfectionism. Although there are adaptive forms of perfectionism, researchers have identified *maladaptive perfectionists* as those who rigidly adhere to lofty expectations regardless of contextual demands and who exhibit harsh self-criticism and self-doubt regardless of their performance attainments [10]. Still further, individuals with mood disorders, such as depression, are often hypercritical of their performances and tend to underestimate the significance of their accomplishments. Although there is conflicting data about the precise nature of the relationship between depression and self-evaluation, there is evidence that depressed mood directly predicts changes in students' self-evaluation over time [3].

Regardless of the source or reasons for excessively harsh or unrealistic performance standards, students possessing these lofty benchmarks are particularly vulnerable to encounter repeated experiences of failure and to become enmeshed in a negative cycle of hopelessness, doubt, and feelings of inferiority. Moderately challenging standards of performance tend to produce adaptive self-reflection and evaluation because they promote demonstrations of mastery success and progress [14]. Suppose Deangelo, the seventh-grade student who was struggling on math tests, received grades of 62%, 71%, 55%, and 69% on his last four math tests. In an attempt to help Deangelo become more engaged in learning and to evaluate his math performance more effectively, his math teacher encouraged him to set goals for his math tests. Deangelo decided to establish a very difficult and challenging goal of 90%. Even if he showed some improvement on his next two tests (e.g., scores of 75% and 77%) there is a high likelihood that his excessively high performance standard would obscure this modest growth. Although many factors influence how a person ultimately reacts to failure, in this situation Deangelo would be susceptible to exhibit feelings of dissatisfaction, anxiety, and low self-efficacy because he did not come close to reaching his goal. However, if Deangelo elected to use a more modest yet challenging standard of 80% (i.e., 9 points higher than his previous high test score), there is a greater likelihood that he would have judged his test score of 75% and 77% in a more favorable manner. Over time, once Deangelo was able to attain or reach his standard of 80%, he should then be encouraged to make more stringent and challenging goals for future tests. The primary point here is that when the standards that individuals set for themselves are excessively high, they are less likely to see minor improvements or shifts in their performance. Interestingly, many researchers have shown that applied self-regulation interventions are often effective in helping students adopt more realistic performance standards in school and to more adaptively reflect on and evaluate their performance attainments [5, 6].

A third dimension of self-standards that can make evaluative interpretations vague and ambiguous is the *specificity* of the standard. A large body or research has shown that "do your best" or general types of standards are problematic because they make it more difficult for students to clearly recognize when progress or improvement is being made [9]. In order for the process of self-evaluation to facilitate or prompt the self-regulation feedback loop, standards must be clear and explicit. When vague or general standards are used as benchmarks to evaluate performance, students will often find it difficult to engage in subsequent reflective and forethought processes and will typically rely on social comparisons to evaluate performance.

Finally, the *focus* of performance standards has direct implications on the things that students attend to and evaluate following a performance outcome [8, 9]. In the social-cognitive literature a distinction is often made between process (learning) and product (performance) goals or standards. Process goals tend to focus on the tactics or strategies needed to perform or learn a task whereas product goals typically pertain to the outcomes of performance. Research with elementary school children across various academic domains has shown that when students are taught and prompted to focus on the process of learning rather than merely outcomes, they will often attain higher achievement and will display more adaptive motivation beliefs. Although researchers have questioned whether process goals are superior to performance or outcome goals in all situations and developmental contexts, it is widely accepted that process goals promote more adaptive self-regulation and self-directedness for children or for those who are first learning how to perform an academic task or skill [14].

Conclusion

In sum, most students will experience some type of failure or lower than expected performance during their primary or secondary school years. These "failure" experiences can serve as valuable opportunities for youth to evaluate and reflect on their approaches to learning and to hopefully develop more strategic and effective ways to perform at a higher level. However, at times, the self-evaluation information that students generate may be inaccurate or prompt them to make maladaptive regulatory and motivation reactions. In order to promote healthy forms of self-evaluation, students should be encouraged to not only become more aware of the

standards they hope to attain but to also rely on standards that are clear and realistic and direct their attention on their own behaviors, skills, and performance rather than on external factors or events.

Negative Reinforcement

Jennifer M. Alexander, Maria G. Valdovinos
Drake University, Des Moines, IA, USA

Synonyms

Parent behavior; Timeouts

Definition

Negative reinforcement is a behavioral process by which a response produces the cessation or reduction of an aversive stimulus, or postpones (either temporarily or permanently) the delivery of an aversive stimulus thereby increasing the probability of any future occurrence of the response [1]. For instance, in the mornings when the alarm sounds, one may hit the snooze button to temporarily terminate the buzzer. Over 6 months time, the number of times one hits the snooze button may increase from once a morning to five times before they get out of bed. There are two common forms of responding maintained via negative reinforcement: escape and avoidance. An escape response terminates the aversive stimulus [3]. For example, a child engages in off-task behavior (e.g., talking to a neighbor, jumping out of their seat) during math time which results in their being sent to the principal's office. This child has escaped an aversive stimulus (i.e., math). In the future, the child will be more likely to engage in off-task behavior during math. An avoidance response results in the prevention of delivery of the aversive stimulus. For example, a child may unload the dishwasher after a parent's initial request to avoid being repeatedly asked or reprimanded. Reinforcement, regardless of it being positive or negative, functions to increase the probability of a response be it a desirable or undesirable behavior [4]. However, there are some side effects to the use of negative reinforcement [2]. Since negative reinforcement procedures rely on the cessation or reduction of aversive stimuli or situations, an individual may avoid the situations altogether or one may develop other maladaptive behaviors (e.g., aggression) to escape or counter the controlling contingencies.

Neglect

Lindsay Weymouth, Tasha R. Howe
Humboldt State University, Arcata, CA, USA

Synonyms

Child maltreatment; Child neglect; Neglected children

Definition

Neglect is a type of maltreatment which occurs when a child's basic needs are not met.

Description

Neglect may include failure to provide educational, emotional, and/or physical necessities [1]. Educational neglect may include failure to enroll a child in school or ignoring special educational needs. Emotional neglect may include failure to provide adequate psychological support, failure to provide affection, failure to remove a child from situations of domestic violence, and/or failure to provide mental health care. Physical neglect consists of failure to provide shelter, abandonment, malnutrition, inadequate supervision, and/or failure to provide medical attention. Consideration must be made to a child's culture and socioeconomic status regarding failure to provide education, emotional, medical, or physical needs [1, 2]. Neglect may also occur in the presence of other forms of maltreatment such as emotional, psychological, physical, or sexual abuse.

In the United States [2], childhood neglect accounts for over half of all the documented cases of child maltreatment. Young children are more likely to be neglected than older children and adolescents. Neglect may be more common in single parent homes and in families who are poverty stricken. Mothers [2] overwhelmingly commit child neglect compared to fathers, perhaps due to their primary caregiver status.

Neglect may be chronic or acute and can have a multidimensional impact on a child's development. Young children who are neglected may show somatic symptoms such as headaches, bed-wetting, stomachaches, and ►enuresis. Gender may influence how older children exhibit symptoms of neglect, such as boys tending to be more aggressive and girls tending to exhibit signs of passivity and low self-esteem [2]. In general children may show physical symptoms such as failure-to-thrive, sleep disturbances, stomachaches, bed-wetting, ulcers, regression in developmental milestones, and stunted physical development due to poor nutrition. In addition to being aggressive or passive, children may also be hyperactive and show signs of incompetence. Neglected children may also show extreme dependence on teachers, lack of enthusiasm, change in academic performance, ►parentification of siblings, and/or learning difficulties. Cognitively, children may have delays in functioning, low self-esteem, and/or exhibit academic difficulties [1, 2]. If neglect is present at certain critical periods of cognitive development, a lack of sensory stimulation may adversely influence brain development [3]. Specifically, neglect may lead to the underdevelopment of the cortex in the brain as well as limbic system dysfunction [4].

Additionally, maltreated children may have insecure attachments to their caregivers and have problems with emotion regulation, which may lead to alterations in the ►hypothalamic-pituitary-adrenal axis, which affects stress regulation. Poor emotion regulation may influence children to show aggressive or withdrawal patterns with their peers. Without proper intervention and treatment, children who are maltreated may be affected well into adulthood. As adolescents and adults, they may abuse substances, show symptoms of psychiatric disorders, and engage in criminal behavior [2].

Treatment for children who have been neglected is often focused on their primary caregivers. Such treatment may include training in hygiene, finance, and family competence, counseling, and referrals to resources that may help the family. In addition, treatment may include child rearing classes and stress management training. Cognitive-behavioral treatment is most commonly used to teach caregivers self-management skills and modify problematic behaviors [2].

Child maltreatment; Child neglect; Neglect

Definition

Neglected children typically have caregivers who fail to provide for their basic needs.

Description

Neglected children are those whose basic needs are not met by caregivers. Maltreatment of children may take the form of educational, emotional, and/or physical neglect [1]. Caregivers may fail to meet education needs such as schooling or special education. Caregivers may be neglectful of a child's emotional needs, such as failing to provide adequate psychological support or affection and/or failing to remove a child from an abusive situation. Caregivers also may physically neglect their children including failing to provide shelter, abandoning them, causing malnutrition, or providing inadequate supervision [1, 2]. Consideration must be made for a child's culture and socioeconomic status in regard to providing educational, emotional, medical, or physical necessities. Neglect may also occur in the presence of other forms of maltreatment such as emotional, psychological, physical, or sexual abuse.

In the United States [2], childhood neglect accounts for over half of all the documented cases of child maltreatment. Young children are more likely to be neglected than older children and adolescents. Neglect may be more common in single parent homes and in families who are poverty stricken. Mothers [2] overwhelmingly commit child neglect compared to fathers, perhaps due to their primary caregiver status.

Neglect may be chronic or acute and can have a multidimensional impact on a child's development. Young children who are neglected may show somatic symptoms such as headaches, bed-wetting, stomachaches, and enuresis. Neo-Cortex

Randall R. Lyle
St. Mary's University, San Antonio, Texas, USA

Synonyms

Cerebral cortex; Cortex

Definition

The neo-cortex is divided into two hemispheres in the human brain. The brain is further subdivided into regions of specialization called lobes. These lobes represent specific areas where particular types of neurons have come together in order to fulfill specific functions such as language production or visual processing. The lobes are the frontal lobes, the temporal lobes, the parietal lobes and the occipital lobes. It is made up of six layers composed of neuron bodies, commonly referred to as grey matter. These six layers measure approximately 2–4 mm. The neo-cortex appears wrinkled with bulges, called gyrus (plural gyri) and the folds in between, known as sulci (plural sulcus). The neo-cortex is thought to be that portion of the brain which is responsible for most of the "higher" functions such as spatial reasoning, motor control, conscious thought, sensory perception and language. It represents about 76% of the volume of the human brain.

Description

The neo-cortex is the outer 2–4 mm of tissue surrounding the brain, an organ within the central nervous system (CNS). The tissue is made up of the body of neurons, which when viewed in the dissected brain appear to be grey. This has resulted in the neo-cortex being referred to as grey matter, as opposed to the myelin covered dendrites extending from the neuron's cell body, which appears white and is thus called the white matter of the brain.

The cortex is divides into two hemispheres, the right and the left. The right hemisphere is more involved in spatial processing, emotional regulation, abstract reasoning as well as motor movement on the left side of the body. The left hemisphere is responsible for logic, language, linear thought and factual memory as well as the motor movements on the right side of the body. The two hemispheres are primarily connected by the corpus callosum, a large tract of myelinated axons known as commissural fibers. The cortex is further divided into four lobes: the occipital, the parietal, the temporal and the frontal. While all of the functions of the cortex consist of a collaboration of the whole of the brain, each lobe serves some specialized functions. The occipital lobe is also known as the visual cortex and is the primary starting place for the processing of visual information and relaying it to the other areas of the brain for appropriate use and function. It is located at the back of the head. The parietal lobe sits atop the occipital lobe and a little forward. It is primarily responsible for processing sensory information. It is also known as the sensory motor strip. The parietal lobe takes the sensory information provided by all of the elements of the CNS and organizes and relays the information so as to organize appropriate action and preparation for movement. The frontal lobes extend forward from the parietal lobes to the forehead. The frontal lobes include the motor strip, responsible for organizes and initiating physical movement; the region between the motor strip and the prefrontal cortex which is largely responsible for regulating emotion and reason, fine motor skills and a portion of executive control function. The prefrontal cortex extends from the top of the forehead to the area above and behind the eyes. It is the primary executive control center for the whole brain. It facilitates the regulation of memory, behavior, many of our social skills and as a primary regulator of the overall organism. The temporal lobes are found on the side of the head extending from the posterior of the orbital prefrontal cortex back to the parietal and occipital lobes and below the

central motor strip and the sensory cortex. The temporal lobes manage much of the emotional processing, language, memory, hearing and general stability of the organism.

The cortex functions by a combination of electrical and chemical processes taking place in the specialized brain cells known as neurons. Neurons are comprised of a cell body, an axon hillock, axons, dendritic branches and terminal boutons. The balance of electrical charges in chemical ions found inside and outside of the cell body of the neuron at the axon hillock determines if an electrical signal will be generated within the neuron. When the chemical balance between the inside and outside of the neuron shifts as a result of the opening of channels in the cell membrane and electrical charge is created. When this charge is strong enough it is sent down the axon to the terminal bouton(s). Here are found vesicles containing neurotransmitters. The electrical charge causes the vesicles to release the required neurotransmitters into a space between the terminal bouton and the receptor on the adjoining neuron known as the synaptic cleft. If the neurotransmitter is taken up by the receiving neuron another electrical charge is generated in the receiving neuron which then proceeds out to other neurons, thus propagating the action potential and completing the various connections to fulfill the action, behavior, or task that was intended. An axon can have many branches and may synapse (connect) with up to 1,000 other neurons. At birth, children are born with over 200 billion neurons. As the infant ages and develops a process known a neural pruning takes place. The developing brain begins a process of forming, organizing and strengthening circuits in the brain for specific functions. As the circuit becomes fully formed, excess neurons are left unattended and eventually die. This process of circuit formation appears to result from a combination of genetic and environmental influences. By the age of approximately 25 the brain has completed its primary formational tasks and has about 100 billion neurons organized into intricate networks providing trillions of connections available every second of life.

Relevance to Childhood Development

The formation and refinement of the connections of the neo-cortex is a slow gradual process taking years to be fully accomplished. Negative influences, physical or emotional, can slow, interrupt, distort or prevent development at any stage of development including prenatal. For example, preventing exposure to language in the first three years of life will likely make the acquisition of language at a later date nearly impossible.

The gradual development of the neo-cortex means the children will develop gradually and slowly and thus will require appropriate assistance and formation at the different stages. Parents especially need to be aware of the stages of development in order to provide appropriate stimulation, environmental resources and emotional support and structure. Knowledge of the levels and stages of cortical development also allows care providers and educators to have realistic goals for performance and skill development.

Neonatal Behavioral Assessment Scale (NBAS)

Lydia Aydlett
Western Carolina University, Cullowhee, NC, USA

Synonyms

Brazelton NBAS; Brazelton scale

Definition

The Neonatal Behavioral Assessment Scale (NBAS) is an instrument designed to assess the neurological and behavioral functioning of newborn and very young infant. It assesses the infants' ability to tune out stimuli, to respond to visual and auditory stimuli, soothability, motor functioning and reflexes.

Description

In 1973, T. Berry Brazelton and his colleagues published the NBAS as a guide to help parents, health care providers and researchers understand the behavioral communication of infants from birth to tow months of age. The scale has 28 behavioral and 18 reflex items; these items do not yield a score, but instead describe multiple developmental areas and describe how the baby integrates these areas in reaction to environmental stimuli. According to Brazelton, newborns are faced with a hierarchy of four essential developmental tasks all of which are surveyed by his scale. The tasks are the regulation of their autonomic

systems, control of their motor systems, regulation of their states of consciousness and their ability to interact socially.

The autonomic nervous system regulates breathing, temperature, and other body functions; vulnerable, high-risk infants spend most of their energy trying to stabilize their autonomic system. Environmental stimuli may disrupt their breathing, and cause them to tremor or startle.

In striving to control their motor system, infants must inhibit random movements and control activity level in order to focus on other developmental tasks. The NBAS assesses the quality of muscle tone, activity level and reflexes.

The next sphere of development is regulation of state or level of consciousness. Infant states range from quiet sleeping to vigorous crying; however, the ability to maintain a quiet, alert state is key to the processing of and responding to environmental stimuli such as voices and faces. To assess state, the scale measures the baby's ability to habituate to repeated stimuli such as light and sounds, the number of transitions from one state to another during testing and the state that predominates during testing.

When regulation and control are possible in the autonomic, motor and state systems, the infant is ready to interact socially. The scale examines the infant's capacity to turn to voices and other sounds, to discriminate between sounds and to follow faces and objects visually and the infant's cuddliness and consolability. Brazelton concludes that newborns are ready to control their behavior in order to respond to the new environment, they are able to communicate through their behavior and they are social organisms ready to contribute to the dynamic social engagement between them and their caregivers.

The NBAS and its focus on infants' behavioral capacities has stimulated the creation of other tests. The most recent is the Neonatal Intensive Care Unit Network Neurobehavioral Scale (NNNS) with its more rigorous analysis of neurological, stress and regulatory behaviors has a more standardized format and wider application. The Assessment of Preterm Infant Behavior (APIB) developed with Heidi Als, Ph.D., Barry Lester, and Ed Tronick evaluates the neurobehavioral organization of premature infants. The Clinical Neonatal Behavioral Assessment Scale uses the format of the NBAS in order to help practitioners engage with parents through the examination of and demonstration their infant's skills.

NEPSY

Marie C. McGrath
Immaculata University, Immaculata, PA, USA

Synonyms

NEPSY-II; NEPSY: a developmental neuropsychological assessment

Definition

An assessment instrument used to measure neuropsychological functioning in children and adolescents between the ages of 3 and 16.

Description

The NEPSY is an assessment instrument designed to measure neuropsychological function and dysfunction in preschool and school-age children. Its name represents an abbreviation of the term "neuropsychology." The first version of the NEPSY was released in Finland in the 1980s; the instrument was revised and published for use in the United States in 1998 by authors Marit Korkman, Ursula Kirk, and Sally Kemp [1]. In 2007, the revised edition of the test (NEPSY-II) was published by PsychCorp, a brand of Harcourt Assessment, Inc., for use with 3–16-year-olds (representing an extension of the first edition's target age range of 3–12 years). The full name of the first edition of the test (NEPSY: A Developmental Neuropsychological Assessment) made the purpose of the instrument clear; the current edition of the test is titled simply "NEPSY-II," with no further explanation of the acronym contained in the revised test's name.

The NEPSY-II is based on the Lurian approach to psychological assessment, which emphasizes the interplay among complex cognitive functions. This approach involves isolating subcomponents of cognitive functions through administration of narrowly-focused assessment tasks, both to enable qualitative observation of individual patterns of performance and to determine the specific neuropsychological deficits underlying functional impairments. The instrument permits assessment of functioning in six domain areas: Attention and Executive Functioning; Language; Memory and Learning; Sensorimotor; Social Perception; and Visuospatial Processing. The test's authors state that the instrument can be used for several purposes: "a *general assessment* for an overview of a child's neuropsychological status, a *diagnostic assessment* based on the primary diagnostic concerns or referral questions, a *selective assessment* with the examiner selecting subtests based on clinical needs, and a *full assessment* for a comprehensive neuropsychological evaluation" (Korkman, Kirk, and Kemp, 2007, p. 2). Clinicians can choose to administer subtests representing all six domain areas measured, or can target specific areas more selectively. The test does not yield an overall score representing global neuropsychological functioning; rather, one or more scores (representing facets of performance such as patterns of correct/incorrect responding or similar/dissimilar performance across related tasks, as well as overall performance) are reported for each subtest administered. As with most psychological tests, users of the NEPSY-II are expected to have had graduate-level training in ▶psychometrics as well as in test administration, scoring, and interpretation.

NEPSY: A Developmental Neuropsychological Assessment

▶NEPSY

NEPSY-II

Matthew J. Holcomb, Andrew S. Davis
Ball State University, Muncie, IN, USA

Synonyms

NEPSY

Description

The NEPSY-II is a revision of the NEPSY [5] and is a developmentally based neuropsychological assessment

instrument designed to measure neurocognitive functioning of children between the ages of 3 and 16. At the time of this publication, no independent studies have been published. The original NEPSY does however, have some published research which may be pertinent to the NEPSY-II. The name NEPSY is a shortened version of the word "neuropsychology" and was chosen as it was considered to be child friendly. The NEPSY-II is similar to the original NEPSY in its theoretical framework as well as continuing many of the positive features of the original NEPSY, such as ease of administration, portability, and dynamic clinical utility [12]. The NEPSY-II is grounded in the theoretical framework of developmental psychology and neuropsychological theory and practice. The measure was designed with the idea of creating a broad neuropsychological measure based on the theories of Luria [8, 9]. For example, Luria was a proponent of independent evaluation of cognitive functioning for unique deficits; an idea that has been incorporated into the construction of the NEPSY-II. Korkman [4], one of the original NEPSY developers, believed that children were a good fit for this form of testing. For example, deficits in children's cognitive functioning typically are not seen in isolation from other deviant expressions such as behavioral problems or difficulty with academics. Children may display pathognomatic signs different from their adult counterparts; which helps to contribute to a lack of concretely defined neurological disorders in children [3].

A child's age is an important component to administering the NEPSY-II because it contains 32 different subtests; many of them are designed for use with specific age groups of children. For a more complete discussion and recommendations for subtest selection the *NEPSY-II Administration Manual* should be consulted [6, 7].

Psychometric Data

The reliability statistics for the NEPSY-II were calculated using a variety of methods based on properties of the individual subtests. For some of the NEPSY subtests, limited variability of functioning in normal children (e.g., tasks involving simple cognitive processes) yield a small range of scores. Additionally, due to the authors of the NEPSY-II designing their instrument to be as dynamic as possible there is difficulty in obtaining useful reliability scores across the test or age groups because subtest selection is highly dependent on independent examiners. The NEPSY-II has demonstrated stability across the six primary age groupings in retest data. Improvements in performance were seen, over time, primarily on the Memory for Designs, Memory for Faces, and Inhibition subtests but were not uniform for age across test of domains. All protocols during standardization were double scored for evidence of interscorer agreement. Results indicated interscorer agreement was very high and ranged from .98 to .99 on subtests with simple scoring criteria, and ranged from .93 to .99 on subtests containing more complex scoring protocol (e.g., Clocks, Design Copying).

NEPSY-II. Table 1 NEPSY-II Domains of Assessment with Corresponding Subtests

Domain	Subtest
Attention and executive function	Animal sorting
	Auditory attention and response set
	Clocks
	Design fluency
	Inhibition
	Statue
Language	Body part naming and identification
	Comprehension of instructions
	Oromotor sequences
	Phonological processing
	Repetition of nonsense words
	Speed naming
	Word generation
Memory and learning	List memory/delayed
	Memory for designs/delayed
	Memory for faces/delayed
	Narrative memory
	Sentence repetition
	Word list interference
Sensorimotor	Fingertip tapping
	Imitating hand positions
	Manual motor sequences
	Visuomotor precision
Social perception	Affect recognition
	Theory of mind
Visuospatial processing	Arrows
	Block construction
	Design copying
	Geometric puzzles
	Picture puzzles
	Route finding

Note: Table developed from the NEPSY-II clinical and interpretive manual [6, 7]

The NEPSY-II was standardized in combination with a number of other valid measures of children's abilities including the *Wechsler Intelligence Scale for Children-Third Edition* (WISC-III [14]), the *Wechsler Achievement Test – Second Edition* (WAIT-II [11]), the *Delis-Kaplan Executive Function System* (D-KEFS [2]).

Clinical Uses

The NEPSY-II provides the examiner flexibility in test selection which renders it a dynamic assessment tool. Many of the tests have been adopted from traditional neuropsychological tasks, but many of the tasks have been updated and improved with sound standardization and normative samples. The most common methods of assessment using the NEPSY-II are General Neuropsychological Assessment, Diagnostic Assessment, Selective Assessment, and a Full Assessment. The Diagnostic Assessment, which is a hypothesis based testing model, is the most unique feature of the dynamic assessment model and centers on six different diagnosis common to children such as Attention-Deficit/Hyperactivity Disorder (ADHD), Pervasive Developmental Disorders (e.g., Asperger's Disorder, Autistic Disorder), and academic disabilities (e.g., Language, Mathematics, and Reading).

Table 1 lists the domains covered by the NEPSY-II and the Subtests that correspond to those domains.

Interpretation of the NEPSY-II

As with all neuropsychological tests, caution in interpretation should be exercised. This is especially true for examiners who have not had extensive training in neuropsychological assessment. Clinicians familiar with many classic intelligence tests will recognize the format of the protocol cover sheet and the familiar easy to follow instructions contained within the administration manual.

Nervous System

Randall R. Lyle
St. Mary's University, San Antonio, Texas, USA

Synonyms

Autonomic nervous system; Central nervous system (CNS)

Definition

The nervous system is made up of the brain, the spinal cord, nerves and ganglia. The body's response to internal

and external stimuli is controlled by the nervous system. Neurons and glia are the two main types of cells which make up the nervous system. Neurons carry information from one place to another by means of bio-electrical and bio-chemical signals. Glia provide support for the neurons and significantly outnumber neurons.

Description

The general term, nervous system, is divided into two primary subdivisions, the central nervous system and the peripheral nervous system. The central nervous system (CNS) contains the brain and the spinal cord. The peripheral nervous system (PNS) contains all the neural tissue outside of the CNS such as sensory neurons that send and receive information to and from the muscles or those that relay information to or from the spinal cord or the brain. The brain and the spinal cord a extremely fragile structures so they are encased in bony structures. The brain is protected by the skull and the spinal cord by the spinal column. The brain sits in the skull surrounded by cerebrospinal fluid (CSF). This fluid serves as a shock absorber which helps to cushion the brain and protect it from damage when minor bumps occur. The CFS also serves as the medium for nutrition for the brain and the spinal cord. Glia cells form tightly packed boundaries between the brain and the body's blood. This is known as the blood brain barrier and it protects the brain from harm from toxins and infections that may be found in the body. The blood brain barrier also locks out many nutrients that the brain cells require for life. As a result, the CSF is the primary means of transport for the nutrients that the neurons and nerve cells need to function.

This represents the major divisions of the nervous system. The nervous system is further subdivided into 7 subsystems which can be found elsewhere in this encyclopedia. They are (1) the spinal cord, (2) the medulla, (3) the cerebellum, (4) the pons, (5) the midbrain, (6) the hypothalamus and thalamus, and (7) the cerebral cortex.

Neural Tube Defects

Edalmarys Santos[1], Chad A. Noggle[2]
[1]Middle Tennessee State University, Murfreesboro, TN, USA
[2]SIU School of Medicine, Springfield, IL, USA

Synonyms

Neural tube disorders

Definition

Neural tube defects refers to the array of developmental disorders and impairments that originate secondary to incomplete or faulty closure of one of the neuropores (i.e., anterior and posterior openings) of the neural tube which is the foundation of CNS formation.

Description

Neural tube defects are a grouping of birth defects that correspond with improper development of either the brain or spinal cord. Approximately 20–24 days after fertilization takes place, the embryo consists of a "primitive brain" that is merely a clustering of several sheets of cells referred to as the neural plate [3]. As development continues, the neural plate begins to fold in the middle creating a groove. As this folding continues to occur, eventually the two creases meet, leaving a hollow center and presenting in a cylindrical fashion, much like the cardboard tube inside paper towel rolls. This is known as the neural tube, which is the building block of the Central Nervous System, which includes the brain and spinal cord. Prior to the brain and spine developing the neural tube must close off at both the superior (i.e., top) and inferior (i.e., bottom ends). These openings are referred to as the neuropores. For successful growth of the brain and spinal cord to occur, these neuropores must close off completely and in the appropriate time frame. Neural tube defects refer to the spectrum of disorders and presentations that originate from incomplete or altered closure of these neuropores. As such, disorders are broken in to open and closed, meaning those that occur due to a neuropore not closing completely (i.e., open) or closing too soon or inappropriately (i.e., closed). In comparison, the open neural tube defects are far more common than the closed. In addition to this distinction is whether it is the top or bottom neuropore that is the sight of the dysfunctional closure.

Open neural tube defects include anencephaly, encephaloceles, hydranencephaly, iniencephaly, schizencephaly, and spina bifida. Incomplete closure of the superior (i.e., top) neuropore leads to disruption of brain growth and development. This is because the superior portion of the neural tube forms several swellings and outpourings in the head that eventually develop into the brain [1]. The degree to which the superior neuropore fails to close generally corresponds with the degree of brain growth disruption. For example, a complete lack of closure of the superior neuropore may lead to Anencephaly in which no brain develops. These fetuses cannot survive and often times are spontaneously aborted or must be surgically removed. Hydranencephaly, iniencephaly, and schizencephaly are additional open neural tube defects that occur secondary to incomplete closure of the superior (i.e., top) neuropore.

When the inferior (i.e., bottom) neuropore does not close properly or at an appropriate time, abnormalities of spinal cord development occur. Spina bifida constitutes an open neural tube defect in which there is incomplete closure of the inferior (i.e., bottom) neuropore [7]. Again, the degree to which the opening fails to close generally corresponds with the severity of lasting deficits. In regards to Spina bifida there are three variations that generally correspond with the degree of abnormalities in spinal cord development. Spina Bifida Cystica encompasses the two most severe forms, meningocele and myelomeningocele with the latter being the more severe of the two [6]. Spina Bifida Occulta is the least severe form and not only the most common form of Spina Bifida, but the most common form of neural tube defect in general, open or closed [6].

As previously noted, the closed neural tube defects occur when the neuropores close too soon or in an improper way which disrupts continued development of either the brain or spinal cord. For example, Holoprosencephaly occurs when the neural tube closes too early, before two cerebral vesicles, or cavities, are formed. With this defect, fused subcortical structures form, and there is a lack of olfactory structures [4]. Although most babies with Holoprosencephaly are stillborn, those who survive usually suffer from epilepsy and weakness of limbs [4]. Additional closed neural tube defects include lipomyelomeningocele, lipomeningocele, and tethered cord.

When the inferior (i.e., bottom) neuropore does not close properly or at an appropriate time, abnormalities of spinal cord development occur. Spina bifida constitutes a neural tube defect in which there is incomplete closure of the inferior neuropore [7]. Again, the degree to which the opening fails to close generally corresponds with the severity of lasting deficits. In regards to Spina bifida there are three variations that generally correspond with the degree of abnormalities in spinal cord development.

In regards to the etiology of the neural tube defects, they are largely multifactorial ranging from genetic influence, maternal health and metabolism, and environmental factors to name a few proposed factors. While some of these factors are uncontrollable to a certain extent, one area that has been shown to play a key role that can be controlled is maternal diet. The most commonly discussed preventive measure is folic acid supplementation during pregnancy. This recommendation comes from empirical findings that have found the risk of neural tube defects to be reduced approximately 50–70% by mother's using folic acid supplementation [5]. The basis for this positive effect is still not well understood only hypothesized. However, while the positive impact of folic acid supplementation is commonly highlighted, and prenatal vitamins are rich in it, oftentimes prenatal vitamin regimens are not started until 5–7 into the pregnancy cycle, which can be after closure of the neuropores would have taken place. As such, there have been recommendations that all females who are sexually active, and thus have the potential of becoming pregnant, should supplement their diet with folic acid if not prenatal vitamins. This has not been discussed in great detail as food fortification alone in the United States has cut the incidence of neural tube defects by 20% [2]; however, it is one way that some preventive steps may be taken.

Brain structure

Definition

Neuroanatomy is the description of the parts of the nervous system encompassing the brain, spinal cord, peripheral nervous system and nerves. It is often referred to as functional neuroanatomy and links the structures of the nervous system with their function.

Description

Neuroanatomy is the careful description of all of the anatomical structures in the nervous system. This includes all of the major and minor structures in the brain, the spinal cord and the nerves, the sensory and motor nerves as well as neurons and glia.

The major subdivisions of the brain are brainstem, made up of the Mid-brain, the Pons and the Medulla. Proceeding upwards towards the top of the brain, comes the Limbic system. The primary structures of the Limbic system are the parahippocampal gyrus, the hippocampal formation, the amygdale, and the hypothalamus. Within the brain is the Diencephalon which is made up primarily of the Thalamus. The cerebrum is divided into two hemispheres, right and left and four lobes. The lobes are the Occipital, located in the rear of the head; the Parietal, anterior to the occipital and stretching somewhat down the sides of the head; the Temporal, stretching along either side of the head just above the ears and forward to just in front of the ears; and the Frontal, found in front of the parietal about halfway across the front of the head forward to the region of the forehead and behind the eyes. The outermost 2–4 mm of the brain is generally referred to as the neo-cortex and is subdivided into six layers where the cell bodies of the neurons reside. At the back of the head and below the occipital lobe is the cerebellum.

The spinal cord proceeds down the back surrounded by the protective bony spinal column in humans. The spinal cord is divided into four major subdivisions, the cervical, the thoracic, the lumbar and the sacral, working from the brain stem downward.

Neuroanatomy further subdivides all of these divisions and subdivisions into an ever finer and more specific description of both structure and function resulting in hundreds of names. These names are associated with the epoch in which the discovery was made resulting in a mixture of modern and ancient languages, explaining why neuroanatomy is considered to be one of the most difficult and demanding specialties.

Neurogenesis

Randall R. Lyle
St. Mary's University, San Antonio, Texas, USA

Definition

Neurogenesis literally means the birth or formation of neurons. In children it refers to the process of the initial formation and localization of neurons as the brain itself is formed in the uterus. In adults it refers to the possibility of the formation of new neurons from stem cells within the already mature brain to both augment and enhance brain function or to replace damaged or dean neurons to restore lost function.

Description

At approximately the fourth week of gestation the human embryo has developed a neural tube which will eventually become the central nervous system. One end begins to form a bulb with a hole in the center which will become the brain surrounding the ventricular system. At about six weeks the nerve cells nearest the inside of the tube will begin to divide and increase in number and move outward. Neurogenesis is the process of more and more neurons being formed and moving outward to form the six layers of the cortex (the grey matter) and from there the

extension of axons to form the larger and denser white matter eventually resulting in a fully formed brain. Glial cells, which will provide the myelin sheath for faster communication between some neurons, will not become active until after birth.

Until recently, neuroscientists believed that humans were born with all of the neurons that they would ever have. Neurons died and unlike all of the other cells in the human body, they could not regenerate. However, recent studies have called this believe into question [2, 4]. It is now thought that stem cells residing in the adult brain may be able to differentiate into new neurons and, if they are able to make meaningful connections with other neurons, a limited number will become fully functional neurons. It is possible that this is the mechanism that makes antidepressant medications effective [5].

Definition

Neurons are cells which reside only in the brain. They are specialized cells used for the transmission of information from one part of the body to another and one part of the brain to another.

Description

While neurons can have a variety of sizes and shapes they are all similar in structure. All neurons have a cell body which contains the nucleus and organelles and which serves as the metabolic engine of the neuron. Attached to the cell body is a single axon arising out of the axon hillock. The axon carries messages out and away from the neuron. Each axon ends in a terminal bouton which has vesicles containing a variety of chemicals called neurotransmitters. An individual axon can end in thousands of terminal boutons, effectively significantly multiplying its ability to communicate with many more neurons. Incoming messages are relayed to the neuron by the dendrites. Neurons do not touch one another. Each neuron ends with a small space between itself and the next neuron. This space is called the synaptic cleft. The synaptic cleft may be the space between two terminal boutons or it may occur anywhere along the dendrite.

Neurons communicate with one another through a complex process of electrical and chemical activity. Changes in the number of differently charged ions on

the inside and the outside of the cell body causes a shift in polarity which becomes an electrical charge which is sent down the axon to the terminal bouton. Upon reaching the bouton, if the signal is strong enough, vesicles on the end of the axon release chemicals, called neurotransmitters, into the synaptic cleft. A process known as the synapse. If the neurotransmitter(s) are received by the next bouton the electrical signal is propagated in the next neuron and the signal continues until it reaches its intended destination. The longer axons are covered in Myelin. Myelin is a fatty substance which encircles the axon. Myelinated axons are able to transmit messages 50 to 100 times faster than non-myelinated axons. This combined bio-electrical/bio-chemical process is completed trillions of times a second and it is exclusively through this process that neurons fulfill all of the tasks required for life.

Neuropsychological Assessment

Mei Y. Chang, Andrew S. Davis
Ball State University, Muncie, IN, USA

Synonyms

Halstead-Reitan Neuropsychological Test Battery; Neuropsychological evaluation

Definition

Neuropsychological assessment is a procedure used to evaluate the behavioral and functional expression of brain dysfunction and identify the impact of ►brain injury or disease on the cognitive, sensorimotor, emotional, and general adaptive capacities of an individual. The primary goal of neuropsychological assessment is to provide information about an individual's functioning that will be useful in his or her environment [1, 2].

Description

Neuropsychological assessment focuses on biogenetic causes of cognitive, behavioral, learning, and emotional challenges through an examination of functional brain-behavior systems [1]. Neuropsychological assessment provides quantitative and qualitative data to describe these abilities in terms of the presence and severity of neurocognitive impairments and emotional-behavioral difficulties. Some of the neurocognitive domains that are generally assessed include cognitive processing, ►memory, learning, visualspatial ability, adaptive skills, attention and concentration, sensory-motor skills, and ►executive functions. In addition to standardized and ►norm-referenced tests, neuropsychological assessment also employs clinical interviews, behavioral observation, and information from other people who are involved with the patient to capture qualitative features specific to the patient's abilities to interact with the environment.

The goals of neuropsychological assessment are to diagnose disorders of the ►central nervous system; to provide consultation on the etiology, rate of progression, and prognosis of known or suspected cerebral pathology; and to offer recommendations, interventions, or referrals for the patient's treatment. Situations that may prompt a neuropsychological examination include differential diagnosis, patient care and planning, identifying treatment needs, evaluating treatment efficacy, research, and answering forensic questions [3].

Hebben and Milberg [4] outlined the uses of neuropsychological assessment:

- Describing and identifying changes in psychological functioning;
- Determining the biological correlates of test results;
- Determining whether changes are associated with neurological illness, psychiatric conditions, developmental disorders, or nonneurological conditions;
- Assessing changes over time and developing a prognosis;
- Offering guidelines for rehabilitation and vocational and/or educational planning;
- Providing guidelines and education to family and caregivers; and
- Planning for discharge and treatment implementation.

Minimum expectations of the neuropsychological tests are sensitivity to the presence of brain damage and the ability to distinguish correctly between the presence of brain damage and healthy brain functioning [4].

The amount of time required for a neuropsychological assessment varies greatly depending upon the patient's functioning and the referral question. After the assessment

process is complete, a neuropsychological report is generated to answer the referral question that consists of the reason for referral, the patient's relevant history and background information, the tests administered and their results, observations and conclusions, a diagnosis, and recommendations/interventions for further treatment. A follow-up interview/feedback session is usually conducted to review and clarify the information contained in the report with the patient and/or caregivers; to provide the patient with an understanding of the problems, and to educate the patient, the family, and the referral source about the condition and how the neuropsychological status relates to their future [3, 5, 6].

Neuropsychological Evaluation

►Neuropsychological Assessment

Neuropsychology

Tracey McLellan
University of Canterbury, Christchurch, New Zealand

Definition

A branch of psychology that studies the relationship between the structure and function of the brain and behavior.

Description

The science of neuropsychology is the branch of psychology that specializes in the study of the relationship between brain function and behavior. That is, neuropsychology is concerned with the evaluation of brain/behavior relationships and it provides a method of studying the brain by examining the behavior of an individual. The examination of brain-behavior relationships can inform a variety of clinical applications that seek to solve human problems. For example, a neuropsychologist may be involved in the planning of training programs to help an individual recover from a brain injury or they may implement strategies to minimize the effects of a brain injury. Neuropsychology is often confused with Neurology. Neurology is a specialist field of medicine that deals with the structural and physiological consequences of brain injury and disease. Neuropsychology deals with the cognitive and behavioral impact of such conditions. Neuropsychology is also known for its multidisciplinary nature because it operates across many areas in psychology and the health sciences.

The examination of brain-behavior relationships involves neuropsychological testing. This testing is a standardized, clinically established procedure designed to assess an individual's level of cognitive functioning. The testing procedure can help identify cognitive strengths and weaknesses' and the testing procedure is used to quantify the severity and scope of cognitive deficits. The quantifiable test data provides a clear picture about the cognitive status of an individual and can often be more useful than neuro-imaging procedures at identifying certain brain injuries. Neuropsychological testing is conducted both for research purposes and for clinical evaluation.

The science of neuropsychology emerged through the work of Paul Broca (1824–1880) and Carl Wernicke (1848–1904). Broca and Wernick identified areas of the brain that were responsible for the production and comprehension of language respectively. Broca described the case of a patient who had suffered a stroke in the left hemisphere of the brain and could only speak the word "Tan," although he could still accurately comprehend language. Broca described this case and others to show that the expression of language was localized in the left frontal lobe. The area of the brain that was injured (the third convolution of the inferior posterior frontal lobe) is now known as Broca's area. Individuals with damage to Broca's area have Broca's aphasia (deficits of speech). Several years later, Wernicke described cases in which patients had lesions of the superior posterior part of the left hemisphere and experienced impairments in the comprehension of language. Much other advancement has since been made in describing neuroanatomical systems that support other mental processes.

Relevance to Childhood Development

Child neuropsychology is concerned with the specific brain-behavior relationships of children. A Child (pediatric) neuropsychologist, for example, might examine how learning and behavior are associated with the development of brain structures and cortical systems. Neuropsychological testing of cognitive abilities such as memory and language skills can provide information about how the brain is developing. Comparing the test scores from one child with other children of similar ages helps develop a profile of the child's strengths and weaknesses. Such a profile can explain why the child might be having difficulties with academic achievement or specific academic achievements. For example, problems with reading may be due to attention difficulties rather than a language disorder. Neuropsychological testing can then inform interventions that capitalize on strengths and negotiate around weaknesses. Testing is also used to track the recovery of children from brain injury and detect the effects of developmental disorders, medical problems and treatment interventions. Child neuropsychologists commonly assess children for Attention-deficit Hyperactivity Disorder (ADHD), dyslexia, difficulties with maths, coordination problems, brain injuries, and developmental disorders. The neuropsychological evaluation is often more detailed than an ability assessment and is it concerned with making assumptions about brain-behavior relationships.

Neuroscience

Randall R. Lyle
St. Mary's University, San Antonio, Texas, USA

Definition

Neuroscience is the study of all things related to the Central Nervous System and the Peripheral Nervous System. This includes the study of both the structure and the function of the brain, nerves, bio-chemical and electrophysiological processes using empirical and theoretical methods. The Society for Neuroscience was founded in 1969 and serves as an organization made up mainly of researchers and physicians active in the study of the brain and related neurosystems for the advancement of theoretical and practical knowledge of how this extremely complex systems manages its functions and for the discovery of ways to heal the system when it damaged by injury or disease.

Description

Neuroscience is the discipline dedicated to the study of the structure and function of the Central Nervous System (CNS) and the Peripheral Nervous System (PNS). Generally, Neuroscience is affiliated with the biological sciences although; in recent years the discipline has expanded to include cognitive sciences, artificial intelligence researchers, and philosophy of mind specialists as well. Early research in neuroscience was limited to forensic, animal and associational studies. That is to say knowledge was derived either by dissection of deceased persons and examining their brains for variations from "normal"; experimenting with animals; and associating functional changes in individuals before and after an injury to the CNS/PNS. Advances in neuroimaging (e.g., MRI, fMRI, TMS, SPECT and PET etc.) have significantly increased our ability to research neurological function as well as refine our understanding of its structure. As a result of the increasing knowledge about neurological function the fields of psychiatry, mental health counseling, social justice and human development are being encouraged to re-examine many long held convictions and beliefs.

Neurotransmitters

Lauren Connell Pavelka
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Acetylcholine; Chemical transmitters; Neuromodulators; Serotonin; Transmitter substances

Definition

Neurotransmitters are chemicals in the brain that stimulate the transmission of nerve impulses.

Description

In the central nervous system (CNS), neurons communicate with each other by sending chemical messages via neurotransmitters. These messages must travel from an axon, across the synaptic cleft, to the dendrite of an adjacent cell. In precipitating communication between neurons by activating receptors in adjoining neurons, neurotransmitters can be excitatory, inhibitory, or both. Increased excitatory neurotransmission can cause mania or seizures, while increased inhibitory neurotransmission can cause depression, stupor, or coma. Schizophrenia, for example, may be attributed to excess levels of dopamine, while depression may be caused by unusually low levels of serotonin. Most psychoactive drugs act upon neurotransmitters to improve function of the CNS.

Listed alphabetically, some principle neurotransmitters include: Acetylcholine, Adenosine triphosphate, Beta-endorphine, Dopamine, Dynorphin, Enkephalins, Epinephrine, Gamma aminobutyric acid (GABA), Glutamate, Glycine, Nitric Oxide (NO), Norepinephrine (noradrenaline), Serotonin (5-hydroxytryptamine), and Somatostatin.

Relevance to Childhood Development

Children who are affected by attention deficit hyperactivity disorder (ADHD), bipolar disorder, or other disorders in the CNS can often be treated with medication that targets specified neurotransmitters to improve CNS function.

Night Terrors

Robert Walrath
Rivier College, Nashua, NH, USA

Synonyms

Parasomnia; Pavor Nocturnis; Sleep terror disorder

Definition

The phenomenon, seen mostly in children, of sudden night time awakening in a state of extreme terror with an inability to be roused from sleep.

Description

Night terrors occur during Stage 3 or 4 slow wave sleep, which differentiates them from nightmares occurring during REM (rapid eye movement) sleep. Behavioral presentation includes screaming, crying, and, typically, descriptions of seeing or hearing frightening things. There are often physiological correlates including sweating, increased breathing, and increased heart rate. Sleepwalking may be evident in some children as well. Episodes may last 10–20 min, during which time the child cannot be awakened [2]. There is characteristically no recollection of the event, although some children may recall the emotion of fear. Night terrors occur up to 18% of children in some studies, usually between the ages of 3–12, and very infrequently in adolescence and adulthood. Fevers, stress and lack of sleep have been postulated as causal, with most episodes resolving spontaneously within a short time [1].

Nightmares

Laura Parres
California State University, San Bernardino, CA, USA

Synonyms

Bad dreams; Disturbed dreaming

Definition

Nightmares are vivid and dysphoric dreams that awaken the individual from sleep. Nightmares are defined as dreams with strong negative emotions which awaken the dreamer and are common during childhood. Nightmares are vivid and terrifying episodes in which the dreamer is abruptly awakened from sleep. Nightmares are strong negative emotions which awaken the dreamer and are common during childhood.

Description

A nightmare is a vivid and dysphoric dream that usually involves some imagined danger or threat to a child that awakens the individual from sleep. They may involve disturbing themes, images, or figures such as monsters, ghosts, animals or people. Common themes in nightmares are a loss of control and fear of injury. Typically nightmares occur in the middle of the night or early morning when REM sleep and dreaming are most likely to occur.

Relevance to Childhood Development

Nightmares are a common childhood phenomena. They are most common in preschool aged children 3–5 years old. During this period is the age in which normal fears develop and a child's imagination is very active. It is estimated that as many as 50% of children aged 3–6 years have experienced nightmares that disturb both their sleep and their parents' sleep.

Non-Normative Life Events

Theodora Koulenti, Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Synonyms

Atypical and major lifetime events

Definition

The term non-normative life events describe significant, unexpected and unpredictable events, for a particular individual, which do not follow the predictable developmental pattern of life-cycle.

Description

Non-normative life events are those that occur unexpectedly, such as natural disasters, loss of a family member and war. Even in cases that death or illness, in specific ages, are statistically considered normative, they are actually

non-normative. They are still unexpected and undesired events, associated with severe effects [5]. Non-normative events may be comprised of both negative and positive events, such as death of a beloved person or winning in a lottery. However, in both cases, they are unexpected and slightly related to chronological age [6].

Life-span developmentalists assert that individual development is deeply affected by age-graded, history-graded and non-normative factors. Features, such as timing, duration order, spacing and patterns of these events may modify the course of individual development. However, out of the three groups of factors influencing individual development (age-graded, history-graded and non-normative) non-normative events are the most unpredictable and can occur at any point of life span. Some of them may result in both permanent and long-lasting effects or in a temporary deviation from what is considered normative [1].

Even though today there is a debate going on about non-normative events, this is not something new. Non-normative events have occurred across the span of different historical periods, due to historical events, such as the French Revolution, Pre-Industrial Period and the period of Great Depression. These historical events resulted in unexpected life changes to a big number of people, such as diseases, early death and poverty [6].

Relevance to Childhood Development

Because non-normative events are unexpected, those who are affected have no opportunity to prepare themselves for the event. Since this kind of events usually occur only to a few people, they do not receive the appropriate support by others. People often have little experience of dealing with the specific non-normative event, they do not actually know how to respond, and therefore less community support resources are available [4]. Moreover, individuals experiencing non-normative life events are at risk of affecting their interpersonal relationships. This occurs because, when a new stressor evolves into people's life, prior strains are intensified, people feel the pressure of competing demands and they have limited available resources to deal with these excessive demands [5].

In the case of non-normative events, experienced in childhood, there is compelling evidence that they could cause serious long-term implications, especially when adverse life experiences are involved [2]. The childhood exposure to traumatic life events is strongly associated with undesirable patterns of physical and mental health outcomes.

As individuals grow older, the influence of non-normative events increases. Researchers explain that this occurs because, with increasing age, people might face losses over which they have no control and individuals often develop a helpless outlook. At the same time, as each individual has experienced a unique set of experiences, chronological age weakens as a predictor of developmental differences in adulthood [1]. In particular, recurrent traumatic events have been reported to reduce person's coping resources in later life and increase vulnerability to psychological and psychiatric disorders [3].

Intervention

Research evidence reveals that, in comparison to half-century ago, people in industrialized Western Societies are today facing an increasing number of non-normative conversions and events, such as early retirement, divorce and separation. Consequently, successful development often depends on people's ability to adapt to both normative but to non-normative changes, as well, through self-regulatory processes [6].

The exposure to non-normative life events, such as a divorce, requires high levels of social readjustment and efforts and it is positively related to high levels of illness rates. Furthermore, research studies have revealed that people facing unexpected and critical life events are at risk of negative development. For these reasons, researchers underline the importance of self-regulation for managing non-normative life events and changes and they highlight the significance of successful adaptation to unexpected changes in life. External stimuli are not the only factors influencing behavior but individuals' responses represent a different influential source for behavior and development. By the processes of self-regulation, in both normative and non-normative events, basic processes, such as goal selection, pursuit and disengagement are involved. In this way people become able to select appropriate goals that can be attained by effort and at the same time be able to restructure goals in cases in which non-normative events have emerged and goals have become unattainable. Therefore, in order for the adaptation, due to non-normative life changes, to be successfully managed, the development of self-regulatory skills is needed [6].

Within a more general framework of a family therapy perspective, an effective intervention for families that experience non-normative events needs to anticipate a deep understanding of the family processes and all the complexities involved, at different stages of the life cycle.

Nonverbal Learning Disability

Robert Walrath
Rivier College, Nashua, NH, USA

Synonyms

NLD; NVLD; Right hemisphere learning disability

Definition

A subtype of learning disabilities characterized by deficits in visual-spatial organization, nonverbal problem solving, adaptation to novel situations, and psychomotor skills, together with academic difficulties in the areas of arithmetic, written expression and, to a lesser extent, reading comprehension. These deficits tend to coexist with relative strengths in single word reading ability and verbal expressive ability. Children with nonverbal learning disabilities are often described as socially awkward and literal in their interpretation of verbal information, due to difficulties noticing and interpreting nonverbal social cues and other pragmatic aspects of communication. They are also described as physically clumsy and as having difficulty with bodily spatial orientation. Children with NLD often are described as having preoccupations and obsessions with certain subjects which they pursue exhaustively before moving on to another topic at some point. There is significant overlap in symptomatology between NLD and Asperger syndrome, leading to the suggestion that they both lie on a continuum of higher functioning autism disorders.

Definition
Norepinephrine is a neurotransmitter that is synthesized in the locus ceruleus and lateral tegmental areas of the midbrain and serves to modulate attention and regulate sleep-wake cycles as well as mood [1].

Description
Norepinephrine is a crucial neurotransmitter of the central nervous system (CNS) that has been linked to the regulation of mood, memory, hormones, cerebral blood flow, and motor behavior [4]. The breadth of functional responsibility held by Norepinephrine is directly related to the scope of its projections throughout the CNS. Primarily formed in the locus ceruleus, which is localized to the rostral pons near the fourth ventricle in the brainstem, Norepinephrine projections are found extending to various areas of the cerebral cortex, limbic system, RAS, brainstem, cerebellum, and spinal cord [1, 2]. Additional noradrenergic neurons with similar projections have also been found to originate in lateral tegmental areas of the midbrain [1].

As previously mentioned, Norepinephrine has been linked a number of functions; however, it is s role in mood regulation represents one area of particular interest. Specifically, Norepinephrine has been linked with both depressive and manic symptoms such that decreases in the activity of Norepinephrine neurons have been linked with some symptoms of depression whereas some symptoms of manic behavior may be related to increases in activity of these neurons [3]. In fact, the linked between decreased activity of Norepinephrine neurons and depression is such that some of the newer antidepressant agents (i.e., SNRIs) seek to inhibit the reuptake of Norepinephrine in order to increase the reserve of Norepinephrine within the system at a given time thereby improving mood.

Normal Curve

Russell N. Carney
Missouri State University, Springfield, MO, USA

Synonyms
Bell curve; Frequency curve; Gaussian distribution; Laplace-Gaussian curve; Natural distribution; Normal distribution; Probability density function

Definition
The normal curve is a theoretical, bell-shaped distribution thought to describe the frequency of occurrence of many natural phenomena, including such varied things as height, blood pressure, reaction time, and scores on cognitive tests. Further, it serves as a mathematical model for describing random events in probability and statistics. http://mathworld.wolfram.com/classroom/classes/ProbabilityandStatistics.html, retrieved on 8/29/08

Characteristics

History

Mathematician Abraham de Moivre published an article on the curve in 1733 as a way to approximate the binomial distribution. This account latter appeared in his book on probability theory, *The Doctrine of Chances* (1738). Another Frenchman, Pierre-Simon Laplace, made use of the curve in describing the distribution of random errors (1783), and continued his work in *Analytical Theory of Probabilities* (1812). In analyzing astronomical data, Karl Friedrich Gauss further described the mathematical properties of the curve in 1809. Later, Karl Pearson termed it the "normal curve." (The synonym, the "bell curve," is not to be confused with the controversial book, *The Bell Curve*, published by Hernstein and Murray [3]. This book dealt with the relationship between intelligence and class structure in the United States.)

The Formula

The normal curve is a family of curves defined by the formula:

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2}$$

This formula consists of real numbers (i.e., 2, pi, and e), parameters (the desired mean, μ, and standard deviation, σ, for the distribution), and the variable x. Symbols π (3.1415...) and e (2.718...) represent irrational numbers, with the exponents of base e being referred to as *natural* or *Napierian logarithms*. The fact that the mean and standard deviation can be of ones choosing is why this formula produces a family of curves (e.g., by design, T-scores have a mean of 50 and standard deviation of 10, whereas current Wechsler and Stanford-Binet IQ scores have a mean of 100 and standard deviation of 15). Substituting a value for x yields a value for the height of the curve on the y-axis, or $f(x)$.

All members of this family of normal curves have a number of common characteristics. First, they exhibit bilateral symmetry. That is, they are symmetrical about a line drawn through the mean, perpendicular to the x-axis. Second, the tails of the distribution are asymptotic, meaning that as they extend out to the left and right, they never quite touch the x-axis. Third, there are two points of inflection at which the curve changes from convex to concave, or vice versa. These inflection points are located at ±1 standard deviation units out on either side of the mean. Fourth, the total area under the curve is 1.0 (or 100%). Finally, for a given value on the x-axis (expressed in terms of standard deviation units above or below the mean), the cumulative area under the curve to that point stays the same.

The Standard Normal Curve

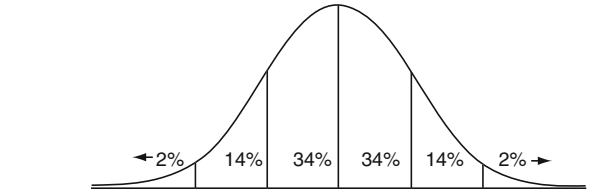
The *standard normal curve* is the specific case of the normal curve where the mean is 0 and the standard deviation is 1 [1]. In this situation, the equation simplifies to:

$$f(x) = \frac{1}{\sqrt{2\pi}} e^{-x^2/2}$$

Standard Scores and the Normal Curve

One cannot describe the relevance of the normal curve to child development without a brief discussion of standard scores. A sample of standard scores are positioned beneath a normal curve as shown in Fig. 1.

The height of the curve represents frequency of occurrence. Below the curve, the x-axis can be marked off in terms of the number of standard deviation units (σs) below or above the mean. Beneath these are laid out z-scores: −3, −2, −1, 0 (the mean), +1, +2, and +3, as well as Scholastic Assessment Test (SAT) scores. Likewise, IQ scores (e.g., as in current Wechsler and Stanford-Binet IQ tests) are listed: 55, 70, 85, 100, 115, 130, and 145 [2]. In the normal curve, these scores cut off fixed percentages of the cumulative area under the curve. For example, according to the normal distribution, approximately 34% of the population falls between the mean (IQ = 100) and one standard deviation above the mean (115). Further, adding the *total* area under the curve to the left of the 115 IQ score, one arrives at 84% (i.e., 50% to the left of the mean, plus 34%). Thus, according to the normal curve, an IQ score of 115 should be the 84th percentile, meaning that 84% of the population have an IQ score below 115. The percentile rank of *any* score on the x-axis



Std. dev.	−3σ	−2σ	−1σ	0	−1σ	−2σ	−3σ
z-scores	−3	−2	−1	0	+1	+2	+3
T-scores	20	30	40	50	60	70	80
SAT	200	300	400	500	600	700	800
IQ tests	55	70	85	100	115	130	145

Normal Curve. Fig. 1 Area and standard scores under the normal curves.

(be it z, T, IQ, etc.) can be derived from a table of areas under the normal curve, as found in statistics' textbooks.

Also, in the normal curve, about 68% of the population falls between −1 and +1 standard deviation units from the mean, approximately 95% falls between −2 and +2 standard deviation units out, and nearly 100% fall between −3 and +3 standard deviation units to either side of the mean.

Normalized Scores

It is important to note that, when testing companies norm tests (e.g., administer a newly-developed IQ test to students of different ages to produce normative data), the resultant distributions of scores are never perfectly normal [6]. So, test developers often *normalize* their data [4]. That is, they assign specific IQ scores so as to reflect normal curve expectations regarding areas under the curve. For example, say that a particular score on their new test was the 84th percentile in their distribution. Since the 84th percentile *should be* the score one standard deviation above the mean in a normal distribution, that score (whatever it was) will be labeled a 115. Thus, later on, someone interpreting that 115 IQ score would be correct in thinking of it as the score representing the 84th percentile. By definition, T-scores are normalized. Also, scores on the major IQ tests are normalized. So, too, are Normal Curve Equivalent (NCE) scores, which are used in Title I programs. However, simple t-scores, and college admissions tests, such as the SAT and ACT, are not. Thus, for example, an SAT score of 600 – while one standard deviation above the mean – does not necessarily indicate that 84% of the students performed below that score when that version of the test was administered. Hence, while one can usually assume normal curve percentages in looking at IQ scores, one must look at the reported percentile ranks that accompany the scores on other tests, such as college entrance tests like the SAT and ACT [5].

Relevance to Childhood Development

Assessment in Special Education

The primary relevance of the normal curve to childhood development is in the assumption of normality with regard to distributions of test scores, such as those resulting from intelligence tests. Over the years, for better or for worse, comparing a child's IQ test performance against the normal curve has been a systematic way of looking at individual differences and classifying children for special education services. Historically, below an IQ score of about 70 (i.e., a score more than two standard deviations below the mean), children began to be classified as mild mentally handicapped, with lower and lower scores defining increasing degrees of mental retardation (i.e., mild, moderate, severe, and profound, respectively). Similarly, scores on standardized measures of adaptive behavior (competencies outside of school) are compared against the IQ score, with an eye toward agreement between the tests.

Likewise, at the high end of the distribution, IQ scores based on the normal curve are used to identify children for gifted programs. Here, the cutoff IQ score required for such programs tends to be around 130 (two standard deviations above the mean); however, cutoff scores vary widely depending on state and/or school district criteria.

Further, children's learning disabilities are often identified by examining discrepancies between IQ and achievement test scores. Differences between the scores are quantified in terms of standard deviation units (e.g., a difference of 1.5 standard deviation units). Again, such scores (and standard deviations) have their foundation in the normal curve.

A more general way that the normal curve is related to assessment is in the practice of *grading on the curve*. This grading approach suggests that certain percentages of grades are expected at the various levels of A, B, C, D, and F. While not precisely wedded to the expectations of the normal curve, this technique none-the-less reflects the impact of the normal curve our view of how to assign grades in the classroom.

Some other Implications

Beyond school-related assessment issues, the normal curve relates to child development in a variety of ways. For example, consider the "No Child Left Behind" (NCLB) Act of 2001. This act seems to ignore the implications of the normal curve. That is, NCLB suggests that *all children*, regardless of where they fall in the distribution of mental abilities, are to keep pace with their classmates.

Other psychological constructs, such as depression and personality, can be measured in terms of normalized scores, with excessive departure from the norm being quantified in terms of deviation units from the mean. Further, the interpretation of physical and health-related measurements make use of the normal curve. For example, physical characteristics, such as height and weight, can be analyzed based on the normal distribution. Indeed, infants and toddlers are routinely compared to tracking charts by which the child's height and weight can be compared to others of their age group. The variation within an age group is roughly comparable to expectations resulting from the normal curve.

Finally, while not emphasized here, the concept of the normal distribution and assumptions of *normality* are pervasive throughout the fields of probability and statistics. Research conducted in the fields of child behavior and development rely heavily on statistical tests to evaluate their findings in terms of statistical significance. http://www.psychstat.missouristate.edu/introbook/SBK11.htm, retrieved on 8/29/08.

Synonyms

Age equivalents; Grade equivalents; Percentile ranks; Scale scores; Standard scores; Stanines; Status scores; T scores; Z-scores

Definition

Scores that provide a measure of an individual's performance relative to that of other individuals possessing similar characteristics.

Description

Unlike mastery-oriented or criterion-referenced tests, *norm-referenced tests* do not yield scores that indicate the percentage of questions that a test-taker has answered correctly, or whether the test-taker has demonstrated competency in the domains being assessed. Rather, norm-referenced scores indicate how a test-taker has performed relative to individuals in the test's norm sample. Generally, norm-referenced test scores are developed through mathematical transformation of *raw scores* (the number of points assigned to an individual's responses) on a test into either a *normal* distribution (often referred to as, and/or visually represented by, a *bell curve*) or a *linear* distribution (in which the shape of the raw score distribution is maintained, rather than smoothed into a normal curve) of scores. Transformation of raw test scores to normally-distributed scores is generally based on the assumption that the trait or skill being assessed (e.g., intelligence) is normally distributed in the

population targeted by the assessment, with most people demonstrating typical levels of performance and relatively few demonstrating significantly higher or lower than average levels of performance, and enables users of test scores to understand and interpret scores in light of the mathematical properties of the bell curve.

The most commonly used types of norm-referenced scores include: *percentile ranks*, which indicate the percentage of individuals in the norm group who obtained lower scores than that of the test-taker; *deviation IQ scores*, which have a mean of 100 and a *standard deviation* (a measure of the variability in a set of scores) of 15; *T-scores*, which have a mean of 50 and a standard deviation of 10; *scale scores*, which have a mean of 10 and a standard deviation of 3; and *z-scores*, which have a mean of 0 and a standard deviation of 1. [several of these terms, including the italicized terms and standard deviation, should have their own entries that can be linked] Since the mean and standard deviation remain constant for each of the score types above, it is possible to determine how a given standard score from any test compares to that obtained by the typical individual in the norm group for that test. For example, a T-score of 70 would be well above average, while a deviation IQ score of 70 would be well below average.

It should be noted, however, that norm-referenced scores alone cannot be used to determine whether or not a given score meets a predetermined standard of performance and/or mastery (i.e., criterion-referenced interpretation). It is theoretically possible for all, or none, of the individuals taking a certain test to meet a performance or mastery standard; therefore, one cannot draw conclusions regarding whether an individual has mastered a given skill simply because that individual performs more or less strongly than other individuals taking the same test. For this reason, it is inappropriate to use norm-referenced scores alone to determine whether individuals have made progress toward standards or goals.

Norm-Referenced Testing

Marie C. McGrath
Immaculata University, Immaculata, PA, USA

Synonyms

Standardized testing

Definition

A type of testing in which scores are derived through comparison of an individual's performance to that of other test-takers.

Description

Norm-referenced tests are designed to measure an individual's traits, behaviors, or abilities (e.g., cognitive ability, academic achievement, personality) by comparing the degree to which the individual demonstrates the trait(s) being assessed to others' functioning in that area. The group of individuals to which a test-taker is compared, often referred to as the *norm sample*, comprises individuals thought to be similar to the population of test-takers (i.e., the *reference population*) in one or more ways (e.g., age, sex, grade level, and/or presence of a clinical condition or diagnosis). Each test-taker's level of performance on a norm-referenced test is determined by comparing that person's performance against that of the corresponding norm group. Norm-referenced tests therefore yield ▶norm-referenced scores, rather than *criterion-referenced scores*, which denote performance relative to a predetermined standard or level of mastery.

Norms

Arthur E. Hernandez
Texas A&M University Corpus Christi College of Education, Corpus Christi, TX, USA

Synonyms

Average; Mean; Median; Midpoint; Mode; Normal; Standard

Definition

The standard, normal or average. What is considered typical or usual.

Description

Although the word *norm* has a variety of definitions depending on usage, for the most part, in terms of child development the word refers to the average and in many cases designates a benchmark for the state of maturity of a particular trait or capability. These benchmarks are often referred to as "developmental milestones" and serve to provide parents with useful standards against which to assess the healthy development of their children.

In terms of standardized testing, the norm refers to comparison group performance against which test takers will be assessed. In this case, the norm defines the average performance for the group often parsed by age or other characteristic trait in order to assure relevance. Norm groups are usually comprised of individuals chosen at random and in a manner that intends to be representative of subsequent test takers. This means that judging the usefulness of a particular score on a "norm referenced" test requires knowledge of the constitution of the comparison group and the recency of the data collection against which normative decisions will be made.

The word norm also describes a set of rules or social expectations that influence or determine particular behavior. These group expectations relate to usual or define "appropriate" individual behavior and derive their particular motivating impetus from the associated and consequent rewards or sanctions. Norms depend on group acceptance, adherence and enforcement.

Nuclear Family

Stacy A. S. Williams
State University of New York at Albany, Albany, NY, USA

Definition

A nuclear family is a family unit consisting only of a father, mother, and children.

Description

Most western societies continue to view the nuclear family as the traditional family, meaning a relationship denoted by a heterosexual, monogamous, and legally married couple (i.e., male and female) with children, living apart from relatives. This particular social structure is often taken to be the ideal social unit that all other family structures are measured against [1, 6]. Within this family structure, the male is often the breadwinner and the head of the household while the female is the homemaker and operates within a subordinate role to the husband. This particular family unit tends to be patriarchal in structure [5].

The nuclear family structure first arose among the wealthy class in northwestern Europe, and has endured, as some argue, as the dominant ideal from the Victorian

era in the West until the 1960s [2]. The nuclear family was seen as the result of a progressive evolution of family structures. This family structure was shaped by three underlying assumptions: romantic love, maternal love, and domesticity. During pre-modern periods, couples married based on family and community dictates. Couplehood was not an outcome of romantic love but of familial obligations. However, evolution of the family structure emboldened couples to choose one another based on mutual attraction. The maternal love sentiment assumed that women had a maternal instinct to take care of young children and that the raising of children was primarily their domain. The third sentiment, domesticity, assumed that relationships within the family were far more important and powerful than relationships outside of the family. As a result, the theories that were generated from this modern period elevated the benefits of the domesticity family structure over others [2].

Some argue that the nuclear family has been under pressure due to an increase in the divorce rate [2]. In 2007, 67.8% of American children lived in two parent households [6], a prominent decrease from 85% in 1970 [3]. Additionally, there are ethnic variations in family composition, with 87% of Asians, 78% of non-Hispanics whites, 68% of Hispanics, and 38% of Blacks living in households with two biological parents. Some scholars predict that, by age 16, 40% of American children's parents will divorce and that this percent will increase by 2% every year [3].

In today's society, the nuclear family is just one social composition of the contemporary and/or postmodern family. Contemporary families may consist of traditional nuclear families or many other types of immediate family relationships with or without children living in the same dwelling or living separately: single divorced parents, single unmarried parents, remarried families, unmarried partners, gay or lesbian partners, single adults, widows or widowers [1].

Though there are several family structures, the traditional structure is often used as the basis of comparison for other family types. Numerous studies exist that document the relationship between family structure and child well-being. Such research often points to the disadvantages for children being raised in non-traditional families. More times than not, research findings suggest that children from single parent families are more likely than their peers from two parent families to participate in risky behaviors and suffer health problems. In addition, children in stepfamilies as compared to their counterparts in two-parent families perform poorly in school, and have behavior and health problems. Additionally, research has documented that single parents are often stressed by economic strains and social pressures as compared to two-parent households [7].

While there are numerous studies documenting the disadvantages of non-traditional families, there are other studies indicating that the relationship between family structure and student outcome is far from predictive. Some of these studies have noted that family structure did not significantly influence student achievement [3, 4], finding that, regardless of family type, parental expectations were a much stronger predictor of student achievement than parental structure. Additionally, O'Connor, Miranda, and Beasley noted that student's ability was a stronger predictor of academic achievement than family structure [3].

In summary, the nuclear family structure comprising of a legally married man and woman with children is often viewed as the traditional family structure. Though this unit is often viewed as the ideal, it continues to be modified due to the increasing divorce rate and societal demands.

Nutrition

Eva D. Sloan
St. Mary's University, San Antonio, TX, USA

Synonyms

Diet; Food; Health; Nourishment

Definition

Having to do with one's overall health and includes a proper balance of diet and exercise.

Description

Nutrition is a broad topic encompassing both the dietary intake and physical activity level of an individual. Several factors can effect one's view of and ability to receive proper nutrition, including: race, gender, ethnicity, culture, time, motivation, money, lack of information, conflicting information, geographic location, etc. ([2], p. 624). One's nutrition is often based on his/her Body Mass Index, BMI = weight in kilograms divided by height in meters squared ([1], p. 501). Improper nutrition can lead to physical health problems including obesity and diabetes and can also lead to emotional issues among some people. For proper nutrition it is recommended to have a proper balance of fruits, vegetables, grains, and proteins in one's diet.

Obesity

Joy Jansen
Neurology, Learning, and Behavior Center, Salt Lake City, UT, USA

Synonyms

Corpulence; Fatness; Overweight; Plumpness; Stoutness; Weight

Definition

Obesity is a condition of excessive body fat.

Description

Excessive body fat is a result of a high caloric intake and low activity level so the body is not burning off extra calories. Body fat is estimated through the calculation of body mass index (BMI). The BMI rates obesity at three different levels. A BMI of 30.0–39.9 is obese. Severely or morbidly obese is a BMI of 40.0 or higher. And, in a case where the presence of a significant comorbidity, such as adult on-set of diabetes or depression, exists, a BMI of 35.0 or higher is classified as morbid obesity. Diagnosis is made when body weight is higher than the set standard for height and body type. Variables causing this condition are complex and include genetic, biological, behavioral and cultural factors. Several serious health complications can occur, particularly cardiovascular disease, hypertension, diabetes (type 2), sleep apnea, and osteoarthritis. In addition, social and emotional issues usually develop. The disease is nor age or gender specific; however, usually begins in early childhood or adolescence and, if treatment does not occur, the probability of adulthood obesity is 80%. Also, diagnosis is more prevalent in males than females. In regards to treatment, maintaining healthy eating habits and a weight-management program, including physical activity, are essential in treating this condition.

Relevance to Childhood Development

Childhood obesity is diagnosed when a child's body weight is 10% higher than the recommended norm for height and body type. A BMI of 25, which is the score for adult overweight, is used to classify obesity in children. The condition is most commonly caused by higher caloric intake and low physical activity; however, hormonal conditions and genetic diseases, such as Prader-Willi and Bardet-Bieldl syndromes, can increase the chance of childhood obesity. Genetics, medications (i.e., steroids and specific psychiatric medications), self-image, social and emotional problems are also contributing factors in the cause of this condition. In addition, low income children are at great risk due to lack of parental availability and opportunity to provide time and resources in promoting a healthy and active lifestyle.

Childhood obesity carries risk in developing serious health problems early in life in addition to complication listed above. Children are susceptible to metabolic syndrome, asthma and other breathing disorders, liver disease, early puberty or menarche, eating disorders, and skin infections. In addition, orthopedic complications can occur. Developing bone and cartilage are not strong enough to bear the excess weight and as a result children can become bow-legged or develop overgrown leg bones. Also, the excessive weight on the hip growth limits range of motion and causes extreme pain. Emotional and social difficulties are at high risk of emerging. Low self-esteem and bullying can occur; thus, leading to depression. Poor social skills and behavior problems are associated with this condition as well as social isolation and social withdrawal. School related anxiety and stress can also become problematic and impact academic performance.

Treatment of obesity is not age specific; however, there are issues unique to childhood. Issues are monitoring school meals, eating meals as a family, limiting snacking, not using food as a reward, creating a balanced food list

Sam Goldstein & Jack A. Naglieri (eds.), *Encyclopedia of Child Behavior and Development*, DOI 10.1007/978-0-387-79061-9,

that the entire family can enjoy, and reduced eating in restaurants. Attending a support group, working with a dietician or counselor is also important. Treatment success for childhood obesity relies on active family and child involvement.

Object Permanence

Caroline McKnight
University of North Carolina, Chapel, NC, USA

Definition

Object permanence refers to a belief we have that objects and people exist independently and distinct from one another and such objects and people continue to exist independently and distinct whether or not we interact with the object or person.

Description

As a major component of Piaget's stages of cognitive development, the understanding of object permanence typically is achieved during the sensorimotor period of development. Piaget believed that the object concept (i.e., belief that objects remain permanent despite our interaction or lack of interaction with them) is developed in stages. During stages 1 and 2, the infant does not continue to search for an object even when it disappears from his or her view. However, by the end of stage 2, the infant is typically able to visually follow objects becoming focused on the object when it is still. In stage 3, the infant tends to anticipate where the object may go next. For example, the infant may look for a toy to emerge from the opposite side of a screen from which the toy entered. It is not until stage 4, however, that the child will physically search for objects and recover them. During stage 5, the young child begins to be less tied to their motor experience in their search for hidden objects and more able to view the object as separate. In stage 6, the child is able to find an object even when it has been visibly transferred among several places. That is, the child is aware that despite changes in location, the object has remained permanent. It is when the child has reached stage 6 of the object concept that Piaget believed the child has accomplished the sensorimotor stage and is ready for deferred imitation and symbolic play.

There remains some controversy on the stages of the development of the object concept in that several researchers have found that infants may achieve certain stages at earlier ages than Piaget hypothesized.

Relevance to Childhood Development

When a child achieves object permanence, he or she acquires an important developmental milestone that sets forth a cascade of other significant developmental milestones. In particular, it is an important link to language development as the child learns to use language to refer to an object that while outside of the child's perception, continues to exist.

Object Relations Theory

Deborah Posner
William Alanson White Institute, New York, NY, USA

Synonyms

Fairbairn's psychoanalytic theory; Good-enough mother; Psychoanalytic theories of development

Definition

A group of psychoanalytic theories built on the assertion that being connected to other people is a basic and essential part of human nature. Object relational theories focus on the early parent-child relationships, and the way those experiences form later adult personality and psychological functioning.

Description

Although the Object Relational theories span some range, they share a basic premise first articulated by W.R.D.

Fairbairn. Fairbairn took issue with Freud's assertion that libido (psychic energy) is pleasure seeking. If that were the case, he asked, then how would one account for the repetition compulsion, people finding themselves in the same unhappy circumstances many times over? Fairbairn proposed a radical change in Freud's classical theory (see Psychoanalysis), and asserted that "libido is not pleasure-seeking, but object-seeking." In Freudian terminology, "object" refers to the other towards whom our energies are directed. In contrast to Freud, who saw sex and aggression at core of human nature, Fairbairn placed human connection at the center of the psyche [1, 2].

The child's bond to the parents is not optional. When one considers the total dependence of an infant and young child, attaching to the parent would be a biological imperative. What *is* infinitely variable is the nature of the experience the child has through that bond, and who the child becomes in order to preserve that bond. The child then creates future relationships, happy or unhappy, using the same models of relationships created or "internalized" in early childhood.

One important aspect of internalized Object Relations theory is that the models developed are of the *relationship* of *self-and-other*. For example, the model of being submissive in relation to a domineering other includes information about both participants in the model. In expecting to be treated in a certain way, one acts as though it is inevitable, and creates a self-fulfilling prophecy. In Object Relations psychoanalysis, the analyst pays close attention to his or her reactions to the patient, using this as information about the relationship roles and expectations the patient is creating. People use what they know and create that which is familiar.

Object Relations theory explains why change is so difficult. Devotion to one's parents has limited what one is allowed to create, and who one is allowed to be. In order to change, the patient must be able to imagine another way of being, and also tolerate the loss of being defined as their parent's child. Change is seen as the ability to have more satisfying and deep relationships, and a sense of personal authenticity.

Object Relations theory has many contributors, some of whom include Michael Balint, Harry Guntrip, and D.W. Winnicott. While each has his own area of focus, there are unifying principles. First, that the human infant is prepared from birth to seek contact with others. Another assumption is that with a "good enough," expectable level of mothering, the child will develop toward health [3]. Object relations theory also values the notion of a private, core self that is coherent, ongoing, and that is the source of creativity.

Relevance to Childhood Development

Object Relations theory is a psychoanalytic theory that can be used in order to consider what children need in order to develop self-knowledge and relationships that will be rich and sustaining throughout life. Knowledge of psychoanalysis can be of immense value when choosing how to support a child's healthy development, and in helping parents provide "good enough" emotional care [3].

Observational Learning

Amy Madewell
Oklahoma State University, Stillwater, OK, USA

Synonyms

Behavior modeling; Emulation; Modeling; Modeling technique; Social learning theory; Vicarious learning

Definition

Observational learning is a social learning technique that occurs via the use of verbal, visual, and auditory information that directs the subsequent behavior of the observer.

Description

Observational learning establishes a conceptual representation of the observed stimuli and interacts with the observers' personal schema prior to reenacting the modeled behavior or act. Since the observer is not instantly required to complete the modeled behavior, the learned behavior is dependent on the cognitive competence of the viewer.

Albert Bandura, a behavioral psychologist, worked extensively to develop studies that modeled behaviors within a developmental perspective. His studies focused on children and their abilities to actively model behaviors [2]. One study used of a Bobo doll (inflatable clown doll) to demonstrate the immediate effects of observational learning. In this study, children watched an adult

aggressively beat up a Bobo doll immediately prior to play time. This study was supported as the children demonstrated the modeled behavior during play on a similar Bobo doll. In result, many studies have generalized this mood dependent component of learning theory and its effects on children after prolonged exposure to violent and sexualized television programming/games. These media effects prime children for similar behavior [1].

Bandura found that four primary factors where necessary for modeling to produce sufficient observational learning. The first factor, attention, states that the level of attention given to the modeled behavior is correlated to the retention rate. For example, if you are watching a mundane reality television program (i.e., The Real World), you are less likely to successfully report detailed contents from the programming. Attention is also influence by your mood state, thus if you are sleepy or sick, you are less likely to recall information that you viewed.

The next important factor in observational learning surrounds the idea of retention. Therefore, one must be able to cognitively digest the information that was viewed and retain that information for later retrieval. The use of elaborate language and mental imagery increase the likelihood that the information will be stored deeply leading to more successful retrieval [1].

The next step involves the attention paid to the model, how it was encoded and how both of these components translate to the ability to reproduce the observed behavior. For example, a student can view another student win a spelling bee and become motivated to participate, but this does not equate to the child's ability to spell immediately. With practice, this child can continue to view the model student to emulate their abilities. Other evidence illustrates a student's ability to imagine themselves succeeding at a task can enhance performance. So, with our previous example, a child can show marked improvement at the spelling bee when attention, retention via practice, and imagery all intersect.

The final step, motivation, is critical to the activation of all the previous three steps. Motivation is the necessary factor for successful emulation of modeled behaviors. Without sufficient motivation, learning will not take place because the modeled behavior will be forgotten before it has a chance to be retrieved. Bandura suggests that there are both positive and negative motivations and his research indicates that negative motivation will lead to increased learning performance [2]. One can understand how observational learning is a developmental tool that models imbued behaviors to encourage children to produce positive behaviors in society.

Cognitive imitation is a form of mimicry whereas observational learning involves the digestion of a new behavior that is incorporated into the ultimate behavior. To conclude, observational learning is a form of improving the subsequent behavior and not to be confused with imitation.

Obsessive–Compulsive Disorder

R. Trent Codd III[1], Michael P. Twohig[2]
[1]Cognitive-Behavioral Therapy Center of WNC, P.A., Asheville, NC, USA
[2]Utah State University, Logan, UT, USA

Synonyms

Anxiety disorders; OCD; OC spectrum disorder; Pediatric OCD

Definition and Description

Obsessive-Compulsive Disorder (OCD), as articulated in the fourth edition, text revision of the *Diagnostic and Statistical Manual of Mental Disorder* (DSM-IV-TR), is a prevalent anxiety disorder characterized by recurrent obsessions and/or compulsions that are time consuming, cause marked distress or significantly interfere with an individual's life [1].

Diagnostic Criteria

OCD is characterized as an anxiety disorder by the DSM-IV-TR [1]. It involves recurrent obsessions and/or compulsions that are time consuming (greater than 1 h a day), distressing, or interfere with functioning. Disrupted functioning may involve difficulties in normal routine, occupational or academic functioning, and usual social activities or interpersonal relationships. To receive a diagnosis of OCD, an adult must recognize that the obsessions or compulsions are excessive or unreasonable. The DSM-IV-TR does not provide separate diagnostic criteria for pediatric OCD; however, insight into the excessiveness or unreasonableness of the symptoms is not a diagnostic requirement for children. If a child or adolescent (or adult) fails to recognize the senselessness of their OCD symptoms they will receive the diagnostic specifier "with poor insight." The specific content of the obsessions or compulsions must not be confined to another Axis I disorder, and the symptoms may not be the result of the effects of a substance or a general medical condition.

Obsessions Defined

Obsessions are defined by the DSM-IV-TR [1] as "persistent ideas, thoughts, impulses, or images that are experienced as intrusive and inappropriate and that cause marked anxiety or distress" (p. 457). They are also described as ego-dystonic (i.e., the obsessional content is experienced as outside of one's control and inconsistent with one's values), even though the obsessional content is recognized as a product of one's mind rather than having been imposed from outside. The most common themes in pediatric populations are fear of contamination, fear of harm to self or others, and urges related to need for symmetry or exactness [16]. It is common for a child with OCD to have multiple obsessional themes.

Compulsions Defined

Compulsions are repetitive behaviors or mental acts, performed in response to an obsession, that function to prevent or reduce anxiety or distress [1]. A subjective sense of being driven to perform the compulsion in order to alleviate discomfort or reduce the probability of a feared consequence is often experienced. There is an important relationship between the obsessions and compulsions: the compulsions are completed to reduce or regulate obsessions or associated anxiety. Avoidance of situations that evoke obsessions, and reassurance seeking are commonly associated with OCD; however, these behaviors are not necessarily considered compulsions. The relationship between obsessions and compulsions is often logical even though the obsessions and compulsive behaviors are not. This is exemplified in the following commonly occurring obsessions and corresponding compulsions: fears of contamination and washing; need for symmetry and exactness (i.e., the need to have things "just feel right") and ordering/arranging, counting, repeating, and touching; fears of harming self or others and checking and reassurance seeking; aggressive thoughts and checking; sexual or forbidden thoughts and attempts to regulate or replace thoughts; scrupulosity/religiosity and praying, and the need to tell, ask, confess, and excessive declarations. The limited research on childhood hoarding (acquiring and saving items) suggests that prevalence rates for children approximate rates found in the adult population [2, 16], but pediatric hoarders may have a unique clinical presentation [14].

Epidemiology

Community studies estimate lifetime prevalence rates of 2.5% in adults and 1–2.3% in children and adolescents [1], and point prevalence rates of 0.5% in children and 1–3% in adolescents [16]. Unfortunately, OCD often goes undetected and thus, estimates of prevalence rates are likely underestimates [2, 4]. Roughly 80% of all cases of OCD have pediatric onset [3] with prepubertal onset more likely for boys and adolescent onset more likely for girls [11].

Comorbidity and Prognosis

Childhood OCD is often associated with a variety of co-occurring disorders including tic disorders, attention deficit hyperactivity disorder, conduct disorder and oppositional-defiant disorder, and anxiety and depressive disorders. Additionally, although at a lesser rate, childhood OCD has also been associated with eating disorders, body dysmorphic disorder, trichotillomania, and skin picking. In addition to psychological factors that are associated with OCD, the presence of the disorder can have devastating effects on a child's social and academic functioning and development. In most situations the disorder maintains throughout adolescence into adulthood, thus, indicating a need for early intervention.

Theories of the Development of Childhood OCD

Neurological/Biological

Structural anomalies have been noted in many areas of the brains of children with OCD including the striatum, dorsolateral prefrontal cortex, and anterior cingulate, including others [13]. Neuroimaging studies in adults have shown that the frontal-striatal-thalamic circuits are

associated with OCD and treatment response. Additionally, several neurotransmitters including serotonin, dopamine, and others are associated with OCD. Treatments based on neurological/biological models generally focus on regulation of neurotransmitter levels and in extreme cases, direct manipulation of brain regions through neurosurgery.

Behavioral

The behavioral model of OCD is generally tied into respondent and operant conditioning model named the two-factor learning theory. Even though this theory is not wholly supported, it has been one of the most practical models as it fostered the development of behavioral treatments of OCD. In the first factor of the two-factor theory, fear of particular stimuli develop through respondent conditioning processes. The second factor utilizes operant concepts. It is assumed that avoidance and escape behaviors – including compulsions – are negatively reinforced through reductions in obsessions and anxiety. Unless this chain can be broken, respondent, and operant extinction processes will not occur.

Cognitive

The cognitive model is based on dysfunctional information processing such as limitations in memory and sensory perception. For example, problems in working memory may cause someone to not remember if they locked the door or left it unlocked. Modern cognitive models focus more on dysfunctional beliefs and interpretations of intrusive thoughts. Cognitive styles that can lead to OCD include overimportance of thoughts, heightened belief that one needs to control thoughts, overestimation of danger, need for certainty, overestimation of responsibility, and a need for perfection. Modern cognitive interventions directly target these cognitive styles and attempt to teach more adaptive cognitive styles or reduce the importance of these styles.

Treatments

There are generally two approaches taken in the treatment of childhood OCD: psychotherapy, pharmacotherapy, or their combination. Pharmacotherapy is the most commonly employed intervention due to its ease of administration, not its effectiveness.

Pharmacological

The first medication to be approved by the National Institute of Mental Health was clomipramine. Since that time, multisite placebo controlled trials have demonstrated the utility of the following selective serotonin reuptake inhibitors (SSRIs): sertraline [10], fluvoxamine [12], fluoxetine [7], and paroxetine [8]. The supportive findings are somewhat complicated by the fact that there are no comparative studies between these agents. However, a meta-analysis of pharmacotherapy for childhood OCD found clomipramine to be more effective than SSRIs, but clomipramine's use is questioned because of the frequent side-effects [6].

Psychotherapies

The most supported types of psychotherapy fall under the cognitive behavior therapy umbrella of treatment procedures. Behavioral procedures generally involve exposure to feared stimuli and prevention of avoidance and escape behaviors. Cognitive procedures that are commonly used in the treatment of childhood OCD include cognitive challenging procedures or reappraisal of obsessions, or acceptance-based procedures. Consistent with current empirical evidence of the superiority of the combination of pharmacotherapy and CBT [15], a combination of these procedures is common.

Exposure with Ritual Prevention

Exposure with ritual prevention (ERP) is generally considered the gold standard treatment of psychosocial treatments for childhood OCD [5]. Although the exact function of ERP has yet to be determined, it is generally based on behavioral models involving extinction and habituation. This treatment generally begins with psychoeducation on OCD and the factors that maintain it. This involves a description of a conditioning model for its development and focuses on the role of escape and avoidance in its maintenance. Next, children are assisted in creating a hierarchy of situations that evoke increasing levels of obsessions and anxiety. At each step in the hierarchy, children are taught that if they allow the obsessions and anxiety to occur and do not escape (either overtly or covertly) that these inner experiences will gradually decrease. The therapist uses ritual prevention procedures to limit escape responses. Over repeated ascending trials through the hierarchy children experience less obsessions and anxiety in these situations.

Cognitive Therapies

Cognitive procedures were added to the behavioral treatment of OCD for two reasons: to increase acceptability of exposure therapy and/or to more directly target the cognitive processes involved in the disorder. Although cognitive procedures sometimes include behavioral exercises that share formal similarities to behavioral treatments, their focus is on challenging inaccurate cognitions or developing reappraisals of one's obsessions. Cognitive

procedures such as cognitive restructuring focus on testing the accuracy of one's cognitions and developing more accurate and adaptive ones. Reappraisal of cognitions targets beliefs about the meaning of obsessions. For example, if a child feels he is dangerous because of obsessions involving harm, the child might be instructed to survey people to see if they have similar thoughts. If other people have similar thoughts, then the child can assume that his thoughts say little about himself.

Acceptance and Commitment Therapy

The use of acceptance and commitment therapy (ACT) [9] procedures with OCD is relatively new and therefore only data on its effectiveness with adults exists. ACT as a treatment for OCD focuses on altering the function of one's obsessions and associated anxiety rather than targeting the content of OCD-related inner experiences. ACT as a treatment for OCD also helps children focus on areas in their lives that they find important and meaningful (called values) and to spend a greater amount of time pursuing these areas. Therefore, ACT as a treatment for OCD does not utilize exposure exercises as they are traditionally conceptualized. When pursuing a valued area of life the child will likely encounter stimuli that occasion obsessions. The child is instructed to continue in her valued direction and to use other ACT processes to help alter the function of the obsession and anxiety.

Neurosurgery

In highly crippling, treatment refractory cases of adult OCD, varieties of neurosurgery or brain stimulation are utilized. To date, there are no published reports of these procedures with children or adolescents. This is likely due to the need for the OCD to be highly treatment resistant, and that it is unlikely that all resources will have been exhausted while someone is still in childhood or adolescence.

Occipital Lobe

Chad A. Noggle
SIU School of Medicine, Springfield, IL, USA

Definition

The Occipital lobe is the most posterior lobe of the cerebral hemispheres and is primarily related to visual processing.

Description

The Occipital lobe is the most posterior lobe of the cerebral hemispheres. It is bordered anteriorly by both portions of the Parietal and Temporal lobes. From a functional standpoint, the Occipital lobes primary role is in vision [4]. Specifically, the Occipital lobe receives primary visual input and mediate perception of visual material before further processing occurs in more anterior regions within the Parietal and Temporal lobes [2]. The Occipital lobe itself can be seen as containing a hierarchy of areas and different processing streams that correspond with the various means of visual processing [3]. First, visual processing can be divided amongst two individual pathways referred to as the ventral and dorsal streams. These originate in the Occipital lobe and are functionally related to object recognition (Ventral stream) and visual action (Dorsal stream) [3]. Working in combination with these pathways are the various areas of the Occipital lobe that correspond with different aspects of visual processing. The first two areas, commonly depicted as V1 and V2 play a role in most aspects of visual processing and thus likely represent those areas depicted as the primary visual cortex. Beyond these more robust areas is V3 which assists in the processing of dynamic form as part of the ventral stream as well as more general form processing as part of the workings of the dorsal stream [3]. In comparison, V4 solely operates within the Ventral stream and serves to assist in recognition of color form whereas V5 operates almost exclusively within the Dorsal stream assisting the processing of motion [3]. Prior to any visual information being processed by the Occipital lobe the information is received by the Thalamus. Specifically, the Lateral Geniculate, Pulvinar, and Lateral Posterior nuclei of the Thalamus initially receive different forms visual information and then relay it onto the cortical areas of the Occipital lobe, with the primary visual areas being the first to receive that information [1].

Ontogenetic Development

Matthew C. Lambert, Leah E. Johnson
Texas Tech University, Lubbock, TX, USA

Definition

Development that occurs as a function of experience rather than as a function of the genetic make-up of an individual.

Description

Ontogenetic development can be conceptualized as the portion of physical, cognitive, emotional, and social development that can be attributed to experiences with the environment and the individuals within the environment. In contrast, phylogenetic development refers to the portion of physical, cognitive, emotional, and social development that can be attributed to an individual's genetic make-up. Development found to be universal in normally developing children across categories such as culture or socioeconomic status can be assumed in many cases to be phylogenetic in nature.

The distinction between ontogenetic and phylogenetic development can often times be blurred by the interaction effect which occurs between the individual and the environment. In many cases both sources of development contribute to any developmental milestone or objective. Uri Bronfenbrenner's ecological systems theory represents a synthesis between internal and external sources of development. Some meta-analytic research on development (e.g., personality, social, emotional, etc.) suggests that the majority of an individual's development can be attributed to ontogenetic sources.

Relevance to Early Childhood

Sources of ontogenetic develop are directly influenced by caregivers and the environments to which young children are exposed. Learning environments that are constructed with intentionality and that purposefully engage children in meaningful activities serve as ontogenetic sources of development. Additional sources of influence are the social interactions of young children with peers and caregivers. Vygotsky's and Bandura's notions of learning through social interactions rely heavily on ontogenetic development; social interactions, in many cases representational play (i.e., role playing), lead to meaningful learning experiences.

Definition

Operant conditioning is the selection of behaviors by their consequences. The study of operant conditioning involves descriptions, predictions and explanations of the effects of reinforcement and punishment on behavior.

Description

Operant conditioning occurs when a consequence (positive or negative reinforcement or punishment) is paired or ceases to be paired with a behavior and it increases or decreases the likelihood that behavior will recur. Psychologist B. F. Skinner [3] called this process "operant" conditioning to express the idea that "changes in rate of occurrence (of the behavior) are brought about by various operations performed upon the organism (p. 21)." In other words, the relationship between a behavior and its consequences operates on the rate at which an individual emits that behavior. By contrast, in ►classical conditioning, the relationship between an unconditioned and a conditioned stimulus can cause a behavior that was elicited by the unconditioned stimulus to be elicited by the conditioned stimulus as well. Operant behaviors, those susceptible to reinforcement and punishment, are sometimes termed "voluntary" behaviors to distinguish them from reflexes and fixed action patterns.

Reinforcement and punishment are the cornerstones of operant conditioning. Table 1 shows possible reinforcing and punishing consequences of behavior.

Getting a New Operant Behavior to Occur Through Shaping

Reinforcement and punishment have measurable effects on behaviors that already occur. In his "puzzle-box" experiments investigating the ►law of effect, E. L. Thorndike positively reinforced cats for emitting a particular response that led to escape from the puzzle box. Generally, he did nothing to encourage the response; he merely waited until it occurred spontaneously. A parent who attempted to train her child to sit quietly through a meal in the same manner would probably wait a long time without the behavior occurring spontaneously. Shaping is the use of successive approximation to produce new behaviors. For instance, a parent might begin by rewarding the child, perhaps with sips of a favorite drink, for something he does occasionally without prompting, such as sitting at the table when called. Once that behavior is established, the parent could make the requirement for earning a drink reward more demanding or specific; perhaps she would only provide the drink reward when the child comes to the table and sits quietly until he receives his dinner. Once he does that regularly, she might increase the duration required to earn a drink, until her child sits quietly through an entire meal.

Operant Conditioning. Table 1 Possible reinforcing and punishing consequences of behavior

		When a behavior occurs, a non-neutral stimulus is	
		Produced	Removed
Consequence produces	Satisfaction	Positive reinforcement: *A behavior has a pleasant consequence*: Nick eats all his vegetables, so he is allowed to have dessert.	Negative reinforcement: *A behavior prevents an unpleasant consequence*: Audrey wears a special nail polish to keep from biting her nails.
	Discomfort	Positive punishment: *A behavior has an unpleasant consequence*: Lucy shouts at her parents, so she must sit in the corner.	Negative punishment: *A behavior prevents a pleasant consequence*: Spencer watches a prohibited tv show, so his video games are taken away.

Decreasing a Behavior Through Extinction

Punishment is one way to decrease the frequency of a behavior, but it is not always the most practical or effective way. Extinction is similar to negative punishment in that is decreases behavior by removing something. Whereas with negative punishment, a pleasant stimulus is removed, with extinction it is the relationship between response and consequence that is removed. Extinction is the condition in which a reinforcer that was previously a consequence of a behavior no longer occurs when the behavior is emitted.

Factors Affecting Operant Conditioning

Many things can affect how quickly an individual acquires a behavior and how much of an impact a consequence has. Hereafter only positive reinforcement will be discussed, however similar effects occur with punishment and negative reinforcement. Factors that affect operant conditioning can be temporal, spatial, perceptual, or a combination of those and can deal with the nature of the response, of the reinforcer or the relationship between them. Experimental analysis of behavior is the empirical study, mathematical description and theoretical explanation of these factors. A non-exhaustive list of factors:

- Rate of reinforcement – how often reinforcement occurs
- Response requirement – how many responses it takes to earn a reinforcer
- Reinforcer delay – the amount of time that elapses between the operant response and reinforcement
- Reinforcer magnitude – the size or amount of each reinforcer
- Reinforcer probability – the probability a reinforcer will be delivered, once earned.

Variability

In laboratory and clinical settings and to some extent in life generally, the factors affecting operant conditioning can vary a lot, a little, or not at all. In interval schedules [2], a certain amount of time must pass before a response will produce reinforcement. Consider a rat pressing a lever for food. In a fixed interval 20-s schedule, at least 20 s must pass between the start of the trial (an event usually signaled by some stimulus) and the reinforced response – any lever-presses before the 20 s are up have no effect, but the first response after 20 s has elapsed always produces food. In a variable interval 20-s schedule, an average of 20 s must elapse between the start of a trial and the reinforced response, but the interval in each trial varies. There are different types of variable-interval schedules. In a mixed interval schedule, reinforcement might become available after 5 s on half of trials and 35 s on the other half. Variable intervals schedules often involve lists of intervals drawn from arithmetic progressions. Although it is not possible to predict when a reinforcer will become available on any single trial in such a situation, the probability that a reinforcer is available increases with time. Random interval schedules are memoryless – the time elapsed does not determine time left.

Microwaveable food is an example of reinforcement that is available on a fixed interval schedule, as it takes exactly the same amount of time to cook each time. The response (opening the microwave door) is reinforced only after a particular amount of time since trial onset (programming the microwave) has elapsed. Buses typically operate on variable interval schedules. Unless your bus always arrives exactly on schedule, it is impossible to time your arrival at the bus stop to coincide precisely with that of the bus. Fortunately, waiting for a bus is not memoryless – the longer you wait, the likelier it is the bus will come. Telephone conversation durations are exponentially distributed. Thus, telephone conversations are memoryless; you cannot predict how much longer someone will be on the phone based on how long that person has already been on the phone.

Just as rate of reinforcement can be fixed or variable, so can response ratio, delay, magnitude, probability and other factors affecting operant conditioning.

Selection by Consequences

The words "selection by consequences" are most often used to describe Darwinian natural selection, or evolution. Of course, the principle applies to operant behavior in a similar manner. With evolution, the environment exerts selective pressure on species such that those individuals (or those genes) that are best adapted to the environment have the greatest reproductive success. With operant behavior, the environment exerts selective pressure within an individual such that those behaviors that are most adaptive for the situation are most likely to recur [1, 4].

By combining simple schedules with different rates, magnitudes, delays, probabilities, response requirements and other factors in laboratory settings, it is possible to study complicated behavioral mechanisms. The study of operant conditioning has provided significant insights into many aspects of behavior, including choice, stimulus control, behavioral ecology and optimality.

Oppositional Defiant Disorder

Megan M. Wolvin, Andy V. Pham, John S. Carlson
Michigan State University, East Lansing, MI, USA

Synonyms

Disruptive behavior disorder; ODD

Definition

An enduring pattern of uncooperative, defiant, and hostile behavior toward authority figures that is not accounted for by the child's developmental stage and results in significant functional impairment in the child's life.

Description

Symptoms

The behaviors and symptoms of Oppositional Defiant Disorder (ODD) become evident before a child is 8-years old and usually is not diagnosed any later than early adolescence. The defiant behaviors often initially emerge in the home setting with adults the child is familiar with but over time the behaviors may also appear in additional settings as well. The defiant behavior is more likely to be observed with watching the child interact with an adult they are close to rather than with a stranger. The onset of oppositional behaviors is typically gradual, usually developing over the course of months or years. Males are more likely than females to receive a diagnosis of ODD before puberty, but after puberty the rates for males and females appear to be similar.

ODD is characterized by a pattern of negative behavior that is evident for an extended period of time. The child may frequently lose their temper as they are easily annoyed with other people. Arguing is common as these children may be spiteful and hostile towards others. Children with ODD have difficulty following rules and may purposefully try to irritate and annoy other people. They do not take responsibility for their actions, instead blaming others for their mistakes. These behaviors occur outside of what is typical for the child's age and development and impair their ability to function in their life.

Prevalence Rates

Various studies have noted different prevalence rates for ODD ranging from 2 to 16%. About half the children who show symptoms of ODD as children will outgrow them and show no symptoms of this or other psychiatric disorders. In 5–10% of children, there will be an eventual diagnosis of ADHD only. An additional 5% of children initially diagnosed with ODD will continue to have ODD and no other disorder. For 25% of the children with ODD, an eventual mood or anxiety disorder may develop. For other children their diagnosis may turn into Conduct Disorder instead.

Causes

While there are no known causes for ODD, a variety of factors have been found to be related to ODD. There may be a biological predisposition to ODD as a child is more likely to have it if one of their parents has it. If a parent is alcoholic and has been in trouble with the law their children are almost three times as likely to have ODD. Children whose parents have marital problems or where violence is demonstrated in the home have a greater likelihood of developing ODD. Some children may develop ODD as a result of a neurological injury or chemical imbalance in the brain.

Diagnosis

According to the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) [2], ODD is a psychiatric disorder where persistent defiant behavior is demonstrated for a period of at least 6 months. In the 6-month period, four or more of the following behaviors must have occurred: (1) frequently losing their temper, (2) frequently arguing with adults, (3) frequently defying or refusing to comply with the rules and requests of adults, (4) frequently purposefully trying to annoy other people, (5) frequently blaming others for their mistakes and misbehavior, (6) frequently touchy or easily annoyed by other people, (7) is often angry and resentful, (8) is often spiteful or vindictive. In addition to demonstrating these behaviors they must occur more frequently than is typically observed in individuals of comparable age and developmental level. Their negative behavior patterns also must lead to significant impairment in social academic or occupational functioning.

Treatment

There are several different forms of treatment that have been found to be helpful with individuals with ODD. Group, individual and/or family therapy is one method of treatment, with individual therapy being the most frequent. Parent management training is another strategy for treating ODD which involves teaching parents to use more effective practices when dealing with the oppositional behavior of their child. Cognitive-behavioral therapy is used to teach the individual effective problem solving skills. In addition, social skills training can potentially help the child develop more positive relationships with their peers.

Oral Consumption

►Drinking

Oral Craving

►Oral Fixation

Oral Fixation

Synonyms

Oral craving

Definition

A fixation in Sigmund Freud's oral stage of development. The fixation manifests out of an obsession to stimulate the mouth, and is typical of infants who are developmentally in the oral stage. A maladaptive oral fixation in later life is thought to results from a failure to resolve the oral conflict during the oral stage; this can occur if the child is weaned too early or late, if the child is not fed enough or fed too excessively.

Description

Oral fixations in adulthood can manifest in two ways. When the child is underfed, they may become orally dependent and obsessed with oral stimulation. The child may grow up to become fixated on oral sex with other individuals regardless of sexual preference. When the child is overfed, the child may be resistant to growing up and revert to a state of dependency, where they act helpless, demand satisfaction, and are often described as having

a "needy" personality. Oral fixations are thought to cause being overly talkative, over-eating, smoking addictions, alcoholism, sarcastic personalities, nail biting, putting fingers in one's mouth, and biting sexual partners.

Oral Reading

Becky Stefanko
University of Detroit Mercy, New Baltimore, MI, USA

Synonyms

Reading aloud; Word recognition in context

Definition

The oral translation of printed or written material, often used as measure of a student's overall reading performance to examine aspects of reading accuracy, fluency, and comprehension that cannot be observed directly from the act of silent reading.

Description

Oral reading performance is used as an indicator of students' overall reading ability. It is used to measure three components of reading, accuracy, rate, and fluency, which have been shown to relate strongly to comprehension (Fuchs et al., 2001, [1]). Students are asked to read aloud from selected grade-level passages, and scores are based on accuracy, rate, and fluency. Listening to students reading aloud provides valuable insights into the covert cognitive processes used to decipher and comprehend printed materials.

Accuracy refers to the precision with which a student's oral reading conforms to the letter-sound conventions of printed English [1]. It is measured as a percentage of words read correctly (WRC). This is determined by recording the number of errors, calculating the number of WRC, and dividing the number of WRC by the total number of words in the passage. Errors include omissions, substitutions, insertions, and mispronunciations. Variant pronunciations resulting from regional, dialectical, or nonnative speech are not considered errors unless they result in changes to the meaning of the text. Self-corrected errors are considered accurate responses. Accuracy is important for comprehension since decoding mistakes can lead to errors that result in changes to the meaning of the text. Student's demonstrating a 95% rate of WRC are said to be reading at an instructional level.

Rate refers to the speed at which the student reads aloud. It is measured as the number of words per minute read aloud for the entire performance, or as the number of words read during the first minute.

Accuracy and rate are components of fluency, but fluency also includes phrasing, expression, and adherence to the author's syntax [1]. Generally, higher scores on accuracy and rate of oral reading indicate greater fluency. Higher levels of fluency are associated with higher overall reading proficiency. Research suggests that increased fluency frees up available attention and memory resources for development of comprehension.

Oral Stage

Jana Sander
Texas A&M University Corpus Christi College of Education, Corpus Christi, TX, USA

Definition

First stage of Sigmund Freud's psychosexual stages.

Description

Sigmund Freud (1856–1939), an Austrian physician, developed a theory of psychosexual stages. He maintained that how the family dealt with the child's sexual and aggressive drives in the first years of life was critical for healthy personality development [[1], p. 16].

According to the theory, the first year of life the mouth is the source of pleasure [[2], p. 14]. The basic human need for food causes the baby to suck the breast or bottle and fulfill the need. If the oral needs of the baby aren't met, the child may develop habits such as thumb sucking, fingernail biting, overeating or smoking later in life [[1], p. 17].

Orientation reflex; Orientation response; Orienting reaction; Orienting reflex

Definition

The typical definition given for the orienting reflex is "...an organism's innate reaction to a novel stimulus" [2], p. 207] but such a definition fails to properly reflect the complexity of the orienting response. While it is typically seen as occurring to a novel stimulus and it is an unlearned response, the orienting response has been studied for over 90 years and entire volumes are devoted to this response. While most studied in mammals, Pavlov, who first described the orienting response in 1910 [3, 5] considered it a response characteristic of animals in general and it has been extensively studied in humans [1].

When an animal is exposed to a novel stimulus or a familiar stimulus that is unexpected, as in a predator detecting a scent of prey (or a prey detecting a predator), the animal will engage in a complex behavioral repertoire of sensory, skeletal-muscular, and autonomic responses that compose the orienting response. According to Sokolov [6], the main factors of a stimulus that evoke the orientation response are novelty, intensity and the significance of the stimulus; Sokolov [7] considered the orientation response as being directed towards the extracting of information from the immediate environment. Like any evoked, innate response, the orienting response will display habituation if the eliciting stimulus is sufficiently repeated, followed by spontaneous recovery if the eliciting stimulus is withheld for a sufficient time following habituation [2]. The orienting response will also display a recovery of the strength of response if an extraneous stimulus is presented during the course of habituation [9].

Pavlov discussed the orienting response as being an "investigating (or investigatory) reaction" as well as a "what-is-it reaction" [3, p. 1, 9, p. 27]. Lynn [3] cataloged the various responses that are collectively referred to as the orienting response.

1. There are changes in the sensitivity of sensory organs-the pupil becomes dilated, the light-sensitive cells of the retina undergo a lowered threshold for light, and the threshold for hearing is lowered to increase sensitivity.

2. There are changes in localized skeletal muscles involved in observing the stimulus-the animal can be seen to turn its head towards the stimulus, its ears are cocked towards the stimulus, inhalation of air for sniffing occurs. In humans, only some of these occur.
3. There are changes in the general movement and muscle tone – the animal typically freezes at least temporarily, the general state of muscle tone is increased and electrical measures of muscle tone (the electromyogram or EMG) shows increases, indicating a generalized state of increased readiness potential.
4. Measures of brain waves are indicative of increased arousal and focused attention – typically this means a faster frequency and lower amplitude pattern of brain waves is seen in the electroencephalogram (EEG), i.e., beta activity predominates in the EEG.
5. A constellation of autonomic nervous system changes can be observed in various systems – blood vessels in the limb constrict (vasoconstriction) while blood vessels in the head dilate (vasodilation); changes in electrodermal activity occur such that the skin's conductance of electricity is increased, referred to as either the galvanic skin response (GSR) or the skin conductance response (SCR).
6. Besides the autonomic changes just listed, there are changes in measures of respiration – a pause in breathing occurs, followed by an increase in the amplitude accompanied by a decrease in the frequency of breathing.
7. Changes in heart rate are observed but which are termed highly variable; most often humans show a decrease in heart rate.
8. Since the writing of Lynn [3], other subsequent writers have added transient changes in the EEG to the above list. These fleeting changes in the EEG, termed event-related potentials (ERPs) are caused by specific environmental events such as a flashing strobe light. The ERP is characterized by a characteristic positive or negative variation (an upward or downward deflection, respectively) in the EEG with specific temporal parameters and which are stimulus specific [1, 8].

Sokolov [5, 6] outlined other orienting response distinctions – the generalized orientation reaction and the localized orientation response; these are characterized by specific EEG patterns and changes and by the extent to which the EEG changes could be localized to distinct cerebral cortex areas. The localized and generalized orientation responses also show differences in the rate that each shows habituation to the evoking stimulus. Sokolov [6] also distinguished between the orientation response as described, which he considered to be "information-gathering" and a defensive response which would be evoked by intense, painful or potentially painful events. Any stimulus in any sensory modality would have be in excess of some minimum value for an orientation response to be elicited; as stimulus intensity increases further, it can reach values that are painfully stimulating, at which point the orienting response is replaced with a defensive response [1].

There are variations in the orienting response from individual to individual; all of the components outlined above do not always occur in all subjects and there are differences in the various combinations and in the magnitude of the component responses of the orientation response [3]. Some of the variations observed with the orientation response are considered diagnostic signs of some psychiatric conditions [4]. The significance of the normal or typical orientation response is still under investigation and might have important roles in the responses that cognitive psychologists term "information processing" [8].

Orthographic Reading Skills

Stacy E. Levin
Argosy University

Synonyms

Orthographic awareness; Phonemic awareness; Phonological decoding; Reading

Definition

Orthographic reading skills refer to the ability to identify patterns of specific letters as words, eventually leading to word recognition. With development of these skills, reading becomes an automatic process. The spelling, pronunciation, and meaning of a word are unified and the information is accessed simultaneously upon visual presentation of an individual word [5, 10].

Description

In the English language, ►orthography is based on the alphabet system and refers to the set of rules applied to reading, spelling, and pronunciation. English orthography is rather complex as words can be read, spelled, and pronounced in multiple ways. Unlike other languages, the relationship between ►graphemes and ►phonemes is inconsistent and cannot be generalized across words. For example, the recognition of homophones, homonyms, and unpredictable words is based on word-specific knowledge [9].

Because of the complexities of English orthography, it is necessary for English-speaking individuals to develop more comprehensive and extensive orthographic reading skills to access a word-specific knowledgebase and promote word recognition. The development of orthographic reading skills involves several components, including ►phonological decoding and ►phonemic awareness [2]; however, orthographic processing abilities are not dependent on phonological processing abilities. Words are identified based on phonological decoding, letter-sound associations and grapheme-phoneme correspondences [10]. As phonological decoding processes improve, phonemic awareness develops and knowledge of letter combinations is formed. Through the process of orthographic coding, print is recoded into phonological and orthographic representations, visual and spelling patterns used to identify individual words. Orthographic representations enable readers to access word meaning based on printed information [2, 5, 10].

Through repeated visual and oral vocabulary exposure, word associations and orthographic representations are strengthened and specific orthographic representations of words are formulated [2]. When individuals have acquired strong orthographic representations, they are able to access this information with fluency and automaticity [5].

Relevance to Childhood Development

Children generally acquire orthographic reading skills by learning the sounds of letters and basic vocabulary sight words. Although reading and spelling both require phonological decoding, reading is taught through visual methods, while spelling is mainly taught through phonology with an incorporation of some visual methods [5, 9]. The acquisition of orthographic word-knowledge is influenced by exposure to the words in print and contextual feedback regarding the pronunciation and meaning of the word [2]. Thus, children who receive repeated exposure to words within the context of the environment have stronger orthographic reading skills, are able to make more informed choices in orthographic tasks, and have improved reading comprehension abilities. As children grow older, their competencies in orthographic and phonological processing abilities increase [3, 5].

Nearly 20–40% of children are considered "at risk" for reading disabilities and encounter challenges in the process of developing orthographic reading skills. Children with reading disabilities present with varied problems. Some have difficulty applying phonological strategies, while others have weaknesses in orthographic word decoding [4]. Children who have impairments in phonological skills related to reading are thought to have ►developmental dyslexia. Subtypes of developmental dyslexia include phonological dyslexia and orthographic dyslexia. Phonological dyslexia involves greater phonological deficits, while orthographic dyslexia is characterized by greater orthographic deficits [4, 8].

Assessment

When children present with reading problems, comprehensive assessments in the areas of general cognitive abilities, reading, and language, such as the Wechsler Intelligence Scale for Children-4th edition (WISC-IV), the Peabody

Individual Achievement Test (PIAT), Woodcock-Johnson III Tests of Achievement, Woodcock Reading Mastery Test-Revised (WRMT-T) or the Comprehensive Test of Phonological Processing (CTOPP), can be beneficial in assessing skills and determining specific deficits (i.e., word recognition, accuracy, fluency, automaticity, phonological decoding, phonemic awareness, orthographic coding) [2, 6, 7].

When deficits of orthographic reading skills are thought to contribute to reading problems, several assessment tasks can be administered.

- Orthographic choice presents children with a list of items requiring the recognition of a target word against a pseudohomophone (e.g., *sammon/salmon*). The words can consist of one, two, three, or four syllables. Achievement on the task is dependent on accuracy and latency during trials [1].
- Homophone choice presents children with a question such as "Which can be eaten?" and requires them to determine an appropriate response from a list of homophones (e.g., *pair/pear*) [1, 2, 7].
- Embedded word presents children with a list of one-syllable words embedded within a strand of consonants, and requires children to identify the words (e.g., cvbdeepdmg). Achievement on the task is dependent on accuracy and latency during trials [7].
- Orthographic awareness presents children with pairs of pseudowords and requires children to identify whether the word "could be a word" or "looks like a word" (e.g., filv/filk) [7].
- Other orthographic tasks require children to delete a letter in a word and to read or pronounce the new word based on its spelling [7].

Intervention

Knowledge of children's specific reading deficits is useful when creating treatment plans. Interventions should be individualized and reflect a particular child's needs and weaknesses [2]. Thus, it is critical to determine whether a training program should primarily focus on weaknesses in phonological and/or orthographic word decoding skills [4].

In general, children with reading problems require extensive, systematic support and structured training. Remedial strategies should be implemented immediately to help children who struggle in developing adequate reading processes, i.e., phonological decoding skills. Early preventive interventions have demonstrated effectiveness in improving children's skills of decoding, and word automaticity and fluency [1, 2, 5, 6].

Deficits in orthographic reading skills are partially influenced by genetic and environmental factors. The speed and accuracy of orthographic coding and phonological decoding are affected by genetics, while orthographic processing abilities improve based on print exposure. Exposure to print can improve the efficiency of orthographic processing and word recognition, which results in better reading performance overall [1–3].

Bottom-up approach; Multisensory teaching

Definition

The Orton-Gillingham reading method is a sequential, multisensory, and flexible approach to teaching language to children with dyslexia [1, 3].

Description

The Orton-Gillingham reading method presents children with the sequential basics of language starting with discrete information that is taught to mastery through the visual, auditory, and kinesthetic learning channels. This multisensory approach follows the sequential pattern of language with students mastering the most basic information before new, more complex information can be taught. By following a hierarchy, student learning is cumulative and flexible. Initially, students learn individual sounds for letters by hearing the sounds, saying the sounds, and writing the letter(s) representing the sounds. This sequence can be altered to focus on writing and spelling as well as reading, Through this approach students learn to read, spell, and write at their own pace [3].

History

During the late 1930s and 1940s, Dr. Samuel Orton and educator Anne Gillingham, developed their multisensory approach to literacy instruction for students with dyslexia. After parting professionally in the 1940s, Orton and Gillingham continued to pursue their approach separately. Orton proceeded with their program in its original form while Gillingham modified the original approach. The fundamental difference was in the area of spelling. Orton's method required students to say the sounds of a word when spelling while Gillingham required students to say the letters of the word while spelling. Despite their differences, their combined work influenced many other researchers and educators spawning fifteen commercial programs [2].

Criticism

The most common criticism of the Orton-Gillingham method is its perceived rigidity. Since the set of skills making up the approach are cumulative and follow a systematic set of practices, some view the process as inflexible and lacking creativity. Orton and Gillingham developed their multisensory method of teaching language to train students with dyslexia to think about language as they are using that language. By learning the systematic rules of language, they believed student could apply those rules when reading and writing [3].

Relevance to Childhood Development

Orton and Gillingham believed that students with dyslexia needed to use the visual, auditory, and kinesthetic channels due to their inherent weaknesses in learning languages. Traditional educators rely heavily on the visual channel when teaching students to read and write. Children with dyslexia try to memorize words as whole units, but due to their limitations, they cannot memorize every word. Orton and Gillingham included the auditory and kinesthetic channels in addition to the visual to address this weakness [2,3].

Through the auditory channel students with dyslexia expand their short-term ear memory. By requiring students to retain small pieces of information received through the auditory channel, their short-term ear memory gradually increases as they are slowly required to retain larger pieces of information. The auditory channel is also used to help students with sound discrimination. Students are taught to voice similar sounds by paying attention to the motor movements of their mouths when forming these similar sounds. The kinesthetic channel requires the students to become aware of the motor movements accompanying production of sounds as well as the creation of motor movements to go along with vowel sounds [3].

Osgood, Charles Egerton

Rebekah R. Pender
San Antonio, TX, USA

Definition

Osgood, Charles Egerton: Born November 20, 1916 in Sommerville, Massachusetts. He died September 15, 1991.

Description

Osgood received his PhD in psychology in 1945 from Yale University and was a professor of psychology at the University of Illinois at Champaign-Urbana from 1949–1984. He was also a research professor at the Institute of Communications Research in the University of Illinois College of Communication. He was the director of the Institute of Communications Research from 1957 to 1984. He served as president of the American Psychological Association from 1962 to 1963. At the height of the Cold War, from 1964 to 1971, Osgood served on the Social Science Advisory Board of the Arms Control and Disarmament Agency. Among his many awards were the American Psychological Association's Distinguished Scientific Contribution Award, which he won in 1960 and the American Psychological Association's Kurt Lewin Award (1971).

Relevance to Childhood Development

Osgood was a distinguished social psychologist, who together with his colleagues George Suci and Percy Tannenbaum in 1957 developed the technique in the form of a rating scale to measure the connotative concepts of cultural, or changes in attitudes toward an object or person, known as semantic differential (Osgood, 2009). Osgood is also known for a conciliatory strategy known as GRIT or "graduated and reciprocated initiatives in tension reduction."

In his original writing he said it stood for "graduated and reciprocated initiatives in tension reduction; later he simplified this to gradual reduction in tension. The basic idea is that a disputant can initiate de-escalation by making a small, unilateral (one-sided) concession to the other side, and at the same time, communicating a desire or even an expectation that this gesture will be matched with an equal response from the opponent. If the opponent does respond positively, the first party can make a second concession, and a "peace spiral" is begun. If the first initiative is ignored, Osgood suggests that it be followed by a second–or even a third–attempt. These concessions should be designed to build trust, but should not be terribly costly (materially or strategically), nor should they suggest weakness. However, they should indicate a willingness to transform the conflict to a more co-operative and less adversarial approach (Step-by-Step De-Escalation, 1998).

Overcorrection

Michelle Johnson, Ivy Chong
Florida Institute of Technology, Melbourne, FL, USA

Synonyms

Positive practice; Positive punishment; Restitution

Definition

A positive punishment procedure in which, contingent on the problem behavior, a person is required to engage in an effortful activity for a brief period [4].

Description

The procedure of overcorrection was created by Foxx and Azrin [2, 3] to decrease aggressive and disruptive behaviors in institutional settings. Overcorrection involves the repetition of a response, usually as a penalty for having displayed an inappropriate behavior. The effortful response is designed to ensure the individual practices the correct and appropriate behavior that is functionally similar to the inappropriate response they previously emitted. It is important to note that this procedure should be implemented immediately upon the occurrence of the problem behavior [4]. Close temporal contiguity between the inappropriate response and the overcorrection procedure is designed to reduce the future frequency of the problem behavior [1]. Finally, making the procedure one that employs aspects of a punishing stimulus, individuals implementing any overcorrection procedure should ensure that the effortful response is related to the problem behavior, previously emitted.

This procedure is easily implemented with individuals in a learning situation, such as a classroom. While it is important to note that the overcorrection procedure was initially intended to reduce problem behavior (e.g., aggression), research has documented its effectiveness in learning environments for skills such as reading and spelling.

Ovulation

Carol D. Daniels
Emporia State University, Emporia, KS, USA

Definition

From the Latin word, *ovum* + *ation,* meaning process. It refers to a process within the ovarian and pituitary endocrine function.

Description

Ovulation is the expulsion of an ovum (egg) from an ovary of a mature follicle as part of the menstrual cycle. It typically occurs about the eleventh to the fourteenth day before the next menstrual period. Sometimes a sharp pain in the lower abdomen will occur on the side that is ovulating.

Relevance to Childhood Development

The female infant is born with a large number of incompletely developed ovum (eggs). Once the child reaches puberty the ovum is extruded form the ovary at ovulation. The initiation of ovulation and menarche is triggered by the release of a series of hormones from several glands. The adrenal glands are the first to release its adrenal androgens beginning around the age of six to eight. These adrenal androgens initiate the growth of pubic hair, skin changes and body odor. The second set

of glands, the hypothalamus, the pituitary, and the gonads (ovaries) initiates major body changes. The ovaries begin to secrete *estrogen* which causes the hips to widen, the uterus and breasts to enlarge, and sets in motion the reproduction cycle. Estrogen also stimulates the ovaries to produce ova (eggs).

Ovum

Merry Sleigh
Winthrop University, Rock Hill, SC, USA

Synonyms

Egg; Female gamete; Female germ cell; Oocyte; Ova

Definition

Female reproductive cell.

Description

An egg, or ovum, is the female reproductive cell. An individual ovum is visible to the naked eye and one of the largest single cells in the body. Across most animal species, eggs are bigger than sperm, a distinction termed anisogamy.

Ova are formed in the ovaries during the prenatal period, reaching a total of around seven million. (This early origin means that a woman's offspring begins its development while she is still in the womb of her own mother.) From the fifth month of gestation and continuing throughout the lifespan, ova will deteriorate and decrease in number. At birth, a female baby has around two million eggs and at puberty, an adolescent has around 350,000. A typical woman will release 400 eggs over the course of her reproductive years, from puberty to menopause. Failure to release an ovum is the primary cause of female infertility.

Ova are released during ovulation, occurring around the mid-point of a woman's menstrual cycle. Following menstruation, the pituitary gland releases follicle stimulating hormone (FSH). FSH enables approximately 20 immature eggs housed in Graafian follicles within the ovary to begin development. As these eggs develop, the release of estrogen helps build the uterine lining, termed the endometrium. A thick lining will be necessary for implantation of a fertilized egg. The gradual rise in estrogen triggers the pituitary gland to release luteinizing hormone (LH) rather than FSH. The LH surge causes the most mature ova to be released from its ovarian follicle. This process is called ovulation. The period of time leading to ovulation can vary between women and between cycles. For example, illness, stress, and travel have been linked to a delay in ovulation. In contrast, the period between ovulation and menstruation is an average of 14 days in healthy women and is called the luteal phase.

The mature ovum can come from either ovary and seems to occur in a somewhat random pattern. How the body determines which ovum is most mature is not fully understood. Sometimes a woman releases more than one egg, creating the potential for twins or other multiples. The follicle that housed the ovum is now known as the corpus luteum and releases progesterone, a hormone that contributes to the thickening of the endometrium and will be necessary to maintain a pregnancy. The progesterone also leads to the death and follicle shrinkage of the ripening ova that were not released.

The released egg is caught up in the fimbriae at the end of the fallopian tube. These finger-like appendages sweep the egg into the fallopian tube, also known as an oviduct. Inside the tube, tiny cilia provide a current that propels the egg toward the uterus. The released egg is surrounded by a loose configuration of cells, or cumulus, that protected and fed the egg in its follicle. The ovum has a 24 h window in which fertilization can occur. If the egg is not fertilized, the corpus luteum dies. The resulting decrease in estrogen and progesterone causes menstruation, or the shedding of the endometrium.

For fertilization to occur, the sperm and egg meet in the fallopian tube. The successful sperm must first travel through the thick outer wall of the ovum, called the zona pellucida. The ovum is designed to allow penetration by only one sperm. If polysperming accidentally occurs, the fertilized egg will not develop. In the fast block to polysperming, the outer surface of the egg undergoes a chemical change that prevents other sperm from adhering to the zona pellucida. In the slow block to polysperming, calcium atoms move into the space between the inner egg and the zona, creating a large barrier between the outside of the egg and the genetic material housed within.

The sperm continues its journey into the innermost part of the egg, which contains the mother's genetic material. At fertilization, the egg contains 46 chromosomes,

twice as many as are necessary. Thus, immediately following fertilization, half of the egg's genes are packaged into the polar body, which is ejected from the egg. The remaining genes within each ovum contain an X-chromosome, leaving the sperm to provide the information necessary to determine the offspring's gender. Once inside this acolyte, the sperm loses its tail and dismantles its head to release the father's genetic material. The two sets of 23 chromosomes fuse to become a new call called a zygote. This zygote immediately begins to divide as it travels down the fallopian tube for implantation in the uterus. If implantation occurs outside of the uterus, an entopic pregnancy results.

The human egg's contributions extend beyond half of the genetic material. The developing organism inherits all of its mitochondria from its mother. In addition, early cell division is controlled by messenger RNA and proteins found in the egg. This maternal RNA will deteriorate once the embryonic genes take over the process of cell division for themselves. These factors refute the notion that genetic inheritance is a simple 50/50 contribution by each parent.

Because ova are stored in a woman's body for almost her entire lifespan, they are vulnerable to damage over time. It is possible that environmental toxins and ingested substances have the potential to harm immature ova stored in the ovaries; however, this type of research is difficult to conduct. One strong piece of evidence is that as a woman ages, her likelihood of having an offspring with a chromosomal abnormality, such as cleft palate or Down's syndrome, gradually increases. This outcome could reflect a weakening of eggs over time, or the possibility that women release healthier eggs earlier in life. These findings also highlight the importance of a healthy lifestyle even before a woman contemplates pregnancy.

Pain Sensitivity

Lauren Stutts
University of Florida, Gainesville, FL, USA

Synonyms

Pain feelings; Pain threshold

Definition

Pain is defined by the International Association for the Study of Pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage" [5]. "Pain threshold" is usually the term used for pain sensitivity in the literature, which is defined as "the least experience of pain which a subject can recognize."

Description

Pain is a subjective experience caused by internal and/or external events [1]. It can be categorized as acute or chronic and can be localized to one part of the body or many parts. Variables affecting pain are complex and include genetic, environmental, and social factors. Diagnosis typically includes assessing pain onset, location, intensity, quality, duration, spatial extent, temporal pattern, physical symptoms, and emotional response [9].

Relevance to Childhood Development

There is significant individual variability of pain sensitivity in children [7]. Children's age, temperament, and developmental level influence their pain sensitivity [8]. Children with a difficult temperament tend to be more pain sensitive [11]. The lifetime prevalence for pain increases with age, and children's understanding of pain and use of pain coping strategies increase with age [4]. Similarly, children's pain intensity and overall distress with medical procedures decreases with age [3]. There do not appear to be sex differences in children's pain sensitivity [6].

Diagnostically, the parent and child are typically interviewed and the child undergoes a clinical examination. If a child lacks the verbal capabilities to communicate pain, then physiological parameters such as heart rate, respiration rate, blood pressure, and electrodermal responses are often assessed [10]. Several pain-specific diagnostic tools have been created for children such as having them rate their pain using facial scales. A child's pain level should continually be monitored as children's physiological and psychological functioning can change quickly.

Children who have early aversive pain experiences can often deter their ability to cope effectively with their pain [2]. Therefore, early intervention is important in order to help children garner positive coping strategies for present and future pain experiences.

Palliative Care

Brenda Moretta Guerrero
Our Lady of the Lake University, San Antonio, TX, USA

Synonyms

Supportive care

Definition

Palliative care is a medical approach that aims to improve quality of life and alleviate suffering of patients and their families. More specifically, the World Health Organization (WHO) defines palliative care as "an approach that improves the quality of life of patients and their families facing the problems associated with life-threatening illness through the prevention and relief of suffering by means of early intervention and impeccable assessment and treatment of pain and other problems, physical, psychosocial, and spiritual" [12]. Similarly, the National Consensus Project for Quality Palliative Care states that the goal of palliative care is to "prevent and relieve suffering and to support the best possible quality of life for patients and their families, regardless of the stage of the disease or the need for other therapies, in accordance with their values and preferences" [10].

Description

Core Principles of Palliative Care

Palliative care represents a paradigm shift in Western medicine from a nearly exclusive goal of curing disease to a focus on enhancing quality of life, regardless of whether or not a patient's illness can be cured. In 1997, Last Acts, the largest coalition of experts promoting quality end-of-life care in the United States, published *Precepts of Palliative Care*, which outlined five key areas of consideration for delivering high-quality end-of-life care [7]. The five core areas of concern include: respecting patient goals, preferences and choices; providing comprehensive care for patients and their families; acknowledging and addressing caregiver concerns; utilizing the strengths of interdisciplinary resources; and establishing systems and means of support.

Building on Last Act's *Precepts of Palliative Care*, the National Consensus Project for Quality Palliative Care published more detailed clinical practice guidelines and outlined twelve core elements of palliative care [10]. Those elements of care include considerations related to: the patient population served; the timing of palliative care; the need for patient and family-centered care; the comprehensive nature of palliative care; the necessity of an interdisciplinary team approach; attention to relief of suffering; the need for quality communication skills and expertise in care of the dying and the bereaved; continuity of care across settings; equitable access to palliative care; addressing regulatory barriers; and finally, overall quality improvement of palliative care practice.

To elaborate on the National Consensus Project's core elements, the patient population served by palliative care

includes persons of all ages, during any stage of life-altering or life-limiting illness; and in the case of terminal illness, continues in the form of bereavement support for family following the patient's death. Because illness affects the patient as well as those who care about him or her, the patient and family are treated as the unit of care and share in a collaborative decision-making process with the patient's team of medical professionals. Additionally, interdisciplinary palliative care teams comprised of physicians, nurses, pain specialists, and other specially trained care providers minister to the needs of seriously ill medical patients and their families by providing not only integrated and expertly skilled medical care; but also culturally and developmentally sensitive social, emotional, and spiritual support. And finally, palliative care can be provided in a variety of settings such as hospitals, nursing homes, assisted living facilities, outpatient care settings, and a patient's home; and involves collaboration and coordination of care across those settings.

Palliative Care Versus Hospice Care

Although palliative care evolved out of the hospice movement and is often confused with hospice care, the two approaches to medical intervention are not synonymous. Palliative care is always provided for hospice patients, but not all palliative care patients receive hospice care. And although both approaches to patient care aim to ease suffering by managing distressing medical symptoms such as pain and both approaches rely on an interdisciplinary team of care providers, hospice care is provided for terminally ill patients with a life expectancy of 6 months or less and who are no longer undergoing curative treatment. Conversely, as noted above, palliative care can be offered to manage a wide range of medical conditions during any stage of illness and can be provided concomitantly with curative treatment. Additionally, over 80% of hospice care is provided in patients' homes in the United States, whereas, much of palliative care is provided in acute care hospitals and other institutional settings. Because hospice care is provided through Medicare, hospice programs receive federal funding. Conversely, non-hospice palliative care is often hospital-based so it is subject to the budgetary constraints and goals of the hospital in which the program is housed. That explains, in part, why hospice care is more widely available than palliative care [4].

State of Palliative Care in America

In 2003, Last Acts released *Means to a Better End: A Report on Dying in America Today* [8]. The report detailed the status of end-of-life care in all 50 states and the District of Columbia on eight key elements of palliative care. Overall, Last Acts found that America's health care system provides, at best, mediocre palliative care for patients who are seriously ill and/or dying. For example, only about 14% of hospitals at the time of the study offered a recognized palliative care program and only 42% had pain-management programs. Additionally, only one-third of one percent of physicians in the United States was certified in palliative care and only slightly more nurses, 0.4%, were palliative care certified. While the report did not address pediatric palliative care and no similarly comprehensive reports have been published detailing the current state of pediatric palliative care, there is reason to believe that the situation is even less satisfactory for critically ill children.

Relevance to Childhood Development

Every year in the United States 54,000 children die and over 500,000 live with life-threatening or terminal illnesses [1, 6]. Many of those children could potentially benefit from pediatric palliative care. In fact, the WHO states that a multidisciplinary approach to children's palliative care should begin at the time of initial diagnosis and continue throughout the course of illness. Further, palliative care should support children's physical, intellectual, emotional, and spiritual selves and alleviate physical, psychological, and social suffering for both them and their families [12]. Clearly, the WHO's recommendations for pediatric palliative care are consistent with the principles of the current adult-based model of palliative care practiced in the United States and elsewhere. Yet, there are important distinctions and unique challenges associated with providing palliative care for seriously ill children.

Pediatric Palliative Care Challenges

In general, the quality of pediatric palliative care has been found to be lacking [1, 3, 6, 11]. One challenge associated with providing quality palliative care for children is that research into pediatric pain and symptom management lags far behind similar research conducted on adults. Consequently, many chronically ill or dying children experience inadequate assessment and management of their pain and are prescribed inappropriate pain medications that have been tested only on adults [1].

In addition to inadequately managed pain, families of seriously ill children report stressful interpersonal interactions with medical professionals who often receive little if any training related specifically to communicating sensitively with pediatric patients and their families. Significant miscommunication often occurs between medical staff, patients, and families regarding prognostic and treatment-related issues such as presence of pain and other symptoms of disease. In fact, researchers have found that

physicians and families frequently differ in reporting symptoms of illness, such as pain; with families reporting more symptoms than physicians [2, 13].

Further, many medical professionals who are touched personally by the suffering they witness during their interactions with seriously ill children and their loved ones receive little acknowledgement and support for their own pain [5, 9]. Over time, professional caretakers who lack sufficient professional support may disengage from patients and their families as they struggle to maintain their emotional balance and objectivity [5]. This professional disengagement may in part contribute to the seemingly insensitive and unhelpful communications that families report while interacting with medical staff.

Another general hindrance to providing quality pediatric palliative care is that too few physicians and treatment centers offer pediatric palliative care and when care is available it is often provided through pediatric hospice. Unfortunately, insurance restrictions that require hospice patients to forego curative treatment may force parents to choose between curative or palliative medicine for their children. It is heartbreaking for families as well as medical professionals to "give up" on curative treatment for a child, even if the chance for recovery is quite slim. Yet, to continue with curative treatment may result in the child not receiving the highest quality symptom management and emotional support throughout the course of their illness [1].

Overall, disjointed, poorly coordinated, and interpersonally insensitive care impedes informed, shared decision-making between parents and health care providers, and ultimately, the challenges noted above lead to unnecessary pain and suffering of seriously ill children and their families.

Recommendations to Improve Pediatric Palliative Care

In an effort to address some of the aforementioned challenges in pediatric palliative care, both the Initiative for Pediatric Palliative Care and The American Academy of Pediatrics have published policy statements regarding comprehensive palliative care for children which include recommendations to improve the current state of pediatric palliative medicine. The policy statement the of American Academy of Pediatrics recommends that more palliative care and family respite programs should be developed to meet the multifaceted needs of seriously ill children from the time of diagnosis throughout the duration of the child's illness. Also, all pain specialists, pediatricians, family medicine practitioners, and pediatric specialists should learn about and become comfortable with palliative care for children. To accomplish that goal, medical and nursing schools should train professionals in the areas of communication skills, palliative medicine, grief, dying, spiritual dimensions of illness and dying, prognosis and treatment uncertainty, and decisions related to discontinuation of curative treatment. Research for studying pediatric-specific pain medications, treatment protocols, palliative care programming, regulation and reimbursement, and grief and bereavement therapy should also receive increased support. And finally, the policy statement includes the recommendation that the pharmaceutical industry assume more responsibility for providing safe and effective pediatric formulations of medications used to manage symptoms of illness and improved labeling and instructions for use of those medications [1].

Although similar to the recommendations of the American Academy of Pediatrics, the Initiative for Pediatric Palliative Care policy statement outlines patient and family-specific objectives for facilities that provide pediatric palliative care. The IPPC's project objectives include empowering family decision-making and care planning efforts, as well as maximizing, as developmentally appropriate, the child's decision-making capacity. Additionally, children's physical, emotional, and spiritual pain, as well as other distressing symptoms should be reduced. Likewise, the emotional, spiritual, social and practical needs of families, including bereavement support before and after the child's death, should be addressed. And finally, continuity of care across different treatment facilities and care providers needs to be better coordinated to meet the multifaceted needs of the ill child and his or her family [11].

If the recommendations from the National Consensus Project for Quality Palliative Care, the Initiative for Pediatric Palliative Care, and the American Academy of Pediatrics continue to gain more widespread support in the medical community at large, more seriously ill children and adults in America will benefit from palliative care in the future.

Parallel Play

Michael O. Brigano
Niagara University, NY, USA

Definition

A form of play during which two children engage in similar play activities in proximity to each other without sharing thoughts, play goals, or engaging in play together.

Description

To understand the parameters of the term parallel play, it is important to understand from where the term is derived. The term parallel play is a form of play or a "stage" of social development which stems from Mildred Parten's [6] landmark study on social interaction. Parten believed that there was a relationship "between the age of children and the degree to which they participated in social groups" [6], p. 264. From a developmental standpoint, she concluded that there is a hierarchy of play states that correlate with age and social maturity.

According to Parten's developmental theory of social interaction and play behavior, the first stage of play that a child will engage in is solitary play behavior. Solitary play behavior is said to be engaged in by very young children in an egocentric fashion to satisfy their own immediate needs, as the child makes no effort to get close to other children. It is believed that solitary play advances into onlooker play where the child observes other children as they are playing, but does not attempt to engage in play with them. This form of play is then believed to evolve into parallel play, where two or more children engage in similar if not identical pursuits with no exchange of feeling or sharing of goals and thoughts. Children engaged in parallel play will observe each other as they partake in similar kinds of play but will never associate. Parallel play is believed to evolve into an associative type of play where children will play alongside each other but continue to function in isolation. When children are engaged in associative play they will speak to each other and share toys while remaining focused on personal needs, wants, and goals, rather than reaching a collaborative goal or outcome of play. Conversely, cooperative play entails playing together to in pursuit of a common goal, and features interaction and the exchange of ideas [11].

Since Parten's study, a significant amount of research has been conducted to determine whether or not there are indeed specific stages of play behavior that emerge as the child ages. Research has also been conducted to determine if play behaviors are reduced or not exhibited at all one a child reaches a particular age or level of social competence. Studies (e.g., [2, 4]) support the position that practitioners "may not be served well in assuming that a preschool child will remain continuously in one type of social interaction for extended periods of time as implied by purely developmental periods of play" (Anderson et al., 2003, p. 19). The high levels of parallel play that continue after the subsequent cooperative stage challenge the concept of an abrupt change between levels as well as the homogeneity of behavior within stages [2, 5, 10].

Smith's [10] longitudinal study disproved Parten's concept of sequential play progression with age. He found that children most often transitioned from solitary play to group play, bypassing the parallel play stage. Unlike Parten, Smith concluded that parallel play is, in essence, an "optional" stage through which children may or may not progress.

Robinson et al. [8] and Anderson [1] state that practitioners should shift the play paradigm from simply to defining states in terms of social maturity or cognitive maturity to studying the play states with respect to the utility of each state in the natural play of young children. Furthermore, defining play states in terms of social and cognitive maturity is not entirely adequate; they support the premise that there is overlap between the behaviors that are exhibited within each hierarchal stage of social play within age groups. Therefore, it can otherwise be stated that these stages do not necessarily occur at a developmental age but may be occur in sequence when presented in novel play situation. For example, a child may be independently playing (engaged in solitary behavior). The child then observes other child that is engaged in an activity that they may be interested in (onlooker behavior), for example, playing with building blocks. If he is interested then he will approach the other child and begin to play next to him, leading to parallel play (manipulating blocks to fit together to make a desired object). The child then will eventually engage in a cooperative play where there is a common purpose or outcome that is desired from their play interaction (building a house out of blocks).

There are several factors that can influence whether a child will progress from solitary play behavior to group or cooperative play. A child may have the cognitive abilities and social competence to engage in group play or cooperative play, but may choose to observe their environment to absorb their surroundings and prepare themselves for cooperative play. Furthermore, a child's personality characteristics, potential developmental delay, and other personal, contextual, and environmental variables should be considered. For example, a child may be introverted, feel uncomfortable engaging in parallel play, and consequently, may not even attempt to engage in any form of interpersonal play behavior. Due to the variables involved in the determination of whether to engage in play interaction, much research has been conducted to explore how the different play states overlap and to discover the purpose and utility of each state.

Anderson [1] mentions that parallel play is a bridge between the other play states identified by Parten. She mentions parallel play is a central link between the other play stages, as evidenced by her research, which found that children continue to engage in periods of parallel play even after attaining the social skills requisite to play cooperatively with peers. This supports the notion that, although a child possesses sufficient cognitive abilities and displays social maturity and knowledge, parallel play still remains a dominant form of play behavior.

The results of Robinson et al. [8] study are consistent with past studies [1, 4, 9, 10] in demonstrating that parallel play is the most prominent play state and most frequently involved in periods of play transition or play shifts. The study also concluded that preschool students continued to evidence high levels of parallel play even after they develop the skills requisite to interacting cooperatively). Moreover, parallel-(aware) play apparently remains prominent in the play episodes of 4-year-old children in child-initiated play settings because of its important dynamic and bidirectional bridging function between other play states [8].

Robinson and looked beyond the cognitive content or social maturity of a play state and analyzed the transitional functions of parallel play. For example, a preschool child who presently enjoys watching interaction of peers during child-initiated play activities should be viewed in transition, and thus practitioners should design interventions to reflect the positive expectations for interactions into higher levels of interactions. This study is consistent with beliefs that parallel play is also viewed as a type of play that serves as a bridge from onlooker play to cooperative play. Moreover, parallel play can be seen as the crossroad between other play states within the natural play episodes children engage in [1]. Consequently, parallel play should not be viewed as a separate stage of child play behavior, but a stage that primes them for further initiated play behaviors such as group and cooperative play. Robinson et al. [8] study also suggests that when it is observed that parallel play is the predominant type of social interaction, a child's social competence should not be a concern. At the same time, parallel-aware play may be used by children as a safe haven to maneuver in and out of social-play situations allowing them to regulate more complex social interactions or planned retreats into solitary activities [3, 7].

In conclusion, parallel play is often referred to as a stage or form of play though which children progress as they develop from solitary players to social players (Baker & Brownlee, 1980). Parallel play is viewed as a bridge between other types of play behavior. Some studies suggest that parallel play is an optional stage, which challenges Parten's developmental theory of play stages. Other researchers suggest that parallel play is often

engaged during a transition between play states. Literature supports that parallel play, along with other forms of social play behavior, should not be viewed as homogeneous stages, but should be examined according to the utility of the context of the play situation. Parallel play has been found to be demonstrated more often than other play behaviors in preschool settings. If this is so, it may be ideal for teachers and educators to promote parallel play behaviors. For example, the introduction of a novel play situation to a child with another child in close proximity may aid them in surpassing solitary and onlooker play behavior, perhaps priming them for more advanced play behaviors and social interactions. Engagement in parallel play has been shown to be an important milestone relative to attainment of more advanced developmental behavior, communication, and social skills.

Relevance to Childhood Development

Analysis of the play behavior of young children has long served to reinforce identification of the developmental skill attainment of preschoolers. Given the inherent limitations of formal psychoeducational evaluation when working with preschool populations, observation of play behavior provides valuable insight into the social and cognitive skills of subjects. Though the previously discussed literature suggests that students may bypass the parallel play stage, frequent observation of play behaviors, including communication, reciprocity, sharing of ideas, sharing of materials, and the degree to which individuals work toward common goals, yields valuable information regarding the developmental stage at which the preschooler functions. Investigation into potential developmental delay may be spurred by careful observations of children who continuously engage in solitary play without proceeding to parallel or cooperative play stages. Likewise, observations of students who play in a dyad or group without extensive verbal communication, reciprocity, or adherence to social norms, when such skills are expected, warrants further investigation. As play is the primary medium through which young children learn and communicate, awareness of developmentally appropriate and inappropriate play behaviors provides insight into potential developmental strengths and weaknesses. Parallel play, though often bypassed by developmentally advanced preschoolers, is yet another piece of the complex developmental presentation of young children.

Paraplegia

Definition

Paralysis of the legs and lower body, typically caused by spinal injury or disease.

Description

Impairment in motor and/or sensory function of the lower extremities, paraplegia is most often a result of traumatic injury to the spinal cord nervous tissue or the resulting inflammation and swelling that occurs around the point of injury. Paraplegia can also be caused by non-traumatic and congenital factors such as spinal tumors, scoliosis, or spina bifida. The areas of the spinal canal that can be affected in paraplegia are either the thoracic, lumbar, or sacral regions. If the arms are also affected by paralysis, quadriplegia is the proper terminology. Monoplegia refers to only one affected limb. Spinal cord injuries resulting in paraplegia are known as either *complete* or *incomplete*. For a *complete* injury, no level of feeling or function exists for the patient below the point of injury. An *incomplete* injury results in the patient retaining some level or feeling or function below the point of injury.

While some people with paraplegia can walk to a degree, many are dependent on wheelchairs or other supportive measures. Impotence and various degrees of urinary and fecal incontinence are very common in those affected. Many use catheters or a bowel management programs to address these problems. With successful bladder and bowel management, people with paraplegia can prevent accidental urinary or bowel discharges. Due to the decrease or loss of feeling or function in the lower extremities, paraplegia can contribute to a number of medical complications that include pressure sores (decubitus), thrombosis, and pneumonia. Physiotherapy, various assistive technologies and vigilant self-observation and care can aid in helping to prevent future and mitigate existing complications.

Parent Behavior

Gregory E. Everett
Southern Illinois University Edwardsville, Edwardsville, IL, USA

Synonyms

Coercion model; Negative reinforcement; Parenting practices

Definition

Parent behavior refers to those practices and actions taken by parents in the course of child rearing that influence child behavior and relate either positively or negatively to child outcomes.

Description

That the behavior of parents, specifically, and overall family functioning, more generally, affects several aspects of child development is a long held and repeatedly documented finding in child psychology. That is, the ways in which parents interact with their children as well as oversee and manage their behavior has long been understood to influence children's cognitive, social, emotional, and behavioral development. Although many aspects of parenting can be referred to as "parent behavior", those issues related to the broad distinction between coercive and noncoercive parenting are characterized as such based on observable behavior and provide concrete examples of the differing ways in which overt behavior are displayed. As the more broad-based topic of Patterson's Coercion model [5, 6] is more fully discussed in this volume, it is the goal of the current entry to only outline those overt parent behaviors associated with coercive vs. noncoercive parenting not discuss the model in specific terms.

Regarding those parent behaviors associated with coercive parent–child interactions, a series of repeatedly occurring negatively reinforced exchanges between parents and children influence both parties and promote change over time. For example, consider the common parental behavior of delivering instructions to children. Assuming coercive interactions, following the initial instruction children may simply ignore the request which causes the parent to in some way escalate their behavior (e.g., repeating the instruction or raising their voice). As a result of this parental escalation the child may then increase their aversive responding by refusing to complete the instructed task or otherwise protesting the instruction. As such, the parent may withdraw the instruction rather than following through and demanding completion thereby reinforcing their child's aversive, escape behavior. Although this cycle of events is well documented over three decades of research, the parent behaviors specific to such exchanges are currently outlined.

Operating within this negative reinforcement cycle are parent behaviors that serve to increase the likelihood that children will fail to complete instructed tasks and may lead to childhood antisocial behavior [1]. Specifically, the act of instruction withdrawal serves to teach the child that they "win" the interaction with their parents and reinforces such behaviors in the future. In addition, over time the parents begin to more frequently rely on ineffective parenting practices in an attempt to control an increasingly uncontrollable child, therefore perpetuating this pattern of coercive behavior [8]. Combined with this increasing reliance on negative child-management practices, is a lack of positive reinforcement for appropriate child behaviors. Rather than recognize and attend to appropriate child behavior, parents provide an abundance of attention for negative behaviors to the detriment of positive occurrences.

Coercive parenting behaviors such as these have been linked to several poor childhood behavioral outcomes across differing groups of children. For example, increased negative parenting behaviors are predictive of young

children's increased negative peer play interactions [2] and are related to poor social skills, academic deficits, and increased antisocial behavior of older boys [7]. Although such findings may indicate that the negative effects of specific parenting behaviors are not the same for all children, there is no doubt that deleterious childhood effects exist. In sum, coercive parental interactions which emphasize negative parenting behaviors and deemphasize positive parenting behaviors evidence a poor managerial style which may increase their children's negative adaptive behaviors and teach them how not to behave, rather than how to behave.

Contrasted to those inconsistent parental behaviors which are the hallmarks of coercive parenting are those behaviors consistent with noncoercive interactions. Differentially referred to as parental warmth [4] or support or engagement [3] among other defining labels, noncoercive parenting reflects an adoption and display of attentive and supportive behaviors. Following from the previous example involving parental instruction giving, those parents behaving in a warm or supportive manner are likely to issue clear instructions that effectively communicate the task(s) to be completed and provide positive reinforcement for appropriate instruction following. In addition, supportive parents may be more likely to provide adequate explanation regarding why appropriate child behavior is expected and what consequences will follow should it not be displayed.

Related to those specific parental behaviors displayed by noncoercive parents during a hypothetical instruction giving scenario are the more general caring, supportive behaviors displayed by such parents throughout the course of daily life. Other such characteristics may include a positive or generally supportive parental affect [8] or disposition and behaviors meant to convey a sense of love and caring on the part of the parent [3]. Such parents are more likely to respond in a timely manner to their children's needs and are both aware and considerate of their children's feelings. Rather than engaging in a series of negatively reinforced aversive interactions which only serve to fuel greater levels of child and parent hostility towards the other, supportive parents provide children the much needed guidance and warmth on which healthy peer and future adult relationships are based.

Parent Intervention

►Parent Management Training

Parent Management Training

Angela N. Maupin, Andy V. Pham, John S. Carlson
Michigan State University, East Lansing, MI, USA

Synonyms

Behavior disorders; Parent intervention; Parent training; Psychosocial treatments

Definition

Parent management training (PMT) refers to an intervention program that trains parents to effectively manage their children's behavioral problems [1]. It has been identified by the American Psychological Association (APA) Division 12 as a well-established, empirically-supported treatment method. PMT can be provided in home or school contexts and can be structured in groups or with individuals depending on the severity of the presenting problem. PMT is typically implemented with parents of children who display disruptive behavior problems.

Description

PMT is a traditional behavioral parent training approach that utilizes the parent as the main change agent to remediate the child's externalizing behaviors. Externalizing behaviors in children constitute a variety of "acting out" behaviors and can range from minor oppositional

behaviors including yelling, defiance and temper tantrums to more severe antisocial behaviors including aggressiveness, stealing, and physical destructiveness [4]. These behaviors are often referred to as conduct problems or oppositional/defiant behaviors.

PMT aims to promote positive parenting through social learning techniques. Specifically, it evolved from two main areas of research: maladaptive parenting and social learning theories. Extensive research has shown that maladaptive parenting styles are significantly related to the increased likelihood of conduct problem behaviors in children. Maladaptive parenting styles that are closely associated with the development of conduct problem behaviors in children include harsh and inconsistent discipline, low supervision and involvement, negative maternal affect, and observed maternal critical statements. Second, social learning techniques are critical components of PMT; social learning relies on operant conditioning principles to promote positive parent-child interactions and decrease oppositional and conduct problem behaviors. Specifically, these techniques include consistent reinforcement of positive, non-deviant behavior, while ignoring or punishing problematic behaviors. PMT combines these two areas of knowledge by working directly with parents to teach them techniques to handle misbehavior while increasing positive parenting practices, including warmth and consistent discipline that have been associated with positive child outcomes.

PMT sessions can vary depending on the severity of the problem. Typically, PMT sessions last 1.5–2 hours per week over the course of 15 sessions. During PMT sessions, the therapist works closely with the parent in helping him or her understand underlying concepts of the training, including positive reinforcement and punishment techniques. Positive reinforcement consists of providing the child with a specific reinforcer (e.g., praise, rewards, points) contingent on observed positive behavior. Punishment techniques include removal of reinforcement contingent on disruptive behavior (e.g., removal of a privilege immediately following aggressive behavior in the child).

Central to PMT is reinforcement of children's positive, prosocial behavior. The therapist teaches the parent how to recognize, define, observe and record problem behavior in their child; this allows the parent to identify problem behaviors in the home. Parents learn how to apply techniques contingent on their child's behavior, and how to apply consequences on a consistent basis. The therapist models specific techniques for parents and coaches parents through practice implementation sessions. After a sufficient amount of practice, the parent should be able to implement the procedures with the child in the home setting. Key components of the sessions involve the practice and maintenance of learned skills so the parent can become efficient in implementation and can utilize the skills to handle future misbehavior. The therapist remains in close contact with the parent; enabling the parent to reinforce previously learned skills, measure the parents' compliance in implementing techniques, and answer any additional questions the parent may have. Finally, the therapist can problem-solve and modify existing plans when techniques do not seem to improve the child's behavior.

Relevance to Childhood Development

The emergence of externalizing behaviors may be observed early in development and may be reported by parents, family members or day care providers. Although toddlers and preschoolers may not meet the criteria for specific externalizing behavior disorders, they may begin to develop presenting symptoms at an early age. When presenting symptoms can be identified early, early intervention may reduce symptoms from escalating or presenting later in development. Typical developmental patterns may mimic some of the less extreme behaviors seen in young children with conduct problems. Such behaviors as defiance, signs of aggression toward siblings, or tantrums may occur as a result for the child's attempt to establish autonomy or set boundaries [2]. These behaviors can evolve into externalizing behavior disorders if they continue past the time where they are considered developmentally appropriate or if they worsen over time and start to interfere with daily activities (e.g., sharing, playing with peers, parental relationships).

When early behavioral difficulties are frequent and displayed at intense levels within the context of familial stress, there is a greater likelihood that the child will continue to have problems as he or she progresses developmentally [3]. At least 50% of preschool children who displayed moderate to severe conduct problems continued to show some behavioral disturbances at school age; 67% of these students displaying continued behavior problems met the diagnostic criteria for Attention-Deficit/Hyperactivity Disorder (ADHD), Oppositional Defiant Disorder (ODD) or Conduct Disorder (CD) at age 9 [5, 6]. A significant number of these children who later become clinically antisocial or criminal delinquents displayed early symptoms in their preschool years. How parents respond to their child's behavior can influence the developmental trajectory of early behavioral symptoms.

Extensive research has shown that PMT can decrease aggressive, oppositional and antisocial behaviors by promoting positive parent-child interactions. Research has demonstrated long-term effects of PMT on child outcomes and parent behavior. PMT can be utilized when early symptoms arise to prevent the emergence of more severe behavior problems later in development.

Parenting Styles

Elizabeth Levin
Laurentian University, Sudbury, ON, Canada

Synonyms

Baumrind's parenting styles; Child-rearing; Child-rearing practices; Discipline; Family structure

Definition

Parenting styles refer to the typical ways parents think, feel and behave in terms of child-rearing.

Description

Parenting takes place in every home with children throughout the world as parents try to socialize their children. Parents differ in the characteristic ways they rear or control their children. Some are more involved than others. Some are more responsive to their children than others. Some have many rules and directives to be followed while others take a laissez-faire approach. Some are loving and kind while others are harsh and

unaffectionate. Parenting styles refer to the typical ways parents think, feel and behave in terms of child-rearing [1, 2]. This means that parenting styles reflect the prevailing parental attitude to the child and this attitude is expressed to the child via the emotional climate of the home. Parenting styles guide parenting practices such as curfews or spanking, but they are not always the same. Parenting styles are the context within which the socialization of the child within a family occurs [3].

The most widely known categories of parenting styles are based on the work of Diana Baumrind [1, 2]. Most of her research has focused on two dimensions of parenting style: authority and affection. Authority or demandingness refers to the degree to which parents try to control their children's behavior by setting rational standards for behavior. Affection or responsiveness refers to the amount and way love is expressed to the child and acceptance of the child's points of view. Based on these dimensions, Baumrind identified three categories of parenting styles. According to Baumrind's work, the optimal parent is both demanding and affectionate and displays an authoritative style. This leads to socially competent and academically competent children. Less desirable in terms of child outcomes are the authoritarian style which can include parents who are more directive and those who are more intrusive, and the permissive parenting style which can include indulgent, nondirective parents and democratic parents.

Using the two dimensions of control and affection suggests a fourth category of parenting style: parents who are low in both authority and warmth. Baumrind initially did not find sufficient numbers of these parents to study as she was concerned with normal patterns of parenting, but others beginning with Maccoby and Martin have described these parents as uninvolved or neglectful and in the extreme might be termed abusive. Children reared via this parenting style have the worst outcomes [3–5].

Most parents do not display only one parenting style. While they may predominantly fall in one of the categories of parenting styles, it is more common that parents borrow from different styles depending on the circumstances, including the age and gender of the child as well as the behavioral issue involved [4]. Parenting style is a characteristic of the parent rather than of the parent–child relationship. In this regard, parents are the most influential component, however children do influence the parent and the relationship is bi-directional. An authoritative parent will ultimately benefit from raising a more compliant child; the child is more likely to comply in the future because the parent is reasonable [5]. An authoritarian parent may increase the likelihood that the adolescent will not listen, thus increasing the parental demands and decreasing compliance over time. A permissively reared child may get into trouble outside the home; the problems escalate as the parent remains uninvolved.

The research then generally favors the authoritative parenting style but the evidence comes primarily from middle class, Caucasian, North American families [3, 5]. The ideal style may be different in other cultures although support for this model has been found in cross-cultural research in Asian families. However in black North American families the authoritarian style has been found to be very effective. More research is needed to determine the effects of social context, culture and specific parenting practices.

Parietal Lobe

Chad A. Noggle
SIU School of Medicine, Springfield, IL, USA

Definition

The Parietal lobes represent the upper lateral lobes of the cortex that is bordered at different points by all three of the other lobes and is functionally linked to somatosensory functioning, visuospatial-linked processes, and areas of academic functioning.

Description

The Parietal lobes are the upper central lobes of the cerebral hemispheres that are separated from the Frontal Lobes by the Central Sulcus, the Temporal Lobes by the Sylvian Fissure and the Occipital Lobes by the Parietal-Occipital Fissure [4]. Functionally, the Parietal lobes are linked to somatosensory functioning, visuospatial

processes, and aspects of academic functioning. First, in terms of its' link to somatosensory functioning, this is related to the fact that the primary somatosensory cortex is localized to the postcentral gyrus of the anterior portion of the parietal lobes. The essential function of the primary somatosensory cortex is processing peripheral sensation of the contralateral (i.e., opposite) side [2]. This ranges from more basic functions such as simple detection of tactile stimulation to high-order processes such as object identification based on tactile cues alone, although the more higher-order the process the greater the involvement of other regions and areas. See *Somatic Sensory Cortex* for more details.

In terms of their involvement in visuospatial processes, the Parietal lobes play a vital role spatial orientation, which allows us to determine where in space we or items are in relationship to other things [1]. This is an essential component of aspects of spatial rotations (flipping and/or rotating items cognitively), hemi-attention (i.e., attention to different sides of the body and environment), and constructional tasks. Finally, the Parietal lobes have also been linked to aspects of academic performance, specifically mathematics and writing. While this functional tie may be made with the Parietal lobes broadly, a narrower link is between these functions and the Angular gyrus, which originates in the Parietal lobes. The influence the angular gyrus demonstrates along these lines is largely related to it representing a cortical association area that provides cross-modal integration of visual, tactile, and verbal information [5]. Essentially it is a convergence point of the Parietal, Temporal, and Occipital lobes, which together correspond with modulation of the aforementioned academic domains. This link has been best exemplified by lesion analysis that has demonstrated that lesions in the dominant hemisphere (i.e., that hemisphere in which language is predominantly housed) that impact the angular gyrus may result in alexia (i.e., impairment in reading) and agraphia (i.e., impairment in writing) [3]. See *Angular Gyrus* for more details.

Parkinson's Disease

Audrey McKinlay
University of Canterbury, Christchurch, Canterbury, New Zealand

Definition

Parkinson's disease (PD) is a chronic and progressive neurodegenerative disorder that is primarily characterized by motor dysfunction.

Description

Idiopathic Parkinson's disease (PD) is a chronic and progressive neurodegenerative disorder that affects around 1/1,000 individuals [36]. The pathology of this disorder is focused on the substantia nigra (SN) and nigrostriatal tract, resulting in the motor symptoms that characterize this disorder [5]. Onset occurs most commonly after the age of 50 and its incidence increases with advancing age [11]. While PD is primarily characterized by motor dysfunction, signs of early cognitive disturbances are also a feature of the disease process [6, 28, 34]. The end consequence of this cognitive decline may be frank dementia. Indeed, research indicates that a substantial number of individuals with PD (~40%) will progress to a diagnosis of dementia (see [12] for review).

Motor Symptoms

Tremor, rigidity, bradykinesia and postural instability are considered to be the cardinal features of PD. However, presenting motor symptoms vary considerably for each individual and may have particular importance for the identification of PD subtypes (see Table 1 for common motor features associated with PD). Initial diagnosis is based on the evaluation of presenting physical symptoms and their history but a definitive diagnosis of PD can only

Parkinson's Disease. Table 1 Common motor symptoms associated with Parkinson's disease [19]

Tremor	Sialorrhea (excessive salivation)
Rigidity	Respiratory difficulties
Bradykinesia	Festination
Postural instability	Freezing
Masked facies	Micrographia
Hypophonia	Decreased blink rate
Dysphagia	Levodopa induced dyskinesias

be made on the basis of autopsy evidence which includes the degeneration and loss of pigmented cells in substantia nigra pars compacta (SNc) and the presence of Lewy bodies [21]. Clinical symptoms of PD only manifest when nigrostriatal dopamine depletion is at around 80%, and approximately 60% of the dopaminergic neurons in SNc have been lost [13].

A number of neurodegenerative diseases can be mistaken for PD. These are generally referred to as Parkinson plus syndromes and include: progressive supranuclear palsy, cortical-basal degeneration, multiple system atrophy, dementia with Lewy body and vascular Parkinsonism. However, research indicates that the degree of clinical diagnostic accuracy is higher when more stringent criteria are applied such as the United Kingdom Parkinson's disease Society Brain Bank Diagnostic Criteria for Parkinson's disease [19].

Description of Characteristic Motor Symptoms

Tremor and bradykinesia are the two most common initial symptoms [37]. Tremors occur predominantly at rest, with a frequency of 4–6 Hz, and diminish on action [19]. However, not all patients with PD manifest a resting tremor as the presenting symptom, and 15% will never manifest a tremor during the entire course of the disease [19, 21]. The etiology of the resting tremor remains unknown [9]. Patients with PD may also develop a postural tremor, 5–8 Hz, that occurs during activity [19].

Bradykinesia is defined as a slowness of movement. It is often used interchangeably with hypokinesia, which refers to slowed movements, but with the addition that the movements performed are smaller than intended (e.g., micrographia), and with akinesia, referring to a lack of spontaneous movement (e.g., lack of spontaneous arm swing when walking) [3]. Bradykinesia is thought to result from deficient output from the Basal Ganglia to the cortex [3].

Rigidity, also a prominent feature of PD, refers to the increased tone or stiffness in the muscles that are resistant to passive movement, and may result in a subjective feeling of tightness and pain in the muscles. The fourth cardinal feature is postural instability, a tendency to lose balance with propulsion and retropulsion. Postural instability is more common in the later stages of the disease and is generally accompanied by festination (i.e., short shuffling steps).

The cause of postural instability is not known, but has been attributed to the degeneration of the globus pallidum, reduced or absent vestibular responses, or abnormal postural reflexes [19].

As stated at the beginning of this section, individuals vary greatly in their presentation of motor symptoms and it has been suggested that differences in motor presentation may be indicative of differences in disease progression [21]. Indeed, two recent studies have suggested that different subgroups of patients with PD can be identified by a combination of motor and cognitive symptoms [14, 26].

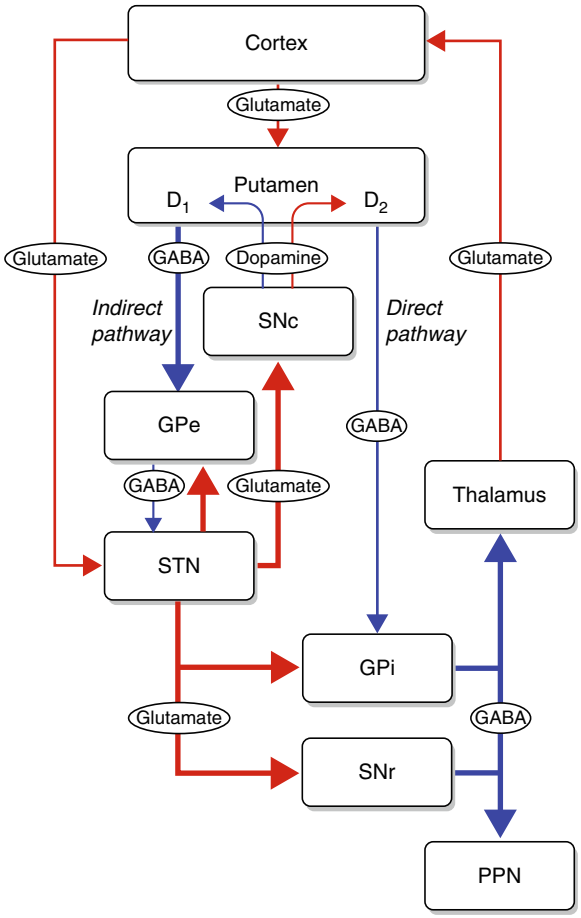
Cause of Deficits Associated with Parkinson's Disease

Dysfunction of the basal ganglia system is considered key to the motor, cognitive, and psychiatric deficits associated with Parkinson's disease. The basal ganglia are a group of interconnected subcortical structures in the forebrain and include the caudate nucleus, putamen (these two structures are often referred to as the striatum), globus pallidus (globus pallidus and putamen are sometimes referred to as the lenticular nucleus) and the nucleus accumbens [32]. Many authorities also include the substantia nigra, subthalamic nucleus and the amygdala as structures of the basal ganglia [15, 16, 32, 38].

Parkinson's disease is characterized by the depletion of dopamine due to the degeneration of dopaminergic neurons in the Substantia Nigra (SN) (see Fig. 1), and not surprisingly, the dopamine theory is used to account for the deficits reported with this disorder. Motor deficits are characteristic of PD and the dopamine theory explains this in the following way. It is suggested that the direct and indirect pathways, described earlier, operate on the GPi/SNr. The nigrostriatal denervation leads to over-activity of GPi/SNr [25, 38], with an overall inhibitory effect on the thalamus. This in turn leads to an under-activation of the motor cortex and a reduction or absence of movement as seen by the presence of bradykinesia or akinesia associated with PD [25, 31].

The cell bodies of the nigrostriatal dopaminergic neurons are located in the SNc and project primarily to the putamen, but also to the caudate. Research suggests that Parkinson's disease first affects the posterior putamen, then the anterior putamen and the caudate nucleus [7, 20]. This explains why motor symptoms are often the first signs for people with PD [29]. In contrast, dopamine depletion associated with Huntington's disease begins in the anterior caudate and initial problems are usually cognitive in nature [22, 23].

Interestingly, it has been reported that neuronal loss in the SN in people with PD is not evenly distributed. Neurons in the ventrolateral part of the SN degenerate to a greater extent than those in the medial part. This has important implications in terms of the projections from the SN. Research indicates that different types of



Parkinson's Disease. Fig. 1 A schematic representation of the basal ganglia using the motor circuit, for a patient with Parkinson's disease.

PD, (e.g., akinetic-rigid type and tremor-dominate type) show different patterns of neuronal loss in the SN, and it is has been suggested that these different patterns of neuronal loss could explain the heterogeneity of motor symptoms [10, 33].

Consistent with the dopamine theory, most medications used to control the motor symptoms that characterize PD are based on dopamine replacement therapy. These treatments, at least in the early stages of the disease, ameliorate many of the motor symptoms, with symptoms only re-appearing at the "end of dose." Further, surgical procedures based on the dopamine model have been reported to be highly successful for some patients.

A depletion of nigrostriatal dopaminergic neurons in the SNc is represented by the thin lines. The direct and indirect pathways operate on the GPi/SNr. The nigrostriatal denervation leads to over-activity of GPi/SNr with an overall inhibitory effect on the thalamus leading to an under-activation of the motor cortex (Adapted from [25, 31]).

Parkinson's Disease with Dementia

Dementia is arguably the most severe psychiatric outcome associated with PD, representing multiple cognitive and / or behavioral deficits which result in a significant decline in the person's level of social or occupational functioning (using DSM-IV criteria). The reported prevalence for Parkinson's disease with dementia (PDD) varies greatly, largely due to methodological inconsistencies i.e., the way in which dementia is defined [2, 4, 30]. However, it is generally accepted that prevalence rates of dementia among people with PD are much higher than in the general population i.e., approximately four to five times that of elderly individuals without PD [1, 12, 17, 27]. While the exact neurophysiological basis of PDD remains undetermined, progression to dementia has been found to be more likely in patients with longer disease duration, of older age, and with more severe motor symptoms [4, 8, 18, 27].

Research indicates that cognitive deficits characteristic of PDD differ from those associated with Alzheimer's disease (AD) [27, 35]. For example, while the initial symptom and essential characteristic of AD is impaired episodic memory, early executive function and visuospatial deficits are characteristic of PDD, with only mild impairments in memory retrieval being evident [24, 27].

Pass Theory

Jack A. Naglieri
George Mason University, Fairfax, VA, Canada

In his seminal works *Human Brain and Psychological Processes* [2], *The Working Brain* [3], and *Higher Cortical Functions of Man* [4], A. R Luria described the brain as a multidimensional system comprised of parts that make specific contributions to a larger interacting whole network. Luria's research on the brain provided the basis for the neuropsychological processing theory of intelligence called PASS, initially described by [1]. The four PASS processes represent a fusion of cognitive and neuropsychological constructs such as executive functioning (Planning and Attention), selective, sustain and shifting, attention (Attention), visual-spatial processing of information into a coherent whole (Simultaneous), and serial processing of information (Successive). These four neuropsychologically defined abilities form the basis of this new theory of intelligence.

The first ability is Planning. This is a frontal lobe function, especially the prefrontal cortex, and one of the prominent abilities that differentiate humans from other primates. Planning plays a central role in forming goals and objectives and then in devising plans of action required to attain these goals. Planning helps us achieve goals through the development and use of strategies to accomplish tasks for which a solution is required. Planning also allows for the generation of solutions, discriminating use of knowledge and skills, as well as control of Attention, Simultaneous, and Successive processes. The second ability is Attention which is associated with Luria's first functional unit (the reticular formation) which allows an individual to selectively focus cognitive activity toward a stimulus over a period of time without being distracted by other competing stimuli. The longer attention is needed, the more difficult keeping focus on a task will become. Intentions and goals (e.g., Planning process) are responsible for control of Attention, which is why these two processes are strongly related. *Simultaneous* is the third ability, needed for organizing information into groups to form a whole allowing recognition of patterns typical in visual-spatial tests. However, Simultaneous processing is not limited to visual content, as demonstrated by the important role it plays in the grammatical components of language and comprehension of word relationships, prepositions, and inflections. Finally, *Successive* ability is needed when working with information arranged in specific series. This includes serial organization of physical movement as well as articulation of sounds, especially sounds in sequence and early reading. The PASS theory was used as the foundation of the Cognitive Assessment System [5] (see ►CAS). This test of intelligence was explicitly developed to operationalize the PASS theory and therefore it is unique among IQ tests.

Pavlov, Ivan Petrovich

Lisa Curb
Oklahoma State University, Stillwater, OK, USA

Life Dates

1849–1936

Introduction

Pavlov was the best known Russian physiologist of his era and one of the most significant experimental psychologists. His early research on the digestive system led to the discovery of conditioned reflexes which has widely influenced neurology and psychology.

Educational Information

Pavlov was Russian. He attended seminary and planned to become a priest like his father. In his teenage years, he read the works of Darwin and Sechenov and became interested in science. Next, he attended the University of St. Petersburg and earned a degree in Natural Sciences. Then he earned a medical doctor degree at the Military Medical Academy. However, he did not plan to become a doctor. He wanted the training to give him the opportunity to advance in physiology [2].

Research

Pavlov researched the digestive system and conditioned reflexes. He used dogs for his research and tried to study them in as normal a state as possible. He developed a stomach pouch to study digestion in part of the stomach, so the dog could fully recover. He discovered before food is put in the mouth there are gastric and pancreatic secretions that happen because of some stimuli previously associated with eating. This led to his work on the conditioned reflexes. He tried to figure out how the brain controls the adaptive behaviors.

This was explained by the methodology of classical or Pavlovian conditioning. Pavlov's dogs were given meat powder. Before it was given, they would salivate when something usually associated with the meat handler appeared. Pavlov then paired the meat power with the ringing of a bell. After a few trials of both meat and the ringing bell being presented at the same time, the dogs would salivate. Even when the food was taken away, the dogs would salivate when the bell was rung. Pavlov showed the stimulus-response patterns.

The meat powder is the unconditioned stimulus and the dog's salivation is the unconditioned response. The ringing bell is the neutral stimulus. However, when the dog begins associating the bell with food, the ringing becomes the conditioned stimulus. The salivation from the dog is the conditioned response. The conditioned response will decrease if the conditioned stimulus continues to be given without the unconditioned stimulus. This is called extinction. His process was readily applicable to humans. It is used to treat phobias in a process called systematic desensitization.

Accomplishment

Pavlov became professor of pharmacology (then physiology) at the Military Medical Academy and later advanced to become the head. One year later, he helped organize the physiology department at the Institute of Experimental Medicine where he became chair in 1895. While there, he published his research *The Work of the Digestive Glands* for which he was awarded the Nobel Prize in Physiology or Medicine 1904. Pavlov continued there for 45 years until his death. Interestingly, Pavlov was the first physiologist as well as the first Russian scientist to be awarded this honor [1].

Contributions

Pavlov's work on the digestive system led to the establishing of the science of neuroendocrinology. He looked at the effect of signal on brain processing to learn more about brain function. His work on conditioned reflex showed how the brain controlled adaptive behavior. This classical conditioning, or Pavlovian conditioning, was instrumental to the development of the behaviorist movement led by John B. Watson. Furthermore, Pavlov's contributions had worldwide impact on learning, memory, psychology, and neuroscience [3].

Paxil (Paroxetine)

Laura Barney
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Antidepressants; Paroxetine (generic); Selective serotonin-reuptake inhibitor (SSRI)

Definition

Paxil® is one of the newest types of antidepressant medications. Paxil is FDA approved for treatment of major depressive disorder (MDD) and panic disorder; however, it has been shown to be an effective treatment for obsessive-compulsive disorder (OCD), bulimia, posttraumatic stress disorder, and other anxiety disorders.

Description

Paxil is a selective serotonin-reuptake inhibitor (SSRI). SSRIs have been available for treatment of depression in the United States since 1988 and have become the medications of choice for treating many psychiatric conditions. Other SSRIs include Prozac, Zoloft, Celexa, and Luvox. Paxil is one of the most potent SSRIs and has a half-life of approximately 14 h. A clinical response may take up to 6–8 weeks; however, most individuals respond within 2–3 weeks. Side effects are generally mild with most SSRIs, including Paxil. These may include upset stomach, diarrhea, insomnia or tiredness, and sexual dysfunction. A typical dose of Paxil is 20–60 mg/day. To avoid withdrawal symptoms, treatment is typically tapered and not discontinued abruptly.

Relevance to Childhood Development

Paxil has been shown effective in treating major depressive disorder and panic disorders in children and adolescents and is becoming the primary treatment for non-OCD pediatric anxiety disorders. This is partly due to the minimal side effects and flexibility in dosage and treatment. Paxil is available in liquid preparations, which may be helpful for younger children.

Peabody Picture Vocabulary Test –Third Edition (PPVT-III)

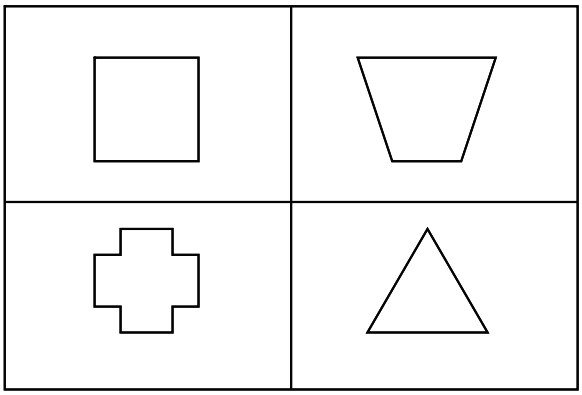
Audrey McKinlay
University of Canterbury, Christchurch, Canterbury, New Zealand

Definition

The PPVT-III is a test of auditory comprehension and is a measure of English hearing vocabulary.

Description

The PPVT-III is one of the most commonly used standardized tests that was first published in 1959 [1] revised in 1981 [2] and again in 1997 [3] with updated norms and illustrations. The PPVT-III is an individually administered, norm-reference, test of hearing vocabulary and designed for individuals ages 2–6 through to 90+ who have reasonable sight and hearing [3]. The PPVT contains four practice items and 204 test items. Items are arranged in 17 sets of 12 in order of increasing difficulty. Each test item each contains four simple black and white illustrations. The examiner says a word and the examinee's task is to select the corresponding picture that they considered best illustrates the meaning of the stimulus word presented [3]. For example, using the figure below, the examinee could be asked to select the picture that would best illustrate the meaning of the word square. A correct answer would require the participant to indicate the first illustration.



The PPVT-III is a relatively easily administered test that has a number of advantages. Firstly, individuals are administered only those items within or close to their critical range (critical range refers to items that provide maximum discrimination for individuals of similar ability). In this way each patient must answer only about 35–45 items of suitable difficulty. Items that are far too easy or hard are not administered and testing takes about 10–15 min [3].

The PPVT-III has two parallel forms, III-A and III-B, each test form has a simple scoring key which enables objective scoring to be completed while administering the test. Total raw score is calculated as the number of correct responses over the critical range. Raw scores can be converted into standard scores with a mean of 100 and a standard deviation of 15 and also age equivalents (previously called mental age), stanines and percentiles.

Relevance to Childhood Development

There are a number of situations where a child's intellectual ability may need to be assessed, e.g., school failure or underachievement. However, a standard IQ test is often not an appropriate or accurate method of identifying the level of intellectual ability. For example, children with hearing impairments may perform very poorly on a standard IQ test but be of average or above average intelligence. Administration of the PPVT-III requires no reading from the patient and no oral or written responses are required. This allows the test to be used with non readers, individuals with written language problems, and hearing impairments. As only a yes/no signal to the examiners pointing is needed to respond to the test items the test may also be used with patients who have speech impairments. For example individuals' with aphasia, stuttering, also the use of eye gaze as a response has been found to be acceptable response making the tests useful for children with severe motor disabilities.

While the PPVT-III is not a comprehensive test of general intelligence, as it measures only one important facet of general intelligence, it can be used as a screen for under achievement. The PPVT-III can be thought of as an achievement test for English vocabulary acquisition and success vocabulary has been found to be one of the best predictors of school performance. However, some caution should be exercised when using the test with different cultural and linguistic background [4].

Synonyms

Clique; Peer affiliation; Peer relations; Peer relationships; Social group

Definition

A peer group is a group of individuals who are approximately the same age, formed from common interests and affective bonds.

Description

Peer groups consist of more than two individuals of similar age, social status, and interest. Peer groups are not only comprised of individuals who are friends. It is possible to have a peer group where some members are friends and others are just tolerated. Every child on a basketball team is in the same peer group, but they are not all necessarily friends. Peer group membership can be based on sociometric status, friendship, and other social categories (e.g., "brains" or "jocks"). Peer groups are based on the interests of the members, whether that interest is sports, academia, or music. It is also possible for an individual to belong to two peer groups simultaneously and it is typical for individuals to change groups radically over time. Some peer groups are centered on prosocial characteristics (e.g., high academic performance, playing sports, and volunteer work) while others are more concerned with deviant behavior (e.g., drug and alcohol use, vandalism, and skipping school).

Several developmental psychologists, such as Sullivan and Piaget, have argued that peer relationships provide a milieu for development in cognitive, social, and emotional areas. Peer interactions provide experience with socializing skills, such as fairness, reciprocity, teamwork, and intimacy, and help mature and enhance children's reasoning abilities and concern for others. Children's peer groups help foster and create their adult personalities. Peer influence can be referred to as socialization. In American culture as children get older they spend more time with their peers, so will initial socialization begins with the parents peer groups contribute a great deal to learning societal norms and standards. Children are not only influenced by their peer groups they also help influence the decision of the group. Values and norms that are initially learned from their parents are often applied to the group.

Acceptance by peers is seemingly important particularly by young adolescents. Rejection from a peer group can be just as influential as acceptance. Adolescents who are rejected by their peers are more likely to display negative consequences: delinquency, drop out of school, or psychopathology. Social rejection is the group responding to an individual. Peer rejection is almost a self fulfilling prophecy because once adolescents decide to reject an individual they begin to treat him or her differently and this treatment begins to cause the individual to act in a way that would further cause peers to reject him or her.

The topic of peer group influence has garnered a lot of attention from child development psychologists over the years. One such psychologist is Judith Rich Harris, who developed the Group Socialization Theory in 1994. This theory asserts that peer groups are the most important socializing agent in a child's life. Harris states that parents are interchangeable, as long as the other socializing agents (e.g., peer group and community) remain the same the child will develop into the same adult.

Peer Nomination Technique

Tamara Del Vecchio
St. John's University, Queens, NY, USA

Synonyms

Peer rankings; Peer ratings; Peer sociometric nominations

Definition

Peer nomination technique is a method of assessing sociometric status in which participants are asked to nominate or rank their peers by the variable of interest.

Description

The peer nomination technique is commonly utilized to assess peer relations or observable individual characteristics. Typically, the nomination process involves asking participants to identify or rank individuals in their peer group based on the variable of interest. The nominations are counted and can be used as either a categorical or continuous measure. Sociometric status can be based on the high number of positive nominations (i.e., popular children), negative nominations (i.e., rejected children), or a low count of both positive and negative nominations (i.e., neglected children) [2]. A summary score, social preference index, is derived by subtracting the negative nominations from the positive nominations. The peer nomination process is also used to assess individual characteristics that are social in nature, such as aggression, by asking participant to report the frequency of the behavior displayed by their peers.

Although peer nominations are correlated with negative academic and social outcomes and have been shown to be more strongly related to objective measures of behavior than self-report, peer nominations can be influenced by a number of variables. For example, race of both the nominators and the peer group can affect the number of positive and negative nominations distributed [1]. Hispanic, Asian, and Caucasian children have been shown to rate their same-ethnicity peers more favorably and less negatively. In contrast, African-American children are more likely to nominate same-ethnicity peers more often in general and in the absence of a positive bias. In general, African-American children are rated more negatively than Caucasian children; however the effect of race decreases as the number of African-American children in the class increases [3]. Methodological issues, such as the way in which nominations are collected, can impact how many and which peers are nominated. More specifically, when provided with a roster of names, participants will endorse negative qualities more often for individuals at the top of the list than those towards the bottom [4].

Peer Relationships

Janett M. Naylor
Fort Hays State University, Hays, KS, USA

Synonyms

Peer group; Peer interactions; Peer relations; Peers

Definition

Interactions, both positive and negative, with same-age mates.

Description

Children's interactions with same-age playmate are multileveled (individuals, relationships, and groups) and are quite socially complex. Like all relationships, peer relationships are essentially defined by the members' characteristics including, style of interaction, as well as shared and unshared history of the members. Peer relationships are imbedded in the large peer group, which has its own set of interaction rules, hierarchy, and cohesiveness.

The basic aspect of peer relationships is individuals' socially exchanging information over a period of time. Typically, these interactions are dyadic in nature, only involving two members and have a reciprocal interdependent style. The second level of interactions is relationships that have their own associated expectations, style, and emotions. Children's dyadic peer relationships are each viewed as distinct entities that are not interchangeable. Relationships with parents are different from relationships with peers and therefore serve different purposes. Peer relationships vary in closeness of members leading to different types of dyads, including friendships, antipathies, acquaintances, etc. Dyads are especially vulnerable because loss of one particular member means the end of the relationship. Vulnerability to dissolution leads to members stressing issues of commitment, attachment and long-term investment. The highest level of peer relationships is groups. Groups are typically a cohesive set of relationships that have a hierarchy and are rather similar across members.

Children's peer relationships develop with age becoming increasingly complex and integrated. Specifically, toddlers spend most of their time playing in small groups. Toddlers are capable of coordinating behavior with others' through imitation, sharing, and altering their own response to match their partners' behavior. During preschool, children interact more often with their peers during play by sharing/helping more often, conversing more often, and recognizing differences of opinion between members. Sociodramatic play is one of the most complex forms of group interactions during preschool. Children use this pretend play to practice language, social skills, cultural roles, norms, and conflict management skills.

Entry into school provides a dramatic shift in peer relations, as children are spending a great deal of time with peers and in a variety of settings. Therefore, the structure of the peer group changes as children and adolescents reorganizing themselves in to social groups or cliques ranging from three to nine same-sex members. The main system of organization of the groups is through a social status network or popularity hierarchy.

Group social status of members can be determined using various methods. Some measures assess children's visibility in the group; others assess children's impact on the group. The most common assessment determines how liked children are by other members of the group. Children and adolescents who are liked by most of their peers are considered, from a research perspective, to be popular. Conversely, children and adolescents who are disliked by most of their peers are classified as rejected. Those who are essentially ignored or who go unnoticed are considered neglected and those who show a mix of likes and dislikes are considered controversial. Average children and adolescents are liked by a typical amount of peers.

The research constructed categories of acceptance described above (popular, rejected, neglected, controversial, and average) are marked by distinct characteristics of members. Popular children and adolescents are socially skilled at initiating and maintaining relationships, do not talk excessively, speak in a clear and communicatively competent manner, as well as are helpful, cooperative, friendly and sociable. Approximately half of rejected children and adolescents are considered aggressive by their peers. They tend to be disruptive, physically aggressive to others, and exhibit negative behaviors (yelling, taunting, etc.). The other half tend to show social withdrawal, timidity, and/or victimization. Very little is known about the origins of both the neglected and the controversial groups of children and adolescents. The average group is typically used as a research comparison or control group.

Peer acceptance has long-term consequences. Being rejected by peers in childhood often leads to increased delinquency, truancy, and drop-out rates in adolescence. School becomes an unfriendly place to be and social support is not available for these children and adolescents to properly cope with the stressors at school. Psychological adjustment is also affected by peer acceptance. For example, children and adolescents who are anxious and withdrawn have lower self-esteem, more anxiety and more depression. However, this relationship is mediated by one's perception of their own peer acceptance. Rejected children and adolescents who are unhappy with their peer group status seem to be more negatively affected by the lack of peer acceptance than those rejected children and adolescents who are content with their peer group status.

Peer Sociometric Nominations

▶Peer Nomination Technique

Peer Tutoring

Judah B. Axe
Simmons College, Boston, MA, USA

Synonyms

Classwide peer tutoring; Reciprocal peer tutoring

Definition

The instructional method of students working in dyads or small groups and systematically presenting their peers with opportunities to practice academic skills.

Description

Peer tutoring occurs in general education classrooms and is the arrangement of students teaching academic content to each other. Multiple arrangements ofstudents can be employed: dyads or small groups, same-age or cross-age groups, same-gender or cross-gender groups, and students with and without disabilities paired together. Peer tutoring has been more effective in low-income areas versus high-income areas with students in Grades 1–3 versus students in Grades 4–6. As peer tutoring involves student autonomy, structured student roles, and interdependent group rewards, it can improve academic outcomes, attitudes, self-concept, and social interactions.

In the model of "reciprocal peer tutoring" and "classwide peer tutoring," a teacher prepares folders containing flash cards with content materials such as sight words, math problems, and science facts. Students take turns being the tutor and tutee. The tutor presents the flash cards one at a time to the tutee. If the tutee is correct with a flash card, the tutor provides praise and tokens as rewards. When tutees make errors, the tutor asks the tutee

to try again. If the tutee is still incorrect, the tutor provides the correct answer. A timer is often used to mark the time each student has to be the tutor and five minutes is the length of a typical tutoring session. At the end of a session, the tutor records the tutee's performance on a child-friendly bar graph (i.e., with animals or other icons). Based on students' performances, flash cards are grouped as either mastered or in acquisition. Mastered flash cards are reviewed periodically. During peer tutoring, teachers can walk around and monitor tutoring sessions or use the time to give extra help to students who need it.

Classwide peer tutoring has many advantages over teacher-led instruction. Many children in a classroom simultaneously receive one-on-one opportunities to practice academic skills with little burden on the teacher. Each peer tutoring dyad can work on different material at any given time to meet the needs of a heterogeneous group of students. Another benefit of peer tutoring is children can practice social skills as interacting with a peer is embedded in the strategy. Fluency, or performing skills with accuracy and speed, is often a focus of peer tutoring programs.

Peer tutoring is strategy that increases "active student responding." Active student responding (ASR) is accomplished when students are not sitting idle and simply listening to a teacher talk. Rather, ASR occurs when students are "doing," or performing behaviors such as talking, pointing, and writing. Peer tutoring is also a strategy used to include students with a range of disabilities, from learning disabilities to autism, in general education classrooms. Typically developing peers can serve as the tutors of students with disabilities and the students with disabilities also take turns being the tutors.

Perfectionistic

Meredith L. Slish
Oklahoma State University, Stillwater, OK, USA

Synonyms

Perfectionism; Perfectionist

Definition

One who attempts to achieve a state of perfection.

Description

One who is perfectionistic suffers from perfectionism – a rejection of performance that is less than perfect. Two types of perfectionists have been identified. A*daptive perfectionists* are those individuals who do not allow their perfectionistic attitudes and behaviors to become debilitating in their lives. Adaptive perfectionists will set goals for themselves, but those goals will be realistic and attainable. Because their goals are not unattainable, they can then derive pleasure from methods to obtain those goals and their measures to attain the goals do not become self-defeating. Such perfectionistic individuals have high self-esteem and are flexible in their standards for themselves and others and thus are well adjusted intrapersonally and socially [7, 13]. These individuals, ultimately, can still gain satisfaction from their performance even if they are not "perfect" [7, 13]. In contrast, *maladaptive perfectionists* usually fear the thought of failure and experience anxiety when they perceive that they have failed. They tend to be overly self critical and feel that the effort they put forth is never good enough. This distorted pattern of thinking leads to their inability to be happy or experience pleasure from any effort made [7]. Perfectionistic behaviors, attitudes, and personality traits have been linked to various psychopathologies including mood disorders such as depression, anxiety disorders, substance abuse, eating disorders, somatic complaints such as migraines and chronic aches and pains, suicidal ideation, and suicide attempts [3, 5, 8, 9, 10, 13].

Childhood Development

Perfectionistic children and adolescents may be more susceptible to develop anxiety disorders, depressive disorders, obsessive compulsive disorders, eating disorders, and suicidal ideations and attempts. Perfectionism has also been shown to significantly impact children's academic performance [1]. Adaptive perfectionism has been positively correlated with academic performance whereas maladaptive perfectionism has been shown to be negatively correlated with academic performance [1]. Also adaptive perfectionism has been positively correlated with self-esteem and negatively correlated with depression. Conversely, maladaptive perfectionism has been positively correlated with depression and negatively correlated with self-esteem [1]. Perfectionism has also been found to account for a significant portion of the variance in depressive symptoms, symptoms of OCD, and difficulties in relationships with peers in children suffering from obsessive-compulsive disorder [14]. Social connection has been shown to be a moderator for maladaptive perfectionism and the presence of social connection has been shown to lessen the effects of maladaptive perfectionism as well as lessen the effects of hopelessness (robust predictor of depression) [13]. If meaningful social connections are a buffer from potential suicide, then perfectionistic children who have a maladaptive perfectionistic style and low social connections may be at an increased risk for suicide than their adaptive perfectionistic peers. Depressive disorders in children and adolescents are often accompanied by another mental disorder such as attention-deficit hyperactivity disorder, behavior disorders, anxiety disorders, eating disorders, and substance-related disorders [2]. Other suicide risk factors for children include psychological disorders, relationships within the family, family history of psychological disorders or suicide, substance abuse, high levels of stress, social isolation, exposure to other people who have attempted or completed suicide, the individual adolescent's previous suicide attempts or ideations, the presence of firearms within the household in which the adolescent lives, social and economic problems, dependent personality types, and problems in personal interactions with others [4, 6, 12].

Peripheral Nervous System

Chad A. Noggle[1], Andrea R. Moreau[2]
[1]SIU School of Medicine, Springfield, IL, USA
[2]Indiana Neuroscience Institute/St. Vincent's Hospital, Indianapolis, IN, USA

Synonyms

PNS

Definition

The Peripheral Nervous System (PNS) refers to those aspects of the nervous system that lies outside of the Central Nervous System (CNS), which includes neuronal connections with muscles, nerves, and other regions of the body.

Description

The PNS is a network of afferent and efferent neurons that connects the CNS with the sensory receptors, muscles, and viscera of the body [7]. Simply put, the PNS includes all the portions of the nervous system outside the CNS [8] and not encased within bone [3]. In terms of the aforementioned neuronal pathways, afferent neurons are the circuitry that transmits messages from the PNS to the CNS whereas efferent neurons transmit messages from the CNS to the PNS. These pathways may also be differentiated across sensory and motor lines in which afferent neurons transmit sensory information back to the receptor and processing sites of the CNS and efferent pathways transmit motor signals to the musculature of the PNS [2]. Thus, the PNS is wholly responsible for forming lines of communication between the Spinal Cord and the periphery of the body [1]. The CNS and PNS are in constant communication with one another [8].

From a hierarchical standpoint the PNS consists of two main divisions that are vested in carrying out various functions, the Somatic Nervous System and the Autonomic Nervous System [6]. The Somatic Nervous System is primarily responsible for interacting with the external environment [3]. This division is composed largely of afferent projections which transmit sensory signals from organs such as the eyes, ear, nose, skin, muscles, and joints to the CNS [3].

The Autonomic Nervous System itself has two primary divisions, the Sympathetic and Parasympathetic Nervous Systems [1]. The primary function of the Autonomic Nervous System, as a holistic entity, is the neural control of internal states through its' influence on internal organs, both peripheral and central parts [8]. The primary role of the Sympathetic branch is the regulation of the fight-or-flight response [4]. As such, the Sympathetic division is involved in those activities the expend bodily energy such as increasing blood flow, heart rate, respiration, and blood pressure [8]. Whereas the sympathetic branch of the Autonomic Nervous System acts to expend energy, the Parasympathetic branch functions to conserve it [8]. Specifically, the Parasympathetic branch comes into play at times of rest in which respiration and heart rate are slowed and digestive processes increase so to restock the body's warehouse of energy. The manner in which the Sympathetic

and Parasympathetic branches compliment one another is antagonistic in nature [5]. Increased activation of one leads to decreased activation of the other. This back-and-forth interaction serves the purpose of maintaining homeostasis of internal system, while also modulating the appropriate reactivity to the environment.

Permissive Parenting Style

Leah E. Johnson, Heather M. Kelley
Texas Tech University, Lubbock, TX, USA

Synonyms

Democratic-indulgent parenting style; Indulgent parenting style; Rejecting-neglecting parenting style

Definition

A style of parenting that has a high level of acceptance but a low level of control or demand.

Description

The permissive parenting style is characterized by a high level of nurturance and low levels of maturity demands from children, low levels of control, and low levels of communication between parent and child. Parents who exhibit permissive parenting are highly involved with their children, but place few demands or controls on them. These parents do little to train their children to be more independent. Children of permissive parents are allowed to do what they want with little input from the parents. Often, permissive parents allow their children to make their own decisions at an age when they are not yet ready to do so.

The permissive parenting style is defined by warm and accepting parents who are uninvolved. These parents can be either overindulging or inattentive [2]. Parents may be deliberately permissive because they believe this style of parenting will foster creative, confident children [4]. Permissive parenting can be categorized as either democratic-indulgent or rejecting-neglecting. Democratic-indulgent parents are loving parents but rarely restrict their children's behavior unless there is imminent danger. These parents tend to be overindulging, often going along with the child's wishes. In comparison, rejecting-neglecting parents do not attend to parenting details due to disinterest or being overwhelmed by life. Different from democratic-indulgent parents, rejecting-neglecting parents are not aware of what their children's interests are or what their children are doing.

Relevance to Childhood Development

Children of permissive parents show many negative outcomes such as the tendency to be unhappy, lacking self-control and self-reliance. These children have been found to do slightly worse in school as adolescents. Also, children with permissive parents tend to be more aggressive, to be somewhat more immature with peers and in school, and less likely to take responsibility for their actions. Permissive parenting may also result in children who are domineering, egocentric, and noncompliant [4]. Children of permissive parents are impulsive and rebellious. The likelihood for being overly demanding and less persistence on tasks is greater for these children as well. The connection between permissive parenting and dependent, nonachieving behavior is particularly strong for males [2].

Personal Narratives

Bernadette Hassan Solórzano
Our Lady of the Lake University Community Counseling Service, San Antonio, TX, USA

Synonyms

Diaries; Histories; Journals; Narrative conversations; Outsider witnesses; Stories; Tales; Testimonials

Definition

Polkinghorne [3] stated that "narrative can refer to the process of making a story, to the cognitive scheme of the story, or the result of the process." (p. 13) "Narrative" is a term that has become increasingly used in mainstream culture to describe such things as cultural narratives, gender narratives, political narratives, survivor narratives, illness narratives, etc [2, 5]. Narratives are used therapeutically in psychology. Postmodern therapy approaches consider narratives as a powerful component of therapy since postmodernist therapists believe that reality is constituted in language and narratives can be used to change understandings of a situation. If clients can create a more empowered narrative, it is the first step to creating an improved future. Personal narratives can be utilized in written or oral form. Michael White and David Epston implemented writing letters to their clients between sessions to continue the therapeutic narratives between sessions.

Description

Polkinghorne [3] wrote that psychology has used narratives throughout their history in the form of biographies, life stories and case studies. Polkinghorne in *Knowing and the Human Sciences* (1988) tracks the history of the development of using personal narratives in psychology. As individual psychology developed, the narrative became the tool of psychologists in helping establish personal identity. Karl Scheibe [4] wrote about identity and narrative.

Human identities are considered to be evolving constructions; they emerge out of continual social interactions in the course of life. Self-narratives are developed stories that must be told in specific historical terms, using a particular language, reference to a particular stock of working historical conventions and a particular pattern of dominant beliefs and values. The most fundamental narrative forms are universal, but the way these forms are styled and filled with content will depend upon particular historical conventions of form and place (p. 131).

Time is important in personal narratives as well. The narrative must also include the development of a future narrative. So the temporal ordering of the events becomes important and must include many events. This provides the opportunities of including overlooked events which can be incorporated to identify strengths, alternative ways of understanding events and imbue a sense of hopefulness for the future.

Relevance to Childhood Development

The power of storytelling has been with us since the beginning of time. Originally, stories of valor and morality were handed down from generation to generation orally until they began to be written down. Jerome Bruner wrote extensively in *Acts of Meaning* [1] about the fact that children learn early on the necessity of balancing their own desires with those of the family. "Telling the right story, putting her actions and goal in a legitimizing light, is just as important. Getting what you want very often meant getting the right story. . . . A "right" story is one that connects your version through mitigation with the canonical version" (p. 86). Jerome Bruner described narratives as an innate way that children understand even before they have words. You can see children create a sequencing of events in their play. Narratives are the product of how we talk to ourselves in order to sort through our thoughts and develop a coherent understanding of our experiences.

Children initially use narratives to sequence and describe what occurred. The next step children create narratives which describe the ordinary sequencing of events and create explanations for when a divergence occurs. Finally perspective and evaluation is introduced to the narrative. The final step is introduced when the narrative includes solving problems.

Perspective-Taking

Phyllis Curtis-Tweed
Medgar Evers College/CUNY, Brooklyn, NY, USA

Synonyms

Interpersonal understanding; Role-taking; Social perspective coordination; Sociomoral perspective-taking

Definition

Perspective-taking is the ability to understand both one's perspective and the perspective of another person.

Description

Perspective-taking, the ability to understand the distinct perspectives of self and other, is a central process in social cognitive development. Perspective-taking impacts the ways in which people understand themselves and interact with other people. It occurs any time and everywhere that an understanding of self and other is required. It varies according to context and the participants in a given context.

According to G. H. Mead [7], a central factor in social cognitive development is the individual's ability to take another's perspective, as that perspective both informs ones understanding of the self and influences interpersonal interaction. Role-taking or perspective-taking includes the understanding of others' thoughts and attitudes demonstrated though cooperative activity. The importance of this premise is reflected by the presupposition that perspective-taking ability underlies many research areas, including interpersonal interaction, aggression and empathy [15], moral reasoning [8], prejudice and ethnic identity [1, 2], resiliency [9] , self theory [6], and Piagetian cognitive stage theory. Perspective-taking has been used as a barometer for the development of social cognitive processes such as moral development and has served as a target for intervention in program development (e.g., Facing History and Ourselves) [4]. Perspective-taking components are considered to be possible predictors of psychological dysfunction and research suggests that perspective-taking ability in combination with interpersonal interaction and personal qualities may protect individuals form psychological disorder and promote resiliency.

The interpretive function of perspective in the development of self-knowledge and other understanding has served as a starting point for many philosophical efforts to explicate human behavior [5]. Habermas [5, (p. 132)] notes that social perspective coordination or sociomoral

perspective-taking may be understood in terms of "the context of the de-centering of the young person's understanding of the world". Perspective-taking is multidimensional and depends upon the independence and interrelatedness of the self-other perspective-taking constructs, life experiences and contextual variability and is influenced by the characterization of adaptive behavior as well as difference individual development. The self\other components of perspective-taking serve interpretive functions within the formation of perspective derived from context where context may be understood as the arena for experience. These perspectives are reapplied to other contexts, informed by experience and re-conceptualized according to the changing requirements of each context. Perspective-taking is generally considered to have hermeneutical properties because it allows for the observation and interpretation of behavior on a conceptual and descriptive level [5].

Relevance to Childhood Development

Perspective-taking processes are grounded in the development of the self and the ability to understand the viewpoints of others. Because it is a cognitive developmental process, perspective-taking development is age related with higher orders of perspective-taking generally being attained with age. Research literature generally concurs that awareness of psychological distinctions between self and others and a perspective of the self as a social entity emerge around the age of 8 years [3]. Prior to this age, perspective-taking is largely undifferentiated. Although perspective-taking may develop across the lifespan, the formative years of this process have been identified as 8–15. Interventions designed to impact perspective-taking development necessarily target these formative years, 8–15, and tend to focus on the classroom where children of this age range spend most of their time.

A major influence in this area has been Selman's models of perspective-taking and of social perspective coordination which focus on understanding the self and others in interpersonal interaction. These models integrate Mead's perspective of role-taking as the fundamental process in social cognitive development with Piagetian stage theory of cognitive development [10–12]. Selman initially developed a stage theory of social perspective coordination derived in part from Kohlberg's cognitive moral development theory and previous work on role-taking ([10]). Selman [12, (p. 6)] defines social perspective coordination and role-taking synonymously as "the developing ability to differentiate and integrate the self and others' points of view through an understanding of the relation between the thoughts, feelings and wishes of each person". Selman's model extends beyond the identification of the capacity to coordinate social perspectives to understand behavior in social interaction in different contexts such friendship, and parent-child relations. Selman [12–14] identifies levels of social perspective coordination/ perspective-taking as follows:

Level 0 egocentric and undifferentiated: The child is egocentric and has difficulty in differentiating the physical and psychological characteristics of others.

Level 1 subjective and unilateral: The child is able to differentiate psychical and psychological characteristics but can only perceive one point of view in perspective-taking.

Level 2 Self-reflective and reciprocal: The ability to take a second-person perspective emerges with some evidence of the acknowledgement of the necessity of reciprocity in relationships.

Level 3 third person and mutual: Children can take a third -person perspective of relationships and mutually coordinate perspectives.

Selman has also identified a fifth level of perspective-taking which emerges around age 14 years and encompasses adulthood. It is in this stage that individuals understand that their perspective-taking may be influenced by systems such as societal values. Empirical research and subsequent programs have focused on providing evidence and intervention for the first four levels.

Phenotype

Jana Sander
Texas A&M University Corpus Christi College of Education, Corpus Christi, TX, USA

Definition

The observable physical and behavioral characteristics of a person.

Description

The phenotype is determined by genes inherited from the parents and is influenced by environmental factors. If one or two dominant alleles are inherited such as dark eyes the person will have dark eyes. However, two recessive alleles are inherited (blue eyes) the recessive phenotype (blue eyes) will be inherited.

Phonemes

Loretta C. Rudd, Macy Satterwhite
Texas Tech University, Lubbock, TX, USA

Definition

In oral language, the smallest meaningful segment of sound (e.g., /d/, /t/, /k/).

Description

Phonemes are the smallest units of speech and they are written as graphemes, or letters of the alphabet. Phonemes are marked as using diagonal lines (e.g., /d/) which refers to the sound the letter *d* makes. Phonemes are abstract units of language and children are able to use the sounds of parts of words to help decode the words. Children use their knowledge of individual speech sounds and begin relating it to the sound of whole words as they become phonemically aware.

Relevance to Childhood Development

Understanding that words are composed of smaller units – phonemes – is a significant achievement for young children because phonemes are abstract language units [2–4]. Children should be exposed to environments rich with language as soon as possible because it will model for children proper word combinations and pronunciation techniques that will encourage children to develop their

own language skills [1]. Children begin to hear acceptable sounds and sound patterns over and over in the words used most frequently in their language. When children can auditorally discern the subtle differences in phonemes (e.g., hit vs. hint; bit vs. sit; bash vs. batch), they are developing necessary skills to become proficient readers [5]. There is evidence to indicate that children who are unable to discern phonemic differences auditorially will struggle with reading [4].

Phonemic

Macy Satterwhite, Heather M. Kelley
Texas Tech University, Lubbock, TX, USA

Definition

The understanding that speech is made up of a series of sounds and that individual words can be broken down into phonemes, the smallest unit of sound.

Description

Phonemics is known in the field of linguistics as the study of phonemes and can also include their written representations. The phoneme is an indivisible unit of human sound in any language which carries meaning. This study includes articulation, or production of the sounds, the auditory perception of the sounds, and the meaning behind the sounds. Phonemic study includes the understanding of the differences between sounds and how those sounds can change the meaning of the words used within a spoken language.

Phonemic awareness is the ability to identify words as having a specific sequence of sound, and then be able to manipulate these phonemes or sounds by blending sounds, isolating sounds, recognizing rhyme, among other tasks. For instance, four year old Matthew might notice that Matthew, Meagan (his younger sister), and Mommy all start with the same sound. This recognition of sound is referred to as phonemic awareness.

Segmentation and blending of sounds are aspects of phonemic awareness which will later be useful to the child as he begins to read and write. For example the word *fish* can be segmented into three phonemes or sounds as /f/, /i/, /sh/. The recognition of rhyme is also useful to young readers and writers. If a child can recognize the rime (or ending segment) of the word *hat* as being *-at,* then he can manipulate the beginning sound to create *mat, fat, cat,* and others.

It is important to note that phonemic awareness is the understanding and manipulation of the spoken sounds of language and should not be confused with the sound-symbol relationship of printed text.

Relevance to Childhood Development

At an early age, young children become aware of the spoken sound. Children hear streams of sound, and soon associate that with meaning. Later, they learn to enjoy and play with language through nursery rhymes, finger plays, and books to begin on such as *Brown Bear, Brown Bear* [3]. Adults can help the young child delight in language play through these experiences and start noticing the sounds and structures of our language.

In our English alphabetic written system, there is a strong relationship between the spoken sound and the printed word, with exceptions. Due to this strong relationship, it is critical that young children be able to recognize the sounds of the language so that they will be able to read and write using our conventional system. This whole system is built upon a rich foundation of oral language. Parents and caregivers should ensure all children are immersed in a literacy-rich environment with conversation, singing, nursery rhymes, and books read aloud repeatedly. These playful actions will not only teach the structure and nature of our language to the children, but will lay a strong foundation of literacy learning for the future. The National Reading Panel [4] suggests that children who have a strong foundation in phonemic awareness are less likely to develop reading problems during formal instructional schooling.

Phonemic Awareness

Sunny Windingstad
University of Tennessee, Knoxville, TN, USA

Synonyms

Orthographic reading skills; Phonological awareness

Definition

Phonemic awareness is the ability to recognize and manipulate the smallest units of sound in spoken communication. This skill is exhibited through identification and manipulation of the sounds of oral language.

Description

The term *phonemic awareness* is often used interchangeably with *phonological awareness*. Phonemic awareness, however, generally applies to the ability to recognize and manipulate the smallest unit of the spoken word, the phoneme, while phonological awareness applies to larger units of language such as syllables, onsets, and rimes [1, 2].

According to Goswami [4], phonemic awareness "refers to the knowledge that a word like *cup* consists of three phonemes, corresponding to the letters *c, u, p*." Not only is phonemic awareness defined as the knowledge of the symbol/sound correspondence, but also the ability to manipulate these relationships in order to demonstrate the awareness.

Phonemic awareness is simple to assess and several formal and informal measures of the construct exist. According the National Reading Panel [3], phonemic awareness can be taught through the isolation, identification, categorization, lending, segmentation, and deletion of phonemes in context. In a meta-analysis of studies of phonemic awareness instruction, the National Reading Panel found the overall effect sizes on reading (d=0.53) and spelling (d=0.59) outcomes were moderate. These same techniques can be used to assess phonemic awareness, as well.

Relevance to Childhood Development

There is debate about the role of phonemic awareness in reading acquisition. For instance, although the International Reading Association [2] references several studies supporting the ability of phonemic awareness to predict later reading ability, the exact role phonemic awareness plays in reading development is unknown. Presumably, phonemic awareness is a prerequisite for decoding the written word because it underlies the appreciation of symbol–sound relationships [5]. Phonemic awareness develops over time.

Phonemic Development

Heather M. Kelley, Kyle A. Litchfield
Texas Tech University, Lubbock, TX, USA

Definition

The part of language development that uses phonology (the part of language involving speech sounds, including pronunciation, fluency, and intonation) phonemic awareness (the understanding that language is made up of smaller

units: words, syllables, and sounds) and phonics to become proficient in speaking, reading and writing language.

Description

Phonemic development emphasizes language development skills with the ultimate goal of proficiently in reading and writing. Phonemic development begins with the skill of phonology – the part of language that involves an individual speech sound that a letter makes. Phonology is well developed in the primary years of life, and children by age 5 have acquired most of the phonemes – individual speech sounds. Phonemes are the smallest units of speech and they are written as graphemes, or letters of the alphabet. Phonemes are marked as using diagonal lines (e.g., /d/) which refers to the sound the letter *d* makes. Phonemes are abstract units of language and children are able to use the sounds of parts of words to help decode the words. Children use their knowledge of individual speech sounds and begin relating it to the sound of whole words as they become phonemically aware [3].

Phonemic awareness develops in children in the elementary years after they have mastered phonology. Phonemic awareness refers to a child's basic understanding that speech is composed of a series of individual sounds, syllables, and words, and provides a foundation for a greater depth of understanding of language. The simplest level of phonemic awareness is to understand that words are made up of multiple sounds that we can hear, identify, and match to similar word patterns such as rhymes. As children gain this knowledge and perform these functions, they are developing auditory discrimination. Children are considered phonemically aware when a child can choose a duck as the animal whose name begins with /d/ from a collection of toy animals. Also, children know that a word such as *bug* is composed of three sounds that can be segmented into those sounds of /b/u/g/. Phonemic awareness has been referred to as a precursor to phonics and necessary for children to learn in order to benefit from phonics instruction.

Phonics is the last stage of phonemic development and refers to the relationship between the sounds in speech and the spelling patterns in written language. The emphasis is on spelling patterns and is based on the prior knowledge of phonology and phonemic awareness. There is no simple way to explain all of the types of phonics information that students need to learn, nor can they be listed in a clean, sequential order, because it is built on a child's foundation of phonemic awareness. Children should be taught the letters of the alphabet first, then consonants, vowels, blends (e.g., *sh, ch*), and phonics generalizations. Phonics generalizations refer to rules to clarify English spelling patterns. For example, one rule is that *q* is followed by u and pronounced /*kw*/, as in *queen* and *quick*. Actual reading and writing will improve the understanding of phonics.

Relevance to Childhood Development

Children acquire speech sounds gradually in the early years of life and it is common to have difficulty understanding preschoolers at the phonology stage because they have not mastered key sounds. Phonology is a precursor in the developmental process of phonemics. Understanding that words are composed of smaller units – phonemes – is a significant achievement for young children because phonemes are abstract language units. Children should be exposed to environments rich with language as soon as possible because it will model for children proper word combinations and pronunciation techniques that will encourage children to develop their own language skills. Children begin to hear acceptable sounds and sound patterns over and over in the words used most frequently in their language.

When students enter the elementary years of schooling they will be mastering phonemes and becoming phonemically aware and advancing to whole words. Phonemic awareness has been found to be very important in learning to read in first and second grade. Children that were able to distinguish among individual speech sounds found it easier to learn and read. As children develop phonemic awareness, they learn to segment, manipulate, and blend spoken language. Children use strategies to decode and encode words as they are trying to read. Listed below, are five developmentally appropriate phonemic strategies very common for children to use as they become more proficient in reading.

1. *Matching sounds to words.* Children learn to identify a word that begins or ends with a particular sound. For example, when shown a brush, a car, and a doll, they can identify *doll* as the word that ends with /l/.
2. *Isolate a sound in a word.* Children learn to isolate the sound at the beginning, middle, or end of a word. After the teacher says the word *hat*, for example, children can identify /a/ as the middle sound.
3. *Blend individual sounds to form a word.* Children learn to blend two, three, or four individual sounds to form a word. The teacher says /b/, /i/, /g/, for example, and the children repeat the sounds, blending them to form the word *big*.
4. *Substitute sounds in a word.* Children learn to remove a sound from a word and substitute a different sound. Sometimes they substitute the beginning sound, changing *bar* to *car*, for example. Or, students change the middle sound, making *tip* from *top*, or they substitute the ending sound, changing *gate* to *game*.

5. *Segment a word into its constituent sounds.* Children learn to break a word into its beginning, middle, and ending sounds. For example, children segment the word *feet* into /f/, /e/, /t/ and *go* into /g/, /o/ [5].

As children are developing their phonemic skills, it is important that children are exposed to a language-rich environment. Singing songs, chanting rhymes, reading aloud, and games give children the opportunity to orally match, isolate, blend, and substitute sounds and segment words into sounds. Phonemic awareness instruction is crucial to the success of the development of skills and should meet four criteria:

1. *Activities should be appropriate.* Children of 4, 5, and 6 years of age should involve songs, nursery rhymes, riddles and wordplay books because these activities are engaging and encourage playful experimentation.
2. *Instruction should be planned and purposeful.* When teachers have an objective in mind as they are teaching phonemic awareness, they are more likely to be effective in focusing children's attention on the sound structure of oral language.
3. *Phonemic awareness should be a part of a balanced literacy program.* Instruction should integrate comprehension, decoding, vocabulary, writing, and spelling. It is important that children perceive the connection between writing and oral language.
4. *Activities should be meaningful.* Connect activities with topics that are relevant and meaningful for the child's life. This will resort and a much more purposeful activity and children will become more motivated to learn [6].

It is important that children have a solid foundation on phonemes and phonemic awareness so they can be most successful in phonics and reading and writing. Second language learners whose native language uses an alphabetic system, such as Spanish, will learn phonemic awareness and phonics much more easily than students whose native language employs a logographic system of symbols without sound correspondences, such as Chinese. Language can be difficult for some to learn so adults and teachers should always be supportive and encourage language exploration and model proper techniques in regard to learning language [2].

As children begin to connect sounds with words, it is essential to encourage reading and writing which will enhance their language skills. Phonics instruction is an important part of reading and writing instruction during the primary grades, but a combination of instruction and actual reading and writing activities is most successful for students. Without this meaningful application of what they are learning, phonics instruction can often become ineffective. There are four stages of phonemic writing development as children progress in their writing skills.

1. *Prephonemic Stage.* Random letters are used to represent whole words or stories. The letters chosen have no relationship to the sounds in the story but are "placeholders for meaning."
2. *Phonemic Stage.* Letters are used that match some of the sounds in the words or stories being written. A letter matching the beginning sound of a word might be used to represent that whole word (e.g., *p* for *people*).
3. *Transitional Stage.* The child spells out words using correct letter sounds. However, writing contains much "invented spelling" in which conventions are not followed. For example, the silent e is often omitted, as in *mak* for *make*.
4. *Conventional Writing.* Some children begin writing as adults do during the primary years, using correct spellings and other writing conventions [4].

Phonemic Reading Skills

Kyle A. Litchfield, Heather M. Kelley
Texas Tech University, Lubbock, TX, USA

Synonyms

Character deciphering abilities

Definition

Skills used to string individual phonemes together to successfully read whole words. Ability to segment individual sounds to successfully read whole words.

Description

As children begin learning to read, they decode words using a left-to-right analysis of letter–sound relationships [1]. Readers must master a variety of skills to recognize, decode, and understand the meaning of words and comprehend what they are reading.

One strategy for children learning to read consists of phonemic skills, which involves learning to read a word by sounding out the individual phonemes, or the smallest unit of sound that distinguishes one word from another [2]. In order for a child to successfully learn to read and write words, they must first be able to analyze the sound of words. Phonemic skills are the foundation to world solving in both reading and writing [2]. Mastering these skills allows learners to read words by thinking about the sounds.

While breaking words apart by phonemes is a help with simple words, such as hat, phonetically breaking up more complex words, such as restaurant, is not as easy. As readers are introduced to these more complex words, they must begin to use phonemic skills in combination with other skills, such as visual, morphemic, linking, and research to comprehend each word.

Relevance to Childhood Development

Learning and understanding phonemes is a critical step for children to master before most will achieve success in reading [3]. As children start the process of learning to read, one of the first ways they are generally taught to decode words is by sounding them out. Breaking whole words down into individual phonemes is a skill that children are taught during early years of elementary school and lay the foundation for academic and reading success later in life.

Phonics

Macy Satterwhite, Matthew C. Lambert
Texas Tech University, Lubbock, TX, USA

Definition

Phonics instruction is a way of teaching the relationship between the sounds and symbols of our alphabetic system of language in reading and writing, usually used in beginning reading instruction through Grade 2 [2]. It is also referred to as one of the ways in which readers solve words.

Description

Phonics instruction teaches children how the sound/symbol relationships of our language work. This knowledge is useful in decoding unknown words which are not sight words. The National Reading Panel [5] states that phonics knowledge is a strong predictor of reading proficiency.

When a teacher points out that the letter *m* represents the first sound in *milk, money,* and *Maggie,* phonics is being taught. Phonics is also being taught when a young reader is taught the difference in the sounds of letter *c* in the words *city, cake, ice,* and *crate.* When youngsters study word families or word chunks such as *–ight* in the words *night, might,* and *fright,* they are engaging in phonics instruction. Phonics instruction and regular spelling instruction go hand-in-hand [2].

Relevance to Childhood Development

As children progress in their language development into young readers and writers, the knowledge of phonics skills becomes invaluable in their journey. However, adults must be cautioned that the instruction of phonics is not an end into itself. Some children will need more phonics instruction than others [1, 2, 4]. Heilman [4] recommends that a "guideline for instruction is that *the optimum amount of phonics instruction a child should be exposed to is the minimum the child needs to become an independent reader" (p. 2).*

Phonics instruction does have its limitations in teaching children to read. The English language is speckled with non-regular spellings of words such as many of the words which come from other languages such as the word *bouquet.* Also confusing are homonyms such as *weak* and *week,* silent letters such as in *comb,* and the many exceptions to our phonics rules such as *been, said, have,* and *come.* These exceptions and derivations are why children need a variety of methods in solving words in addition to phonics instruction.

Phonics instruction is most valuable when supported with other literacy instruction of comprehension and vocabulary through language-rich texts and experiences [3, 6]. It is within the context of these rich literacy experiences that children will be able to apply and use their phonics knowledge, yet not get stumped on the irregularities of the English language.

Phonological Awareness

Christopher Pilat, Lisa Kilanowski-Press
Niagara University, Niagara, NY, USA

Synonyms

Phonemic awareness; Phonological learning; Phonological sensitivity

Definition

Phonological awareness is the ability to understand and recognize the sound structure of the spoken language.

Background

As early as the 1940s many researchers claimed that the inability to recognize the sound structure of the spoken word was often apparent in dyslexic (incapacity to read) cases. Despite these findings, phonological awareness has only been a main focus of reading research since the 1970s and 1980s. It was around this time that the relationship between phonological awareness and reading was established [2]. The early neglect of researchers focus on the relationship between phonological awareness and reading is understandable considering phonological awareness does not involve written letters; rather, phonological awareness refers to one's awareness of the sound structure of oral language. Since the 1970s, however, phonological awareness has been consistently found to be the best predictor of future reading success [4, 5, 11, 17].

Phonological awareness is best conceptualized as a broad entity made up of separate skills. Scheule and Boudreau [12] suggest that there are simple, shallow level phonological awareness skills and complex, deep level phonological awareness skills. These shallow skills include separating words into their respective syllables, identifying as well as generating rhymes, and being able to recognize words that share the same beginning sound. At the more complex level of phonological awareness is the ability to recognize, separate, and manipulate words into their smallest sound units also known as phonemes. This more intricate ability is commonly referred to as phonemic awareness.

Scheule and Boudreau [12] identify some common skill sets in the sequence of phonological awareness. This sequence complements the suggestion that phonological awareness skills range from simple to complex. In ascending order from simple skill sets to more complex skill sets are the ability to separate words into syllables, rhyming, matching words by onsets and rimes, segmenting words into their respective onset and rimes, segmenting initial and final sounds, blending sounds into words, segmenting words into individual sounds, and deleting and manipulating phonemes. (For a graphic representation refer to Scheule and Boudreau [12].)

The initial ability of a child to recognize that a word is made up of separate sounds is intuitive. Therefore, in most cases the child will not consciously tell you how many syllables there are in a word; rather, they will just demonstrate an understanding that the word is made up of separate sounds rather than one big sound. Research shows that children begin demonstrating phonological awareness by understanding that words break down into smaller groups of sounds. The child's awareness that words are made of individual sounds comes much later in his/her phonological development [17].

The ability to rhyme is usually developed through nursery rhyme books. A child can demonstrate this skill in different ways. He/she could be presented with three words (cat, mat, dog) and told to provide you with the two words that rhyme. The child could also simply be asked what word rhymes with cat. Research shows that nursery rhymes can be memorized by children as early as 3 years of age [17]. Although not consciously aware of their ability to rhyme, children will be able to generalize this skill to understanding the phonology of a word.

To match initial sounds of the word the child could be presented with a list of words (bat, dog, ball) and asked which two words have the same beginning sound. As well, the child could be presented with a list of words (bat, dog, ball, bank) and asked which word is not consistent with the rest of the beginning sounds (dog). Similarly, the same type of exercise would be feasible to match ending sounds of the word. However, in this case, you would provide the child with a list of words with similar endings (duck, tuck, truck, rabbit) and ask them to identify the words with similar endings or the word that does not belong.

Segmenting words into onset and rimes and segmenting words into initial and final sounds are similar

skill sets and should be discussed together. Research shows that segmenting the word where the onset and rime divide is easier than dividing an initial and final sound [16]. The onset is the initial phoneme in a word and the rime is the vowel and consonant that follows. For example, in the word "dog" the onset is /d/ and the rime is /og/. If the child were to divide an initial and final sound he/she would divide the word as such /do/ and /g/. The ability to segment is complex because of a concept referred to as coarticulation. Coarticulation pertains to the phenomenon in which vowels can be articulated in isolation, but a consonant must be coarticulated with a vowel. For instance, the vowel /a/ has an exclusive sound when spoken by itself. However, the /t/ sound changes depending on the word that is spoken (take-/tuh/, tap-/tah/). This is the most likely reason that it is more difficult for a child to separate an initial sound from a final sound than it is for them to separate an onset from a rime [17].

The ability of a child to blend individual or separate sounds into a cohesive word comes much later on in Scheule and Boudreau's [12] phonological progression scale. This is a much more difficult concept for children to grasp. This ability is dependant upon most of the previous skills that have already been mentioned. Naturally, children must be aware that whole words are made up of separate sounds before they begin to blend the separate sounds into a whole meaningful word. Up until now the focus and skills involved in the phonological awareness progression have concentrated on segmentation where as this ability focuses on blending. When orally presented with the individual sounds of the word (/s/ch/oo/l/) the child will be able to blend the different sounds into a cohesive and meaningful word (school).

The next skill along the ascendancy of phonological awareness abilities is the segmentation of words into individual sounds, also known as phonemic awareness. Scheule and Boudreau suggest that this foundation is critical for future reading success, more so than any other skill in the progression of phonological awareness. A child who possesses this ability will understand and demonstrate that the word tap can be segmented into the individual sounds or phonemes /t/a/p/. Adams [1] suggests that this ability develops around the age of 6 years old. The child is now ready to make appropriate use of the alphabetic principle to read unknown words without the direction of someone else.

The ability to segment words into phonemes usually leads to the ability to delete and manipulate phonemes. This is the understanding that the deletion of a phoneme will change the meaning of the word. Children will also be aware that they can manipulate individual phonemes to make different words at this stage. For example, if the child were to remove the /t/ in top and insert a /m/ in the place of the /t/, the child would understand that he/she has changed the meaning of the word. Further, if the child were to manipulate the word /top/ in reverse order, he/she would be aware that the new word would be /pot/.

When progressing along the complex continuum of phonological awareness skills, Scheule and Boudreau [12] suggest that the acquisition of phonemic awareness skills begins with onset-rime segmentation. A typical child will then ascend up the gradient of skills to acquire the other steps necessary for phonemic awareness including, the ability to segment initial and final sounds, blend individual sounds into words, segment words into sounds, and delete, add, and manipulate phonemes. As stated previously, the skills that comprise phonemic awareness are necessary components of phonological awareness, and tend to begin to develop around the time that the child enters preschool and kindergarten [17].

It is important to distinguish between phonological awareness and phonemic awareness which are closely related but not the same. Phonological awareness is the ability to understand the sound structure of language where as phonemic awareness is the ability to manipulate and isolate individual sounds known as phonemes. Confusion tends to surround the differences between these two topics because they are so closely related in both meaning and spelling. It is important to remember that phonemic awareness is one of the skills that comprise the concept known as phonological awareness.

It is also important to distinguish between phonological awareness and phonics. Phonological awareness in its pure form only refers to the sound structure of *oral* language. It does not actually have anything to do with written language. In contrast, phonics is the teaching of the alphabetic principle; the knowledge that different sounds of a language are represented by written symbols on paper. Phonological awareness is not dependent on phonics; however, phonics is dependent on phonological awareness. Children must understand the phonological structure of a word before they can learn the letters that correspond to those different sounds. Understanding the alphabetic principle, however, has shown to strengthen a child's phonological awareness [12].

Relationship to Early Childhood Development

There remains a lack of research about how phonological awareness tends to develop in children. There are, however, some theories which posit a possible developmental path that phonological awareness follows. The Lexical

Restructuring Model [8] hypothesizes that children learn words holistically early in language growth. As their language develops they learn to represent language in single phonemes. In this model then, vocabulary is the driving force of the development of phonological awareness. Once a child's vocabulary increases so does their ability to understand that words are represented by small units of sound rather than holistic units. They develop a lexical base which helps them generalize knowledge from word to word and draw comparisons. Children use this lexical base to identify words by syllables eventually progressing to identifying them by individual phoneme representations. When children develop the ability to recognize that words are made up of individual phonemes, they are now ready to learn the alphabetic principle.

Ziegler and Goswami [18] propose a theory which they refer to as the psycholinguistic grain size theory. They hypothesize that a child's phonological representations of words become finer grained and more complete over time rather than becoming more segmental as the Lexical Restructuring Model posits. Further, the psycholinguistic grain size theory suggests that repeated exposure to vocabulary and the spoken structure of language provides the foundation to develop phonological awareness. However, they claim that learning at the phonemic level does not happen until reading instruction begins. Children learn phonemic awareness through orthographic (written structure) representations of the word. Children who have reading difficulties are unable to efficiently use phonological representations of words to understand the orthographic representation of words. Thus, these children have a problem learning the alphabetic principle.

Based on others research, Christensen [5] describes a developmental trajectory of phonological awareness which begins with knowledge of rhymes. Rhyme knowledge is usually acquired by the child through nursery rhymes and childhood language games. From this intuitive knowledge of rhymes, the child becomes receptive to the onset-rime structure of language and syllables. While these abilities generally develop before a child learns to read, phonemic awareness occurs after reading instruction has commenced.

Whatever model one chooses there is little doubt that phonological awareness is indicative of future reading skills as evidenced by the myriad of researchers who adopt this view [4, 5, 12, 15, 17]. These future reading skills refer to phonemic awareness, the alphabetic principle, reading vocabulary, reading fluency and reading comprehension. Reading comprehension is the ultimate literacy skill that educators want children to attain. It is referred to as an outcome measure because it draws upon all of the abilities associated with reading to succeed. Because phonological awareness predicts all of the skills necessary to comprehend reading, it is arguably the foundation of reading literacy.

Since it is clear that phonological awareness has a strong effect on future reading success, it is relevant to discuss current reading literacy problems. Contrary to what many believe, the ability to read does not occur naturally. In fact reading draws upon many cognitive skills to function [2] and needs intense instruction to develop [3]. There are 15–20% of Americans currently diagnosed with a language disability; most of this percentage is accounted for by dyslexics, or those who do not have the ability to read [10]. Nearly 80% [3] of the 3 million children ages 3–21 (NICHCY, [9]) diagnosed with a Learning Disability have dyslexia. Further, the most common type of dyslexia, dysphonetic dyslexia, occurs because of a deficit in phonological awareness. Specifically, a dysphonetic dyslexic is unable to match the phonological sound of a word to the orthographic counterpart. These staggering statistics demonstrate how important it is for a child to fully develop phonological awareness. Unfortunately, nearly 20% of students are affected to some extent by deficits in phonological awareness [3].

As discussed earlier, phonological awareness helps students relate oral language to written language. It has been shown to predict a child's word reading ability [14]. Birsh [3] suggests that if children fall behind in attaining a proficient level in word reading, they only have a one in eight chance of catching up to their same age peers. Luckily, deficits in phonological awareness can be detected as early as kindergarten and first grade. In fact, it is absolutely necessary to identify these children as early as possible and intervene appropriately. If these students who lack a proficient level of phonological awareness go unidentified until third grade they will likely continue to be plagued by reading disabilities.

Birsh [3] further discusses a study supported by NICHD, which showed that 74% of the children who went unidentified with reading deficits until third grade continued to evidence a reading disability in ninth grade. To add upon these somber research findings, many students who have a reading disability are not recognized until third grade [6].

Maughan [7] uncovered long-term effects of reading difficulty through a review of the literature. Self reports suggest that adults face much embarrassment and anxiety when required to fill out a form, write checks, or even

write a single letter. Often books are avoided by these individuals as a source of information. If one considers the importance of written material as a means of retrieving information, this finding is significant. Also uncovered were occupational attainments of disabled readers. Specifically, those who traditionally struggled with reading were more likely to be unemployed at 23 years of age, and more likely to remain unemployed than their non-disabled peers. Maughan [7] also makes reference to educational attainment as the strongest predictor of occupational success. Considering the importance that reading has in educational attainment, it is reasonable to assume that a disability in reading can have a negative impact on future job success as well.

Maughan [7] also found that studies reveal that struggling readers whose problems persist into adulthood have low self-esteem. This low self-esteem leads to many other problems not directly associated with a disability in reading. However, because a reading disability leads to low self-esteem, it can be considered an important risk factor for other problems in adulthood. In fact, reading disabilities have shown to be present in individuals with conduct disorder, emotional disturbances, and depression. This finding is logical considering the frustration that an individual displays when struggling with a reading task. This frustration is persistent throughout the day because reading is so deeply engrained in the navigation of society.

Given all of the research that is available on phonological awareness there are still many inconsistencies present. Although it is no longer a mystery how phonological awareness develops it is still not an exact science either. Also, many researchers use different terminology when discussing phonological awareness. Some researchers use different terminology in describing the same concept or the same terminology when describing different topics. A common example is the tendency of researchers to interchange the terms phonological awareness and phonemic awareness when indeed they represent two different abilities. As well, both the number and types of skills that ought to be considered part of phonological awareness differ between researchers. Perhaps these inconsistencies provide evidence that further research is needed to make this concept more cohesive. There also needs to be more research conducted to eliminate the persistence of phonological deficits into adulthood. As well, research regarding the longitudinal detriment caused by reading disability across the lifespan is still limited. Despite these inconsistencies and limitations, there is little doubt that phonological awareness is absolutely necessary for a child to succeed in reading literacy.

Phonological Development

Heather M. Kelley, Matthew C. Lambert
Texas Tech University, Lubbock, TX, USA

Definition

The part of language that involves developing speech sounds including pronunciation, fluency, and intonation.

Description

There are approximately 44 speech sounds in English. Speech sounds used combination with other speech sounds produce an oral language. Phonological development refers to forming and using speech sounds to clearly communicate language. As more sounds of a language are acquired, language becomes clearer, and pronunciation, fluency, and intonation all improve. Intonation involves pitch – how high or low a voice is when producing a sound; stress – how low or soft a word is spoken; and juncture – the pauses or connections between words, phrases, and sentences. Articulators must be used simultaneously to communicate effectively and include the front and back of the tongue, teeth, lips, roof of the mouth, vocal cords, and lungs. Not only do articulators need to be manipulated to create sounds, but they must also be connected together rapidly in order to form words and communicate ideas. Also, regional and cultural differences exist in the way people pronounce phonemes. It is important to note that those learning a second language may have to learn how to produce new sounds that are different from their native language. It is often difficult, particularly for older children and adults, to properly incorporate new sounds in their speech as they learn a nonnative language.

Relevance to Childhood Development

Children acquire speech sounds gradually in the early years of life and it is common to have difficulty understanding preschoolers because they have not mastered key sounds. A child's language and speech abilities grow according to their need to use it, their interests, and the meaning it has for them. Language acquisition is fostered by positive interactions regarding language between the child and an adult. It is important to recognize that phonology develops gradually in early childhood, and preschoolers can be expected to struggle with speech sounds throughout much of this period. Harsh correction or insistence that children start over again will not be useful and may even inhibit or discourage further language learning and exploration.

Environments rich with language will model for children proper word combinations and pronunciation techniques that will encourage children to develop their own language skills. Children begin to hear acceptable sounds and sound patterns over and over in the words used most frequently in their language. Rules become incorporated by children in phonological development such as adding the phoneme /s/ to make things plural or learning that only certain sounds are compatible in the English language. For example, children will learn that phonemes /d/ and /p/ typically will not be pronounced in succession. Most phonological rules are acquired before age five.

Phonological development also plays a crucial role in reading instruction during primary grades. Children use their proficiency in pronouncing sounds in conjunction with phonics, which are associations with sound-symbol correspondences, as they begin to read and write. Inventive spelling will be common as children learn to write because they will be relying on the phonemic skills. More experience in spelling will provide students with a more conventional manner of spelling.

Speech problems with young children can cause a great source of anxiety for parents wondering if their child is normally developing. Stuttering, inability to pronounce some sounds, restarting sentences, and stumbling over words are all very typical and common errors for preschool speech. Researchers have identified the approximate ages at which various sounds are spoken accurately. This information is often presented in developmental charts that caregivers, teachers, or parents use to assess phonological development (Table 1).

Children at an older age that cannot pronounce many early acquired speech sounds may be at risk for serious speech delays. Children that make irregular substitutions such as pouncing *rabbit* as *abbit* may also be at risk. Continual stuttering, especially at an older age is a true disfluency that can be caused by physiological issues and may be a hereditary condition. Preschoolers are most likely recommended for evaluation and speech therapy when teachers, caregivers, and parents cannot understand them. In deciding if a speech challenge should be

Phonological Development. Table 1 Typical order of acquisition of specific speech sounds for girls and boys

Age of acquisition	Girls	Boys
3 years	P, b, m, w, d, n, k, g, h, ng	P, b, m, h, w, d, n, k, t, g
4 years	l	ng
5 years	J, y	y
6 years	Sh, ch, r, zh, f, wh	Zh, wh, j
7 years	S, z, th, v	F, l, r, ch, sh, s, z, th, v
7–9 years	Bl, br, dr, fl, dl, kr, pl, skw, sl, str, tr, pr, other blends	Bl, br, dr, fl, dl, kr, pl, skw, sl, str, tr, pr, other blends

addressed, one should evaluate to what degree a child can communicate. If a child is communicating well, intervention should be postponed.

Phonological Disorders

Synonyms

Articulation disorder; Developmental phonological disorders; Speech sound disorders

Definition

A group of disorders where individuals fail to use appropriate speech sounds for their age and dialect.

Description

Children often make some speech errors as they learn language, and certain speech errors are typical at different developmental ages; therefore, age and severity are important to note during assessment. There are a number of speech errors that are common to phonological disorders, including omissions, additions, distortions, and substitutions. Phonological disorders interfere with academic and occupational achievement, as well as social communication. The causes of phonological disorders are structural problems with the main speech mechanisms, neurological problems that can cause fine motor problems with speech muscles, and unknown causes. Only about 3% of children present with phonological disorders of unknown origins. Further, phonological disorders are predominantly found in males. Speech difficulties may also be associated with mental retardation, hearing impairments, and severe environmental deprivation. If these conditions are present, the speech problems need to be in excess to those usually associated with the disorder to make a diagnosis of phonological disorder.

Speech-language pathologists (SLPs) evaluate phonological disorders by listening to the individual's speech and may use a formal articulation test to record speech errors. Further, an oral mechanism examination is used to assess whether the individual's mouth muscles are functioning properly. Speech-language pathologists have a number of treatment procedures to help improve articulation and reduce speech errors. Many of the treatments involve demonstrating how to produce the correct sound, helping individual's recognize correct and incorrect sounds, and practicing the sounds.

Phonological Learning

Laurice M. Joseph
The Ohio State University, Columbus, Ohio, USA

Synonyms

Phonological awareness; Phonological coding; Phonological processing

Definition

The term phonological is derived from the Greek root phone, which means voice or sound. Phonological learning refers to the science of phonemes (speech sounds).

Phonemes are the smallest unit of speech. Phonological learning refers to acquiring the system of speech sounds of a language through phonological awareness, phonemic awareness, phonological coding, and retrieval of phonological codes [13].

Description

Phonological learning involves becoming aware of sounds of spoken language (phonological awareness), holding that information in working memory (phonological memory), accessing phonological information, retrieving that information (retrieval of phonological codes), and making associations between sounds and printed symbols (e.g., alphabetic letters). A hierarchy of phonological awareness skills consists of (1) rhyming, (2) alliteration, (3) blending, (4) segmentation, and (5) manipulation. In 1998, the International Reading Association distinguished between the terms phonological awareness and phonemic awareness. Phonological awareness involves identifying and manipulating larger units of speech than the individual phoneme (e.g., words, syllables, onsets, and rimes). This was considered to be easier than phonemic awareness, which involves identifying and manipulating individual speech sounds (phonemes). Across phonological skills, recognition of sounds has been found to be easier than production of sounds [14]. Rhyming is considered to be the most basic phonological awareness skill, and it involves having children recognize words that sound alike, categorize words that share common sounds, detect words that do not share common sounds (e.g., oddity tasks), and produce words that sound the same as other words. Alliteration involves having children identify initial sounds in words by recognizing the beginning sounds in words, categorizing words according to the same beginning sound, deciding whether two or more words have the same beginning sound, and producing the beginning sound of a word,. Blending refers to *stringing* individual sounds of words together to produce part of a word (e.g., /sl/ -/i/-/p/ or a whole word (e.g., /sl-i-p/). Segmentation refers to becoming aware of the sequence of sounds in a word, identifying each sound segment in a word, and saying each sound segment in a word. This skill progresses from segmenting syllables to individual sounds in a word by clapping to each syllable or individual sound in a word as each sound is orally produced and by breaking the sounds of a word apart and saying each syllable or every individual sound of that word. Manipulation of phonemes consists of deleting (e.g., removing the /c/ in the word /cup/ and left with the word /up/, substituting (e.g., removing the /c/ and replacing it with the /p/ sound to make another word /pup/, and reversing individual sounds in words to form new words (reversing the word /top/ and saying the word /pot/. When students recognize, produce, and manipulate the sounds of spoken language, they likely go through a process of holding those sounds in memory so they are likely to rapidly retrieve them again. This is likely to occur when children are provided with ample opportunities to engage in phonological awareness exercises. Moreover, it has been reported in seminal studies that early training in phonological awareness has been predictive of reading decoding and spelling achievement in the primary grades (e.g., [2, 11]).

Phonological awareness has been found to assist children with acquiring the alphabetic principle which involves recognizing that each letter corresponds to each basic sound in speech as well as making letter-sound connections [1]. In other words, an awareness and manipulation of sounds in spoken language leads to making associations between letters and sounds in written language. This is also referred to as *phonics*. Among phonological awareness skills, phoneme segmentation is the best predictor of word recognition for primary grade children [7]. When children begin making correspondences between letters and sounds, they may go through a process referred to as *phonological recoding* as they learn to decode words that are a part of their spoken language repertoire [10, 14, 15]. Initially, children decode words in a one-to-one sequence fashion (e.g., /s/-/i/-/t/) and then progress to making hierarchical decoding of words which involve looking at standard letter-sound spelling patterns of words (the *orthography* of language) and using a letter or letters in a word to cue the sounds of another letter or other letters in a word (e.g., using the letter *e* in the word *site* to cue the long /i/ vowel sound or using the vowel combination of *ea* to cue the long /e/ sound in the word *seat* [6].

Relevance to Childhood Development

Four levels of developing phonological awareness consist of (1) becoming aware of speech flow as a collection of individual words; (2) distinguishing syllables in spoken words (3) recognizing and producing onset and rimes (4) becoming aware of phonemes in words [5]. These basic phonological awareness skills such as rhyming, alliteration, syllable segmentation can be evident in children as young as 2 or 3 years old. More advanced phonological awareness skills such as segmenting individual sounds in words, blending sounds in words, and manipulating sounds in words are observed in children during kindergarten, first, and second grades during formal schooling. These skills are critical because they have been found to be precursor skills to reading and spelling words with ease [2].

The relationship between learning phonological skills and learning how to read and spell is also a reciprocal one of children acquiring some phonological skills to help them learn to read and spell and engaging in reading and spelling activities frequently to enhance their phonological skills [3, 4, 9]. Many children who have been identified as having a specific learning disability or who have been referred as dyslexic have phonological processing problems [3, 12].

Many young children may learn phonological skills at home especially if they have resided in homes where their caregiver(s) engages in elaborate verbal interactions with them as well as reads with them often and discusses the words and events in the stories they are reading. Even though many young children have been given these rich early language and literacy experiences and are emerging as developmentally expected in their literacy skills, they find it challenging to conceive of spoken words as comprised of individual sounds. This is especially the case for children who have not had rich early language and literacy experiences at home. It is for these reasons that educators cannot assume that children have learned phonological skills. Therefore, educators need to teach children phonological skills in an explicit and systematic fashion [8]. Most preferably, explicit and systematic instruction on phonological skills should begin as early as preschool and continue well into the early primary grades (i.e., kindergarten, first, and second grade) so that children eventually read words effortlessly rather than laboriously in subsequent grades. There are several scientifically supported methods and programs that school districts and educators can adopt for teaching phonological skills to children. In general, teaching phonological skills explicitly means breaking down the tasks of teaching phonemes into parts. For instance, the teacher may begin by presenting each sound of a word in isolation to the students and providing them with many opportunities to practice each sound by incorporating multiple activities/lessons before moving onto the next sound. This may be followed by asking children to discriminate one sound they learned from the other sound that they learned. Eventually, the teacher will teach the students to say all sounds together in a given word. In subsequent grades, phonological skills can be reinforced and embedded within formal school curriculum to ensure that students retain these skills.

Phonological Loop

Robert Walrath
Rivier College, Nashua, NH, USA

Synonyms

Articulatory loop; Phonological short term memory

Definition

A component of working memory that deals with auditory or verbal information. It consists of two parts: a short term store of phonological information and an "articulatory rehearsal" process that functions to help maintain the information.

Description

Baddeley [1] describes the phonological loop as part of working memory; together with the visuospatial sketchpad, episodic buffer, and central executive. Essentially, all auditory or verbal information is immediately entered into the phonological store, where it will be maintained for 1–2 s. The articulatory rehearsal process helps maintain information in the phonological store through subvocal rehearsal of the information. This process also allows visual input access to the phonological store, provided it can be converted to phonological information and subvocalized.

Phonology

Macy Satterwhite, Loretta C. Rudd
Texas Tech University, Lubbock, TX, USA

Definition

The part of language involving speech sounds, including pronunciation, fluency, and intonation.

Description

Phonology is one of the four components of language, the other components being semantics, syntax, and pragmatics. During the early years of life (birth to 5 years of age) children's language develops gradually. One fundamental way that children's language develops in the preschool years is that they begin to produce speech sounds more clearly with improved fluency and intonation [3]. There are approximately 30 speech sounds in the English language and remarkably children acquire the rules for producing most of these sounds within the first 5 years of life and the more complicated blends by age 9!

Relevance to Childhood Development

The ability to communicate effectively is a foundational skill that most typically developing children accomplish with little trouble. The area of phonological development is no exception. Children seem to acquire speech sounds rather effortlessly and most often communicate their wants and needs effectively.

There is a fairly typical sequence for acquiring speech sounds with some slight variations in acquisition by gender. While it may appear that phonological development is easy, the production of some speech sounds requires the combination of various parts of the body (e.g., the tongue, the teeth, the lips, the roof of the mouth, the vocal cords, and even the lungs). The developing child must coordinate all of these body parts in harmony to produce a single sound. Quite a remarkable feat by any standard! One theory for how children accomplish this task is that they hear acceptable sounds and sound patterns repetitively in the words used most frequently in their language. It is believed that the first 100 words or so that most children learn, will contain almost all the key sounds of their language [2, 3]. As they hear and learn words, they are also learning the rules for how making sounds and sound combinations.

While most children acquire speech sounds easily, some children may struggle. The most common phonological challenges revolve around poor articulation of speech sounds. Children should acquire the sounds of *p*, *b*, *m*, *w*, *d* by age 3 [2]. If a 5 year old has difficulty producing the b sound, there probably is some sort of delay and a speech therapist may need to be consulted. Another common delay in phonological development is the substitution of one sound for another. When children substitute *w* for *r* or *d* for *th*, they are usually still understood. However, when a child substitutes a *d* for *r*, there is usually confusion on the part of the listener. Children who use these irregular substitutions are at greater risk for future speech delays.

Finally, children who have phonological disfluency, such as single-sound disfluency (e.g., b-b-b-b-b-ball), repetitive words ("the ball. . . .the ball. . . .the ball. . . ."), or long pauses between phrases may suffer from some type of speech delay. If these phonological disfluencies hinder communication between the preschooler and parents, teachers, caregivers and peers, a speech and language evaluation should be implemented in an effort to lessen the effect on the social and emotional development of the child [4].

Physical Abuse

Stephanie Dvorak, Tasha R. Howe
Humboldt State University, Arcata, CA, USA

Synonyms

Battered child syndrome; Child abuse; Harsh discipline; Physical punishment

Definition

A non-accidental physical injury a child sustains at the hands of an adult, usually stemming from attempts at discipline.

Description

While definitions of abuse vary by locale, in general, most states advocate a definition similar to this one: a non-accidental physical injury a child sustains at the hands of an adult, usually stemming from attempts at discipline [2]. Many states also include a length of time the injury must last, such as 24 or 48 hours. States also include a "risk of harm" clause to allow children at risk of physical abuse to be removed from harmful environments before abuse occurs [3].

Physical abuse often occurs during stressful situations like discipline periods. The child is usually punished by an angry parent and this corporal punishment escalates into abuse resulting in injury [6]. Serious injury and death can result when adults do not realize the strength difference between themselves and children. Approximately 1,400 deaths occur in the U.S. each year from abuse neglect and about 14,000 children are seriously injured. While about 900,000 cases are substantiated each year in the United States, because most cases are never reported, it is estimated that millions of children each year are victims of maltreatment [1, 5, 6]. Risk factors such as poverty, lack of education, being a single parent, alcoholism, other drug use, and a history of abuse increase the probability of a person harming a child [1].

Indicators of child physical abuse include broken bones that cannot be explained or are unusual, bruise marks that have patterns such as fingers, hands, or belts, bruises that are not in typical areas where normal childhood activity causes bruising (i.e., knees), burns of various types including burns to the hand or foot (called "sock" and "glove" patterns), cigarette burns, radiator or burns from other hot objects, bite marks, black eyes, choke marks, circular marks often found on the wrists or ankles that indicate twisting or tying up, and unexplained abdominal injuries [6].

The effects of abuse on children include poor self image, acting out, school problems, flashbacks, nightmares, sleep problems, drug and alcohol abuse, feelings of sadness, depression, withdrawn or clingy behavior, anger and rage, self destructive tendencies, or aggressive and disruptive behavior [1, 6]. If the long term effects of abuse are to be minimized, identifying and treating problems early on is crucial [6]. Every state has laws regarding reporting child abuse and whom they identify as mandated reporters. Mandated reporters are required by law to

report suspected cases of child abuse. Some of these professionals include: teachers, social workers, doctors, childcare providers, medical examiners and coroners, law enforcement officials, bus drivers, coaches, and mental health professionals [4].

Physical Aggression

Amy J. Kaye, Cynthia A. Erdley
University of Maine, Orono, ME, USA

Synonyms

Antisocial behavior; Assault; Fighting; Overt aggression; Physical bullying; Violence

Definition

Physical aggression is behavior causing or threatening physical harm towards others. It includes hitting, kicking, biting, using weapons, and breaking toys or other possessions.

Description

Developmental Course

Most children display their highest levels of physical aggression in toddlerhood and show a decline in these behaviors with age. Physical aggression seems to be present as early as 12 months of age in at least half of children, and shows a normative increase in the second year of life that persists through the third year and begins to decrease around age 4 years [1]. In fact, research generally shows four distinct trajectories of physical aggression. In the two most common trajectories, making up as many as 80% of children, physical aggression is either high or moderate early on and declines to a low or almost zero level. A third trajectory includes children who consistently engage in almost no physical aggression. The smallest group is that of children on a fourth trajectory. Those on this trajectory engage in higher levels of physical aggression than their peers and continue to engage in this high level consistently over time [2].

An important characteristic of physical aggression is its fairly high level of stability throughout development. Those who are highest in aggression in early childhood continue to be highest into adolescence [2]. In fact, 1 year stability coefficients have been shown to be high in children as young as 24 months old [1].

Gender differences in levels of physical aggression appear to emerge in the second year of life. Although boys and girls show similar levels of physical aggression in infancy, boys generally surpass girls at 2 years of age and later [1]. Although some girls do engage in levels as high as those of boys, the percentage of boys in the highly physically aggressive group is greater than that of girls in this group [2, 14].

Types of Physically Aggressive Behavior

Generally, aggressive behavior is defined and assessed in a quite vague manner. It is often grouped not only with other forms of overt (e.g., verbal) and covert (e.g., relational) aggression, but also with other forms of antisocial behavior that may not be particularly physical in nature. When it is separated from non-physical aggression, researchers often fail to assess for the particular nature of the physically aggressive behavior. Two major types of aggressive behavior have been described in the literature. *Proactive aggression* refers to goal-directed behavior in which the aggressive child is generally unprovoked by others. *Reactive aggression*, on the other hand, is engaged in when a child is angry and provoked by others [4]. The difference between these types of physically aggressive behaviors may be important in the understanding of processes underlying aggressive behavior and in the development of interventions targeting that behavior. Unfortunately, these types of aggression are often distinguished only in theoretical models.

Predictors of Physical Aggression

Several factors are correlated with childhood aggression at the individual, family, peer, and societal level. Biological factors play a role in childhood aggression at the individual level. Temperament, a characteristic said to be inborn and identifiable in infants, is one of the earliest individual correlates of aggressive behavior. Difficult temperament, associated with a set of problems including difficulty soothing and adapting to the rhythm of social interactions, has been consistently associated with more chronic aggressive behavior [8]. Evidence also suggests that a number of other biological processes, including heart rate, neuroendocrine levels, and skin conductance, play a role in the development of physically aggressive behavior, presenting a picture of these children as chronically underaroused at a basal level [15]. This is consistent with proactive aggression, in which children may be seeking arousal through engaging in aggression without provocation from others. More consistent with reactive aggression, physically aggressive children seem to show heightened cortisol levels during stressful situations [9]. It may be that those children who are the most physically aggressive demonstrate both proactive and reactive aggression, with unique processes underlying each.

Family factors, particularly maternal characteristics and mother–child interaction, are among the most consistent predictors of aggression. Family conflict and maternal hostile parenting appear to be the strongest of these family factors [6, 12, 14]. They have been shown to be associated with physically aggressive behavior even into adolescence, and their key role highlights the risk for the establishment of a coercive family pattern in which antisocial behaviors are learned and reinforced. Children who are at high risk for engaging in chronic physical aggression are also those whose mothers began childbearing early, have low educational attainment, low income, high depressed mood, or smoked during pregnancy [10, 12, 14]. These parents appear to have particular difficulty teaching their children to regulate the physically aggressive behavior that is common in toddlerhood. There is also evidence that mothers of physically aggressive children themselves engaged in high levels of antisocial behavior during their school-age years, providing some support for an intergenerational transmission of such behavior from mother to child [14].

Socialization factors, including those within the peer group as well as larger neighborhood effects, also play a role in physically aggressive behavior. Research suggests that antisocial children not only tend to select more antisocial friends, but also tend to engage in more antisocial behavior over time when they are a part of such peer groups. A process of mutual socialization appears to occur in which children model antisocial behavior for their antisocial friends and receive reinforcement for this behavior in turn [5]. Furthermore, modeling and reinforcement of physically aggressive behavior is likely occurring at a larger neighborhood level. Neighborhoods with the most physically aggressive children are those in which mothers report that high levels of antisocial behavior occur on a regular basis [12].

Models of Physical Aggression

Although research has been relatively consistent in identifying a number of correlates and predictors of physically aggressive behavior, the processes behind the development of this behavior are less clear. Understanding how it is that such behavior may develop and persist in particular individuals is important for interventions targeted towards decreasing problem behaviors. A number of theoretical models stemming from findings in the area of predictors suggest some potential processes through which physical aggression may develop.

Two related theories of physically aggressive behavior exist that follow from the findings on biological correlates. First, the fearlessness theory suggests that low levels of arousal at a resting state, as have been found in physically aggressive children, are indicative of low levels of fear. Infants and children with low levels of fear may in turn be more likely to approach novel situations and thus more prone to behave aggressively due to a lack of fear surrounding provoking situations. The stimulation-seeking theory is another way of explaining a link between low levels of arousal, approach behavior, and aggressive behavior. This theory suggests that individuals with low levels of arousal are likely to seek out the arousal that they lack by engaging in novel situations. As such, they may be more likely to engage in provoking situations that would elicit aggressive behavior [15]. These models match up well with findings on the biological correlates of physically aggressive behavior and suggest potential targets for interventions (e.g., training on an understanding of the potential consequences of one's actions or redirection towards more appropriately stimulating activities).

Another influential model, Crick and Dodge's [3] social cognitive information processing model, proposes that aggressive children display deficits and distortions in their social cognitive processing that lead to such aggressive behavior. Crick and Dodge [3] proposed that during any social interaction, six steps contribute to a behavioral response including the encoding of internal and external cues, the interpretation of cues, the elucidation of goals, the construction of a response, a response decision, and

the behavioral enactment of that decision. The behavioral response is influenced at all of the six stages by memories of past experiences, rules that the child has learned about that situation and behavior, social schemas, and social knowledge. Aggressive children are said to display a hostile attribution bias in which they misattribute hostile intent to peer provocations that are ambiguous in nature. For example, an aggressive child who is bumped in the hallway is likely to assume that the other child purposely bumped him or her and in turn engage in physical aggression to retaliate. Aggressive children also tend to display a selective attentional bias in which they attend to aggressive environmental cues more often than nonaggressive cues, ultimately making use of fewer cues to guide their behavior. Finally, aggressive children tend to endorse primarily aggressive and fewer assertive solutions to social problems and expect that these aggressive solutions will lead to positive outcomes and rewards [4].

A model suggesting more fundamental executive functioning deficits also exists to explain the process through which physical aggression develops. Executive function refers to processes through which individuals self-regulate their thoughts, emotions, and behavior. It includes such cognitive abilities as working memory, planning, self-monitoring, problem-solving, and response inhibition. This model is based on the finding that physical aggression begins to decline for most children in the late toddler years, the same time during which major developments in executive functioning have been shown to occur. It suggests that physically aggressive children do not make the expected gains in executive functioning, particularly working memory, during early childhood. Although there has been less empirical examination of this hypothesis in young children, executive functioning certainly appears to be more clearly linked to physical aggression in adolescence and young adulthood than does general cognitive development [13]. This model is also supported by the finding that hyperactivity and opposition in kindergarten, behaviors that are often linked to executive functioning deficits, are both powerful predictors of chronic physical aggression [10].

Relevance to Childhood Development

Physically aggressive children are at risk for a number of negative outcomes throughout childhood and into adolescence. It is clear that physical aggression is a strong behavioral predictor of peer rejection in childhood. Peer rejection, in turn, is related to a host of negative outcomes in childhood and adolescence including depression, loneliness, delinquency, and school dropout [7]. Children who are both aggressive and rejected appear to be at the greatest risk for poor psychological adjustment. At the same time, however, physical aggression is an independent predictor of these same internalizing and externalizing difficulties. Chronic physical aggression in elementary school predicts to continued physical violence, school dropout, and contacts with police in adolescence [2, 7].

Not only are aggressive children more rejected than their non-aggressive peers, they also tend to be more victimized physically and relationally by their peers. It may be that those individuals who are physically aggressive towards their peers are also physically victimized as retaliation (e.g., bully-victims). Those peers who fear physical attacks from the aggressive child may use relationally aggressive strategies to avoid and exclude the aggressive child from the peer group. As such, the aggressive child is both physically and relationally victimized by his or her peers, which in turn can lead to further internalizing and externalizing difficulties and associations with deviant peer groups [11].

Piaget, Jean

Daniel Patanella
New York City Department of Education, New York, NY, USA

Life Dates

1896–1980

This work represents the scholarship of the author and does not imply any official position of the New York City Department of Education.

Educational Information

Piaget earned a Ph.D. in natural sciences from the University of Neuchâtel in 1918.

Accomplishments

A precocious child, Piaget displayed an avid interest in natural science, publishing several research papers prior to graduation of high school at the age of 15. He then attended the University of Neuchâtel, where he earned both his bachelor's and doctoral degrees. He developed an interest in psychology and human development at this time, and completed his post-doctoral training at both the University of Zurich and the Sorbonne in Paris. It was here, as well as in his experiences supervised by Theodore Simon (1872–1961) in a Parisian boys' school established by Alfred Binet (1857–1911), that he began to formulate the ideas he would pursue throughout his unusually long and rich scientific career.

Piaget, influenced by both natural science and philosophy, envisioned human development as occurring in distinct stages that would unfold in an unvarying progression given a nurturing environment. Different stages would exhibit uniquely distinct cognitive styles of explaining the world. The focus in Piaget's theorization was clearly the intellectual development of the child, at the relative expense of studying socialization. This also set Piaget apart from other stage theorists such as Sigmund Freud (1856–1939) and Erik Erikson (1902–1994), who offered theories based on emotional development.

Piaget is best-known in psychology for his theories on cognitive development. However, Piaget's contributions to the social sciences are far more extensive than that typically recapitulated in developmental psychology textbooks. He conceptualized a model of moral development that, while simple compared to his model for cognitive development, would provide the basis for the career-spanning explorations of Lawrence Kohlberg (1927–1987). His research techniques of carefully structured clinical interviews coupled with methodical recording of descriptive data influenced sociology's research methods; it is for this reason that when Piaget was brought to Harvard for an honorary degree in the 1930s, it was for his contributions to sociology. His investigations into domain-specific areas such as the development of mathematical ability had clear educational implications. In sum, Piaget can be best thought of not only as the premier cognitive stage theorist but also as a grand intellect spanning and influencing multiple areas of expertise.

Piaget published more than 50 books throughout his career, making him one of the most prolific authors within psychology. Representative books include *Language and*

Thought of the Child (1923) [8] and *The Child's Conception of Physical Causality* (1927) [6]. Piaget also had a fruitful life as an educator. He served various posts as a professor at the University of Geneva from 1929 until 1980, including Professor of Sociology, Professor of Experimental Psychology, and Professor of the History of Scientific Thought. He also was a professor at both the University of Lausanne and Sorbonne. Simultaneously to his teaching positions, he also served as the Director of the International Bureau of Education, the Director of the Institute of Educational Sciences, and the Director of the International Centre for Genetic Epistemology (all in Geneva). He received honorary doctorates from well over 30 different Universities, including Harvard and Cambridge. On the global stage, Piaget was involved with the United Nations Educational, Scientific, and Cultural Organization (UNESCO) in the late 1940s and 1950s, participating in conferences as a children's advocate and even serving as the president of the Swiss Commission to UNESCO.

Contributions

Piaget's life work represents one of the cornerstones of cognitive psychology, and his influence within the fields of child development and education are indeed vast. While Piaget's theories have been supplanted by an array of information-processing models, and stage theory is no longer of central importance in contemporary developmental psychology paradigms, it is important to remember and appreciate the crucial role Piaget's work in providing developmental psychology one of its grand scale theories. Piaget defined developmental psychology in the same way that Freud defined clinical psychology and that Skinner redefined behavioral psychology. He provided a powerful centrifugal force that not only shaped how generations of psychologists viewed the world, but also stood in sharp contrast to his immediate predecessors. Despite the fact that Piagetian theory is no longer the dominant one pursued by active developmental researchers, mastery of the basics of Piagetian theory is still essential for students of developmental psychology, and textbooks still devote significant space (sometimes whole chapters) to the man and his work.

Piaget's Cognitive Development Theory

Joy Jansen

Neurology, Learning, and Behavior Center, Salt Lake City, UT, USA

Definition

Jean Piaget's theory of cognitive development in children conceptualizes the process of children's intellectual growth (learning) from a biological perspective.

Description

Piaget's theory is founded on genetic epistemology. His theory is the result of intense investigation, specifically focusing on the nature and timing of events in life, by observing children engaging in specific tasks developed by Piaget. From his qualitative research Piaget proposed a framework of cognitive development in four specific stages. The four stages are: sensorimotor, preoperational, concrete, and formal. Each stage is associated to specific years in a child's life and identifies elements that occur within the framework of these years.

Sensorimotor

Sensorimotor stage (birth–2 years) is the period of a child's life when learning occurs through interaction, specifically senses and motor skills, with the physical environment. Piaget called these interactions "circular reactions," providing three separate reactions relative to age within the stage. These circular reactions are primary, secondary, and tertiary. Primary circular reaction (1–4 months) is the time when the child is stimulated by his/her own action, such as sucking of the thumb or blowing bubbles, and if the same action is repeated the same response is achieved. Secondary circular reactions occur between 4 and 12 months. This is

the time frame when a child becomes aware that a continual stimulus can be experienced when interacting with the environment. Also during this time frame, children begin to understand that although an object leaves their line of vision it does not indicate the object is gone. This is also known as object permanence. Between 12 and 24 months, the child now understanding that through partaking in action, within different conditions, the same stimuli is created but with variation. Around a year and a half, a child begins to demonstrate the ability to hold a mental image beyond an immediate event, otherwise known as mental representation. A child also develops the ability to solve simple problems indicating the child is using mental combinations. Deferred imitation, the ability to remember an experience and reenact it after time has past, is also seen during this stage. At the end of the stage, children begin to pretend. Instead of using a toy as more of an object which provides stimulus, the toy now becomes associated with life experiences.

Preoperational Stage

The second stage is the preoperational stage (2–7 years). During this stage, children begin to use symbols, conceptualization of time (present, past, and future) and the progression from centrism to de-centrism. The ability of a child to use symbols indicates that he/she is capable of taking an item and allowing it to represent something else. For instance, a common example is the written language. However, in relation to children, creative play is a good example. Children who partake in creative play, for instance, replacing checkers for animal crackers or using a log as a seat, demonstrate they can take an object, understanding the literal identity of the object and change it for their individual purpose. Children also develop the understanding of time in relation to past, present and future events; thus, a child is able to take events from the past and relate them to a present situation. For instance, a child, learning how to ride a bike that has had an accident, can indicate the understanding of "hurt" within a future context even though the event occurred in the past. Another example is children demonstrating an understanding when told that their parents will return within a specific timeframe.

In addition, it is a time of life in which the child is egocentric. A child believes his/her point of view or conceptualization of an event or idea is solely correct; thus, this egocentrism influences how a child interacts and communicates with others. Throughout most of the stage, a child will demonstrate centrism. Centrism is the focusing of one aspect of an issue due to the inability to look at the concept from a broader understanding. For instance, children when asked if they live in the United States will respond no and provide the state in which they reside. Another example is when blocks in a specific color but in various shapes are shown to a child. The child is only able to group the shapes by color and do not recognize that the blocks can also be grouped by shaped. However, it is when a child is able to move beyond the focusing of one concept and demonstrate the ability to consider and understand multi-levels of a concept that the child demonstrates decentrism, indicating cognition development to a higher stage. In Piaget's theory, it is the progression to the concrete operations stage.

Operational Stage

The concrete operational stage (7–11 years) is the time when a child begins to relate to information logically, also known as operations. A child also demonstrates conservation and reversibility. Conservation is the ability to understand although something may change in appearance the quantity remains the same. For instance, if a child is shown five sticks of gum in a row and than the same pieces remain in the same row but distance between gum pieces is increased, the child conceptualizes that there are only still five sticks of gum regardless of distance between them. Reversibility is when the child realizes that an object is capable to go back to or close to its original appearance. A child who takes a ball of play dough and creates a flower with it, realizes that if the flower were to be put into a ball of play dough again it would resemble the previous ball of play dough. Two other concepts children learn during this stage are classification and seriation. Classification is the ability to recognize more than one way to organize a group of objects. For instance, go back to the previous example of block colorization. When a child is able to classify he/she not only recognizes the color of the blocks but also the blocks are different shapes in which both can be organized into groups. Seriation is the ability to organize items in a sequential order such as size or weight.

Formal Operational Stage

Formal operational (11–15 years) is the final stage of Piaget's theory. It is at this level in which children demonstrate the ability to engage in abstract thinking, using skills such as deductive and hypothetical reasoning. It is during the these years that adolescents learn and begin to solve complex problems through cautious and systematic processes, share and propose their own ideas and concepts as well as go through the process of evaluating their opinion being proposed. In addition, it is during these years that sets the foundation for identity formation, the understanding of others psychological experiences and

perspectives, and the ability to consider different views and relative of importance in decision making. Beyond the age of 15, Piaget believed that cognitive development is gradual and incremental.

Organization and Adaptation

Piaget theorized that children are able to transition from one stage to the next due to two complementary processes, organization and adaptation. Each process consists of relative elements. Schema is the element relative to organization. Two elements exist in the adaptation process, assimilation and accommodation. Organization is the natural, systematic arrangement of mental structures of associated and interconnected information. Schema is the mental structures of set of associated perceptions, ideas, and/or actions used to interpret experiences. There are three types of schemata: behavioral, symbolic, and operational. Behavioral schema is the most basic and first mental structures created. It is schema that is present from birth (sensorimotor stage). Symbolic schemata are the mental structures that represent an object or action. This schema emerges at the age of 2 years of age (preoperational stage). At the age of seven (concrete operational stage), operational schema develops. Operational schemata are mental structures created through logic in relation to objects and experiences.

Piaget believed that individuals have a desire for a state of cognitive equilibrium; thus, when disruption occurs, individuals will strive to return to a balanced state. Returning to a state of equilibrium is achieved through the process of adaptation. Adaptation is the adjusting or changing of schemata relative to the environment. Assimilation is when new concepts are introduced and incorporated into pre-existing schemata specific to the external environment. For instance, a child has an over all understanding of the concept of insects but when a specific insect, such as an ant, is introduced, the ant now becomes a part of the insect schema. Accommodation is the modifying of pre-existing schemata or the creation of a new scheme which occurs due to new experiences. For example, a child, who has a schema for an ant in an artificial environment, is exposed to an ant colony outdoors. The child now modifies or creates a new schema relative to the ant in the outdoors such as learning an ant lives in a colony. Assimilation and accommodation influence one another. As assimilation occurs, mental structures are accommodated and vice versa.

Relevance to Childhood Development

Piaget's theory can be understood simply as an invariant approach of maturation, a natural, biological drive, of how child learn; thus, it is a process in which children progress through at the same age regardless how a child's capability and brightness. Cognitive development occurs due to explorations and experiences that begin as egocentric processes and transition into social ones. Piaget's concepts have been and continue to be a major influence on the research of children's social and emotional development as well as the advancement in the creation and implementation of educational best practices. In the end, it is the driving theory in which the discipline of cognitive development psychology is founded.

Synonyms

Piaget's preoperational stage

Definition

The preoperational period refers to the second stage (2–7 years) in Jean Piaget's theory of cognitive development which spans toddlerhood, preschool and early school ages. This stage is characterized by the child's beginning to use symbols, understanding tasks of conservation and showing progressions from centrism to decentrism and from egocentric thinking to perspective taking. Piaget defined his preoperational stage into two substages: the preconceptual stage (2–4 years) and the intuitive stage (4–7 years) [1, 2].

Description

Piaget's preoperational period is marked by the accomplishment of several cognitive tasks occurring in the preconceptual and intuitive substages. These core abilities dictate how the young child interacts with and makes meaning in their world.

Symbolic thinking is a hallmark of this stage. According to Piaget, a child in the preoperational stage is capable of taking an item and allowing it to represent

something else. The use of symbols can be seen in milestones that are typical during these ages. For example, the preoperational child will begin to use words, images and gestures to represent objects and events in the world [2]. During the preconceptual stage, the emergence of symbol use occurs with the rapid acquisition and development of language, imaginative play and deferred imitation of activities occurring around them. With symbolic functioning, the child quickly becomes proficient in understanding and using language. In a reciprocal process, the child is also increasingly able to solve problems and learn from the language of others. Similarly, symbolic functions are also postulated to be integrated into play. With the ability to use symbols, children also begin to develop an understanding of time. Children in this age group are developing an understanding of events in terms of past, present and future and can thereby, for example, relate past events to present situations [3, 4].

Despite the advancing cognitive development of the 2–4 year old child, thinking occurring during the preconceptual stage is marked by egocentrism. A child at this age believes that only his/her point of view is solely correct and has difficulty taking the perspective of another person. In fact, the egocentrism of this age has an effect on how the child will interact and communicate with others [2, 4].

As the child develops and cognitive processing becomes more complex, these are changes in the child's thought processes involving things such as understanding of relationships, numbers and classifications. This is the mark of the intuitive stage. During this developmental substage, the child uses mental operations such as classification or quantification. However, they are not aware of the principles used to perform the operations. Thus the preoperational child can solve problems but cannot explain the principles underlie the operations that they have used [1–3].

Another important skill that is acquired during the pre-operational period is conservation. To be successful at conservation, the child must recognize that even when an object's appearance is altered that the object's basic attributes remain the same [1, 4]. For example, the preoperational child would have difficulty accepting that a tall thin glass of juice that looks full is the same quantity as an equally tall but broader glass that looks only half full.

Conservation is a very difficult concept for the preoperational child and is closely related to their difficulty with perspective taking/egocentrism. First, the child does not have the ability to grasp the idea of reversibility (the notion that one can mentally reverse or undo a given action). The preoperational child also tends to focus on the end state of an action as opposed to the process by which the change occurs. Finally, the developing child may be expected to display centrism, thus leading them to focus their thinking and attention on only one aspect of an object or situation [1–3].

In Piaget's theory, when a child is able to move beyond focusing on one concept and demonstrate the ability to consider and understand multi-levels of a concept then the child demonstrates decentrism, indicating that cognitive development has progressed to the concrete operational stage [1, 4].

A final phenomenon of preoperational thinking is horizontal decalage. This time lag refers to the uneven nature of the child's abstraction abilities for understanding conservation of particular objects, substances or qualities. This explains why the child may develop logical abilities about one type of conservation task but may lag in their understanding of conservation in other areas [1, 2].

Relevance to Childhood Development

Jean Piaget's theory of cognitive development is one of many models of cognition in childhood. His preoperational stage of development describes the child's cognitive development from 2 to 7 years of life in terms of two stages through which every child is hypothesized to progress. While Piaget's states are yoked to an age range, the actual age of the child is seen as less important than the order in which these tasks are accomplished. Additionally, Piaget's theory generally describes development as smoothly progressing between qualitatively different stages. However, recent work has demonstrated that development involves a gradual and inconsistent movement between cognitive processes. For instance, individual and cultural differences may alter the path of cognitive development and lead to comparable cognitive outcomes. While the validity of Piaget's stage theory of development has been disputed by recent theorists, his observations and ideas have considerably shaped the field of cognitive development and inspired more recent theorists [1–3].

Piaget's Preoperational Stage

►Piaget's Preoperational Period

Piaget's Sensorimotor Period

Katherine Simpson Spencer
Argosy University/Atlanta, Atlanta, GA, USA

Synonyms

Piaget's sensorimotor stage; Sensory motor stage

Definition

The sensorimotor period refers to the earliest stage (birth to 2 years) in Jean Piaget's theory of cognitive development. This stage is characterized as the period of a child's life when learning occurs through a child's sensory and motor interactions with the physical environment. These interactions are known as circular reactions and are a means of building schemes in which infants try to repeat a chance event caused by their own motor activity [1]. Piaget separated his sensorimotor period into six sensorimotor substages: reflexive schemes, primary circular reactions, secondary circular reactions, coordination of secondary circular reactions, tertiary circular reactions, and mental representations [1–4].

Description

Reflexive schemes is the substage that occurs from birth to 1 month of age and is a period of development in which newborns automatically respond to particular forms of stimulation [1, 4]. Reflexes include those such as the sneeze or the Moro response (i.e., specifically infantile startle pattern) that are not cognitively relevant [2, 4]. Other reflexes, such as sucking, eye movements, and movements of the hand and arm undergo developmental change in later substages. Piaget conceived these initial reflexes as infants' first sensorimotor schemes through which they begin to learn about the external environment [1]. For example, if you place a finger in an infant's hand and press against his/her palm, he/she will spontaneously grasp the finger. In later substages of sensorimotor development, infants will learn to grasp other objects and begin combining schemes to learn about these objects.

Around 1–4 months of age, infants enter the second substage of *primary circular reactions*. At this stage, infants start to gain voluntary control over simple motor habits centered on their own body [1]. Infants also begin to demonstrate scheme-scheme coordination [2]. For example, an infant may grasp an object and bring the object to the mouth to suck. Babies in this stage may be observed to habitually suck their fists or thumbs [1, 2, 4]. They also begin to anticipate events and vary their response based on environmental demands, such as crying due to hunger and quieting when his/her mother enters the room, knowing food was on the way [1, 2, 4].

The *secondary circular reactions* substage (4–8 months) is characterized by imitation [1, 2, 4]. As infants begin to reach for and manipulate objects in their physical environment, they attempt to repeat interesting events they have caused [1, 4]. For instance, an infant may continue to squeeze a toy that makes noise over and over again, and thus build a sensorimotor scheme of squeezing. From this stage forward, babies show an increasing interest in their actions on objects and events in the external environment, becoming an explorer of objects [2].

Infants 8–12 months of age begin to combine schemes into new, more complex action sequences in the *coordination of secondary circular reactions*. In this substage, they begin exhibiting intentional or goal-directed behavior, and they begin learning to solve simple problems [1, 2, 4]. Children at this substage begin to master object permanence, or the understanding that objects continue to exist when out of site (or covered by a cloth) [1, 2]. However, Piaget found that infants in this substage do not yet have a clear image of the object as persisting when out of view, as evidenced by the A-not-B error [1, 2]. Also in this substage, children become more able to anticipate events and imitate more complex behaviors. A child at this stage may cry in response to his/her mother walking towards the door, anticipating her leaving.

When an infant is between 12 and 18 months of age, Piaget considered he/she to be in the tertiary *circular reactions stage*. At this time children explore objects by acting on them in new ways, such as using a stick to get an object out of reach or pulling a small rug on which a toy rests. Children at this age also imitate unfamiliar behaviors, such as making funny faces or scribbling on paper. Piaget believed that children's capacity to use trial-and-error to experiment with toys and their physical environment leads to a more advanced understanding of object permanence and success on the A-not-B task [1, 2, 4].

The last substage of Piaget's sensorimotor period is called *mental representation*, and characterizes children ages 18–24 months. By the end of this substage, children have the ability to create mental representations, or

internal depictions of information that the mind can manipulate [1]. Piaget referred to this substage as "the invention of new means through mental combinations" [4]. Children begin finding solutions to problems suddenly rather than through trial-and-error experimentation. Eighteen to twenty-four month olds mentally represent their experiences and experiment with actions internally [1, 2, 4]. This enables them to solve advanced object permanence problems, which enable them to solve problems involving invisible displacement, or finding a toy moved while out of sight. Mental representations also enable them to remember and copy behaviors of models that are not present (deferred imitation) and engage in make-believe or symbolic play [1, 2, 4]. A symbolic system that can be shared with others facilitates communication and socialization, which is enhanced in later developmental stages [2].

Piaget's sensorimotor period is followed by the preoperational stage (2–7 years), concrete operational stage (7–11 years), and formal operational stage (11–15 years). According to his theory, children are able to transition to the next stage due to organization and adaptation processes of assimilation and accommodation. Children learn behavioral, symbolic, and operational schemata that are assimilated and accommodated into their repertoire, thus enabling them to successfully reach a state of cognitive equilibrium at one stage and move to the next cognitive stage [1–4].

Relevance to Childhood Development

Piaget's cognitive theory is one of many models of cognition in childhood. His sensorimotor stage of development describes the first 2 years of a child's life in terms of six substages through which every child progresses. In general, his writings describe development as a smooth progress between qualitatively different periods; however, recent work has demonstrated that development involves a gradual and inconsistent movement between cognitive processes [3]. For instance, individual and cultural differences may alter the path of cognitive development and lead to comparable cognitive outcomes [3]. While the validity of Piaget's stage theory of development has been disputed by recent theorists, his observations and ideas have considerably shaped the field of cognitive development and inspired more recent theorists.

Piaget's Theory of Moral Development

Daniel Patanella
New York City Department of Education, New York, NY, USA

Synonyms

Autonomous; Heteronomous; Imminent justice; Moral constraint; Moral realism

Definition

According to Piaget's theory, there are three broad stages of moral development. In the first, the child is still mastering motor and social skills and unconcerned with morality. In the second, the child exhibits unconditional respect for rules and submission to authority. In the last stage, the child recognizes that rules are arbitrary and can be changed with group consensus; the intentions of an actor (rather than just the consequences of the action) should be considered in judging the morality of an act.

Description

Overshadowed by both his own theory of cognitive development as well as the more elaborate moral development theory of Lawrence Kohlberg (1927–1987), Jean Piaget's theory of moral development has both inspired empirical research and attracted scholarly attention in its own right. While Piaget (1896–1980) spent much of his career refining his theory of cognitive development and did not revise

Author's Note
This work represents the scholarship of the author and does not imply any official position of the New York City Department of Education.

his theory of moral development beyond his initial book on the subject, *The Moral Judgment of the Child* (1932), his theory provided an important psychological framework for conceptualizing moral development for researchers. Although other psychologists researched and wrote about morality prior to Piaget's 1932 book (see [8, 12], for an overview of pre-Piagetian moral research), it is Piaget's theory that is remembered as the true beginning of the psychology of morality.

Piaget is sometimes erroneously portrayed as a "pure" cognitive psychologist, disinterested in both the social aspects of children's development as well as their behaviors outside the laboratory. The formulation of his theory of moral development contradicts this stereotype in many ways. In the first section of *Moral Judgment of the Child*, Piaget observed children playing marbles and researched the various rules related to the many different variations on marble games that children played, and Piaget stressed that older children's conceptualization of the fairness of rules is largely based on the consensus of the child's peer group in determining the structure and consequences of new rules. There is certainly a strong social aspect to this. Interestingly, Piaget's insinuation that moral judgment is a type of behavior partially anticipates the radical behaviorism of B. F. Skinner (1904–1990), in which private mental actions are assumed to be subject to the same laws as observable behaviors. Piaget spends the beginning of the second chapter of *The Moral Judgment of the Child* justifying his decision to concentrate on judgment; the stated morals of a child may reflect simply reflect the social desirability of the expressed sentiments, and the relationship between morals and moral behavior may be tenuous. But judgment is an action and, therefore, is a process that can be studied.

Stages of Moral Development

According to Piaget's theory, there are three broad stages of moral development. As with his theory of cognitive development, these stages are envisioned as occurring sequentially and in a linear fashion. Although movement from one stage to another takes may place on a continuum, Piaget envisions the stages as exclusively distinct from one another. Once a stage is attained, regression to a previous stage does not occur. It is not possible, according to Piaget, for a developing child to skip past stages, and although there is a correlation between biological age and attainment of a given stage the maturing morality cannot be reduced to a purely biological phenomenon. Rather, Piaget views the maturing morality as the result of cognitive development and interactions with the environment. It is important to note that Piaget does not make an explicit cross-mapping between his stages of moral development and his stages of cognitive development, nor are these stages widely known by unique names as are the stages in his theory of cognitive development. These stages are best understood in contrast with one another, just as in other stage theories.

Piaget's first stage of moral development encapsulates up to the child's fourth year or so. It could be considered "pre-moral" in a sense because the child does not truly interact socially with others. On one end of the spectrum, the child is still attempting to master basic motor skills necessary to play. On the other, the child is capable of imitation but plays alone in ritualistic fashion, either in solitude or in parallel with peers. Piaget does not focus on this stage as it has little to do with moral judgment, and occasionally subsequent researchers omit this period entirely, describing Piaget's theory as having only two stages [3, 6].

Piaget's second stage of moral development is characterized primarily by what he terms "moral realism." This refers to the young child's belief that rules are always externally given, cannot be altered, and must be literally obeyed. Submission to adult authority is made without question, and referred to as "moral constraint." Obedience, by definition, must be good. Children in this stage focus on the consequences of the actions rather than the intentions of the actor, and cannot conceptualize that sometimes well-intentioned actions sometimes have unintended and harmful consequences. There is the belief, known as "imminent justice," that all transgressions will ultimately be severely punished. In Piaget's research, children within this stage would follow the rules of a game of marbles that their older peers taught them, and fail to tolerate any deviation from those rules. They were also unable to take the intentions of a character in a fictional story into account when judging what Piaget called the "naughtiness" of the character, fixating on the undesirable outcomes of the story. Piaget often uses the word *heteronomous* in describing this stage, and it roughly spans from the child's seventh to eleventh year.

Piaget's third stage of moral development stressed reciprocal cooperation. Older children will follow the spirit of a rule, rather than the explicit letter of the rule, and recognize that since rules are arbitrary they may be changed with mutual agreed consent. Fairness is key; rules may be applied selectively and critically evaluated within context. The intent of an actor becomes more important than the consequences of his actions, and must be taken into account when judging his actions and determining his potential punishment. When punishment is to be given, it should be proportional to the violation or

transgression it is directed toward. These children tend to be older and more cognitively developed and therefore view adults more as equals than as authority figures to be unilaterally obeyed. Piaget describes this stage as *autonomous*, and found it primarily in children aged eleven and older.

Empirical Support

Empirical research for Piaget's theory of moral development is mixed. While Piaget used multiple methods to generate his theory (such as clinical interviews and observations), most subsequent research conducted by other psychologists exclusively utilize the presentation of his short moral dilemmas in story format. Virtually all research conducted in investigation of Piaget's theory only partially supports his framework, as with Harrower [5, 7], Sherwood [11], Cowan et al. [4], and Gabennesch [6]. As examples of research that entirely fails to support the theory, MacRae [9] and Bandura and McDonald [1] provide early examples. In general, subsequent research calls into question the universality of the ages at which children attain the different stages, specifically the roles culture and socio-economic status may play in moral development.

Relevance to Childhood Development

Unlike Kohlberg, whose theory of moral development presented a life-span approach stretching into adulthood, Piaget presented a theory that is explicitly limited to childhood. This may account for its continued presence in educational literature; for while Kohlberg's theory received a greater amount of critical and scientific attention within the larger field of psychology, Piaget's focuses exclusively on children and the types of activities they engage in, such as game-playing. This lends the theory an applicability and freshness to educators and child psychologists alike. While the theory displays similar drawbacks to those noted regarding Piaget's cognitive theory as a whole (e.g. a reliance on discrete stages, an overestimation of older children's abilities, an underestimation of younger children's abilities), its importance to the history of modern developmental psychology and its relevance to education must be acknowledged.

Synonyms

Placebo effect; Placebo response

Definition

A placebo can be described far easier than it can be defined or explained; some writers argue there is no one placebo effect but instead many such responses [4]. While the word placebo itself is Latin for "I shall please," the term first appeared in a medical lexicon in the 1800s, as Hooper [7] defined a placebo as a treatment administered more to please or placate than to benefit the patient. Another early attempt to define placebo was that of Wolf [18] who gave this definition: ". . .any effect attributable to a pill, potion, or procedure, but not to its pharmacodynamic or specific properties," (p. 100). Benedetti et al. [4] stated that the

placebo effect is a "psychobiological" effect that can be attributed to either expectations of improvement or ▶classical conditioning. In a similar light, Bausell [1] concluded that a placebo was a physiologically or pharmacologically inert substance that can have a physiological effect if delivered or administered to a patient who believes the substance will result in an effect. Stewart-Williams and Podd [14] drew this distinction: "A placebo is a substance or procedure that has no inherent power to produce an effect that is sought or expected. A placebo effect is a genuine psychological or physiological effect, in a human or another animal, which is attributable to receiving a substance or undergoing a procedure, but is not due to the inherent powers of that substance or procedure," (p. 326). A more precise definition of a placebo is not yet firmly agreed upon and an operational definition has been termed premature and problematic [12, 14, 15].

Description

Since first observed scientifically by Beecher [2], many of the properties of what will function as a placebo have been delineated, if not a complete explanation. A placebo is nonspecific in that they are not designed or focused to produce an effect on a specific disorder or condition and placebos work on a wide range of complaints and problems; typical medical treatments are precisely designed to address targeted conditions [1]. A placebo can be any intervention, encompassing words and gestures, pills and procedures, as well as devices and surgery [10]. An intervention that is presented to a patient in an authoritative or positive way and with apparent enthusiasm for the intervention, coupled with confidence, warmth and empathy will result in a greater placebo response [1, 15]. Beecher [3] argued there was significant evidence to conclude that placebos were more effective in the presence of increased stress. Colored pills are more efficacious as a placebo than a plain white pill; placebos given more frequently are more effective than infrequent placebos. An uncomfortable, invasive, active or sophisticated intervention is more effective as a placebo than the opposites [1, 6]. A more costly placebo is more effective than less expensive treatments [1, 15, 16]. A treatment that used to treat an unrelated condition but which will produce discernible but unrelated side effects such as elevated body temperature, known as an "active placebo" enhances a placebo's effects [14, 15]. The name given to a placebo has been shown to influence its effectiveness [10]. The likelihood of observing any placebo effect is lowest in a double-blind study, higher in a single-blind study and the highest in an uncontrolled study [15]. A placebo response is likely to be a greater effect for measures involving self-report and or psychological phenomena that for objective, quantifiable measures of symptoms [8, 10]. The types of conditions to which placebos have been tested range from blood sugar levels, cholesterol levels, weight loss, blood pressure, various pain syndromes, the healing of ulcers, nausea, inflammation and immune system response, depression, the ability of cardiac rehabilitation patients to tolerate exercise, depression, Parkinson's disease and Alzheimer's disease [1, 5, 8] although this list should not be considered exhaustive. A commonly reported patient's response rate for placebos has been given as being 30% [2] but published studies have found response rates ranging from 0 to 100% depending upon the condition [10].

As indicated by this quote, "the study of the placebo effect is the study of the psychosocial context around the patient" ([4], p. 10390), the psychology of the recipient is a variable in the placebo effect, albeit not completely understood. Some writers have argued that a placebo could be considered physically inactive but not psychologically inactive [14]. The proposed mechanisms behind any placebo response place the individual receiving the placebo at the center of the phenomenon. Although different writers lean in favor of one explanation over others, the number of purported explanations is small: classical conditioning, expectancies and anxiety reduction.

There are many similarities between classical conditioning outcomes and a placebo effect. In both cases, a variable that does not have any inherent active properties is observed to have active properties. In both instances, the inactive agent has a prior relationship with an active agent. Most any adult has had a pairing of clinical routines and events or even just a medical professional followed on numerous occasions by receiving oral pain relievers if not other medications; as a result, sorting out any conditioning effect from other aspects of a placebo is difficult [15].

A patient's expectations or expectancies would be beliefs or rules the patient has acquired or self-generated about a healing outcome [15]. As to how beliefs or rules as a description of event-response outcomes could result in a medical outcome, Kirsch [9] argued that classical conditioning is the means by words as symbols become active variables to affect physiology. Others have shown that instructions given to subjects in classical conditioning procedures can either facilitate or reverse the expected conditioning outcome [17]. Vallance [15] concluded that expectations/expectancies may at times rely on conditioning although there are other cases in which conditioning could operate independently and not be recognized in conscious, cognitive terms.

The anxiety-lysing effect of any therapy has been proposed as another mechanism underlying the placebo. Saline delivery has been found to reduce the emotional aspects of pain but not the noxious-sensory aspect of experimentally-produced pain [15]. Petrovic, Dietrich, Fransson, Andersson, Carlsson, and Ingvar [11] found that analgesia from placebo administration activated brain areas involved in emotional responses [15]. Anxiety itself can produce pain relief via stress-induced analgesia, which runs contrary to anxiety reduction as a placebo-analgesic mechanism [13].

University of Texas Health Science Center - Houston, Houston, TX, USA

Synonyms

Afterbirth

Definition

The placenta is a semi-permeable membrane that serves as a support organ for the fetus by facilitating the exchange of oxygen, nutrients, and waste products between the fetus and the mother.

Description

The placenta is a composed of a semi-permeable membrane that is dark reddish-blue or maroon in color. It averages nine inches (22 cm) in length and seven inches (18 cm) in diameter. The placenta typically weighs about one pound (500 g).

Relevance to Childhood Development

The placenta develops out of tissue from both the outer layer of the *blastocyst* (trophoblast) and the lining of the mother's *uterus*. It is connected to the fetus via the *umbilical* cord. The purpose of the placenta is twofold. First, as a semi-permeable membrane, the placenta serves as an exchange site between the *fetus* and the mother by permitting the passage of some materials between them. Oxygen and nutrients are transmitted from the mother to the fetus, while carbon dioxide and waste materials are transmitted from the fetus to the mother. Second, the placenta serves as a barrier of protection for the fetus by preventing the passage of certain materials through the mother's bloodstream. After delivery of the fetus, the placenta is expelled from the mother's body as a result of uterine contractions.

Plasticity of the Brain

Tracey McLellan
University of Canterbury, Christchurch, New Zealand

Synonyms

Brain malleability; Capacity of the brain to change; Changes to the brain

Definition

Brain plasticity, from the Greek word *plaistikos* meaning to form, refers to the capacity the brain has to continuously change its structure and therefore function throughout a lifetime. Plasticity allows the brain to respond to external changes in the environment as well as internal changes in the organism. Brain plasticity reflects more than the maturation evident in human development. Plasticity also reflects the ability to change with experience. Experiences like learning new information and strategies mean that the brain has changed in form and function. The new behavior has changed the brain and the changes to the brain facilitate the new behavior [7]. In normal aging, neurons (brain cells) start to die from adolescence. This normal process rarely results in individuals experiencing significant declines in cognitive functions for several decades, if at all. This is because the brain engages in plasticity and the structure of the brain is changed to compensate for the slow neuronal loss [6]. Change also occurs as a result of injury (lesion). After an injury, the brain undergoes at least some re-organization to produce behaviors that have been lost. Complete restoration of function is not possible but brain plasticity can partially compensate for the damage.

Change in the synapse is the principle way in which the brain changes [6]. Synaptic change reflects alterations in axons, dendrites, the structure of existing synapses, and the number of synapses per neuron. For example, dendritic branches on some neurons are longer and more branched in the brains of older individuals. It should be noted that there are limits to the amount that the brain can change and research has not fully accounted for how such limits are manifest. It should also be noted that not all brain plasticity is functional. Dysfunction may be evidenced or implicated, for example, in the development of some degenerative diseases of aging, such as Alzheimer's disease.

Relevance to Childhood Development

Brain plasticity is most evident during early development and adolescence. Infants are regularly exposed to the objects, events, and people that shape their experience and therefore the changes to their brain. A child's early interactions directly influence the essential connections that occur in the brain. As a child acquires new knowledge and encounters new experiences, the elaborate cortical networks of the brain engage in modification and reorganization. Unused networks are pruned away during the early developmental years [4]. There are several stages of basic childhood brain plasticity. The first stage occurs prenatally when the brain is being "built." Disruptions, for example, due to alcohol [9] and poor nutrition [5] can result in brain impairment. During the first year of life, the postnatal brain engages systems or not depending on the exposure to adequate sensory input. More refinement takes place between 3–5 years of age, after which the brain has reached 90–95% of the average adult volume.

The skills for developing language and spatial abilities reach a peak from this age until puberty due to the large amount of activity in the parietal lobes that slows dramatically after puberty. Just before puberty, the frontal lobes are also the site of much activity and will again engage in plasticity in early adulthood. So many changes take place in the brain during the teenage years that most teenagers need to sleep much longer than they did previously, and they often have difficulty coping with early start times in the morning.

Brain injuries are unfortunately too common with children. Modes of injury include motor vehicle and bicycle accidents, falls, sporting injuries, and child abuse. It was once assumed that children were more resistant to brain injury than adults were because their brains were still developing and could demonstrate greater plasticity to compensate for certain trauma. That is, it was assumed the equivalent brain damage to a child and an adult would result in fewer problems for a child than an adult. This is known as the "Kennard Principle." However, there is now considerable evidence to the contrary, with many researchers suggesting that the outcome for children suffering brain injury is worse than the outcome for an equally injured adult [2, 3, 8]. Much of these studies also highlight that the difficulties faced by individuals who have experienced early brain trauma may not be evident until later in early adulthood when demands are placed upon vulnerable cortical networks. It is suggested, therefore, that adequate follow-up should be made right through to early adulthood. The brains of children are also vulnerable to psychological trauma as well as physical trauma. All experiences change the brain and, hence, child maltreatment, specifically resulting in a diagnosis of PTSD is associated with dramatic changes in the brain. For example, DeBellis et al. [1] found abused children with PTSD had less brain volume, larger lateral ventricles, and a smaller corpus callosum than did healthy control children.

Synonyms

Child-centered play therapy; Non-directive play therapy; Play-group therapy

Definition

Play therapy is a theoretical model which uses the therapeutic power of play to address various mental health issues.

Description

Play therapy is a theoretical model which provides an avenue for individuals to prevent or solve psychosocial problems as well as improve issues of self-acceptance and self-esteem. Although, play is a tool which can be used in therapy across all ages, play is used typically with children. In a traditional therapy model, the use of talk is the primary tool which is not always effective with young children because of the developmental limitations of their expressive language skills. However, children are able to understand more about their world than they are able to verbalize. Thus, through the use of play therapy children are provided a modality to express their thoughts

and feelings without using words. Essentially, play becomes a child's language of expression [7].

Play therapy has its early roots in psychoanalytic theory and is founded in the works of Sigmund Frued, Melanie Klein and Anna Freud. The first reference of the power of play in a therapeutic setting was documented by Sigmund Freud and his work with Little Hans [11]. Freud's work with Little Hans was expanded upon by the British psychoanalysts Melanie Klein and Anna Freud (daughter of Sigmund Freud). Melanie Klein [14] started to use play in order to analyze children under 6. She believed that play was essentially the same as free association used in adult psychoanalysis, while Anna Freud [10] utilized play as a means to facilitate positive attachment to the therapist and gain access to the child's inner life.

In [24], Carl Rogers, in response to the strict, prescriptive modalities of psychoanalysis and behaviorism, developed non-directive therapy, which came to be known as client-centered therapy. Emphasis was placed upon the relationship between the client and the therapist based upon genuineness, acceptance, and trust. Virginia Axline [3], who was mentored by Rogers, developed a new therapeutic approach for working with children based upon Rogers' person-centered theory called non-directive play therapy. Axline's account of working with a young boy, Dibs [2], is well known and is one of the key references in regard to non-directive play therapy. Play Therapists such as Moustakas [18] and Schaefer [25] have expanded upon Axline's ideas and introduced different models integrating family therapy, narrative therapy, and cognitive behavior therapy along with play therapy techniques. More recently, British drama therapists Sue Jennings [12] and Ann Cattanach [8] have introduced play therapy methods which integrate drama therapy work with children.

Today, psychoanalytic play therapy continues to be widely practiced around the world and focuses primarily on object relations and attachment theory. The play therapy model involves establishing a warm relationship with the child, accepting the child and his or her feelings as they are, reflecting the child's feelings in a way that allows the child to gain insight, and allowing the child to take the lead in therapy. A core belief for child-centered therapists is that children are capable of directing their own growth when provided empathy, warmth, unconditional positive regard, genuineness, and a safe place [7]. Many play therapists include art, drama, music, dance, and sand trays in their therapy. Overall, play therapists approach play therapy from a wide range of theoretical perspectives. Among the many types of play therapy being practiced today are Adlerian [7], cognitive-behavioral [15], existential or relationship [19], Gestalt [20], and Jungian analytical play therapy [1].

Techniques of play therapy tend to take the form of non-directive (as per Axline) or directive. In directive play therapy, the play therapist is actively involved in and takes charge in the play interactions with the child. In non-directive play therapy, the child takes charge of the play and makes his or her own rules, with the caveat that no one gets hurt. In both modes, the child is assured that what is said and done in the office remains private unless they are in danger of harming themselves.

Many play therapists will meet with the parent(s) prior to beginning formal play therapy with the child in order to get a proper social and developmental history, and will meet with the parent(s) every so often in order to provide information about child development, suggestions for parenting, and alternative ways to communicate with their child. It is important that details of the session with the child not be transmitted to the parents in order to maintain privacy, promote the child's free expression in their play, and establish trust of the therapist. The therapist will communicate to the child's parents their understanding of the child's needs or conflicts without divulging details of the therapy.

Once formal play therapy begins, the therapist observes and/or directly participates in the child's play and begins to recognize themes and patterns or ways of using the materials that are important to the child. Over time, the therapist helps the child begin to make meaning out of the play. This is important because the play reflects issues important to the child and typically relevant to their difficulties. Pledge [21] notes that, as with any projective technique, caution needs to be taken in interpreting the themes of a child's play, as acts that seem violent and/or destructive may just be activity or testing the limits of a new situation. She also notes that for children of a young age, it is the process of play therapy, not the production of insight that provides relief and healing for them.

Play therapy has been shown to be effectively practiced across a number of settings, including schools, hospitals, residential treatment, community clinics, and private practices as well as been shown to be effective in addressing various mental health concerns [5]. Research documents play therapy as a valid technique in the treatment of conduct disorder and aggression [9], behavioral disturbances [26], separation issues surrounding parental divorce [6], sexual abuse [23], and Attention-Deficit Hyperactivity Disorder [13]. In 2001, Ray et al. [22] completed a meta-analysis of 94 research studies investigating the clinic effectiveness of play therapy. The 94 studies measured the effects of play therapy conducted by American play therapists and contained over three

thousand subjects, with a mean age of 7.1 years. The 94 studies included 20 different client groups with difficulties such as Conduct Disorder, Anxiety/Fear, Speech and Language Difficulties, Depression, Sexual Abuse, and Post-Traumatic Stress Disorder. Results of the meta analysis revealed a large effect size ($d = 0.80$), showing that play therapy is a highly effective intervention technique for a variety of childhood difficulties.

In 1982, the Association for Play Therapy (APT) was developed. The Association for Play Therapy [4] reports that play therapy "helps children become more responsible for behaviors and develop more successful strategies, develop new and creative solutions to problems; develop respect and acceptance of self and others, learn to experience and express emotion, cultivate empathy and respect for thoughts and feelings of others, learn new social skills and relational skills with family, [and] develop self-efficacy and thus a better assuredness about their abilities."

Although play therapy may seem simple to the untrained eye, it is a challenging therapeutic endeavor requiring training and skill. The practice of play therapy requires extensive specialized education, training, and experience. Play therapists have earned an advanced degree (Master's or Doctorate) in a mental health field such as counseling, social work, or psychology.

Play-Based Assessment

Tony Wu
Walden University, Diamond Bar, CA, USA

Synonyms

Alternative assessment; Child-center assessment; Early-childhood evaluation; Play assessment

Definition

A type of clinical evaluation technique used to assess the functioning of children in the area of emotional and behavioral domain, developmental qualities, using both qualitative and quantitative methodology.

Description

The importance of early intervention and prevention has garnered international recognition and support [2]. In that regard, early intervention is aimed to provide services to individuals who need services before these issues escalate into severe problems. Critical to this process is an appropriate and efficient assessment approach. In the past, practitioners have found it difficult to obtain ecological valid and reliable data when using traditional assessment tools. To address these concerns, play-based assessment has gained popularity due to its sound theories and age-appropriate methodology [1].

For adult psychological evaluation, verbal communication is the primary method of gathering data; however, assessment with young children requirement a different approach. It has been long recognized that children learn and express themselves through play; it is through play that they explore the world and develop cognitive capacity and problem-solving skills [7]. It is through the quality and quantity of play that a clinician is able to determine and evaluate a child's development and functioning through a variety of objective and subjective instruments.

Studies have shown that children with social delays engage in simple play and are less likely to spend time in group play [3]. Johnson and Ershler [4] further indicated that developmentally delayed children engage in less sophisticated play than their typical peers. In general, children with developmental delays played with toys in a restricted manner and were not able to engage in constructive and dramatic plays. Studies have suggested that both qualitative and quantitative nature of play were indicative of children's cognitive, academic, and social development [5].

Given the utilities of play-based assessment, here are a few guidelines for practitioners. First, in order to meet the needs of both assessor and child, the assessment procedure should be pleasurable, flexible, and positive for the child. Secondly, assessment should take place in the child's nature environment, so he or she can play at ease and the appropriate level. Thirdly, it is important to offer choices in play for the children, allowing them to direct their own play. If a child is disabled, then the evaluator needs to consider the barriers to the play. For example, if the child has communication difficulties, other modes should be offered such as symbols, drawing, painting, pictures, and other objects of references, along with additional nonverbal gestures [6].

Definition

A relationship built between peer groups of children or adolescents with a therapist specializing in play therapy, using group therapy techniques in a playroom setting as a means for youth to explore themselves and others (e.g., how one acts, thinks, and feels) through play.

Description

Play is the universal language used by children to communicate their understanding of the world around them where the toys depict the words of the child. Play therapy is to children as talk therapy also known as narrative therapy is to adults. Typically, play-group therapy,

commonly known as group play therapy is when a minimum of two or a preferred maximum of four children or adolescents currently functioning at similar developmental stages interact with each other and the therapist in a therapeutic playroom setting. However, the number of group participants should be evaluated on a case-by-case basis. Schaefer [3] recommended that the length of the group session should also be considered on a case-by-case basis with a group of preschool to elementary-aged children should range between 20 and 40 min, while children in middle or high school may attend the group for 1 h.

Landreth [2] described group play therapy as differing from the concept of group counseling due to the fact that it is not necessary to have group rules as well as group cohesion among members to promote growth; this is simply done by observing other children which ultimately empowers a child to attempt new things. It has been suggested that the use of play-group therapy may be more beneficial and expedite the therapeutic process with youth. Berg et al. [1] described group play therapy as a way to provide a sense of universality among the group members fostering a realization that other children experience problems too and they are not alone in dealing with real-life situations allowing children to increase their self-concept.

As with a group counseling session, the first step in play-group therapy is to create a safe and nurturing environment. Once this environment is established, the group process seeks to promote the expression of emotions while at the same time establishes the chance for children to offer empathy to other children in the group setting. When a child discovers that they can also be helpful to someone else in the group the comradery built among members increases one's self-esteem and self-concept. The primary goal of play-group therapy is to foster social interaction skills and develop emotional coping skills. This typically utilizes a series of different modalities of play such as: art, music, board games, games, sand tray therapy, and other directive and nondirective forms of general play.

The primary role of the group play therapist is to facilitate an environment for growth, personal sharing of one's story, a sense of universality, acceptance, and the development of social and coping skills. It is important for the group play therapist to verbally track the behavior and name the emotions expressed during the session by each group member. This is done by also including the child's name for example, the therapist would state, "Gavin, you're playing with the puppets" or "Samantha, you seem to really enjoy playing in the sand." There are many theoretical foundations and therapeutic modalities that are used in play-group therapy just like those that are used in individual play therapy and other types of therapies. The group facilitator decides which approach to utilize in the group setting based on their particular specialty area and the population of children being treated. Some types or styles of play-group therapy that are frequently used by clinicians consist of: sand tray therapy groups, art therapy groups, child-centered group play therapy, adlerian group play therapy, jungian play-group therapy, cognitive-behavioral group play therapy, and gestalt play-group therapy.

Additionally, another key aspect of the play-group process is for the play therapist and the group members to set limits to ensure safety and enhance the child's ability to express negative feelings while maintaining self control. The limit-setting serves to protect the play therapy room as well as uphold the legal and ethical standards of the profession. When working with children it is important to note as Schaefer [3] mentioned that although the child is the foci of treatment it is important to include the parents or guardians as the client(s) due to legal and ethical considerations. In essence, play-group therapy serves to provide a medium of treatment where children can learn from other children's experiences while expressing their own emotions though the use of play.

Pleasure Principle

David Brandwein
Kean University, Union, NJ, USA

Synonyms

Lustprinzip (German); Pleasure-pain principle; Pleasure-unpleasure principle; Unpleasure principle

Definition

The pleasure principle, originally developed by German philosopher Gustav Fechner, and borrowed by Sigmund Freud [2–5], is a psychoanalytic concept according to which psychological processes and actions are governed by the immediate gratification of needs and the avoidance or release of unpleasurable tension.

Description

Freud's approached the study of the mind from a biological perspective, both due to his medical training and of prevailing notions of the nineteenth century, when he started his practice of medicine. He conceived of the individual as a store of dynamic energy that both needed to be continuously discharged and then continuously replenished. Freud conceived of two different types of energy, Eros (life instinct) and Thanatos (death instinct, aggression). The energy behind the life instinct was called the libido, which managed the instinctual drive towards survival and replacement of energy through conversion into more specific human needs (sex, food, safety).

Instincts drive and direct behavior, the end result of which is the satisfaction of needs derived from the instincts. Needs lead to tension, and behavior is directed towards tension reduction. At first, Freud called this concept the unpleasure principle [2], but later changed it to the more common usage, the pleasure principle, which is a direct translation of Fechner's "lustprinzip". The pleasure principle aims to keep excitation or tension as low as possible by aiming toward the immediate gratification of instinctual needs, most of which, in Freud's original conception, were sexual in nature. Freud [5] ascribed this aim to what he called the id, which includes other biologically determined drives, such as the impulse to love and to seek gratification. The id's function is to bring about the satisfaction of instinctual needs on the basis of the pleasure principle. The energy of the id is invested in either in action on an object that would satisfy an instinct or in images of an object that would give partial satisfaction. This hallucinatory wish fulfillment is called primary process thinking. The id's energy is so mobile that it is easily discharged or transferred from object to object or image to image [6]. Eventually; however, the ►reality principle interecedes, driven by ego, and the mind learns to delay and/or avoid gratification of needs based on the real-world consequences of immediate and actual gratification.

Relevance to Childhood Development

According to Freud, the pleasure principle plays a key role in the developing child's life. He believed that an infant's life is mostly governed by the pleasure principle, and theorized that there were "pleasure zones" in the body that changed as the infant developed into a child. This formed the basis of Freud's theory of child development, based on psychosexual stages, and his theory of psychopathology, which occurred due to "fixation" at one of the stages due to an inability to satisfy the need/needs relevant to that particular stage.

Freud's psychosexual theory of child development was based on the pleasure that could be derived from each of the body's erogenous zones, which his stages were organized around. This notion of infant and child sexuality was quite controversial at the time, and remains so today, and in fact, this notion was one important factor in the schism between Freud and some of the other important psychoanalysts at the time (Jung, Adler, etc.).

The first erogenous zone, or zone of pleasure for a developing infant is the mouth, and thus infancy (birth to age 1) is called the oral stage of development. In this stage, the child desires oral gratification, and sought it out via sucking on the mother's breast for nurturance and, later on, by ingesting food through the mouth. At this stage, and other stages, the life instinct (Eros) compels the infant to do what it has to do to survive. Once this is mastered, the zone of pleasure moves to the anal area, leading to the anal stage of development (typically age 1–3), where elimination becomes the focus, as survival (mostly ingestion of food) would be impossible without elimination. Again, instinct drives the behavior, and provides pleasure when it is done. Next, the erogenous zone shifts to the phallic area, and the phallic stage of development (age 3–5), where pleasure is experienced through the penis/vagina. In healthy development, according to Freud, the end of this stage brings resolution to the Oedipal complex and ►identification with the same-sex parent, as well as the introduction of the superego.

The next stage is characterized by latency (age 5 to onset of puberty), where Freud felt sexual drive were repressed and no new area of bodily excitement emerges, and finally the genital stage (adolescence), where the sexual urges recur but are now directed toward a peer of the opposite sex. Bronski [1], among others, has taken issue with the idea that the end result of healthy development is the enactment of sexual urges in relation to a peer of the opposite sex. He advocates for the inclusion of sexual urges directed toward a peer of the same sex in the conversation about healthy sexuality and healthy development.

Positive Affect

David N. Miller
University at Albany, SUNY Division of School Psychology, Albany, NY, USA

Synonyms

Positive affectivity; Positive emotions

Definition

Positive affect refers to the extent to which an individual subjectively experiences positive moods such as joy, interest, and alertness.

Description

Positive affect is one aspect of pleasurable and positive experience. Although positive affect overlaps to a significant degree with the concept of positive emotions, they are not identical. Positive affect is more closely related to mood states whereas positive emotions involve positive feelings as well as characteristic patterns of physiological arousal, thoughts, and behaviors [1]. Positive affect is usually measured through the use of self-report scales, such as the Positive and Negative Affect Schedule [2], in which respondents are presented with words describing both positive and negative moods and asked to rate each according to the extent that it describes them. Although these scales were originally designed for adults, more recently they have been adapted for use with children and adolescents.

Research suggests that individuals who have high degrees of positive affect are generally more extraverted than people with negative affect, and that they also experience a greater variety of mental and physical health benefits. Moreover, although positive affect is often contrasted to negative affect, these constructs can be independent of each other. Specifically, individuals can be high or low on one dimension whether they are high or low on the other [1]. For example, in determining whether a child or adolescent is experiencing depression or anxiety, assessing the degree of positive affectivity may be useful. Research suggests that youth with depression experience substantial levels of negative affect but not positive affect, whereas youth with anxiety disorders often experience both negative and positive affect. Although positive affect appears to a large extent to be genetically determined, it is not exclusively so, and can be enhanced through both cognitive and behavioral modification [1].

Positive Practice

Michelle Johnson, Ivy Chong
Florida Institute of Technology, Melbourne, FL, USA

Synonyms

Overcorrection; Positive punishment; Restitution

Definition

A type of overcorrection procedure, in which, contingent on the problem behavior, the student is required to engage in correct forms of relevant behavior until the behavior has been a repeated a number of times [2].

Description

This process ensures the individual practices the correct response according to a predetermined number of repetitions or duration, contingent upon problem behavior or incorrect responding. The behavior emitted during the repetition interval is related to the inappropriate response and is designed to ensure the individual learns the correct response to emit in the future [1]. An example of this procedure includes having the learner appropriately dispose of ten pieces of paper contingent upon throwing trash on the ground. The effort required to emit the appropriate behavior is designed to teach the learner the appropriate response (e.g., throwing trash into the garbage can) and to reduce the future frequency of the inappropriate behavior of concern (e.g., disposing of garbage on the ground/floor).

Relevance to Childhood Development

Positive practice has been implemented in multiple learning contexts for children with developmental disabilities. Not only has it been utilized within clinical settings, such as those mentioned, above, but the procedure has been implemented within the context of skill acquisition during the completion of education tasks [3]. The procedure provides the learner with the opportunity to emit the correct response, thus exposing the learner to multiple trials of the correct response.

Positive Reinforcement

Pei-Hsuan Hsieh
University of Texas at San Antonio, San Antonio, TX, USA

Definition

Positive reinforcement involves the increase in the frequency of a behavior as a result of the presentation of a stimulus.

Description

There are many theories founded by psychologists and educators that attempt to explain how people learn. A prevalent theory that has been utilized and researched for over 80 years is operant conditioning. Originated by B. F. Skinner in the 1930s, operant conditioning attempts to define how different types of reinforcers and punishments can strengthen and weaken behaviors.

There are two types of reinforcers that strengthen behavior: positive and negative. Positive reinforcement is a way to encourage a good behavior by providing a constructive reinforcer to the person. These reinforcers increase the odds that the positive behavior will occur again in a similar situation. When using positive reinforcement, it is important for the reinforcer to be preferred or wanted by the person. If not, the person's behavior is unlikely to change and the behavior is unlikely to occur again. Negative reinforcer encourages a behavior by removing an unpleasant stimuli.

Relevance to Childhood Development

For school children, many types of positive reinforcers have been developed to persuade children to behave in class. The most basic of these is smiley face stickers. Other examples include extra recess time, free homework passes, and toys from a treasure box.

For adults, positive reinforcers are more complex. Personal success is often a reinforcer that adults find rewarding. Other positive reinforcers for adults include pay-checks, raises, and praise.

Positron Emission Tomography

Nina Foster
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Functional imaging; PET

Definition

Positron Emission Tomography (PET) is an imaging technique that produces a high resolution spatial three-dimensional image. PET is used both for clinical and research purposes, in order to identify areas of the brain associated with various psychological tasks and to assess cortical areas associated with various psychological and neurological disorders.

Description

Positron Emission Tomography (PET) produces high quality images that are hemodynamic, chemical, functional, or metabolic from which conclusions of physiological variables can be determined. Before scanning takes place the individual is injected with glucose or another chemical that contains radioactive atoms [1]. During scanning, when the glucose or other radioactive material begins to decay a positron is released and collides with an electron that emits two gamma rays going in exact opposite directions [2]. The detectors record the arrival of rays along the outside area and quantify the difference in arrival time to figure exactly where they were produced [1]. The computer determines how many rays are coming from specific areas and how much of the chemical is located in that area. A three-dimensional image of the studied organ is formed. The areas with the most radioactivity, hence the most bloodflow, are shown as the areas with the most activity [3]. PET images are usually coupled with Computerized Tomography scans which give two sets of data, anatomy and metabolism, that can be merged into a unique image to form the final result [4].

Postconventional Moral Reasoning

►Postconventional Morality

Postconventional Morality

Andrea Green, John Snarey
Emory University, Atlanta, GA, USA

Synonyms

Kohlberg's third level; Postconventional moral reasoning; Principled moral reasoning; Stages 5 and 6 of moral judgment development

Definition

Postconventional morality, a concept developed largely by psychologist Lawrence Kohlberg, identifies the ethical reasoning of moral actors who make decisions based on rights, values, duties, or principles that are (or could be) universalizable. This means that the principles are separable from the authorities or persons who hold them, they are open for debate and generally agreeable to individuals who seek to live in a fair and just society, and they withstand tests of logical comprehensiveness. Postconventional morality, as distinguished from postconventional moral reasoning alone, also includes principled moral behavior, or moral action.

Description

Lawrence Kohlberg's (1927–1987) stage theory of moral reasoning includes three levels of development — preconventional (Stages 1 and 2), conventional (Stages 3 and 4), and postconventional (Stages 5, 6, and a metaphorical Stage 7). The postconventional level reflects a moral philosophy that is principled, structural in form, and independent of the specific content of a given moral dilemma. Kohlberg's stage model began with the great philosophical questions: "What is virtue?" and "What is the good?" Kohlberg, following the views of philosophers Plato, Immanuel Kant, and John Rawls, answered that the first virtue is *justice*, defined as equity or equal respect for all people. Regarding justice reasoning, Kohlberg also followed Jean Piaget [3, 4] and applied a systematic stage framework called structuralism, the analysis of invariant, paradigmatic relationships between ideas, to moral reasoning. Thus, Kohlberg's three moral levels are each a systematic framework for describing the worldview that the individual constructs in his or her moral imagination in order to enact equity and fairness for all people. Each stage constitutes a separate moral philosophy, a unique construction of the sociomoral world.

The three levels are developmentally ordered. That is, they outline a course of moral judgment, stimulated by environmental sociomoral issues, that progresses from simple to more complex modes. Development is the qualitative reorganization of meaning, and this restructuring of experience informs the notion of cognitive stages. Kohlberg used the word "stage" to suggest qualitative differences in the individual's modes of thinking about or solving the same problem at different ages of the lifespan. Development, then, is movement toward greater ease in adaptation, differentiation, and integration of distinct modes of thought in an invariant and hierarchical developmental sequence. Individual moral actors always prefer solutions to problems at the highest levels available to them. This is the foundational and driving force underlying movement from one stage to another, more adequate, stage [1, 2].

Postconventional Morality as the Telos of Moral Judgment Development

Kohlberg named the three developmental levels preconventional, conventional, and postconventional, relative to the orientation of the moral actor toward the agreed-upon societal arrangements and norms called conventions. Preconventional moral thinkers, typical of children ages 4 through 10 years, are aware of social conventions, but only as the arbiter of rules and standards with the capacity to exact consequences for breaches in conduct. Conventional moral reasoning, typical of most adults, is concerned with maintaining familial expectations as well as maintaining, supporting, and justifying

the social order. Conventional morality might also be called conforming morality; maintaining the social order is considered valid in its own right. Kohlberg's postconventional morality, the rarely observed third level, is also known as the principled level, because here, the moral agent defines moral values and principles as completely separate from the social conventions maintained by societies and institutions. Separating moral principles from the institutions and persons who claim them allows the moral agent to use those principles to interrogate socially agreed-upon standards and arrangements in relation to individual rights and duties to all members of the society. Postconventional morality, then, recognizes that society itself is a system of arrangements and represents the impartial application of generalizable and logically consistent norms and egalitarian practices to all members of society.

Kohlberg demonstrated that an individual making a transition from conventional to postconventional morality is often characterized by the belief that moral choices are personal and subjective. The transitioning moral actor views conscience as arbitrary and relative, along with the ideas of "duty" and "morally right." This moral actor embraces a worldview that places him or her outside of the norms of society, making decisions without the strong commitments to the social order that are evinced in conventional thinking. While recognizing that normative rules are defined by particular societies, such persons ground moral choices in universal principles that transcend the norms of society.

Within each of Kohlberg's three levels of moral reasoning are two related but distinct stages, which are integrated and structured as separate but complete systems of philosophical and cognitive orientation. (See entry, *Kohlberg's Theory of Moral Development,* for more information.) As the most complex patterns of sociomoral reasoning in Kohlberg's moral judgment development model, Stages 5 and 6 reflect autonomous morality based on mutual respect, reciprocity, and equality. Fairness, at the autonomous level, involves cooperation and reciprocal exchange. This moral orientation is "society-creating" rather than "society-maintaining."

Stage 5 thinkers view "the right" as upholding the basic rights, values, or principles of a society, even if those rights conflict with the existing laws and concrete rules of the social group. This person is aware of the rights and values that would be granted to anyone who lived in a moral society; the validity of group laws are tested for consistency with those fundamental rights and values. The Stage 5 individual recognizes human values and basic rights that exist prior to social arrangements, rules, and laws. This prior-to-society perspective yields a worldview in which the moral point of view and the societal point of view may be juxtaposed and differentiated. The social group is seen ideally as a social contract between the collective and the individual, with the individual capable of opting in, or out, of this arrangement. Kohlberg used the example of Sir Thomas More to illustrate a postconventional moral conscience at Stage 5 [1, p. 382].

Stage 6 thinkers construct a moral worldview by imaginatively taking the roles of all participants in a given situation while also considering all of the contextual issues of each individual. The person chooses right action as a matter of conscience, in accordance with self-chosen ethical principles that appeal to logical comprehensiveness, universality, and consistency. Principles are abstract and ethical; they encapsulate reciprocity for the equality of all human rights and respect for the dignity of all human beings. They are not opinions or values but guiding standards for moral decisions and action. This individual recognizes and lives out the basic moral principle of respect for all human beings, affirming in thought and action that each human life is valuable and has the right to be treated with dignity and fairness. This human rights orientation is the principle of justice, and in Stage 6 the moral agent inhabits a worldview in which all moral decisions are transacted from this universal principle. Kohlberg considered that Martin Luther King, Jr., particularly as he expressed himself in his "Letter from a Birmingham Jail," illustrated the use of postconventional justice reasoning at Stage 6 [1, pp. 382–383].

Exemplars of Postconventional Morality

Kohlberg identified at least a dozen historical figures whom he regarded as exemplars of postconventional morality. His moral exemplars included Marcus Aurelius, William Brennan, Archibald Cox, Martin Luther King, Jr., Janusz Korczak, Abraham Lincoln, Sir Thomas More, Andrea Simpson, Socrates, Baruch Spinoza, and Henry David Thoreau [7]. What made these people worthy of such designation, for Kohlberg, was that, beyond their principled moral reasoning, they all had taken tangible moral action, such as the use of nonviolent public dissent, critical speeches, and protest marches. Consequently, most faced penalties, and almost half of them died for their moral stance.

Nevertheless, Kohlberg found so few contemporary adults who transacted moral decisions at Stage 6 that it was difficult for him to study this stage empirically. This presented a problem in the continued evolution of Kohlberg's theory, because the model itself was derived

from, and built upon, the assumption that universal, principled justice reasoning, the hallmark of Stage 6, was the ideal endpoint of moral development. Kohlberg omitted Stage 6 from the standardized edition of his scoring manual, citing its empirical rarity. Additionally, cross-cultural studies conducted around the world documented only limited evidence of Stage 5 thinking [6], causing some critics to doubt the universality of postconventional moral reasoning as defined by Kohlberg's stage model.

James Rest and Postconventional Morality

James Rest (1941–1999), a neo-Kohlbergian developmental psychologist, built on Kohlberg's work by studying the hierarchical nature of the moral development stage model. Rest's research led to the development in the early 1970s of the defining issues test (DIT), a moral judgment test that shortened the time-consuming task of measuring moral reasoning with Kohlberg's moral judgment interview (MJI) and its complex scoring manual. The DIT2, a revised version that has been in use for over 10 years, shortened the number of test dilemmas, updated the 1974 language of the DIT, and included new test problems [8]. Both the older and the updated measure have yielded results that support a significantly different definition of postconventional morality from that of Kohlberg.

Kohlberg's structural-developmental stage model defined moral judgment in terms of justice, an understanding of morality defined by John Rawls as the way in which major social institutions distribute fundamental rights and duties and apportion social advantages so that one group is not favored over another. Instead of stages with distinct justice operations, DIT research favors the notion of schemas as the formative cognitive structures, constructed by the individual in relation to environmental interaction, that follow a developmental sequence. The term "schema" marks a departure from Kohlbergian stage theory in that DIT evidence does not support the strict, stair-stepping sequence of levels of moral judgment or the assumption that individuals occupy only one level at a time. Remaining in the definition of "moral schemas" are Kohlberg's core ideas of emphasizing cognition, the construction of patterns of thinking from sociomoral experience, and moral judgment moving from simpler to more complex modes. Accordingly, DIT research suggests three schemas, the Personal Interest schema, roughly associated with Kohlberg's preconventional level, the Maintaining-Norms schema, associated with the conventional level, and the Postconventional schema, which reflects the core ideas of Kohlberg's postconventional level.

Postconventional schemas capture the moral actor's shift from conventional to postconventional thought that is the hallmark of moral development. The defining characteristic of the Postconventional moral schema is "that rights and duties are based on sharable ideals for organizing cooperation in a society, are open for debate and tests of logical consistency, experience of the community, and coherence with accepted practice" [5, p. 41]. Both of Kohlberg's postconventional stages characterize this schema, although the schema here is more broadly defined than Kohlberg's stages and does not attempt to describe universal ideals. Postconventional thought as suggested by this understanding is ideal based, nondogmatic, and subjective; it is open to experience but must withstand tests of logical coherence. Ideals are open to debate, interpretation, and practice. Social norms are viewed as alterable, and the postconventional thinker literally separates them from the moral sphere. Deviation from social norms has the potential for good when laws are unjust or biased in favor of one group or people or particular institution. The positive, constructive features of postconventional thinking include the ability to envision creative and shared idealized avenues where humans can interrelate. The criteria for the postconventional schema are rational and psychological; the criteria for postconventional stages were philosophical and justice oriented.

Rest and his colleagues propose four rational criteria essential for definition as postconventional schema. The first is understanding the moral purpose behind societal norms and codes. The postconventional thinker considers norms and obligations as social arrangements that can be renegotiated and re-verified, given new circumstances and social arrangements, in contrast to the Maintaining Norms (conventional) thinker, who looks to the norms and obligations themselves as a source of authority. The second characteristic of the postconventional thinker is an appeal to an ideal. Such ideals may include those of guaranteeing basic human rights, engendering caring relationships among all people, or ensuring a living wage for all workers. In addition, to be postconventional, these ideals must be sharable, the third criterion for this schema. Sharability means it is not ethnocentric. It should serve group goals, enhance and facilitate cooperation from others, and be consistent with the common good. Sharability remains open to rational critique and is subject to modification with additional experience and new evidence. Finally, postconventional thinking must embrace full reciprocity. Full reciprocity entails not only uniform application of social norms, but also demands that the social norms themselves do not favor some members of a society at the expense of other members of the society.

From results of DIT research, Rest and colleagues operationalized a broader definition of postconventional morality, thus suggesting a developmental typology in empirical and psychological terms that avoids the philosophical criticisms of the stage theory as postulated by Kohlberg. The DIT-informed definition of postconventional moral reasoning does not propose a normative philosophical theory.

Relevance to Childhood Development

Children do not exhibit postconventional morality. Understanding the nature of postconventional morality, however, can provide direction for moral education efforts with children. Education aimed toward creating postconventional thinkers highlights the need for "just learning environments" and leads to improved pedagogies for justice reasoning. That will, in turn, promote the development of morally mature persons able to serve as teacher-citizens of community schools and as public citizens of a democratic society evolving toward the realization of justice and equality for all.

Kohlberg developed methods of moral education that promoted moral development and mature character, including exposure to moral exemplars, classroom moral dilemma discussion, and Just Community programs in which democratic education was a normative feature. His approach to moral education taught that attention should be given both to promoting the role taking and moral judgment development of individual students and to enhancing the moral cultural environment of classrooms and schools.

Postpartum depression (PPD)

Definition

According to the American Psychiatric Association's *Diagnostic and Statistical Manual, fourth edition, text revised* (DSM-IV-TR) [2] post-natal depression (PND) is recorded as a specifier of a major depressive episode which has its onset postpartum. PDN is usually diagnosed between the sixth and twelfth week after childbirth and shares the characteristics of a major depressive episode.

Description

More specifically, PND is classified as Major Depressive Episode with Postpartum Onset and is characterized by depressed mood most of the day, nearly every day, or loss of interest or pleasure in all or almost all activities most of the day, nearly every day, accompanied by at least five of the following features: weight changes, sleeping problems, psychomotor agitation or retardation, fatigue or loss of energy, feeling of worthlessness or excessive inappropriate guilt, diminished ability to think or concentrate, and recurrent thoughts of death or suicidal ideation and the episode must have its onset within 4 weeks after childbirth [2]; even though it is most commonly diagnosed between 6 and 12 weeks after childbirth [20]. PND is also commonly associated with mood fluctuations, mood lability, and preoccupation with the child's well-being [2], while more recurrent thoughts of death or suicidal ideation, or recurrent thoughts of harming the baby may be present in women with PND [20].

Post-natal depression (PND) affects women in various socio-cultural environments around the world during a sensitive period of their lives. Prospective studies have demonstrated that PND affects approximately 10–15% [10, 12] or 20% [24] of women after delivery in western countries, while 1 in 1,000 women may experience psychotic episodes [24]. On the other hand, some have reported prevalence estimates for PND between 6.5 and 12.9% [20], while others have reported slightly different prevalence estimates according to geographical location and population; for example Gonidakis and colleagues [10] reported a prevalence of 19.8% in Greece, Rahman and Creed [21] reported prevalence estimates of 56% in Pakistan, Chaaya and colleagues [6] reported prevalence rates of 21% in Lebanon, and Cox and colleagues [9] reported a prevalence of 53.6% among adolescents.

Moreover, PND is thought to be unique compared to the other mood disorders in that PND is highly related to several neuroendocrine alterations. PND differs also in that it has implications for the psychosocial adjustments that have to be made in everyday functioning and on future family planning decisions, while breast-feeding has implications on treatment decisions [2]. Additionally, Bernstein and colleagues [5] report that even though non-postpartum and postpartum depression (PPD) are both characterized by low energy level and restlessness/agitation, non-PPD is more closely associated with more sad mood, more suicidal ideation, and more reduced interest, whereas in PPD sad mood is less prominent but psychomotor symptoms (restlessness/agitation) and impaired concentration/decision-making are more dominant.

Within this context, it is essential also to distinguish PND from the "baby blues" [2] or the "maternity blues" [22]. The "baby blues" affects nearly 70% of women within the first 10 days postpartum; however, it is transient and does not appear to interfere with everyday functioning [2]. The "baby blues" is typically characterized by mood lability, sudden occasions of crying, irritability, and sleep difficulties that last approximately for the first 2 weeks postpartum [22]. Nonetheless, if these depressive symptoms persist for more than 2 weeks it is more likely that the mother will develop PND [22].

Postnatal depression is now recognized as a major public health concern, since it is the leading cause for maternal morbidity and mortality and has adverse long-term effects on the family as a whole and on the infant's individual emotional, cognitive [12], and growth [16] development. Concern about PND accelerates even more in the light of evidence suggesting that women with PND also suffer from anxiety or even panic attacks [2].

One of the most vulnerable populations to PND is adolescent mothers. Estimates of adolescent depression during the early postpartum period vary from 32 to 60%. Teenage mothers are also more prone to later substance use, delinquency, adverse life events, and persistent mental health problems [9], making this population worthy of clinical attention. In addition, adolescent mothers, compared to adult mothers, face a lot more hazardous conditions, such as poverty, physical or sexual abuse, and family dysfunction, combined with their immaturity, that potentially hinder the development of positive maternal self esteem [9] and thus expose their infants to worse developmental outcomes.

Risk Factors

Considerable literature on risk factors associated with PND designate that these cluster around the following six variables: socio-demographic factors, personality and psychological factors, stressful life events, social support, obstetric and biological factors [14], and factors associated with the puerperium period [10].

Socio-demographic factors include young as well as old maternal age, low socio-economic status, low educational level [14], unemployment [10], and poverty [20]. Psychological and psychiatric problems include personal and family history of depression and depression, anxiety, or both during pregnancy [2, 4, 10, 14], a history of other non-psychotic mental disorder [10, 20], antenatal emotional problems [14] and prolonged symptoms of "baby blues" [2, 4, 10, 22]. Personality and psychological factors refer to characteristics of neuroticism, introversion, perfectionism [14], obsessionality, especially with cleaning [10], dysfunctional cognitive style, high interpersonal sensitivity, attributional style [14], low self-esteem [4, 14], history of physical or sexual abuse [14], and unplanned or unwanted pregnancy [4]. Stressful live events refer to negative or stressful life events associated with pregnancy and childbirth, especially within the past year, as well as high levels of daily hassles [14]. The social support variable refers to low social support both during and after pregnancy, including poor partner relationship [10] reflected in low partner support, low availability of people to depend on during pregnancy and the early postpartum, and the woman not having close relationships with her own parents, and especially her mother [14].

Obstetric and biological factors include history of miscarriage and pregnancy termination, as well as biophysical and hormonal changes [14]. Finally, during the puerperium risk factors related to the development of PND mainly refer to the infant's behavior and

temperament [4], and most specifically to more sleeping difficulties and excessive crying [10], as well as to elevated childcare stress [4]. Moreover, PND development is related to the expectations of the mother in having more support and help during the puerperium [10].

Explanational schemes of how PND develops indicate that a single risk factor cannot predict PND. Rather, it is the combination of factors that increase the woman's vulnerability to PND [13]. In addition, it is suggested that different factors can predict PND in different assessment times [10]. Examples of such explanational schemes include the one provided by Zinga and colleagues [24] who have suggested that some women, and especially primiparous, find it difficult to transit into motherhood, especially if the pregnancy was unplanned or unwanted, and experience low self-esteem for not being able to look after their child. These subsequently lead to child temperamental difficulties and a vicious cycle develops. Moreover, others suggest that if low self-esteem is associated with perfectionism or obsessionality could predispose some women to PND, since they seem to be more vulnerable to the unplanned and unpredictable stressors of being a parent, such as night time crying [10, 14].

Additionally, it is suggested that women with inadequate social support from her partner, her family, and her friends, that provide help, esteem, and understanding [9], are more likely to develop PND, and especially if these women are immigrants experiencing more language barriers [9, 24]. On the other hand, a non-stressful antenatal environment and adequate levels of social support can have clear protective effect postnatally [9, 24].

Nonetheless, it appears that the predicting factors of PND in Africa, the Far East, and the Middle East are somehow different from those in Western societies. For example, Nakku and colleagues [15] reported that in Africa risk factors for PND included single parenthood, marital discord, divorce, and polygamy, female sex of the infant, absent of breast-feeding, as well as physical problems in the infant such as low birth-weight, ill health, and birth abnormalities. Furthermore, Rahman and Creed [21] reposted that in Nigeria as risk factors of PND include variables such as poverty, having five or more children, an uneducated husband and lack of a confidant friend; the authors also reported that poverty associated with more psychological symptoms during pregnancy predict depression persistency for 1 year after delivery. Finally, the risk factors associated with PND identified in Lebanon include lack of social support, prenatal depression, stressful life events, lifetime depression, vaginal delivery, little education, unemployment, and chronic health problems [6].

Relevance to Childhood Development

Generally, postpartum psychiatric difficulties can cause considerable family distress and disturbance, and can impair the woman's ability to function properly [20] and carry out her previous normal tasks, as well as her coping with the care of her infant [15]. Post-natal depression in particular, which is now considered as a major health problem, has been further identified as posing further implications for parenting, nurturing abilities and overall life skills [9]. More specifically, PND has been found to impact the mother-infant relationship and the mother-infant attachment and bonding, resulting in childhood developmental deficits and in adverse cognitive, emotional, and behavioral outcomes [10, 14, 15, 20].

Regarding the concept of maternal functioning, it seems that PND women show more personal, household, and social and overall functional impairment than non-PND women. PND women who cannot achieve previous functioning may be unable to shower, pay bills or even seek help for depression or other health-related matters both for themselves and their infants. In addition, functional impairment in women with PND has also been associated with poor infant growth and decreased breastfeeding in the postpartum period, even though these mothers might continue to provide good physical infant care despite symptoms of depression in the postpartum period [20].

In a study investigating the relationship between PND and everyday functioning, Posmontier [20] noted that women with PND had a trend of having more help with cooking, running errands, and physical infant care than women without PND, and that women with PND were 12 times less likely to achieve pre-pregnancy functional levels than non-depressed women. Additionally, it was shown that PPD predicted lower personal, household, and social functioning, but physical childcare did not seem to be affected. Investigating this phenomenon further, the author suggested that although women with PND provided the same level of physical infant care as non-depressed women, PND women were unable to provide necessary nurturing interactions with their infants due to poor social function. Research on this ground revealed that although mothers with PND provide similar levels of physical infant care, they are more anxious, less affectionate, less playful, less verbally interactive, less likely to read with their infants, and show less mutual attentiveness [20, 24]; consequently the children of these mothers are

more likely to experience deficits in creative play and develop insecure attachment.

Relevant to the above notion of functioning is the qualitative research conducted by Barr [3], who showed that mothers with PND were less likely to transit and adopt into their new roles of motherhood. This delay in adaptation to the new role resulted in suspended competence regarding parenting skills, which subsequently was associated with a lack of maternal-infant attachment. Barr [3] also reported that even thought depressed mothers provided physical care for their children, this was done in an unthinking, "mechanical," instinctive manner. Moreover, the participants in this study reported a reduced ability to function due to fatigue; they reported also an inability to plan ahead or even engage in a decision-making process. This inability to plan caused these women distress and diminished their confidence about their caring abilities; accordingly, the participants in the study reported that they were afraid to stay alone with the child frighten by the thought that something would go wrong. Additionally, due to the impaired mother-infant attachment, depressed mothers seemed to be frustrated struggling to find the sense of love for their children, for example they reported feeling that the child was not theirs and not wanting to be near them [3].

Additional features of PND mothers include intrusiveness and irritated behavior towards the infant [2, 24], as well as showing less sensitivity, less contingently, and more negativity to their newborn [24]. Subsequently, these lead to further long term implications for the child's development, beginning from difficulties in attachment, followed by cognitive and emotional delays, which are mediated by the severity and chronicity of maternal depression [24]. Examples of these implications come from studies investigating the mother-infant relationship, which have indicated that infants of depressed mother are less likely to look at their mothers, or show positive affect; and they also show lower physiologic reactivity.

Furthermore, it is well documented that successful parenting in infancy and early childhood can predict successful child development, and especially healthy social development [23]. Furthermore, successful parenting is believed to be influenced by the sense of parenting self efficacy (PSE), i.e., the parents' perceived efficacy to completely and effectively perform their roles as parents. High levels of self-efficacy and perceived competence in the parenting role has been positively associated with observed parenting competence, including warmth, sensitivity, and engagement, and thus positive children's developmental outcomes, whereas low self-efficacy has been associated with self-doubt, high levels of anxiety, interpreting challenges as threats, and assuming more responsibility for failure, which are reflected in parenting as discouragement and deterioration, leading to increased problem behavior in children [23]. Congruently, a study with adolescent mothers showed that maternal competence was inversely related to depression while social isolation was directly associated with depression [9].

Further research within this context, indicated that maternal depression mediates the relationship between PSE and early-onset behavior problems and conduct problems in children, suggesting that maternal depression is a potential disruptor of caregiver confidence in early childhood [23]. These findings should be alarming for the scientific community, since it is also well documented that early-onset behavior r problems are positively linked to the development of more severe conduct problems in middle childhood and adolescence, including delinquency and substance use [23].

One other concept related to PSE is that of maternal self-esteem, which is an important early parenting attribute closely associated with mother-infant bonding and subsequent effective parenting. The development of high maternal self-esteem depends on the mother's ability to interact with and care for her infant [9]. In a study among 168 teenage mothers, it appeared that elevated depressive symptoms were associated not only with low social support, which constitutes a risk factor as reported above, but also with decreased maternal confidence in caretaking ability, and thus lower maternal self-esteem [9].

In respect, adolescent mothers with low self-esteem have been found to vocalize less with their infants, to be less flexible, to be more likely to give inappropriate stimulation and to be at higher risk for child maltreatment [9]. Nevertheless, adolescent mothers form a population with special characteristics, different from those of adult mothers. More specifically, teenage mothers' abilities to parent effectively are excessively challenged by the predisposing factors of family dysfunction, emotional immaturity, life stress, poverty, sexual abuse, school failure, hopelessness, and poor social support. Moreover, depressed adolescents seem to have less confidence in their abilities to interact with and care for their children and are also more vulnerable to experience persistent as well as recurrent episodes of depression [9].

With regards to the infant's temperament, it should first be noted that infant temperament is defined as the infant's behavioral style, and particularly how the infant behaves in relationship to the environment and the care he/she receives. Subsequently, how the infant's temperament is exhibited and perceived by the mother determines the developing relationship between the infant and

mother. When there is synchrony between the mother-child dyad it is said to be "Goodness of Fit." When "Goodness of fit" is not present the infant is perceived as difficult and/or demanding by the mother and this asynchrony of the relationship makes the infant vulnerable to long-term negative outcomes. Moreover, maternal perceptions and beliefs about the attributes of the infant affect the ways she cares for her infant and the symbiotic relationship, which will subsequently support the child's cognitive development [13]. Thus, a mother with PND is more likely to feel that her interactions with her infant are negative, since her perceptions are filtered through her negative mood.

In investigating the symbiotic relationship between the mother and the infant, McGarth and colleagues [13] reported that depressed mothers were more likely to report that their infants were more difficult, compared to non-depressed mothers, and this remained stable over time, from the second to the sixth month postpartum. In order to explain their findings, the authors assumed that for a mother with PND caring for her newborn might be overwhelming, causing her excessive stress and anxiety, as well as feelings of isolation.

Other reports on the topic suggest that the negative emotional responses of a PND mother are likely to elicit feelings of fear and withdrawal in the infant, reinforcing the mother's negative perceptions [13]. Moreover, an active and demanding infant may pose a further burden on a mother who is also suffering with PND and possibly intensify the depressive symptoms the mother is experiencing, and thus leading to more negative outcomes in the child, and particularly the development of an insecure attachment between the mother and the child [13].

Concerning the issue of cognitive development, research revealed that children of depressed mothers exhibit significant intellectual deficits, but this was true only when the depression in the mother occurs within the first year postpartum [8]. Nonetheless, it is suggested that the influences for positive cognitive development, such as play, conversation, and teaching to the child specific skills, are hampered by the mother's immobilization due to PND and the impaired mother-infant attachment [8].

Furthermore, research on the familial transition of depression from the mother to her children revealed that antenatal and post-natal depression lead to increased psychiatric problems in children at 11 [19] and 16 years [18]. More specifically, Pawlby and colleagues [19] assessed 129 11-year old children of mothers who were depressed at 3 months postpartum for emotional and behavioral problems and they found that of these 129 children 31 (24%) met DSM-IV criteria for an emotional or behavioral disorder. Eleven children had emotional disorders (separation anxiety, social anxiety, depressive episode not otherwise specified), 11 had behavioral disorders (oppositional/defiant disorder, conduct disorder, attention-deficit and hyperactivity disorder) and 9 had both types of disorder. Boys and girls were equally likely to have a disorder. Moreover, these children also showed significantly higher rates of teacher-rated behavioral and emotional problems [19]. Collectively, it was estimated that the children of mothers who met criteria for postnatal depression at 3 months were 4 times more likely to suffer from a psychiatric disorder themselves at 11 years of age compared to controls, whose mothers were well following childbirth [19].

In their second study [18], with adolescents at the age of 16, data showed that 18 (14.2%) of the 127 adolescents, 14 (20.3%) girls and 4 (6.9%) boys, had a depressive disorder according to DSM-IV criteria. Ten adolescents had a major depressive disorder, which was superimposed on dysthymia. Six adolescents had a diagnosis of depression not otherwise specified, 3 of which were superimposed on dysthymia, and 2 adolescents had a diagnosis of dysthymia. Furthermore, 6 of the 18 depressed adolescents (4 girls and 2 boys) had planned or made suicide attempts. Generally, there were no significant differences in the mothers' age, parity, ethnicity, social class, educational level, or marital status at birth or at 16 years, or in the ethnicity or educational attainment of the depressed adolescents, compared with those who were not depressed, however the depressed adolescents were more likely not to live with both biological parents [18].

Most notwithstanding, however, was the finding that each depressed adolescent had been exposed to maternal depression and that adolescents who had been exposed to maternal depression at some point since conception were significantly more likely to be depressed at 16 years than adolescents who had never been exposed. In addition, it was revealed that 65% (11/18) of the adolescents with depression were initially exposed to depression during the antenatal period and that adolescents who were exposed to antenatal depression were 4.7 times more likely to have a diagnosis of depression at 16 compared to the offspring who were not so exposed [18].

Bearing in mind that history of depression during pregnancy can predict PPD and that the longer a woman is incapacitated by PPD the more she is at risk for lifelong and recurrent depression and suicide [20] Pawlby and colleagues [18] investigated the outcome in children of mothers with antenatal, postnatal and recurrent depression within their 16 years of life. Findings revealed that adolescent depression was also associated with a greater number of periods of exposure to maternal depression

and that the depressed adolescents in their sample were exposed 2.82 time periods to maternal depression compared to the 1.31 exposure times for non-depressed adolescents. Subsequent logistic regression also showed that even thought initial exposure during pregnancy predicted inverse adolescent outcome, it was no longer itself a significant predictor when account was taken for the chronic nature of the mother's depression. Rather, maternal depression in pregnancy was a strong predictor of depression in the adolescent offspring, but was mediated by subsequent periods of depression during the child's lifetime. Finally, the odds of the offspring being depressed at 16 years increased by 1.74 for every period of maternal depression from pregnancy to 16 years [18].

These two studies replicated the strong familial association between maternal and adolescent depression and also showed that women who experience depression during pregnancy are almost 10 times more likely to have a recurrence. These studies also showed that, even thought it was not the effect of maternal depression in pregnancy per se that predicted adolescent depression, most of the children who were depressed at 16 years had initially been exposed in the antenatal period (65%) and were at greater risk for future exposure because of the strong likelihood of recurrence of maternal depression later in the child's life [18]. Based on these findings, combined with the already established knowledge about the adverse outcomes related to adolescent depression, management for PND and the risk factors associated with it seem mandated.

Finally and interestingly, in non-western, developing countries one of the most adverse outcomes related to PNS is poor infant growth. Rahman and colleagues [21], in their study in Pakistan, reported that depression around childbirth is associated with impaired infant growth and development, while prolonged PPD appeared to be associated with impaired weight gain in the first year of the infant's life. Similarly, Adewuya and colleagues [1] investigated the outcome of PND in a Nigerian sample and reported that infants of depressed mothers had statistically significant poorer growth weight compared with the infants of non-depressed mothers at 3 and 6 months postpartum. Adewuya and colleagues also reported that depressed mother were more likely to stop breast-feeding earlier and that the infants experienced more physical illness, such as diarrhea and infections. However, they also hypothesized that poor growth could be related to the emotional unavailability of the mother to the child, leading to psychosocial deprivation and non-organic failure to thrive [1].

Management

When considering the subject of effective management it should firstly be acknowledged that antenatal depression and anxiety are both incapacitating and distressing conditions and therefore important to treat in their own right [14]. In the light of evidence suggesting that there is substantial likelihood that antenatal emotional problems are associated with obstetric complications including premature delivery and intra-uterine growth restriction [14], and can also predict the development of PND after childbirth pose a greater need for timely and effective management. This is also highlighted by the fact that the longer a woman is "handicapped" by functional deficits due to PND, the more she is at risk for impaired mother-infant interaction and subsequent long-term growth [16], cognitive, behavioral and emotional problems in her child [20] and the evidence suggesting that when maternal depression is treated, adverse child behaviors improve [9].

Currently, whilst postnatal depression can be neither reliably forecast nor prevented, some form of antenatal screening and assessment focused on the risk factors related to PND, such as psychiatric history, current emotional problems and social supports, is likely to benefit many pregnant women in terms of their immediate and future well-being [14]. Thus, the most appropriate element of a timely and sound management would be the identification of the risk factors that predispose an individual in developing PND and treat them before PND occurs [14]. Screening women for depression and anxiety, for example, during pregnancy and attending to these problems before childbirth would operate as a protective factor for future episodes. Indeed, there are indications to advocate for the routine screening of at risk women in the antenatal period in order to avoid, recognize and manage postpartum psychiatric morbidity and its consequence on mothers and their developing children [15]. Furthermore, because suicide due to depression is the leading cause of death among women during the perinatal period, screening for mood disorders is mandated by public health reports and professional bodies working in this clinical area [19].

During the postpartum period, clinicians should be aware that the "baby blues" can potentially lead to PND and that it might be an indicator for an already existent depressive or anxiety disorder. Thus, in the first 2 weeks following childbirth, screenings for the "baby blues," depression, and anxiety symptoms should be applied in order to identify those women who are at risk of developing clinically significant psychiatric disorders and with the intention to provide an opportunity for prevention and therapeutic intervention early in the course of the disorder [22].

Nonetheless, adequate and well designed preventive programs initiated during pregnancy and would accompany the women throughout the first 3 months after delivery are not yet available [11].

Furthermore, it is suggested that clinical assessment for functional impairment in women with PND is critically important because of its detrimental effects on family stability, health maintenance, help-seeking for depression, and social skills necessary for positive interactions with the infant, spouse, family and friends [20]. In addition, ongoing evaluations of the "goodness of fit" within the mother-infant dyad, while also exploring interventions for depressed mothers which provide guidance about interactions with their infants and the appropriateness of the infant behaviors are also recommended [13].

With regards to intervention programs, literature reveals a number of suggested strategies. One possible intervention is pharmacological treatment. However, breast-feeding can have implications when considering pharmacological treatment [2], thus this approach should be implemented only if alternative interventions have been proved ineffective. Educational initiatives, psychological interventions, dietary and hormonal supplements, and sleep management programs are just a few examples of alternative practice [24].

Educational initiatives are based on the assumption that by providing women and their families with information about what to expect during the puerperium period can reduce anxiety, and therefore minimize the impact associated with these psychosocial factors [24]. Within this context, Barr [3] suggests on-going education, counseling and support to new mothers in an attempt to facilitate them in adapting to their new maternal role, with an aim to help these women review their thinking, beliefs, and understanding about mothering and help them adapt to their new social role on a more realistic ground.

Further suggestions made by McGarth and colleagues [13] propose engraining nurses and other healthcare providers in the process of education, who will be able to teach mothers techniques, such as infant massage [17], aiming to improve maternal mood and facilitate relationships between the mother and the child. Moreover, nurses can encourage new mothers, for example, to be attentive to their total amount of sleep time or help mothers to problem solve regarding the infant's sleep wake cycle [13]. Considering the maternal-child attachment, nurses could help mothers identify the positive characteristics of their infants, support mothers in acting in ways that will promote the normal growth and development of the infant, and provide feedback and/or further guidance about the dyadic interactions and the appropriateness of the infant's behaviors in order to improve the mother–infant relationship [13].

Psychotherapeutic approaches which show some promise against PND include interpersonal therapy (IPT) and cognitive-behavioral therapy (CBT). IPT is a time-limited (up to 12 sessions) approach, primarily aiming to remit depression, to alleviate interpersonal distress, and assist the mother with building or making better use of social supports. At the beginning of therapy, the mother is educated about depression and its functional and interpersonal effects; the symptoms, safety, functioning level, and the relationships and supports of the individual are carefully assessed; a current crucial interpersonal problem related to the development of PND is chosen; and the individual is encouraged to use or recruit social supports. During the middle phase of IPT an effort is made to link interpersonal events with dispute and symptoms, issues that are in dispute as well as maladaptive patterns of communication are identified, and the individual is helped to evaluate expectations, learn to communicate her needs and emotions, and expand her understanding and perspectives, while she is also helped in learning how to better use or recruit supports. Concerning the mother-infant attachment, within the context of IPT mothers are assisted to become more attuned and responsive to their infant's during the recovery period and also to recruit or use supports to help with childcare. During the final stage of therapy, therapeutic gains are reviewed, contingency plans for the event of recurrence are discussed, and the mother is encouraged to contact a physician for early treatment. Additionally, future problems and stressors are discussed, in order to facilitate autonomous problem solving, assistance into differentiating between normal sadness from clinical depression is provided, and feelings related to the ending of therapy are openly discussed [11].

Finally, CBT as proposed by Cho and colleagues [7] is also a time-limited approach (approximately 10 sessions), designed to be applied to women at risk for PND during pregnancy and focuses on educating the individual about depression, scheduling pleasant event, and changing negative automatic thoughts to more realistic ones. Moreover, attention is placed also on components of marital interventions, in order to promote acceptance through better understanding of the personalities of one's spouse, to improve communication skills, to promote the use of I-statements, and to make and exchange a list of rewarding positive behaviors from the other spouse. During the first three sessions of therapy the focus is on educating the mother about depression, goal-setting, and increasing

pleasurable activities. During the following three sessions, the mother is taught cognitive restructuring techniques in order to become able to identify and challenge irrational and overly negative thoughts, and especially thoughts related to marital interaction. Session 7–9 focus on assisting the mother to improve marital relationships, while communication skills and behavioral exchange exercises are taught and acceptance of the other spouse is promoted. In the final session, plans for the future are discussed.

PTSD

Definition

Posttraumatic Stress Disorder is an anxiety disorder that develops in some people after exposure to a traumatic event.

Description

Posttraumatic Stress Disorder develops in some people after they experience or witness an event during which they or others were either harmed or under serious threat of physical injury. Rape, torture, a car accident, being kidnapped, bombings, and natural disasters are all examples of events that could lead to the development of PTSD. Further, the person's response to the traumatic event must involve fear, helplessness, or horror [3]. Symptoms usually begin within 3 months of the traumatic event; however, they can emerge years later. PTSD is classified as such if symptoms last for more than a month, and cause impaired functioning in important aspects of their lives. When PTSD symptoms last for a period of less than 3 months PTSD is considered acute, however, when the symptoms persist for more than 3 months PTSD is considered chronic [3].

According to the DSM-IV-TR, to have a diagnosis of PTSD one must exhibit symptoms in three areas: intrusive recollection, avoidant/numbing, and hyper-arousal [1, 3]. Intrusive recollections are symptoms in which one re-experiences the traumatic event. This often happens through flashbacks, which are usually triggered by a sound or smell that is reminiscent of the event. For example, the smell of smoke could cause someone to relive the experience of being trapped in a burning car, during which they may lose touch with reality. Similarly, the trauma may be re-experienced at night, through dreams.

Avoidance behaviors are present in people with PTSD; they may avoid activities or places that are associated with the trauma. Also, the anniversary of the traumatic event can be especially difficult for some. Additionally, people with PTSD often become emotionally numb and lose interest in activities that they previously enjoyed. They may feel detached from loved ones and may be unable to experience certain feelings or emotions, such as love. The third group of symptoms, hyper-arousal symptoms, includes hyper-vigilance, an increased startle response, sleep disturbances, irritability, aggression, and anger [3].

Research has shown that women are more likely to develop PTSD than men [8]. It has also been found that certain genes, as well as exposure to childhood trauma, heighten the risk of developing PTSD in adulthood [6].

Relevance to Childhood Development

Studies indicate that between 15 and 43% of girls and 14 to 43% or boys have experienced one or more traumatic events. Of these children, 3–15% of girls and 1–6% of boys develop PTSD [2]. However, when studies examined high risk samples, they found that nearly all of those children who witness parental homicide or experience sexual abuse developed PTSD [2]. In children PTSD is often caused by events such as a kidnapping or a car accident, physical or sexual abuse, refugee situations, or from witnessing violent acts either on the street or in the home.

Although it has been found that children can experience the entire range of posttraumatic stress reactions that adults experience, age and developmental maturity can influence children's reactions, as well as the ways in which their symptoms manifest [3]. While adults may have feelings of fear, helplessness, and horror when faced with a traumatic experience, children may respond by behaving in a disorganized or agitated manner. Further, children might express aspects of the trauma through repetitive play, and may even reenact the trauma. Like adults, children often have frightening dreams, yet their dreams may have unrecognizable content [3, 4].

Additionally, young children may regress to earlier developmental stages as a result of having been exposed to trauma. For example, a child who had stopped the wetting bed may suddenly begin to do so again. In a way, fear can interfere with their learning. Further, because children depend on adults for protection, it may be particularly difficult for them to deal with the failure of others to protect them in the case of a traumatic event. This may lead them to become insecure about being provided with protection in the future [4].

Additionally, there are several factors that may increase or decrease the chance that a child will develop PTSD. These factors are: the severity of the traumatic event, the parent's reaction to it, and the child's physical proximity to the event [4]. Those children who experience the most severe trauma often have the most severe PTSD symptoms. Further, those who experience a greater amount of parental support and less parental distress tend to report lower levels of PTSD symptoms. The same is true for those who experience the event from a distance rather than from close proximity [4].

In conclusion, PTSD can severely affect the psychological development of children. However, parental support may help to buffer the negative effects that trauma can have on children.

Practical Intelligence

Synonyms

Contextual intelligence; Street smarts

Definition

The ability to find the best fit between oneself and the demands of the environment through (a) adapting to the environment in order to meet goals, (b) changing the environment in order to meet goals, or (c) moving to a new environment in which goals can be met.

Description

Coined by Robert Sternberg as part of his triarchic theory of intelligence. He theorized that individuals create the best fit between themselves and their environment through shaping, selection, and adaptation. Shaping involves changing factors in the environment to meet the individuals needs, whereas adaptation involves making changes to oneself to better fit with the surrounding environment. Selection involves finding an alternative environment that better suits the needs of the individual. Individuals who are of high practical intelligence, even to a level of giftedness, are superb in their capacity to apply their skills and abilities in any setting, to thrive in any environment. They are intuitive and gather information from their environment to utilize and apply in new situations.

Sternberg's theory of practical intelligence has been heavily challenged by Gottfredson. In particular, Gottfredson argued that Sternberg's assertion that traditional measures of intelligence do not assess practical intelligence is inaccurate. She argued that traditional measures of intelligence correlate highly with individual characteristics and behaviors (such as survival skills and income) thought to be reflective of practical intelligence. Additionally, Gottfredson challenged Sternberg's claim that practical intelligence is distinct from general cognitive ability such as the *g* factor (i.e., Spearman's theory).

Practical intelligence is argued to be a better predictor of real world performance, or success out of school, than are traditional IQ measures. In fact, practical intelligence correlates very little with measures of academic achievement, suggesting that individuals who are academically strong may be no better at solving practical problems than are those individuals weaker in academic achievement.

Aside from Sternberg's Triarchic Abilities Test, the assessment of practical intelligence has generally involved tacit knowledge inventories, which are noted to be reliable and valid measures. In support of Sternberg's assertion, although tacit knowledge inventories have been shown to overlap to some degree with traditional measures of intelligence, the correlation between such measures is poor.

Prader-Willi Syndrome

Brady I. Phelps
South Dakota State University, Brookings, SD, USA

Definition

Prader-Willi Syndrome (PWS) is a rare developmental disorder, afflicting approximately 1 in every 10–15,000 children, yet is the most common genetic cause of danger-to-life obesity in children [3, 4]. The symptoms of PWS are numerous and diverse; PWS is considered a spectrum disorder, meaning that not all symptoms will be observed in all affected individuals [3].

The genetic basis of PWS is complex, [1]. First reported in the 1950s, the initial discoveries of the genetic errors underlying PWS were outlined in the 1980s as being deletions on chromosome 15, but only deletions on a paternally-contributed chromosome 15 produce the PWS phenotype. Oddly enough, similar deletions on a maternally-inherited chromosome 15 produce an entirely different syndrome, that being Angelman Syndrome. This finding led to the conclusion that gene activity and expression in humans may be a function of the chromosome on which the particular copy of that gene resides. This discovery is now known as "genomic imprinting," [4]. In the 1990s, additional research indicated that PWS could also be the result of inheriting both copies of chromosome 15 from the mother, an outcome referred to as "uniparental disomy," [1, 3].

The symptoms and behavior seen with PWS are described as emerging in two stages. A website maintained by the National Institute of Child Health and Human Development lists the following:

- Stage 1: As newborns, babies with Prader-Willi can have low muscle tone, which can affect their ability to suck properly. As a result, babies may need special feeding techniques to help them eat, and infants may have problems gaining weight. As these babies grow older, their strength and muscle tone usually get better. They meet motor milestones, but are usually slower in doing so.
- Stage 2: Between the ages of 1 and 6 years old, the disorder changes to one of constant hunger and food seeking. Most people with PWS have an insatiable appetite, meaning they never feel full. In fact, their brains are telling them they are starving. They may have trouble regulating their own eating and may need external restrictions on food, including locked kitchen and food storage areas [3].

The overeating and obesity are typically described as defining features of PWS, and the likely physiological defect is in the hypothalamus of the afflicted individuals, as this brain structure has been implicated in the regulation of both appetite and satiation, [1]. Although investigations of the brains of PWS-afflicted individuals are sparse, one such study found a reduction in the number of neurons that release oxytocin as their neurotransmitter in the paraventricular nucleus of the hypothalamus, [5] [1]. Swaab et al. [5] proposed that this would disrupt the normal feedback mechanisms of hunger and satiation and account for the excessive appetite of PWS-afflicted individuals. Some of the other symptoms of PWS have been listed as being lower than normal IQ and or learning disabilities, yet some individuals with PWS have near normal IQ. Oral motor difficulties, including abnormalities in voice pitch and resonance, as well as sleep apnea have been described in PWS. Other behaviors of concern include temper tantrums, stubbornness, a dislike for changes in daily routine, repetitive behaviors and repetitive questioning. One study found that significant numbers of individuals with PWS engaged in some form of self-injurious behavior, such as picking at the skin, excessive nose picking, or self-biting, [6]. There is no cure for PWS; early and on-going interventions such as the methods of applied behavior analysis can address the behavioral deficits and excesses [2]. Human growth hormone has been used to help address the obesity and muscular deficits, [3]. If the obesity of a person with PWS is controlled, a normal life span is expected. In the absence of such interventions, a significantly shortened lifespan has been reported, [7].

Pragmatics

Lee A. Wilkinson
Nova Southeastern University, Fort Lauderdale, FL, USA

Synonyms

Natural language; Social communication; Social discourse; Social language; Social skills

Definition

Pragmatics is broadly defined as the ability to understand and use language in social-communicative contexts.

Description

Pragmatics is the area of communication function that involves the use of language in social contexts (knowing what to say, how to say it, when to say it, and where to say it). It is the ability of natural language speakers to communicate more than that which is explicitly stated and to understand another speaker's intended meaning [4]. Pragmatics includes both the verbal and nonverbal aspects of communication and may be thought of as a conversational code of conduct or a set of rules for communication [1, 2]. We learn this system of rules naturally and implicitly. If one has good pragmatic skills, he or she is able to communicate an appropriate message effectively in a real world social situation. Pragmatics involve the following social linguistic skills: (a) using language for different purposes (e.g., greeting and requesting); (b) changing language according to the needs of a listener or situation (e.g., talking differently to a peer than to an adult and speaking differently in a classroom than on a playground); (c) understanding non-literal language (e.g., metaphor, irony, figurative language, sarcasm); and (d) following rules for conversations (e.g., taking turns and staying on topic). The pragmatic aspect of language also includes appropriate eye contact, intonation, and the body movements and gestures that accompany communication.

Relevance to Childhood Development

Children must be fluent and capable in the areas of pragmatic language in order to interact and participate successfully in school [13]. When typical children engage in reciprocal conversation they are aware of the knowledge, interests and intentions of the other person, as well as the social rules which determine pragmatic competence. In contrast, children with poor pragmatic skills have significant problems using language socially in ways that are appropriate or characteristic of children their age. Many children with developmental disabilities have difficulties learning the complex rules of social interaction. For example, pragmatic language disorders are the most prominent communication deficit in children with autism spectrum disorders [3, 12].

Because social communication deficits are among the core challenges of autism spectrum disorders, an evaluation of pragmatic competence is always a vital part of the assessment process [8]. However, few standardized tests can effectively evaluate and quantify the complexity of pragmatic language. Valid norms for pragmatic development and objective criteria for performance are also limited [11, 13]. Indeed, formal testing may not identify the presence of a social pragmatic problem, thereby preventing the child from receiving the appropriate support. Assessment of pragmatic social skills requires more than a traditional standardized testing approach [6, 7]. Less formal naturalistic assessments are necessary, including observations of children's pragmatic competency in everyday contexts (e.g., classroom and playground) and the use of developmental checklists [8]. Given that pragmatic language is a critical part of everyday communication and social interaction, it is imperative that interventions for children with autism spectrum disorders focus on social linguistic skills [5, 6]. Programs designed to enhance social communicative competence include the SCERTS Model [9, 10], a comprehensive developmental-pragmatic and research-based educational approach, and the Social Thinking Curriculum [14], a social cognitive approach to understanding social communication and reciprocity.

Precision Teaching

Judah B. Axe
Simmons College, Boston, MA, USA

Synonyms

Standard celeration charting

Definition

Systematic measurement of educational performances used to make instructional decisions.

Description

Precision Teaching was originated in the 1960s by Ogden Lindsley, a student of B.F. Skinner. Lindsley's goal was to transfer the measurement systems used to study environment-behavior relations in the laboratory to teachers' use in the classroom. Precision teaching involves selecting a particular behavior to increase, such as orally reading printed words, and charting the student's performance of the skill each day [1]. Examination of trends allows the teacher to either proceed with an instructional tactic if progress is being made or make a change to instruction if progress is limited.

Fluency is a hallmark of precision teaching. Whereas educators are typically interested in students' accuracy with academic material, precision teachers also place emphasis on speed. Measuring both accuracy and speed presents a more complete picture of a student's performance. For example, a student who answers ten single-digit mathematics problems correctly in 1 min is performing very differently than a student who takes 10 min to accurately complete the same ten problems. Fluency and automaticity developed through precision teaching have the capacity to improve retention, generalization, and "endurance," or resistance to distraction.

Precision teachers measure fluency and make educational decisions using the standard celeration chart [2]. On this chart, days are represented by vertical lines and behavioral frequencies by horizontal lines. Examples of behavioral frequencies are words read correctly per minute, math problems performed incorrectly in 2 min, basketball shots made in 10 min, and lines drawn in 30 s. The range of frequencies on the chart is from one time per day to 1000 times per minute. Behavioral frequencies are plotted on a logarithmic scale. This allows the reader of the chart to observe proportional changes in behavioral frequency. For example, the change from one per minute to two per minute is the same distance on the chart as the

change from ten per minute to 20 per minute and from 100 per minute to 200 per minute. Examining frequencies over time represents celeration. Both correct behaviors and incorrect behaviors are charted and the goal is to cause acceleration of the correct behaviors and deceleration of the incorrect behaviors.

Precision teaching involves having students practice skills fluently. Precision teachers time students' performance of skills often with 1-min timings. If multiple timings for a skill occur in a day, the fastest performance is typically charted. When teachers examine performance over 3 or 4 days and fluency is not increasing, a change must be made to the instruction. This conforms to a basic tenet of precision teaching: "the child knows best." That is, when a child is not learning, it is not the fault of the child, but an indication that the teaching must change. Another tactic of precision teaching is to target tool skills, or prerequisite skills, required to perform composite skill. For example, precision teaching with a child with cerebral palsy and fine motor delays who needs to learn to write her name would involve teaching writing lines fluently to facilitate the later development of name writing.

Standard charting conventions allow readers of charts from all over the world to be able to quickly examine a chart and understand the performance displayed. Chart shares occur at the annual meetings of the Standard Celeration Society and the Association for Behavior Analysis International.

Preconventional Level

►Preconventional Moral Reasoning

Preconventional Moral Reasoning

Amie Senland
Fordham University, Bronx, NY, USA

Synonyms

Preconventional level

Definition

Preconventional moral reasoning is the first of three levels of moral reasoning in Kohlberg's Structural Theory of Moral Development. At the preconventional level, children judge right and wrong based on external rather than internal standards, and emphasis is placed on avoiding punishment and maximizing self-interests [1, 3, 4, 5, 6].

Description

Preconventional moral reasoning is the first of three levels of moral reasoning in Kohlberg's Structural Theory of Moral Development, a cognitive-developmental approach to moral development that describes six invariant, sequential, universal, and progressively complex structural stages of moral judgment across the life-span [4]. The preconventional moral reasoning level is followed by the levels of conventional and postconventional moral reasoning. The preconventional level of moral reasoning consists of two stages, the second of which consists of a more complex and advanced sociomoral perspective than the first [4].

The first stage of preconventional moral reasoning is the Obedience and Punishment Orientation Stage (also known as Heteronomous Morality), which is Stage 1 in Kohlberg's theory of moral development [4, 6]. During this stage, children do what is right to avoid being punished by adults they perceive as larger and more powerful. At this stage, children operate from an egocentric perspective, where they are unable to separate their own point of views from those of others or are unable to consider others' interests [4, 6]. For example, a child at this stage would obey the rule "do not cross the street without mommy" out of fear of punishment for not

obeying the rule rather than an internalized understanding that the rule is in place for his or her safety.

The second stage of preconventional moral reasoning is the Naively Egocentric Orientation (also known as the Individualism, Instrumental Purpose, and Exchange Stage), which is Stage 2 in Kohlberg's theory of moral reasoning, where children judge right and wrong from a concrete individualistic perspective [4, 6]. During this stage, children become aware that others are also pursuing their own interests. Since there may be multiple conflicting interests, the right course of action is considered relative. Children tend to follow rules that are in their own best interests and to focus on fair exchanges/deals with others, where one person does a favor or something nice for someone else in order to receive the same in return [4, 6]. For example, a child may agree to share the new video game that he received as a birthday present with his friend, *only if* his friend also agrees to share his new board-game with him.

Relevance to Childhood Development

Most children under the age of 9 and some adolescents use preconventional moral reasoning, as well as many adolescents who are criminal offenders or have serious conduct problems. As an example of an application, DiBiase et al. [2] EQUIP for educators is a primary and secondary prevention program for children in grades 5–8. A portion of this program aims to prevent potential developmental delays in moral judgment (e.g., a failure to progress beyond preconventional moral reasoning), with the goal to foster more mature moral judgment and social decision-making.

Preference Assessments

Derek D. Reed[1], James K. Luiselli[2]
[1]University of Kansas, Lawrence, KS, USA
[2]The May Institute, Inc., Randolph, MA, USA

Synonyms

Stimulus preference assessment

Definition

A relatively brief procedure—taking many different forms—in which a clinician or educator quickly identifies stimuli in a learner's environment which may serve as possible reinforcers in the acceleration of target behaviors (including academic skills).

Description

In order to maximize the efficacy of any reinforcement-based program, proper decision-making skills should be employed regarding the selection of the rewards used to motivate the child—especially when the child is unable to voice his/her preferences due to a developmental disability (see [1]). A common means of selecting stimuli to function as rewards is to employ some assessment of the child's preferences of activities, tangible items, edibles, or even staff and/or caregivers. Such a procedure is termed a "stimulus preference assessment." Common to all preference assessment techniques is the presentation of several potential rewards, with data taken on what choices the

child makes. These choices are then analyzed to generate a preference hierarchy. Several empirically-supported approaches to this technique have been discussed in the behavioral psychology literature. Using a single-stimulus approach [4], a clinician offers numerous items/activities individually to the child across multiple trials. The clinician records the number of times the child reaches for the item and engages in or consumes the item to generate an overall hierarchy across the stimuli. An adaptation of this procedure actually pits stimuli against one another in a two-stimulus choice format [3]. Because this choice procedure allows for greater precision in relative preference amongst the stimuli, its results are often interpreted as more valid. A third commonly used technique uses multiple stimuli in a choice format, with multiple successive choice trials wherein chosen items are removed in sequence [2]. For example, the child may make an initial choice between six items, with the next successive trial featuring a choice between the five items not chosen on the first trial. This process is repeated until only one item remains in the stimulus set. The most natural preference assessment consists of a "free-operant" procedure in which the child is provided free access to all stimuli in the assessment for a fixed period of time. The clinician then records how much time the child engages with each item in the set or how many times the child consumes/touches each item.

Relevance to Childhood Development

According to a review of scientific literature conducted by Cannella, et al. in 2005, stimulus preference assessments are generally valid predictors of reinforcing stimuli with individuals with severe to profound developmental disabilities. Due to the various communication deficits in this population, these findings highlight the effectiveness of preference assessments for individuals with developmental disabilities. Perhaps more importantly, Cannella and colleagues also found evidence that interventions providing choice amongst items identified as preferred via preference assessments led to increases in desired behaviors and reductions in problem behaviors.

Prefrontal Cortex

Gretchen Schoenfield
University of Arizona, Tucson, AZ, USA

Synonyms

Anterior frontal lobes; Prefrontal region

Definition

The prefrontal cortex is found in the cortical regions of the frontal lobes, which are anterior to the primary and association motor cortices. It is divided into the dorsolateral, orbitofrontal, and medial regions. The prefrontal cortex is believed to be involved in planning complex cognitive behaviors and in the expression of personality and appropriate social behavior.

Description

The prefrontal cortex is the largest part of the *frontal lobes* and is located in their anterior region. Bidirectional linkages between the prefrontal and other brain regions exercise regulatory control over perceptual stimuli and attentional processes. Using multimodal internal, external, and contextual cues, the prefrontal cortex functions to ensure that movements and behaviors are selected at the appropriate time and place [2]. Functions of the prefrontal cortex include sustaining attention and concentration, abstract reasoning and concept formation, hypothesis testing, goal formulation, effective self-monitoring of behavior and self-awareness, inhibition of inappropriate or impulsive behaviors, and the anticipation, evaluation, and initiation of goal-directed behavior [1, 4]. These skills are commonly referred to as *executive functions*.

Children gradually develop executive skills that involve sophisticated representations about the world around them. Research examining the development of

prefrontal structures and processes in early childhood is limited. Extant studies suggest that structural maturation of the prefrontal cortex occurs rapidly during childhood, and is characterized by fractionation of age-related functions and skills. *Neural networks* purportedly organize into distinct functional systems – a process that may continue until late childhood or adolescence [7]. Complex skills develop as a result of these maturational changes, and thus the period between early and middle childhood is thought to be particularly important to the development of related processes. However, several of the functions localized within the prefrontal cortex are complex and thus involve numerous subprocesses that are associated with more than perceptual input and motor output. Behavioral manifestations of these subprocesses are therefore difficult, if not impossible, to isolate [6].

Asymmetry of Function

Consistent with lateralization of function within the left and the right hemispheres, the left prefrontal region is involved in speech and language, and the right frontal area plays a role in facial expression and nonverbal movements. Researchers have proposed that the left and right regions area associated with different aspects of memory processing. For example, the left prefrontal region is said to be involved in encoding, and the right is said to be critical to retrieval processes [8]. The left prefrontal cortex has been implicated in strategy formation, as well as in awareness of sequences and external events. The left prefrontal system is also instrumental to *working memory*. The right prefrontal system is involved in decision-making based on environmental cues. Lateralization of prefrontal function has also been found in memory processes. For example, left prefrontal activations have been observed during verbal learning in verbal working memory tasks, as well as in encoding. The right prefrontal cortex has been shown to activate during retrieval of information and in autobiographical memory.

Prefrontal Regions

There are several ways to divide the prefrontal cortex, among the most common being into the following three subregions: the dorsolateral, orbitofrontal, and medial prefrontal cortices. These subregions have varying but overlapping functions.

Both inhibitory and excitatory control are necessary for effective filtering, attending, and monitoring of information. The dorsolateral region of the brain is thought to be involved in exercising such control, as well as monitoring and integrating different cognitive processes, all of which facilitate execution of the complex tasks necessary to strategy formation and rule-governed behavior [3]. The dorsolateral region has also been associated with brief storage of data and their organization; this internalized record is referred to as *working memory*.

The medial prefrontal cortex is located posteriorly, has been implicated in planning and directing complex motor movements, and plays a role in memory function, intentionality, and attentional processes. These areas are also said to be involved in drive and emotional capacity. Recent studies have suggested that the medial region is important for aspects of social cognition, such as choice of appropriate behaviors in a given situation, as well as judging and inferring mental states of other people [5].

The orbitofrontal cortex is a large area within the frontal lobes that contains several of its own functional subregions. It receives inputs from all sensory modalities and sends output to the *amygdala* and *hypothalamus*, and facilitates physiological aspects of emotional responses. The orbitofrontal region is said to be involved in processing of unpleasant auditory stimuli, learning new visual information, and observing and attending to stimuli with affective qualities.

Damage to the Prefrontal Region

Damage to the prefrontal region has been associated with several problem behaviors, including poor initiation, impulsivity, disinhibition diminished self-awareness, emotional lability, poor judgment, misperception of social cues, difficulty with planning and the execution of goal directed behavior, and impoverished abstract thinking. Perhaps the most famous example of damage to the prefrontal cortex occurred in 1848 to Phineas T. Gage, a foreman of a railroad construction crew tasked to clearing an area for eventual placement of a rail line. Gage poured gunpowder into a drilled hole of a rock, added a fuse, and then tamped the charge down with a 13 lb. iron rod. The powder exploded with a force that shot the iron rod through the left side of his face. Gage recovered physically within approximately seven months, but was left with profound changes in personality and social functioning.

Prejudice

Lynnika Rouse[1], Kimberly Booker[2], Steven Paul Stermer[3]
[1]University of North Carolina, Chapel, NC, USA
[2]Texas Woman's University, TX, USA
[3]Oklahoma State University

Synonyms

Bias; Bigotry; Discrimination; Partiality; Preconception; Predisposition; Prejudgment; Race; Racism

Definition

Prejudice refers to a preconceived judgment, opinion or attitude directed toward certain people based on their membership in a particular group. It is a set of attitudes, which supports, causes, or justifies discrimination. Prejudice is a tendency to over categorize.

Description

Prejudice is a preconceived attitude that has commonly been used in referring to judgments of one's race, but is also used when referring to sex, ethnicity, religion, and sexual orientation. The most comprehensive and accepted definition of prejudice was introduced by Gordon Allport [1]. Mr. Allport defined prejudice as "aversive or hostile attitude toward a person who belongs to a group, simply because he belongs to that group, and is therefore presumed to have the objectionable qualities ascribed to that group."

Prejudice can be classified into three different categories: cognitive prejudice, affective prejudice, and conative prejudice. Cognitive prejudice refers to what people believe is true, stereotypes. These beliefs include expectations, impressions, criticisms, and assumptions. Affective prejudice refers to what people dislike and like. It holds an emotional aspect of prejudice. Conative prejudice refers to how people are inclined to behave [4] and be can be observed by others through discrimination. There is a correlation between the three types of prejudice and are entwined so closely; it is impossible to define one without defining the other [7]. However, all three do not have to exist within one individual for prejudice to exist.

There are several different explanations for the origins of prejudice. One explanation considers personality as an origin of prejudice. According to the personality theory of prejudice, people are prejudice because it meets particular needs associated with their personality. These researchers theorize that certain personality types contribute to discrimination, such as closed-mindedness, dogmatism, and authoritarianism [8]. Accordingly, individuals who have developed prejudice in this manner are not just prejudice toward one group, but have a tendency to be prejudice towards anyone who does not belong to their group. Another explanation for prejudice is that it is learned and it develops through social learning. The social learning view states that negative attitudes toward different groups are acquired due to what children see and hear from parents, teachers and friends and because they are rewarded for assuming these views [2]. The media may also play a role in the social learning theory of prejudice. Many times the stereotypes that are portrayed in the media may be a person's main source of information pertaining to particular groups of people. Accordingly, prejudice can be learned through conditioning and these attitudes can develop throughout the lifespan. A third perspective is called the social identity theory. This explanation suggests that people divide their social world into two categories-us (the in-group) and them (the out-group). Contrasting beliefs and feelings are usually attached to members of one's in-group and to members of out-groups [2]. Members of the in-group are viewed

more positively while members in the out-group are viewed more negatively. Some researchers suggest that individuals may identify with specific groups in order to boost their self-esteem.

Relevance to Childhood Development

Research has found that children can differentiate among people based on racial cues as early as 3 years of age. By the age of 4 their racial awareness allows them to distinguish explicitly among members of different racial groups [6]. By the age of 4, children who belong in an ethnically dominant group are able to precisely identify the group in which they belong to, they are able to show preferences for this group, and display strong biases towards their in-group. It is believed that by around the ages of 6 and 7, these biases peek and then show a gradual decline as the child ages. However, some research indicates that the biases remain at the same level until the age of 12. It is developmentally appropriate for children to notice differences and this alone is not an issue. Problems occur when negative values are taught, learned, and attached to the differences.

Prejudice can have a negative effect on the social and moral development of children. Due to misconceptions or negative experiences a child may never socialize with someone belonging to an out-group. This child may go on believing negative things about all people belonging to particular groups and may even see a positive person belonging to an out-group as an exception. [5] believes that children taught to hate different racial, ethnic, religious, or national groups are suffering a corruption of their moral development. He states that this moral corruption satisfies the definition of psychological abuse. These children are not able to show tolerance or respect for individual differences.

Prelinguistic Communication

Patricia E. Spencer
PSpencer Consulting LLC, Rockport, TX, USA

Infants are communicators long before the ability for symbolic language emerges. Although the term "prelinguistic" can generally refer to all stages prior to the emergence of language, it is typically used to refer to the period in which communication appears to be intentional, using gestures or vocalizations – usually in combination with facial expressions and actions on objects – in ways that suggest they represent messages directed to a communication partner. This period encompasses the ages of around 8–18 months in typically-developing children and usually culminates in acquisition of a burgeoning vocabulary and production of connected or multiword expressions.

The behaviors which make up prelinguistic communication rarely occur in isolation but usually consist of a bundle of behaviors across modalities. Vocal, gestural, object-related, postural, and gaze behaviors frequently co-occur.

Eye gaze, especially a pattern of directing visual attention sequentially to an object or event and a potential communication partner is often taken to be a marker of communicative intent and has a predictive relation with language outcomes [5, 9]. Development of gaze proceeds in a standard fashion, with the ability and propensity to focus on faces present at birth, although the neonate's focal range is limited to about 18 inches. Visual attention to faces or objects or events gradually becomes more flexible, and between and 10 and 15 months of age typically-developing children become capable of integrating or switching gaze between an object/event and a communication partner.

Vocal behaviors have particular communicative salience to most parents, and as any parent knows, crying is both the earliest and most enduring of these behaviors. Crying is not, however, an intentional communication

during the early months and first year of life but is instead a baby's natural response to discomfort [4]. Only at about a year of age have "fake" or intentionally communicative crying acts been noted. In fact, earlier reports that parents could identify differences in meaning in infant crying have not been replicated. It now appears that only a cry that indicates intense discomfort or an "emergency" can be differentiated from others when they are presented to parents out of context.

Although crying persists, it is not the only vocalization produced by young infants, and other "vegetative" or spontaneously emitted sounds are common [6]. The quality of these sounds is dictated primarily by the maturity of the vocal tract and articulators and progresses through stages in which sounds made at the back of the throat with lax oral articulators (cooing or gooing) are joined by vocalizations that appear to be vocal play. These include raspberries, squeals, and screeches of various kinds. Vocalizations consisting of primarily open vocal tract, or vowel, sounds change over time to include consonant-like sounds. Productions referred to as "marginal babbling" that include vocalic and slowed closures of the vocal tract emerge near the middle of the first year of life. So-called "canonical" babbling of reduplicated sounds that closely approximate the sound units of the language in a child's environment emerge somewhat later, typically around 7–10 months of age. Canonical babbling requires more flexible and quicker control of articulators and is predicated both on physical maturation and at least to some degree on the child's listening experiences. Children who are deaf, for example, are typically delayed in this stage of prelinguistic vocal development [7]. The production of consonant–vowel syllables in canonical babbling is soon followed by variegated babbling in which diverse consonant–vowel combinations occur in what sounds like an intoned utterance but as yet has no clear representational meaning.

Gestural behaviors also have strong communicative salience – from the waving of arms (and usually legs) of a young infant that, although prompted by the infant's internal state or state of arousal and clearly without a direct message being intended, is interpreted by parents and other adults as having meaning – to the showing of or pointing to an object in later infancy. Holding out or showing an object to another is a relatively early form that, combined with eye gaze, is routinely considered to be intentional. Indeed, sharing an object of attention with another is a prerequisite for successful communication, and when infants initiate joint attention around an object, they can be said to be intentionally communicating. Typically emerging between about 9 and 13 months, and having been documented in infants across multiple varied cultures [1], such behaviors correlate with other indications that the infant recognizes causal relations [3]. Use of objects in representational ways, or as tools, is another indication of the transition to understandings of causality [2].

Pointing to direct attention is perhaps the most recognizable of prelinguistic gestures and is one that persists and frequently accompanies linguistic communication throughout life. The pointing hand shape itself, with the index finger extended, has been seen during early months of life and becomes an intentional signal late in the first year or early in the second year of life [2, 8]. In prelinguistic contexts, it is especially likely to co-occur with vocalization and with eye gaze alternating between object of attention and communication partner.

According to Adamson [1], first words typically occur at about 13 months of age, but the range of emergence in typically-developing children is great. Language "onset" is often assumed to occur when about ten words are used expressively (on average at about 15 months but again with large individual variations), although by this time the child can be expected to have a significantly larger receptive vocabulary. Watt et al. [10] found that production of conventional gestures such as pointing as well as initiation and engagement in joint attention episodes predicts rates of language acquisition. In addition, language comprehension in the second year of life is predictive of later language skills.

Premack Principle

Elizabeth G. E. Kyonka
West Virginia University, Morgantown, WV, USA

Definition

According to Premack's principle, highly-probable behaviors reinforce less-probable behaviors and improbable behaviors punish more probable behaviors.

Description

What is a Reinforcer?

Consider the following situations:

1. A rat presses a lever and earns a pellet of food
2. A child finishes his homework and is permitted to play a video game
3. A teenager helps with yard work, so her parents lend her the family car.

What is the reinforcer in each of these situations? Is it the food pellet, the game, the car? Or, is the reinforcer the behavior made possible by access to the object: eating, playing, or driving? What makes a reinforcer reinforcing? Traditional notions of reinforcement, such as the law of effect, describe reinforcers as anything which, presented concurrently or shortly after a response, makes that response more likely. A rat presses a lever because previous lever-presses were followed by access to food. One knows that food (or eating) is a reinforcer because when food delivery is made contingent upon lever-pressing, the rat becomes more likely to lever-press. The last sentence does not explain the one before it; they are merely different ways of saying the same thing. Is there a way to define "reinforcer" so we can predict which behaviors will be reinforcing in particular situations?

One possibility is that there are different classes of behaviors. Some are reinforcing responses, perhaps because they address needs or reduce drives. Other behaviors – operant responses – are susceptible to being reinforced. This is the trans-situational view expressed by Meehl [5]. Access to any reinforcing response could serve as a reward for any operant response: if playing video games reinforces homework completion, it should also reinforce any other behavior that is not itself a reinforcing behavior, such as vegetable-eating or tooth-brushing.

Premack [6, 7, 8] presented another possibility, namely that any behavior can serve as a reinforcer for any other behavior that occurs at a lower rate, when there are no contingencies in place [6]: "Reinforcement results when an R of a lower independent rate coincides, within temporal limits, with the stimuli governing the occurrence of an R of a higher independent rate (p. 219)."

The "independent rate" of a response (R) is the probability of an individual choosing to make that response when no other response is required prior to making it and it produces no new opportunities to make other responses. Suppose that, left to her own devices, a teenager borrows the family car for several hours every Saturday night but only does a few hours of chores per month. She will be more likely to complete her chores if she must do so in order to borrow the car. Access to the car reinforces chore completion.

Punishment

If behaviors with high independent rates reinforce behaviors with low independent rates, Premack [9] reasoned that independently-unlikely behaviors punish highly likely behaviors. Imposing chores as a consequence of using the family car should decrease the rate of car use.

Limitations of Premack's principle

The concept that more probable behaviors will reinforce less probable behaviors (and less probable behaviors punish more probable behaviors) makes it possible to predict effects of one response on another, which is an improvement over the trans-situational view. However, the predictions are not necessarily correct. One problem with this principle is that the independent rate of a response can depend on its context: other available activities and the individual's history making the response. A prediction of Premack's principle is that spontaneous contiguity – when a high-probability activity follows a low-probability activity by chance – should have the same effect as contingency (increasing the likelihood of the low-probability activity). However, it does not [8].

A typical result of Premack's experiments that cannot be explained by Premack's principle is that the reinforcing response occurs at a lower rate when it is contingent on another response than it does independently [6]. According to Premack's principle, the rate of the operant response should increase so that access to the reinforcing response equals its independent rate (or decrease so that access to the punishing response equals its independent rate). However, that may not be feasible if there is a great difference in probability of high- and low-probability responses, but there is a 1:1 contingency (for example, it takes an hour doing homework to earn an hour playing video games) between responses. A violation of Premack's principle also occurs in the opposite situation: if the

high-probability response is only slightly more likely than the low-probability response but the contingency varies, the low-probability response can actually reinforce the high-probability response [4].

Response deprivation theory [11] refines Premack's principle in a way that corrects its mistaken predictions. According to response deprivation theory, it is the baseline ratio of independent rates of behaviors that determines what happens when one becomes contingent. Response B will reinforce response A in any condition when the contingent ratio of A to B is greater than the baseline ratio.

Relevance to Childhood Development

A few of the many examples of the successful application of Premack's principle are included in the above table. In spite of the theoretical shortcomings of Premack's principle, it has proved tremendously useful in applied behavior analysis and behavior modification.

Population	Operant	Reinforcer
Nursery school children [2]	Sitting quietly and looking at the blackboard	Running and screaming
Third grade children [1]	Answering test questions	Listening to tapes
Eight, 10 and 12 year-old boys [3]	Toothbrushing	Swimming
Middle school boys [10]	Achieving academically	Playing intramural basketball

Premature Infants

Teresa L. Davenport
Ball State University, Muncie, IN, USA

Synonyms

Premature birth; Premie; Preterm birth

Definition

An infant born prior to reaching full term. A period of 37 weeks is considered full term. Some practitioners also consider low birth weight infants, those weighting less than 5.5 pounds (2,500 grams), as premature [1]. However small for gestational age and premature birth may well occur without the other.

Description

Premature infants are frequently born developmentally immature. The two most frequent complications involve fully developed respiratory and neurological functions with a low birth weight, and it is this low birth which places them at a high risk for a variety of immediate health problems and future development problems. Research has shown that the smaller and infant is at birth, the more likely he or she will experience significant immediate and long term problems. However, it is important to note that although premature infants are at greater risk for health and developmental problems, many infants born prematurely do not experience significant immediate health complications or long term health or developmental problems due to advances in neonatal interventions. Furthermore, many infants who initially experience health complications or developmental delays overcome these health complications and appear to catch up developmentally to their later born cohorts within the first years of life. However, the risk factor of perinatal complications for these child is double that of a normal birth [3].

The Centers for Disease Control and Prevention (CDC) reported 12.7% of all births in 2005 were preterm [2]. The CDC reported that from 2002 to 2005, this rate increased approximately 9% [2]. There are a number of factors which contribute to the rise in the birth of premature babies, including more births by women over 35 years of age, increasing rates of multiple births, increased management of maternal and fetal conditions, increased substance abuse (e.g., tobacco, alcohol), and increased stress, and abnormalities in the mother's uterus or cervix, and many more [6]. Socio-economic factors of the mother, such as being poor, young, having little or no access to medical care, can also increase the risk of having a preterm birth [5].

Many premature infants have immature bodies which are not prepared to function independent of their mother. Premature infants may experience a variety of health problems after birth including breathing difficulties, heart problems, and difficulty fighting infections, among many other potential problems. Many premature infants end up spending time in a Neonatal Intensive Care Unit (NICU), a specialized department of hospitals which caters to the intensive needs of premature infants. Examples of specialized treatment for premature infants would be reducing exposure to light and noise, regulating the amount of handling of the infant by medical staff, minimizing interruptions to sleep and rest, massage, and many other considerations. In one common treatment for premature babies, called "kangaroo care," parents hold the premature baby skin-to-skin to their chest for extended periods of time, which has been found to promote improved oxygenation, body temperature regulation, breathing rate, feeding and greater overall survival rates [1, 6]. Premature infants will often spend many weeks in the hospital after birth before they are strong enough to go home. Parents of premature infants may need education by hospital staff on how best to care for their child at home in order to meet any special needs.

Children who were born premature are at risk of long term developmental problems as well, such as learning disabilities and Attention Deficit-Hyperactivity Disorder (ADHD) [4]. Children who were born prematurely tend to have more learning problems, lower achievement levels, and are more likely to be enrolled in special education programs. Many States have early intervention programs targeted toward children who fail to meet developmental milestones at appropriate ages. In addition, the National Office of Head Start funds numerous programs aimed at serving children with developmental delays to prepare them for entering school [7]. Such programs would greatly benefit premature infants who display developmental delays [3].

Prematurity

Jacqueline P. Parsons
St. Mary's University, San Antonio, TX, USA

Synonyms

Neonate; Preemy; Premature; Premature baby; Premature birth; Preterm baby; Preterm birth

Description

A full-term birth for a human is 40 weeks gestation. Several human organs do not reach maturity until between the 34th and 37th week; therefore when an infant is born at 37 weeks gestation or before, the infant is considered premature. According to the March of Dimes, between 8% and 10% of all human births are premature using this definition.

Typically, a premature baby weighs significantly less than a full-term baby, and requires special medical care, which usually takes place in an area of the hospital called a neonatal intensive care unit (NICU). Immature infant lungs, intracranial hemorrhage (brain bleeds), jaundice, anemia, etc. are a few of the myriad complications of prematurity. Premature babies are at a higher risk for developmental challenges, physical challenges, and/or death versus infants born at full-term gestation. Early identification of these challenges is crucial in the potentially successful treatment or arrest of the developmental disorders. Currently, a baby who weighs over 800 g has better than a 90% chance of survival, while a baby who weighs less than 500 g usually has between a 40% and 50% chance.

Causes

Smoking, drinking, drugs, poor nutrition, and stress can all increase risk for prematurity. More commonly, however, prematurity is caused by non-lifestyle factors, such as structural abnormality in the uterus, multiple births, disease, or the mother's age (too old or too young).

Symptoms

In addition to being smaller, premature babies have a different appearance than full-term babies. They usually have more hair, are less active, and have shinier, more transparent skin. They may feed poorly and occasionally stop breathing. Their cry is usually weaker than that of a full-term baby, if they have the strength to cry at all.

Complications

Complications may include cerebral palsy, hydrocephaly (brain fluid accumulation), vision problems, digestive problems, brain bleeds, anemia, and low blood pressure. The child may also experience developmental delays, behavioral problems and/or cognitive issues. Many of these complications can be serious, requiring surgery, medication, and hospitalization. Some can also lead to permanent disabilities.

Treatment

In some cases, premature delivery can be stopped before the baby is born. If symptoms of early labor appear (contractions, pain, diarrhea, vaginal bleeding), the labor might be stopped with medications which relax the muscles. There is also a surgical procedure which actually sews the cervix shut, which may prevent the labor from progressing. Physicians often begin by recommending bed rest for a woman who believes she may be entering early labor.

If these measures fail to prevent the early birth, then doctors must treat the complications and work to ensure the baby's proper development. Vision, digestive, and brain problems may be addressed surgically. If the child experiences a brain bleed and/or cerebral palsy, long term physical and occupational therapy may be necessary, as well as treatment for spasticity, which may include botox injections or a baclofen pump.

Parenting in the NICU

Parenting in the NICU is much more complex then parenting at home. Despite the extra people, machinery, and activity of the NICU, it is important for parents to spend time holding their baby and bonding. In the NICU, this is called Kangaroo care. Similar to a mother kangaroo caring for its infant, as the kangaroo holds the baby in its pouch, the parent holds the child on their bare chest, making a physical connection between parent and child. Physical touch is extremely helpful for the bay's development. Another important consideration is breastfeeding. Most smaller preemies cannot breastfeed, so when possible, mothers are encouraged to pump their breast milk to make available to the baby. This provides the best food for the baby's tube feeding, and also starts the milks supply so it will be ready when the baby is ready.

Life after the NICU

Most pediatricians have three criteria for allowing a preemie to go home. She must be able to regulate her own body temperature, feed, and gain weight. But just because these conditions are met does not mean the baby or family can go home to a normal life. Premature babies

often need frequent doctor visits, extra care in the home, and may require future hospitalizations. All these demands can be very stressful for a family. Some parents seek counseling to help them deal with the challenges of this new life. Another good option is the support group. There are even online support groups which can be very helpful for busy parents when it is hard to leave the house.

Prenatal Development

Raymond S. Dean, Renee Grizzle
Ball State University, Muncie, IN, USA

Synonyms

Embryonic and fetal development

Definition

Prenatal development is defined as the process of growth and development within the womb from fertilization until birth. During this process, the zygote grows into an embryo and then a fetus.

Description

In the process of fertilization, a sperm cell from the male and the ovum (egg) of the female join in the female's fallopian tube in conception. The prenatal development that occurs during the 38 weeks of pregnancy is typically separated into three periods: (1) the germinal period (the period of the zygote), (2) the embryonic period (the period of the embryo), and (3) the fetal period (the period of the fetus). A different way to describe the passage of time in pregnancy is to use 3-month time periods, immediately following conception, called trimesters [1–4].

The Germinal Period

The germinal period is the period of prenatal development that takes place in the first 2 weeks after conception. During this cell division, the fertilized ovum (zygote) travels down the fallopian tube toward the uterus. This period is characterized by rapid cell division and duplication (mitosis). By the fourth day, the zygote contains more than 50 cells and is now called a blastocyst. Cells on the blastocyst form the embryonic disk, a cell mass in which the embryo will begin to develop. Additional cells on the blastocyst will eventually form the trophoblast that will later provide nutrients and support for the embryo. The blastocyst will further differentiate into multiple layers which will later become every system, organ, and body part in the human being. After moving to the uterus, the blastocyst begins the process of attaching itself to the lining of the uterine wall. Implantation occurs approximately 7–14 days after conception. During the germinal period, the placenta is formed and will be connected to the embryo by the umbilical cord. The placenta will permit food and oxygen to reach the organism and waste products to be removed. Complications that interfere with development in the germinal period result in the death of the zygote. Approximately 10–20% of fertilized eggs complete the process of implantation and continue to develop [1–4].

The Embryonic Period

The second stage of gestation, the embryonic stage, occurs between the second and eighth week of prenatal development. The rapidly growing organism implanted in the uterine wall is now called an embryo. The embryonic period is the most critical stage of prenatal development as the embryo is the most susceptible to harmful agents in the environment. In addition, this period is a critical time in the development of the brain and spinal cord. The life-support systems of the embryo that consist of the amnion, the umbilical cord, and the placenta develop rapidly. In the first week of the embryonic period, the embryonic disk forms three layers of cells: the ectoderm, the mesoderm, and the endoderm. These systems will later form the nervous system, the circulatory system, the digestive system, and other organs. Throughout the remainder of the embryonic period, these organs and major body systems

will develop rapidly. By the sixth week after conception, the embryo begins to resemble human form, begins to move slightly in the womb, and can sense its world [1–4].

The Fetal Period

The fetal period is the final stage of gestation and begins two months after conception and lasts for approximately 7 months (until birth). This period is usually marked by the appearance of the first bone cells at about eight weeks. During this time, the fetus becomes more active although physical activity declines in last 3 months of pregnancy. Physical growth and development continue and facial features become distinguishable. At three months, the genitals can be identified as male or female and at four months the structures of skin have formed. The cerebral cortex in the brain enlarges and by 6 months the fetus has developed a grasping reflex. During last 2 months of prenatal development, fatty tissues develop and increased functioning of various organ systems occurs. The age of viability, the time at which the fetus has better than average chance of survive out of the womb without special medical intervention, occurs at the 7 month mark. Although babies have been born before 24 weeks and survived, a lack of oxygen due to their immature lungs will likely negatively impact their physical, cognitive, and social/emotional development. During the fetal period, the fetus receives antibodies from mother's blood to protect against illnesses. The fetus also practices swallowing and breathing and ingests some amniotic fluid as a result. Furthermore, research suggests that the fetus appears to learn from experience during this final stage [1–4].

Definition

Prenatal development is the process in which an *embryo* or *fetus* (or *fetus*) gestates during pregnancy. Normal prenatal development lasts about 38 weeks and is divided into three stages: *germinal*, *embryonic*, and *fetal*. During these three stages of gestation, the original single-celled *zygote* develops into an *embryo* and then *fetus* [1, 2].

Description

Germinal Stage (Pre-Embryonic Stage). Prenatal development starts from the fertilization, or the union of individual male and female gametes, and lasts until birth. Conception normally takes place in the fallopian tube. The fertilized cell, the zygote, soon divides into two, then four, then eight cells, and so on. In the germinal stage, which lasts about ten days, the zygote assumes the bumpy appearance of a mulberry and is called a *morula*. During the next four days, the morula continues its journey down the fallopian tube toward the uterus. At the same time, the morula's cells divide and the zygote becomes progressively more complex. Within 36 h from fertilization, the zygote enters a period of rapid cell division and duplication, the mitosis. By the fourth day, 60–70 cells exist and form a hollow, fluid-filled sphere, a *blastocyst*, which implants itself on the uterine wall between the seven and ninth days. As the blastocyst implants itself on the uterine wall, it further differentiates, and at the beginning of the second week, the *embryonic disk* is formed [1, 7].

The blastocyst consists of the outer cell mass, the *trophoblast*, the inner cell mass or the *embryoblast*, and the *blastocyst cavity*. The trophoblast becomes responsible for nourishing the inner layer of the blastocyst, from which the embryo and the inner embryonic membrane, the *amnion*, will develop. The trophoblast also develops an outer embryonic membrane, called the *chorion*. The cells of the amnion produce *amniotic fluid* that helps to control environmental temperature of the fetus and protects it from trauma and infection. As the amnion expands with the growth of embryo, it fuses with the chorion. Together these two layers form the *amniotic sac*, which is a fluid-filled membrane in which the fetus develops. The amniotic

sac is commonly known as the *bag of waters* or the *membranes* [2, 3].

Embryonic Stage. The second stage of gestation, the embryonic stage, lasts from the implantation of the blastocyst on the uterine wall until approximately the eighth week of pregnancy. During this time, the embryo's cells continue to multiply and begin to differentiate to form various body tissues and organs [3]. In addition, the external features of the embryo begin to develop. Due to the rapid growth and formation of the body parts that take place during this stage, the embryo becomes extremely venerable to interference with healthy development. Thus, *teratogens* such as drugs, bacteria or viral infections, and other outside influences can easily cause congenital abnormalities in the developing embryo [3, 7].

As the embryo is forming, the embryonic disk differentiates into three specialized layers of cells, called the *germ layers*. The germ layers are called the *ectoderm*, *endoderm*, and *mesoderm*. The upper layer, the ectoderm, will become the skin (only epidermis), nails, hair, teeth, sensory organs, and the nervous system including the brain and spinal cord. The lower layer, the endoderm, will form the digestive system, liver, pancreas, salivary glands, and respiratory system. Later, the middle layer, the mesoderm, will differentiate into the inner layer of skin, bones, most of the circulatory system including the heart and major blood vessels, connective tissues of the gut and integuments, muscles, reproductive system, and urinary system including the kidneys [5, 7].

After the implantation of the zygote, the *placenta* develops. The placenta is a temporary structure that functions as an organ and endocrine gland. As an organ, the placenta is responsible for the metabolism and transfer of the nutrients and wastes between the mother and the embryo or fetus. As an endocrine gland, the placenta secretes the various hormones of pregnancy. The placenta is shared by the mother and the embryo or fetus and grows throughout pregnancy. Development of the maternal blood supply to the placenta is usually complete by the end of the first trimester of pregnancy (approximately 12–13 weeks) and, thereafter, allows the transfer of nutrients and oxygen from the mother to the fetus and the transfer of waste products and carbon dioxide back from the fetus to the mother. The placenta is connected to the embryo by the *umbilical cord* [3]. The umbilical cord develops from the amnion, and is usually attached to the center of the placenta. Oxygenated blood flows from the placenta to the fetus through the large umbilical vein in the umbilical cord. Additionally, two large arteries in the umbilical cord carry fetal waste to the placenta. By the end of the embryonic stage, circulation is established and the embryo takes on human appearance with the formation of legs, arms, and a head [3, 7].

Fetal Stage. The final stage of gestation, the fetal stage, is initiated by the formation of the first bone cells. It usually starts around the ninth week and lasts to the end of pregnancy. During this stage, the fetus begins to take on characteristics of an infant, and increases its weight and length until it reaches full term. Specifically, the fetus grows from an inch-long (2.54 cm) organism weighing less than an ounce (28 g) to about a 20-inch-long (50 cm) baby weighing approximately 7.5 pounds (3,400 g) at birth. This phase is characterized by growth and refinement of existing structures and organs. Few new structures (i.e., hair, nails) appear. The exposure to teratogens in this period tends to result in functional defects rather than major morphological impairments. Additionally, during this period, fetal movement begins, and the life sustaining reflexes, such as sucking and swallowing, are established [4, 5, 7].

Between the 8 and 12th week, the fetus grows to about 3 inches in length. Activity levels also increases, as the fetus stretches its body and moves its limbs inside the womb. The genitals are forming, but the gender of the fetus is difficult to determine. Moreover, the organs, muscles, and nervous systems become organized and connected. During this period, the heartbeat can be detected with a stethoscope for the first time. Spontaneous fetal movements are present. Twelve weeks marks the end of the first trimester of pregnancy. By the end of the 12th week, the face is well formed, the genitourinary tract is completely developed, and the gender of the fetus is clearly discernible [4, 7].

In the second trimester, from the fourth to the sixth months of pregnancy, the fetus continues to grow and change. By the 16th week of intrauterine development, the fetus has increased its size considerably. At this time, the fetus is approximately 7.5 inches (19 cm) long and weighs about 3.3 ounces (100 g). Although the skeleton is still soft cartilage, the bones begin to harden, especially in the legs. In the fourth month, the fetus continues to be very active, averaging in one movement per minute, and the mother starts to experience fetal movements called *quickening*. At 20 weeks of growth, the fetus measures about 8.75 inches (22 cm) in length and weights approximately 10 ounces (300 g). The fetal heartbeat can be detected using a standard fetoscope, and the muscles of the fetus are already well developed. At 24 weeks, the fetus is about 12.5 inches (32 cm) long and weighs approximately 1.25 pounds (600 g). The structure of the eye is complete. The eyelashes and eyebrows are formed. Little subcutaneous fat exists. The alveoli (tiny air sacs) are formed in the lungs. Genitalia are well developed. Moreover, the body of the fetus is covered in fine downy fuzz,

the *lanugo*. The lanugo has a wooly appearance and it is coated with whitish cream called *vernix caseosa*, which protects the skin of the fetus [7].

During the third trimester, or last 3 months of the pregnancy, the fetus triples its weight. Also, the fetus practices some behaviors and movements, such as swallowing and breathing. With the progression gestation, fetal heart rate slows and becomes more variable. Moreover, fetal heart rate and movements become synchronized. These changes are related to the growth of the fetus and the maturation of the heart. The third trimester ends with the birth of the baby, which normally takes place around 38th week of the pregnancy [3, 4, 7].

Prenatal Screening

Renee Grizzle
Ball State University, Muncie, IN, USA

Synonyms

Assessment of major maternal and fetal risk factors; Pregnancy assessment; Prenatal diagnostic methods; Prenatal testing

Definition

Techniques used to monitor pregnancy, maternal functioning, or fetal development and identify disease or defect.

Description

Conditions that are present before birth can potentially be corrected if identified prior to delivery. The primary methods of prenatal assessment involve a medical examination and history of the mother which hold risk for the fetus. In addition, other screening tests involve:

Maternal blood test: Blood samples from the mother are taken between the 16th and 18th weeks of pregnancy [6, 7]. If these samples contain high levels of alpha fetoprotein (AFP), the women is considered at high risk for delivering children with defects in the formation of the brain or spinal cord. Further medical assessment and intervention can be taken subsequently [6].

Ultrasound or ultrasound sonography: When an ultrasound is directed into the abdomen of the mother, a sonogram is produced that provides views of the uterus, fetus, and placenta. This picture provides a view of fetal growth as well as the sex of the fetus. In addition, an ultrasound can detect multiple pregnancies, uterine abnormalities, and fetal death [1–7]. A first-trimester screen is often given between the 11th and 13th week of pregnancy which consists of a blood test and an ultrasound. Ultrasound use in excess of five times per pregnancy may increase the chance of low birthweight [1].

Sonoembryology: Sonoembryology, the use of high-frequency transvaginal probes and digital image processing, has made detection of defects possible at earlier periods of embryonic growth [4, 6].

Amniocentesis: Amniocentesis is the extraction of amniotic fluid with a syringe inserted into the woman's abdomen between the 14th and 18th weeks of pregnancy. This fluid provides information within one to two weeks on the sex of the fetus in addition to the potential for genetic deficits and chromosomal disorders. Amniocentesis is associated with a small risk of miscarriage; however, it remains the most widely used prenatal diagnostic method in the United States. Women who receive this procedure before the 15th week of pregnancy greatly increase their risk of miscarriage. In fact, the procedure causes a higher risk of morbidity than chromosomal disorders [6].

Chorionic villus sampling (*CVS*): Between the eight and 13th week of pregnancy, tissue from the ends of villi that surround the embryo can be tested for the presence of birth defects and disorders. Although results can be available within 24 h, chorionic villus sampling is rare because it is an invasive procedure that carries a greater rate of miscarriage or neonatal death than amniocentesis. In addition, chorionic villus sampling is associated with fetal limb deformity and this risk increases the earlier the procedure is administered [1, 2, 6].

Embryoscopy or Fetoscopy: The insertion of a fiber-optic viewing endoscope through the women's cervix may be able to provide early diagnosis of embryonic abnormalities as early as six weeks [1–3, 6]. A close

inspection of the fetus through the scope with a light source can aid in the identification of limb and face defects [1–3, 5].

Preimplantation genetic diagnosis: Preimplantation genetic diagnosis can be used to identify genetic defects in cells that have yet to be implanted in the mother as a part of the process of in vitro fertilization [6].

Umbilical cord sampling or *fetal blood sampling:* This technique can assess for infection, chromosomal abnormalities, metabolic disorders, and immunodeficiencies by taking a sample of the blood of the fetus through the umbilical cord. However, this technique is associated with miscarriage and several other health risks [6].

Preoperational Stage (Piaget)

Kathleen B. Aspiranti
University of Tennessee, Knoxville, TN, USA

Definition

The second of Piaget's Jean (1896–1980) four stages of cognitive development, the preoperational stage ranges from roughly ages 2 to 7. In this stage children can verbalize thoughts but think intuitively rather than logically. The key development of this stage is learning to form internal representations.

Description

The preoperational stage occurs before children acquire operational thinking, which is the ability to use logical thought. Children in this stage can carry out overt behaviors such as counting but are not yet able to use mental operations such as adding and subtracting, which are considered internalized behaviors. The rules regarding operations are logical since they never produce contradictions, and Piaget describes preoperations as infralogical because they usually generate contradictory conclusions [1]. For instance, a child in the preoperational stage may say that the purpose of clouds is to make the wind blow, or that grass grows because bugs run around pulling at them until they grow into tall blades. Although these explanations do not sound reasonable to an adult, it is how children try to explain the mysterious natural events of everyday life.

There are two different types of internal representations: symbols and signs [2]. Children first learn to use symbols, which are personal representations of familiar objects. They may use a bucket as a hat or a towel as a cape since these symbols are similar in shape and texture to the objects they represent. Signs, however, do not resemble the objects that they represent. The word *dog* does not have any similarity to the animal except for the language that it is assigned. As children grow, they begin to use more signs than personal symbols to represent objects. Language, both verbal and written, is a common sign that is used. According to Piaget, representational thought must be present before vocalizations can be considered to be language. In this sense, thinking is not dependent on language and thinking must occur before language can be formed.

The preoperational stage has several identifying characteristics, most of which focus on what the child can not yet do instead of what he can do. One of these characteristics is egocentrism, in which a child views and understands the world only from his own point of view. The child has difficulty telling the difference between what he thinks and feels and what others think and feel. This can be seen when two children have an egocentric conversation where instead of talking to one another, the children talk around each other without appearing to pay any attention to what the other is thinking. In a sense, the children are talking to themselves while in the presence of others. After the preoperational stage egocentrism continues to decline but never fully disappears, even in adulthood.

Another example of egocentrism is a child's inability to understand spatial relations. Piaget instructed a preschooler to stand in front of a table with a model of three mountains of different sizes [3]. A doll was placed at another corner of the model and the child was asked which of a selection of pictures corresponded to the view that the doll saw of the model. The preschool children could not recognize that the doll would have a different perspective of the mountains than they did, and almost always picked the picture of their own view of the mountains.

Preschool children also do not take into consideration all of the features of an object. The child tends to focus on one feature of the object and ignore other features. If two identical glasses are filled with the same amount of water and one glass is poured into a taller, thinner glass, the child will focus on the height of the water while disregarding the width [3]. Children focus on the before and after states but ignore the processes in the middle where the same water is poured into the new glass. This concept of centration also applies to mass and number as well. When a row of eight gummi bears are spread out, a child will say that there are more bears because the row is longer, even though they watched the bears being spread out. The child centers on the length of the line instead of the number of bears in the line. This concept of centration also affects a child's ability to identify an object even if its appearance has changed. For example, putting on a mask does not make a person a witch; the person underneath the mask has not changed.

Some other characteristics of the preoperational stage include animism and one-dimensional classification. Animism refers to the belief that all things are living. Children in the first part of the preoperational stage believe any object that affects people is alive. For instance, a table is alive, and if it is scratched the table will hurt or be sad [1]. Children in the second half of the preoperational stage believe only objects that move are alive, even if they cannot move by themselves. This may mean that a car, a stone, a bicycle, and a bird are all alive because they can move, whereas a table is not alive because it cannot move. In addition, children in the preoperational stage cannot seriate objects by putting them in order of size, shape, and color. Often, a child in the later years of the preoperational stage can focus on one dimension of the objects such as color, but they will quickly become confused if asked to also separate by size and shape.

Relevance to Childhood Development

The preoperational stage assists the child in developing his sense of self and creativity. The egoism evident in this age group aids the child in determining what his needs and wants are, and as he progresses to Piaget's concrete operational stage he will begin to assimilate the feelings and opinions of others into his own mind. The child's ability to focus on a single aspect of an object and to attribute characteristics such as emotion, sensitivity, and history to these objects allows the child to create situations outside of the actual. This later develops into an ability to focus on a specific problem or aspect of a problem and to think creatively in order to find a solution to a situation or question that may otherwise seem to have none.

Pretend Play

Tonya R. Hammer
University of Houston Clear Lake, Houston, TX, USA

Synonyms

Dramatic play; Fantasy play; Imaginative play; Symbolic play

Definition

Pretend play is the stage of play engaged in by children who are capable of assigning action to symbolic objects. Children will take on roles, assign meaning to objects, and transform their reality into a world of its own. Pretend play creates a world in which children can express their ideas and feelings about their life, either by themselves or with others who will engage in the fantasy with them.

Description

Pretend play is a necessary component in the development of children. Pretend, or imaginative play, helps children to develop their social and emotional skills, their language skills, and their problem solving or thinking skills. Pretend play allows children to strengthen their social and emotional skills by providing them with the ability to take on the life of another person, real or imaginary. Through play, emotions that may not be acceptable in reality now become "okay." Pretend play can also expand on the child's vision of reality and increase their self-esteem. In the world of pretend, the child can be anyone or anything they can think of, they are not limited by time or space, or societal rules or constraints.

But pretend play not only strengthens a child's social and emotional skills, but their language skills as well. Through pretend play the child can experiment with his or her own language capabilities, including repeating what he or she has heard from their parents, siblings, and peers, without the fears associated with talking in front of adults. After all, they are in another world. By creating their own language during pretend play, children begin to first understand the power of language. As children grow and develop, the pretend play advances as well and not only is the spoken word enhanced but also the written word. Children will engage in school or office play, mimicking what they have seen on television or in their parents own life. Letters will be written, forms completed, "tests" taken, all before the child has ever entered a classroom. This imaginative play helps them to develop their cognitive skills on all levels.

This cognitive development includes the building of problem solving skills and abstract thinking. As children create their world of make-believe, roles need to be assigned, castles built, moats crossed, and governments elected, all of which are problems for them to solve. The creativity of children will astound if allowed to flourish. The castle can be built with popsicle sticks and rubber bands and in their minds will withstand any attack of the enemy. But should it not, they will solve the task before, set a new goal, and rebuild. Their perseverance and tenacity is incredible. The abstract thinking will also amaze. Adults look at a pile of rocks and see a pile of rocks, children see a great fort, or a volcano, or a tower to be climbed. The ability to utilize abstract or symbolic thinking is a high level thinking skill. The development of these capabilities eventually will lead to greater things such as understanding that numbers are symbolic of quantity and letters together represent words and language.

Pretend play is vital to the development of young minds. Adults interacting with children should encourage imaginative play, and provide the objects necessary to create the new worlds. A cardboard box can become the next space shuttle, the next Indy 500 winner, or a new two story home on the beach in Malibu, all that is needed is the mind of a child.

Preterm Baby

►Prematurity

Preterm Birth

Teresa L. Davenport
Ball State University, Muncie, IN, USA

Synonyms

Premature; Premature birth; Premature infants; Prematurity

Definition

Infants are considered premature if delivered prior to reaching full term. Thus, a birth is considered preterm if the baby is born prior to completing 37 weeks of gestation [4].

Description

Infants born before the pregnancy has reached term, approximately 37 weeks of gestation, is considered premature. The Centers for Disease Control and Prevention (CDC) reported 12.7 of all births in 2005 were preterm [2]. The CDC indicated that from 2002 to 2005 preterm births rose 9% and concludes this trend is due to a rise in late preterm births, those from 34 to 36 weeks gestation, which it reports rose 25% since 2000 [2]. The rise in number of preterm births is likely due to several factors, including more births by women over 35 years of age and older, increasing rates of multiple births, increased management of maternal and fetal conditions, more frequent substance abuse (e.g., tobacco, alcohol), increased stress, and abnormalities in the mother's uterus or cervix, among others. Maternal factors, such as being lower socioeconomic status (SES), age when giving birth, and inadequate access to medical care, also increase the risk of preterm birth [3, 5].

Preterm babies are at risk for numerous complications immediately after birth, as their physical development may not have prepared their bodies to function completely independent of their mother, such as breathing problems, heart problems, difficulty fighting infections, and many other health conditions [1, 6, 7]. Health complications and the procedures and medications used to treat these complications may in turn cause long term health or lifelong developmental problems [4]. Preterm babies are also at significant risk for having low birth weight, which has been related to many serious developmental problems in later life (e.g., inattention, language delays, low intelligence) [4]. The risk of serious developmental problems increases the earlier a baby is born. In addition, these babies are more likely to experience significant developmental problems in the future.

Importance to Child Development

Clinicians who work with individuals who were born preterm will want to determine the exact length of the pregnancy of that individual as it may indicate that individual's level of risk for developmental problems. As noted above, the number of risk factors associated with the pregnancy increases the likelihood the individual will experience long term developmental problems. Clinicians, therefore, consider the number of risk factors the individual's mother experienced during her pregnancy with the him or her.

Proactive Aggressors

Tamara Del Vecchio
St. John's University, Queens, NY, USA

Synonyms

Bullies; Instrumental aggressors

Definition

Perpetrators that engage in aggressive behavior with the intent to obtain a reward or coerce others.

Description

Proactive aggressors are individuals that engage in aggressive behavior in a premeditated and "cold-blooded" manner with instrumental, reward focused goals. Proactive aggressors can engage in either physical or relational aggression. Bullying is considered a form of proactive aggression in which individuals in a position of power engage in repeated aggressive acts towards an individual to obtain status or dominance.

Proactive aggression has its origins in social learning theory in which individuals learn aggressive behavior through vicarious reinforcement and maintain the aggressive behavior due to its instrumental properties. In contrast to reactive, impulsive aggressors, proactive aggressors have fewer emotion regulation and attentional difficulties [2]. Although, proactive aggressors exhibit less empathy and sympathy for those who are victimized [2]. Within the social information processing framework, proactive aggressors are less likely to attribute hostile intent to peers than their reactive aggressor counterparts. However, proactive aggressors are more likely to expect a positive outcome for their aggressive behavior than reactive aggressors [1]. This overly positive expectation has been associated with an overestimation of social competencies. Proactively aggressive bullies are perceived to be more popular with their peers and better able to manipulate peer groups than reactively aggressive bullies who are often peer-rejected.

The frequency of aggressive behavior decreases over time for a vast majority of children. However, for a small group of children who engage in elevated levels of aggressive behavior, their aggression level remains stable and is predictive of negative developmental outcomes such as delinquency, criminal offending, Oppositional Defiant Disorder and Conduct Disorder [3].

Profound Mental Retardation

Lindsay J. Cummings
Argosy University, Atlanta, GA, USA

Synonyms

Cognitive impairment; Developmental delay; Developmental disabilities; Intellectual disability; Mental deficiency

Definition

Profound Mental Retardation (MR) is defined by the presence of significantly sub average general intellectual functioning as well as significant limitations in adaptive functioning present prior to the age of 18 years. Individuals with a diagnosis of Severe MR generally obtain IQ scores below 20–25 [1, 3, 4].

Description

Profound MR is described by *Diagnostic and statistical manual*, 4th Ed.-text Revision (2000) as impairment comparable to a range of IQ scores that fall below 20–25 [2]. Individuals with Severe MR are severely limited in the areas of intellectual functioning and adaptive skills, typically exhibiting extensive deficits in sensorimotor skills during early childhood. They are also likely to experience severe deficits or lack of functioning in the areas of self-care, home living, social skills, community use, self-direction, health and safety, functional academics, leisure, and

work skills [2]. Symptoms are likely to manifest in both the individual's ability to master a range of cognitive skills and their ability to respond to environmental cues [5]. Individuals who fall within this diagnostic category comprise approximately 1–2% [2] of all individuals with Mental Retardation. Unique to this level of impairment is the strong likelihood of an identified etiology of genetic or neurological syndrome resulting in MR, as well as a variety of other physical and psychological symptoms present from birth or early childhood. Ambulatory and communication skills within this population are likely limited or absent entirely [2, 5]. Concurrently, the presence of additional physical impairments such as Cerebral Palsy, epilepsy, and vision or hearing difficulties have been found to increase with level of intellectual impairment [5]. Co-morbid medical complications are also common. Training within the domains of motor skills and self care can improve functioning within a supervised environment. Some individuals with profound MR are able to perform non-complex tasks with close monitoring. Extensive levels of care and support are typically required throughout their lives [2].

Relevance to Childhood Development

A diagnosis of Profound MR has weighty implications for both the child and his caretakers throughout development. Accessing services the child is entitled to often requires a working knowledge of government and school systems, including the Individuals with Disabilities Education Act (IDEA). This program provides adaptive education to all children within the least restrictive environment possible. Adaptations may also include school-provided speech, physical, or occupational therapies as appropriate. Within the family or caretaking environment, education of the parent or primary caretaker is essential regarding available resources and developmental expectations. Because the development of children with Profound MR is severely limited in most cases, families of children with this diagnosis should be aware of what it means for their child in particular [2, 3, 4]. It is imperative that the family be knowledgeable on matters of developmental expectancy as well as the amount of support the child will need through school age and beyond. Also of note is the likelihood of additional medical complications caused by, or related to MR. These conditions may affect development or opportunity for development in ways that are not expected.

Progeria Adultorum

▶Werner Syndrome

Progeria of the Adult

▶Werner Syndrome

Progeria or Hutchinson-Gilford Syndrome

▶Progeria Syndrome

Progeria Syndrome

Brady I. Phelps
South Dakota State University, Brookings, SD, USA

Synonyms

Progeria or Hutchinson-Gilford Syndrome

Definition

Progeria syndrome is a very rare, genetic syndrome that is characterized by greatly exaggerated premature aging; an individual with progeria syndrome generally succumbs to heart attack or stroke by age 13 [6]. In more detail, progeria is a sporadically occurring, autosomal disorder meaning that only one copy of a gene is necessary for the condition [3]. To understand the basis for progeria's occurrence, a brief summary of genetic mechanism is

needed. The recipe for generating and following competent genetic instructions is relatively simple to understand. The molecule of genetic inheritance, DNA, is a string of DNA nucleotides which accords a nearly identical RNA nucleotide string. The RNA nucleotide string is itself transformed or translated into an a chain of amino acids that can become folded into a protein [2]. The alphabetical code or nucleotides for DNA and RNA are differentiated from one or the other by their chemical bases: adenine (A), cytosine (C), guanine (G), and thymine (T); in RNA, uracil (U) substitutes for thymine [2]. In the case of progeria syndrome, a genetic mistake occurs in the lamin A (LMNA) gene in that the normal genetic codon (a triplet of nucleotides) for the amino acid glycine which should be GGC (glycine GGC) is converted into glycine GGT [5, 6]. This error in glycine production results in an abnormal form of a protein lamin A, known as progerin, which itself results in a disrupted, faulty inner layer of the cell's nuclear membrane (the membrane surrounding the cell's nucleus); the inner layer of the nuclear membrane is itself known as the nuclear lamina [4].

The consequences of a faulty nuclear lamina are that the fidelity of the inner nuclear membrane is disrupted. The processes involving DNA–RNA translation and amino acid production are all internal to the cell's nucleus [1]. Production of proteins and lipids outside the nucleus is the function of the cell's endoplasmic reticulum [1]. The faulty nuclear lamina adversely affects the endoplasmic reticulum's mechanisms of communicating coherently with the genetic mechanisms inside the cell's nucleus [5]. The connection between these events and the signs and symptoms known as progeria syndrome is not completely understood [5].

As mentioned above, progeria is, fortunately, very rare. The [6] study examined 15 children, and those participants were thought to be approximately 50% of the world's known cases of progeria at that time. In the 15 participants in this study, the diagnosis of progeria was formalized at a median age of 19 months. All 15 children appeared aged when enrolled in the [6] study. Children with progeria exhibit a failure to thrive early in life, remaining small, with minimal body fat. They typically display protruding eyes, thin sclerotic skin, suffer from osteoporosis, alopecia and progressively worsening cardiac and cardiovascular impairments [5, 6] until death occurs typically due to myocardial infarction and or stroke in the early- to mid-teenage years [6].

Progeria is not the only genetic disorder typified by premature aging; two other somewhat similar conditions are Werner's syndrome and Cockayne's syndrome [5]. Despite the fact that there are no treatments for progeria, this syndrome is a condition of clinical attention as a possible model of normal aging. Apparently, abnormal lamin A protein or progerin accumulates in normal cells as a function of aging and progeria-like nuclear changes have been observed in cell cultures obtained from aged persons but whether or not progerin contributes to normal aging is not known [5, 6].

Projection

Edward B. Jenny
Immaculata University, Immaculata, PA, USA

Synonyms

Identification; Projective identification

Definition

Projection is a defense by which internal events such as feelings, motivations or thoughts are attributed to another person or object. The effect of this process is to prevent the individual from experiencing uncomfortable psychological states as originating within the self. Once projected

onto another, these feelings or experiences can be dealt with as an external rather than internal threat or tension. In psychological testing, projection is the process by which test-takers inject personal meaning or feelings into responses given to test items.

Description

Projection was first described by Freud who used the term in various and sometimes contradictory ways. In the scientific terms of the day, projection had to do with establishing a correspondence between two objects. In psychological terms, this generally meant a correspondence between an internal experience and an external person or object. Often the experience that was projected was an uncomfortable or conflicted felling such as anger. A child may, for example, project hostile or angry motivations onto figures or objects in his or her environment. This prevents the child from having to accommodate these feelings into his or her sense of self.

Although regarded as a primitive defense, projection is nonetheless developmentally appropriate when encountered in children. Projection allows the child to manage intense feelings that might be incompatible with their growing sense of self and need for attachment. For instance, from a child's point of view one cannot simultaneously maintain an attached, warm relationship with a parent and at the same time harbor intense anger toward this same person. By projecting this hostility outside of the self, the child is able to maintain the positive affective attachment to the parent and at the same time discharge aggressive feelings.

As children develop greater ego-strength, they are better able to integrate opposing feeling states and can begin to recognize that it is possible to have both positive and negative feelings for the same attachment object. In adults with more severe psychopathology, this ability is often compromised.

One prominent example of projection in work with children is play therapy in which the child allows toys to take on psychological roles. Often toys are placed in competition with each other representing the competitive drives within the child. A play therapist can utilize this process to help children understand and express their feelings in a controlled manner.

Finally, in psychological testing, projection occurs when an individual injects elements of their own personality into responses to test items. For example, in a storytelling task an individual might make up a story in which the characters are described as thinking and feeling in ways that are really reflections of the respondent's own feelings and thoughts.

University of California, Santa Barbara, CA, USA

Synonyms

Performance-based assessment; Personality assessment; Projectives

Definition

A broad category of psychological tests and techniques designed to measure aspects of personality and emotional functioning.

Description

Projective assessments include such diverse tools as the Rorschach Inkblot Test, Thematic Apperception Test, Roberts-2, story telling, figure drawings, and sentence completion tasks. Many contemporary assessment researchers prefer the term "performance-based assessment" in order to more accurately capture the nature of the task. Although there is a wide array of projective tests and techniques available, they are similar in so far as they require a patient to respond to some type of open-ended prompt, cue, or stimulus. Projectives are quite commonly used by clinical and school psychologists to assess their child and adolescent clients' personality style, feelings, cognitive processes, emotional distress, and global psychological functioning [1, 2].

Tests Versus Techniques

The grouping together of several different forms of assessment under the term "projective" can be misleading because these methods differ widely in terms of structure and empirical support. For example, the Rorschach Inkblot Test [3] and Hand Test [5] can rightfully be referred to as psychological *tests* (because both rely on standardized administration and scoring techniques and a normative sample) and have substantial research support in child and adolescent populations. Other projective techniques that have been subject to the same standardization (e.g., Roberts-2) [4] can also be categorized as psychological tests. In contrast, unstructured story-telling, sentence

completion, or drawings should be best thought of as psychological *techniques* because they do not rest on standardized means of administration, scoring, and interpretation.

Research Support

Because some projectives are tests and some are techniques, it is impossible to accurately describe the empirical support for this entire category of measurement. Tests such as the Rorschach, Hand Test, Naglieri's Draw-a-Person, and Roberts-2 have garnered much research support with child and adolescent populations. Like all tests, these measures are reliable and valid for some assessment questions and under some circumstances. Conversely, because projective techniques cannot be evaluated under standardized conditions, research evidence for these tools is lacking.

Proprioception

Brady I. Phelps
South Dakota State University, Brookings, SD, USA

Synonyms

Kinesthesia or the kinesthetic sense

Definition

Proprioception is derived from the Latin word, *proprius* meaning, "belonging to one's self"; proprioception is one of the sensory systems often grouped together as the "somatosenses" or "body senses" [2]. In the case of proprioception, this sensory system informs us about the position and movement of our body and limbs in space. The sensory receptors of proprioception are known as proprioceptors; the main proprioceptors are muscle spindles that are stretch receptors in skeletal muscles that provide information about muscle length to the central nervous system as well as stretch receptors known as Golgi tendon organs in the ligaments connecting skeletal muscles to bones and joints [1]. Although the Golgi tendon organs are considered to be stretch receptors, they assess the contractile force of contraction being exerted by muscles. Additional proprioceptors within joints respond to the degree of force as well as the direction of a limb's movement. The muscle length detectors which lie in parallel with and inside skeletal muscles provide sensory information that does not produce conscious sensations but is instead utilized to plan and control movements [1, 2, 4, 5]. A normally functioning proprioceptive system is a prerequisite for controlled and coordinated movement; an athlete or a dancer no doubt has acquired the ability to make rapid and acute discriminations amongst the stimuli provided by their proprioceptors, even though the sensory information is largely "unconscious." An individual with proprioceptive deficits can learn to make compensatory behaviors to function more normally [3, 6].

Proprioception is a sensory mechanism that we are not aware of until it is missing or disrupted. The symptoms of proprioceptive disorder are those of a loss or deficits in sensory information pertaining to body or limb position, movement and of "ownership" [7]. An individual with damage to proprioceptors or the central nervous system mechanisms of proprioception would have symptoms of dissociation of one's limbs. A limb might be perceived as "not belonging" to the person or being disconnected from the person [6]. Besides these atypical sensory experiences, a person with disorders of the proprioceptive system would have severe deficits in the ability to initiate, terminate and or control movements, as proprioception is a major component of the timing, sequencing and coordination of movements [1]. An afflicted person would be "taken by surprise" by some of his or her own limb movements [6].

Prosocial Behavior

Mark A. Barnett
Kansas State University, Manhattan, KS, USA

Synonyms

Altruism; Helping behavior

Definition

Prosocial behavior is commonly defined as a voluntary action that benefits another individual or group of individuals. Although the term, in its broadest sense, may refer to any positive social behavior, researchers have tended to focus on interpersonal behaviors such as helping and comforting that are performed for individuals who are perceived as needing assistance. Prosocial behavior refers to a person's action, not his or her intent; thus, prosocial behavior can be motivated by self-oriented (i.e., egoistic) and/or other-oriented (e.g., altruistic) reasons.

Description

The capacity to engage in prosocial behavior emerges at an early age and evolves during childhood and adolescence [4]. However, large individual differences have been found in children's tendencies to display prosocial emotions and behaviors in response to others. The following brief review describes some of the factors that contribute to the development of, and individual differences in, prosocial responses in children.

Age Differences

Children as young as 1 or 2 years old may appear upset when observing another individual who is sad or in distress and they may attempt to help and comfort that individual. However, early attempts to offer assistance (e.g., giving a cherished teddy bear to a sad mommy) often reflect the child's egocentrism and the inability to fully comprehend the other's perspective. The tendency to help others typically increases during childhood and adolescence, and the individual's prosocial responses tend to become more appropriate to the specific situation and target.

Age-related changes in prosocial behavior tend to be associated with increases in cognitive empathy (i.e., the capacity to take the other's perspective and to identify his or her thoughts and feelings) and affective empathy (i.e., the capacity to vicariously experience the emotions of others). Although both capacities are important in the development of prosocial behavior, the child's inclination to help and comfort has been found to be more closely associated with affective than cognitive empathy. Indeed, individuals who are skilled in perspective taking but are lacking in emotional responsiveness may use information acquired about another person's thoughts and feelings, not to assist, but to deceive and take advantage of the other.

Increases in the frequency of engaging in prosocial behavior during childhood typically are accompanied by age-related changes in moral reasoning, values, and abilities [2, 3]. Whereas young children tend to assist others for egoistic reasons (e.g., to obtain material or social rewards; to avoid disapproval), older children are more likely to help for altruistic reasons (e.g., to make the other person feel better). In addition, in comparison with their younger counterparts, older children are more likely to have internalized society's prosocial values and are more competent to perform a broad range of appropriate prosocial acts for others.

Gender Differences

Girls tend to be more emotionally responsive to others and more helpful of others than are boys. However, these gender differences are quite small and are influenced by how, and the context in which, these variables are assessed. For example, the stereotypic belief that girls are more likely than boys to respond prosocially toward others may inflate the gender difference reported in studies relying on the ratings of parents or teachers.

Biological Influences

Some theorists and researchers contend that prosocial behavior in humans reflects a pre-programmed, biological function. For example, sociobiologists view sharing and cooperation among humans as an inevitable extension of the numerous instances of helping reported within various insect and animal species. Evolutionary psychologists emphasize that prosocial acts are enacted preferentially for one's kin and are essential to the survival of one's gene pool and species. Evidence for the heritability of prosocial behavior comes from twin studies in which monozygotic (i.e., identical) twins are found to be more similar in their tendencies to engage in prosocial behavior

than are dizygotic (i.e., fraternal) twins. Although the existence of a single "prosocial gene" is unlikely, heredity may play a role in a constellation of cognitive, affective, and behavioral characteristics that have a genetic basis and contribute to individual differences in the tendency to help and comfort others.

Socialization Influences

Socialization experiences contribute to individual differences in children's tendencies to engage in prosocial behavior [1]. Parents who are loving, supportive, and satisfy their child's own emotional needs enable the child to be emotionally available and responsive to the needs of others. In addition, the development of prosocial behavior is promoted by parents who encourage their children to attend to and learn about other people's thoughts and feelings, model prosocial emotions and behaviors on a regular basis, and provide opportunities for their children to engage in (and get reinforced for) the comforting and helping of others, including siblings and peers.

The discipline technique that has been found to be most effective in encouraging the development of prosocial behavior in children has been labeled induction [5]. A parent who uses induction explains to the child why his or her behavior is inappropriate and should be changed by emphasizing the negative impact of that transgression on others. Children whose parents use induction as their primary disciplinary technique have been found to display higher levels of affective empathy and prosocial behavior (and lower levels of antisocial behavior) than children whose parents rely on love withdrawal or physical punishment to discipline. In a relevant observation, preschoolers who have a history of being physically abused by parents have been found to respond to peers' sadness and distress with anger and physical attacks rather than prosocial emotions and behaviors.

Research on the influence of prosocial television (e.g., Mr. Rogers' Neighborhood, Barney and Friends, Sesame Street) indicates that the viewing of prosocial models tends to have a modest, favorable impact on children's inclination to engage in positive social interactions with peers. Not surprisingly, a child who views a prosocial television program with an adult who encourages the child to learn the "prosocial lesson" tends to gain more from the educational experience than a child who views the program alone.

Socialization experiences within the broader culture also contribute to differences in children's prosocial behavior. Collectivistic cultures (e.g., Taiwan), which emphasize group efforts and outcomes, tend to encourage more sharing and cooperation in the home and school than do individualistic cultures (e.g., USA), which emphasize interpersonal competition and individual achievement. As might be expected, children raised in collectivistic cultures generally have been found to behave more prosocially toward peers than children raised in individualistic cultures.

Other Characteristics of Prosocial Children

In addition to the tendencies already noted (e.g., heightened affective empathy), other distinguishing characteristics of prosocial children have been identified. For example, children who engage in relatively high levels of prosocial behavior tend to be sociable, assertive, well-adjusted, and well-liked among peers. Furthermore, helpful children are able to regulate their emotions such that the emotional arousal associated with observing another's need or sadness elicits affective empathy (and prosocial behavior) rather than personal distress (and inaction or, in some cases, antisocial behavior).

Relevance to Childhood Development

Prosocial behavior, as an important expression of the child's moral development, provides a benefit to individuals, families, and society. Individual differences in the tendency to engage in prosocial behavior emerge early in childhood and are relatively consistent from preschool through adulthood. Researchers continue to explore the antecedents of prosocial behavior and the factors that influence its development and expression.

Prosopagnosia

Brady I. Phelps
South Dakota State University, Brookings, SD, USA

Synonyms

Face blindness or facial agnosia

Definition

The term prosopagnosia is derived from the Greek word *prosopon*, meaning "face" and the Greek word *agnosia* which means "without knowledge." Prosopagnosia is a deficit in the ability to recognize faces. This disorder is one type of visual agnosia, characterized by deficits in visual perception while still having normal vision; the afflicted individuals are not blind or often not greatly visually impaired in any usual sense of these conditions. Yet individuals with visual agnosia cannot visually recognize familiar objects, [6]. Individuals with prosopagnosia cannot recognize familiar faces or even their own face in a mirror or a photograph. Individuals with this facial agnosia must "know" who they are seeing in the mirror but have difficulty accepting the fact that they cannot recognize their own face. Kolb and Whishaw [4] describe a case of a woman who only became fully cognizant of her disorder when she was "introduced" to her identical twin sister. Since the afflicted twin could not recognize her identical twin, the afflicted twin was very surprised to learn that the apparent stranger was her identical twin. Prosopagnosics can discriminate human faces from other similar images and can properly recognize facial expressions and individual facial features such as a prominent mustache; these features come to be relied upon as a means to identify individuals.

For some time, prosopagnosia was considered to be the outcome of brain injury or infection, typically said to be bilateral damage or sometimes unilateral damage, confined to the right hemisphere of regions of the cerebral cortex, specifically the lateral occipital cortex, inferior temporal cortex and or the fusiform gyrus. The latter is sometimes referred to as the facial fusiform area, [1, 2, 4]. More recently, evidence has come forward that some cases of prosopagnosia could be occur in individuals with no known history of any brain injury or infection. These cases are referred to as congenital or developmental prosopagnosia [5], and are argued to be the failure to develop facial recognition mechanisms of the brain, [1, 2].

Some researchers have argued there are specific brain areas solely for facial recognition, sometimes termed "modules," and this position is referred to as the "modular hypothesis," [1, 7]. Others have proposed that the facial fusiform area can become specialized for facial perception-recognition but it is capable of becoming specialized for whatever complex object a person spends a great deal of time staring at, and most individuals do spend a great deal of time studying faces. As a result, this position has been termed the "expertise hypothesis," [3, 8]. Another way of framing these two different perspectives on facial recognition and the relevant brain mechanisms is to ask whether the face is a special, unique stimulus for which the brain evolved specific perception-recognition mechanisms (modularity hypothesis) or whether the face is a complex stimulus but not necessarily special or unique but the brain acquires acumen in facial perception-recognition via repeated and prolonged exposure (expertise hypothesis), [1, 8]. Both positions have their respective evidence and prosopagnosia has been interpreted in terms of either position [1].

A related question is whether prosopagnosia is just another type of visual agnosia or whether it is a unique but related disorder, arguing to the proposed unique brain areas for facial perception-recognition [2]. Most often, prosopagnosia is considered to be a form of apperceptive visual agnosia. Apperceptive visual agnosia is defined as a deficit or failure to perceive objects even though visual acuity is relatively unimpaired [2]. Apperceptive visual agnosia has to be distinguished from associative visual agnosia which can be defined as an inability to correctly identify objects that are visually perceived, despite that observation that the objects can be drawn or matched against similar objects [2]. The detailed features that distinguish these two disorders is beyond the scope of this short definition.

A person with prosopagnosia will never recover the ability to recognize faces by sight alone, regardless of the etiology. But as mentioned above, such a person can learn adaptive behaviors with which to recognize individuals. By learning to make discriminations among specific features of the face, body, gait, or other aspects of a person, specific individuals can be recognized.

Protective Factors

Charles Bell, Andy V. Pham, John S. Carlson
Michigan State University, East Lansing, MI, USA

Synonyms

Buoyancy; Plasticity; Resilience

Definition

Factors that facilitate the attainment of positive outcomes.

Description

In the study of education and psychology researchers have investigated the role of specific factors that lead to either (a) desired outcomes such as strong academic performance and favorable social interactions or (b) undesired outcomes such as school dropout and troubles with the law. Those factors that promote the attainment of desired outcomes are referred to as "protective factors." Those factors that result in less desired outcomes are referred to as "risk factors." Risk and protective factors play a significant role within children's lives and highly influence cognitive, social, and emotional development. These factors are often the focus of prevention and early intervention approaches within child populations.

Protective factors play a critical role in the resilience some children demonstrate. These factors are often thought to exist along five dimensions: individual, family, community, school, and peer. Individual protective factors include positive temperament, high expectations, and a perception of high social support. In sum, the more protective factors that one has, the greater likelihood that they will experience positive outcomes when faced with adverse risk.

In order to gain a better understanding of how protective factors promote positive outcomes, researchers have focused their efforts on undesired outcomes such as substance abuse. The National Institute on Alcohol Abuse and Alcoholism (NIAAA) estimates that over 17 million people in the United States abuse alcohol or suffer from alcohol dependence. However, some individuals that are faced with the risk of substance abuse are able to beat the odds. Researchers have labeled these individuals "resilient" and they focus on identifying the factors that helped those individuals overcome that obstacle. The protective factors that lead to positive outcomes for those at-risk for substance abuse include social class, high social support, parental support, self-awareness, high cognitive ability, and good coping skills. Resilient children have sparked the interests of many researchers, thus making them the focus of much research pertaining to children's development.

When resilient children encounter risk factors (environmental or genetic) they are often able to overcome those obstacles. However, the degree to which each child is vulnerable to a specific risk factor also plays an important role in resilience. Children that demonstrate characteristics that make them more vulnerable to risk factors, such as low self-esteem, are more likely to produce undesired outcomes when those risk factors are present [2]. Thus, vulnerability serves as a mediator in the interaction between protective and risk factors [3].

Throughout the investigation of protective factors many researchers have centralized their efforts on disadvantaged youth residing in poverty-stricken environments. The rational for this decision is that disadvantaged youth experience a higher level of risk factors, which places them at a higher risk for undesired outcomes. Research has shown that undesired outcomes, such as high school dropout, leads to a significant reduction in financial resources [5]. School dropouts head nearly one half of welfare families and represent one half of the prison population [2]. Thus, researchers have concentrated their efforts on this particular population because those individuals have the most to gain from research in this area.

The identification of several protective factors has facilitated the development of prevention and intervention programs for at-risk children. Mentor programs such as the Boys and Girls Club are designed to help children develop self-esteem, competency in a particular subject, and a higher level of social support than previously established. Programs of this sort help shift a child's vulnerability levels in favor of the protective factors in place. As a result of the success of these efforts on a local level many programs have expanded to the national level in an effort to carry out this same purpose in many underserved areas.

Psychoanalysis

Deborah Posner
William Alanson White Institute, New York, NY, USA

Synonyms

Psychoanalytic Theory; Psychoanalytic treatment; Psychodynamic treatment

Description

Psychoanalysis began as the work of Sigmund Freud in 1895 [1].

Psychoanalysis is a psychological treatment based on two fundamental principles. First, that unconscious ideas and motivations underlie much of human experience, and second, that childhood experiences greatly influence later psychological functioning.

These ideas have permeated much of contemporary Western culture, and are widely accepted, including the ideas that childhood experiences influence adult character, that we are not always aware of the reasons we do things, and concepts such as the "super ego," and the "Freudian slip." However, it was the founder of Psychoanalysis, Sigmund Freud, who first proposed these profoundly influential principles at the turn of the twentieth century.

Early in his career, Freud trained and worked in Vienna as a neurologist. In his clinical practice, Freud was presented with a variety of difficult cases in which the patient's symptoms did not correspond to neuroanatomy. Patients would have paralysis of a limb with no medical explanation. For example, in "glove anesthesia," the patient experienced no feeling in the hand. However, Freud knew that due to the arrangement of nerve pathways, that pattern of numbness is not anatomically possible. In his efforts to understand this and other strange

symptoms, Freud developed a powerful theory of the human psyche, and the treatment for suffering caused by the mind. This he called "Psychoanalysis." According to psychoanalytic theory, the human psyche has powerful needs and wishes, many of which are in conflict with each other. Needs and wishes that are unacceptable to the individual are kept separate from awareness, or "unconscious" through repression or dissociation. Although out of awareness, these needs and wishes do not lose their power. Rather, they make their presence felt in symptoms and suffering.

Since Freud's time, the field of Psychoanalysis has developed from the work of one person to the work of many. As in most areas of expertise, psychoanalytic theory has expanded and evolved since its inception. and reflects the conditions of our time. In fact, it is probably now more accurate to describe "Psychoanalytic Theories [2]." For example, Interpersonal/Relational Psychoanalysis posits that the individual can only be known within a matrix of interpersonal relationships, and pays close attention to the therapist/patient relationship [3]. Self Psychology Psychoanalysis focuses on the individual's sense of vitality and resilience, and pays close attention to the therapist's attunement to the patient's experience [4]. These are only two of a number of differing psychoanalytic approaches to psychological treatment. Psychoanalysts no longer are constrained to the role of mostly silent observer, but can choose any number of ways to engage with the patient.

However varied, there are basic principles about human psychological functioning that underlie all psychoanalytic approaches:

1. Unconscious motivation: An individual's conscious thought is only the "tip of the iceberg." A majority of mental processes are not in awareness.
2. Importance of the past on present functioning: Current character and psychological functioning is greatly influenced by early childhood experiences, and develops in the context of childhood relationships.
3. Defense: The individual develops an array of skills and techniques to manage threatening psychic experience.
4. Transference: An individual responds to current relationships using templates and expectations learned in important past relationships, thus creating familiar, repetitive, and limited experiences.

Psychoanalysis has been called "The Talking Cure." Psychoanalytic technique derives from the observation that unconscious and troubling ideas show up in the communications, both verbal and non-verbal, of the patient. Treatment sessions are held multiple times per week to foster continuity and intensity. Topics of exploration are infinitely varied, and may include early history, current life, dreams, fantasies, and the experience of the treatment relationship with the psychoanalyst. Typically, the patient will recreate and re-experience with the psychoanalyst the important relationship patterns of the patient's daily life. The psychoanalyst listens to the patient's communications with a highly trained and open attention, and works to increase the patient's awareness of his/her unconscious assumptions and motivations.

This greater awareness leads to the patient learning the ways previously unconscious and inaccurate assumptions serve both to protect the patient from uncomfortable truths, and to recreate familiar, though limiting, experiences. With increased self-knowledge comes the increased ability to make new choices in life. Unlike more symptom-focused and short-term treatments, the goals of psychoanalysis are focused on improving a person's ability to lead a more satisfying life. The patient is increasingly able to deal directly with formerly distressing truths. Symptom relief is understood to occur as the underlying conflicts are gradually resolved. The results of a beneficial course of psychoanalysis are often felt in many aspects of a person's life, and can be long lasting.

It is a quote, often attributed to Freud, the inventor of psychoanalysis, that psychological health is the ability "to work and to love." These are the goals of psychoanalysis.

Relevance to Childhood Development

Psychoanalysis is theory(s) of the development – not of the human brain, but of the human mind. It is the study of how we make meaning out of everyday experiences. Psychoanalysis lays out ways in which an individual learns to relate meaningfully to others, manage emotion, strive for goals, cope with loss, and especially, develop self-understanding. Much of psychoanalytic theory concerns the immense impact the family has on the child's later psychological functioning. Knowledge of psychoanalysis can be of immense value when choosing how to support a child's healthy development.

Psychoanalytic Theories of Development

►Object Relations Theory

Psychoanalytic Theory

Deborah Posner
William Alanson White Institute, New York, NY, USA

Synonyms

Psychoanalysis; Psychoanalytic treatment; Psychodynamic theory; Psychodynamic treatment

Definition

Psychoanalytic theory is an approach to understanding the human psyche, and the treatment of psychological disturbances.

Description

Sigmund Freud invented psychoanalysis as a theory of the human psyche and a treatment for psychological disturbances. Freud's work spanned the years of 1895 to 1939. Freud's theories have had profound impact on Western culture. Many of Freud's ideas, considered radical during his time, have become commonplace today. Consider the notion of unconscious mental activity. Before Freud, it was assumed that we are aware of all that we know. Today, it is generally assumed that we may have unconscious reasons for doing what we do.

As in most areas of expertise, psychoanalytic theory has expanded and evolved since its inception. In the past 100+ years, psychoanalytic theory has developed from being the work of one person into the work of many, and reflects the conditions of our time. In fact, it is probably now more accurate to describe "Psychoanalytic Theories."

Before discussing a selection of different psychoanalytic theories, it would be useful to identify unifying principles. These include:

1. Unconscious motivation: An individual's conscious thought is only the "tip of the iceberg." A majority of mental processes are not in awareness.
2. Importance of the past on present functioning: Current character and psychological functioning is greatly influenced by early childhood experiences, and develops in the context of childhood relationships.
3. Defense: The individual develops an array of skills and techniques to manage threatening psychic experience.
4. Transference: An individual responds to current relationships using templates and expectations learned in important past relationships, thus creating familiar, repetitive, and limited experiences.

The theories described below include Classical Freudian Theory, Interpersonal/Relational Theory. and Self Psychological Theory.

Classical Freudian Theory

Freud's early and groundbreaking description of the mind is the Topographical Model. Here Freud described the mind in three parts: the *unconscious*, which is the location of unacceptable thoughts; the preconscious, the contents of which are accessible to consciousness; and the conscious, which is the material that we are aware of at any particular point in time. While this theory is commonplace in today's culture, in Freud's time the notion of unconscious mental activity was radical [1].

As Freud continued his clinical and theoretical explorations, he addressed the limitations of the Topographical Model, to a large degree replacing it with what is termed the Structural Model.

Instead of dividing the mind between unconscious and conscious, Freud's structural theory of the mind described three separate agencies, all to a great extent unconscious. The id is a "seething cauldron" of impulsive "excitation" and raw energy looking for expression. The ego is in charge of regulating the energy of the id, and interfacing with the reality of the external world [3]. The ego has been described as the "rider on the horse" which is the id. In other words, the id is the source of power, and it is the ego that regulates that power, attempting to get the maximum satisfaction possible within the constraints of the acceptable, civilized external world. If we were only id, the human species would not survive long. The superego is a collection of morals and prohibitions that have been internalized from the parents.

Freud viewed human nature as fundamentally based on biological, instinctual "drives" of sex and aggression that are constantly pressing for expression [2]. Freud described the sexual drive as present from birth, centered on the most powerfully relevant bodily zones, and evolving in stages as the individual matures. The initial "oral phase" is in infancy, in which the sexual drive is focused on the mouth, sucking, and the pleasures derived. The following phases, "anal" and "phallic" culminate in the most

mature organization, "genital." Other people are vehicles for the expression of the drives [2].

In Freud's view, the most significant developmental task is the Oedipal conflict. This occurs around the age of 5 or 6, when the focus of the child (boy) is on genital intercourse with the parent of the opposite sex (mother). The father is viewed a dangerous rival. The child experiences castration anxiety, the fear that the father will cut off the child's offending genital to maintain power. The boy resolves the Oedipal conflict by identifying with the father, and internalizing his morals and strictures. Since he can't beat his father, he joins him. This is the beginning of the super-ego. Freud had difficulty accounting for the development of women, especially of the super-ego in women. In critiques of Freudian theory, this has been a point of great contention. However, when evaluating Freud's theories, it is also useful to consider Freud's theories in the context of his time.

Classical Freudians understand the psyche and psychic development in terms of conflict, and the ability to successfully balance gratification and social requirements.

As seen in the Oedipus conflict, to exist in a social world with a measure of safety, the drives must be controlled. The ego and superego work to hide threatening and unacceptable impulses, and relegate them to the unconscious. The psyche spends a great deal of energy defending against these impulses, or allowing a small amount of gratification in disguised forms. It is the pressure from these unconscious, unacceptable, but powerful ideas that causes mysterious but distressing symptoms.

Treatment According to the Classical Freudian Model

Psychoanalytic treatment in the Freudian model aims to discover the unacceptable, drive-based thoughts that have been relegated to the unconscious, freeing them from repression so that expression through symptoms will no longer be necessary. This is called making the unconscious, conscious.

In the classical model, psychoanalytic sessions are held four or five times each week. The patient typically reclines on a couch with the analyst sitting out of view. The patient is instructed to say whatever comes to mind, without censoring, a method called "free association." As the patient talks, conflictual material appears in disguised form, often noticeable in the appearance of defenses and in the transference, where patterns of relating to significant others are erroneously applied to the relationship with the analyst. Patients are also encouraged to report dreams, which are explored for unacceptable impulses that have been allowed disguised expression. The analyst listens carefully for these thoughts and impulses and will speak to the patient about them, giving voice to the disruptive compromises the patient has made in her psychic functioning and making the unconscious conscious. As less psychic energy is used in maintaining repression, the patient will gain greater functioning and greater satisfaction in life. Troubling symptoms will no longer be as necessary for the expression of formally repressed wishes. In classical Freudian psychoanalysis, the area of examination is mainly the patient's inner world. The analyst functions more as a "blank screen" upon which the patient's relational and psychic experience can be transferred and observed. The analyst avoids being pulled into actions, for example, the gratification of the patient's wishes, or adding personal influence into the patient's free association, and works to maintain a position as a neutral observer and interpreter of the patient's psychic experience.

Interpersonal/Relational Theory

Interpersonal/Relational psychoanalysis has roots in the work of a number of psychoanalytic theorists, including Harry Stack Sullivan, Sandor Ferenczi, Erich Fromm (see entry herein), and Clara Thompson. Interpersonal/Relational theory developed in the United States and although it maintains basic Freudian psychoanalytic principles such as unconscious motivation, transference, and defense, the Interpersonal/Relational theorists moved away from Freud in a number of highly significant ways.

Freud saw conflict and psychopathology as arising from deep within the individual, and related to the strength and development of biologically based drives for sex and aggression. The Interpersonalists, beginning with Sullivan (1892–1949), see the individual as embedded in relationships from birth. Interpersonalists believe that an individual's behavior can only be meaningfully understood in its particular social context [7]. Sullivan postulated that profound, destabilizing anxiety is the cause of psychopathology, and that this anxiety is generated or "caught" from other significant people. Interpersonal/Relational psychoanalysts are also interested in "character" which is understood to be developed in the context of relationships, the most significant being early relationships with family. The individual learns which aspects of his/her potential self are acceptable to the caregivers, and which aspects trigger unacceptable anxiety in the caregivers. The child cannot risk the parent's rejection, and gradually shapes his/her "self" in a way that acknowledges the parts that are acceptable in their environment, and hides or denies the parts that are not acceptable.

This limiting of awareness is called "selective inattention," which is different than Freudian views of "the unconscious," in that information is kept out of awareness in order to maintain a particular view of interpersonal reality. According to Sullivan, "problems in living" are seen as arising from long held assumptions, limitations, and distortions about the "self-in-relationship" to others. Symptoms are viewed as efforts to manage anxiety, the underlying cause of psychopathology.

Because the Interpersonal/Relational analyst believes that the individual can be understood only in the context of interpersonal relationships, the therapy focuses on the particulars of relationships, and the thoughts and feelings that the individual is experiencing. This includes the "here and now" relationship with the analyst. It is assumed that relational patterns in the patient's life will be activated in the therapeutic relationship, and that inquiry into that experience is highly productive [6].

The analyst is often actively engaged in expanding the patient's access to previously excluded (inattended) information. This is called the "detailed inquiry." The detailed inquiry presumes that each narrative is composed both by selecting and excluding information so that the story makes sense to the teller. The analyst attempts to deconstruct the narrative through curiosity about what has been excluded. The goal is expanding awareness of previously disconnected aspects of the self. This leads to increasing the patient's self-understanding and greater flexibility and satisfaction in the world.

In contrast to the Freudian model which positions the analyst as an outside authority looking in objectively, the interpersonal analyst believes analytic neutrality is impossible due to the nature of human interaction, and considers his or her own reactions not as interference, but as essential information to be considered.

In contrast to the classical Freudian model, Interpersonal/Relational analysts range widely in the way they engage the patient. A basic principle, however, is that one person cannot be understood as a "self" in isolation, and that mutual influence is inevitable.

Self Psychology Theory

Self Psychology began with the work of Heinz Kohut (1923–1981). Kohut, a psychoanalyst working in Chicago, began as a classically oriented psychoanalyst, but over time, developed a theory and technique that broke with Freud in fundamental ways. Kohut's theory reflects the context of his time. Unlike Freud, whose world was contending with the influences of Darwin and the World Wars, Kohut spoke in the 1970's of individuals who felt they were living fragile lives without meaning. Kohut was concerned not with a patient's effort to regulate intense animal drives, but rather with an individual's sense of emptiness, inadequacy, and isolation. This theory reflects the concerns of the post-modern era, in which the search is to create personal meaning, instead of discovering an impersonal, objective, Truth.

Self Psychology shares with other psychoanalytic theories the basics of unconscious motivation, the influence of early childhood on current functioning, defense, and transference. However, these basic terms are defined and understood quite differently. Unlike Freud's conflict model, Self Psychology uses a "deficit model." Self Psychology sees psychopathology as the result of development gone awry due to parental failures.

Kohut's thinking began with his approach to patients with pathological narcissism, which he viewed as their attempt to survive without a solid, healthy "self." While Freud saw investment in the self (narcissism) as in opposition to interest in others, Kohut proposed a developmental arc of "*healthy narcissism*," in which love of the self provided a stability of self-regard and vitality that allowed for healthy love toward others. The development of healthy narcissism begins in early childhood with three particular types of experiences between child and caregiver, or "selfobject." Kohut used the term "selfobject" to emphasize that this is an "other" who is used by the child's for essential self experiences. Kohut is not concerned with the selfobject's experience as a separate being.

The first of these three essential experiences is the selfobjects "who respond to and confirm the child's innate sense of vigor, greatness and perfection [5]." When this appears in treatment, it is termed the *mirroring transference*.

The second essential selfobject experience allows the child to feel merged with an idealized, infallible, and omnipotent other, and to feel strong through that merger. In treatment, this is called the *idealizing transference*. The third essential selfobject experience is the opportunity to identify the self and the selfobject as similar in a significant way. This is called the *twinship transference*.

Kohut argued that the caregiver's attunement to the child's healthy, age-appropriate narcissistic needs is necessary. It is also necessary, and inevitable, that any caregiver will be imperfectly attuned. The world will intrude, and the child will have disappointments. In a benevolent environment, however, the child is gradually challenged and is increasingly able to cope. The self becomes less grandiose and more realistic while still maintaining internal strength. These experiences Kohut termed "*transmuting internalizations*." The intense pressures for sex and aggression outlined in Classical theory Kohut viewed as

not primary, but rather as residual evidence of struggles at the level of self [4].

Self Psychology views treatment as providing the three selfobject experiences described above, allowing the developmental process to resume its natural progression toward health. These selfobject experiences are seen as ways of meaningfully structuring the use of the selfobject. Instead of the classical method of "interpreting the infantile wish" so it can be relinquished, the self psychologist focuses on "vicarious introspection," the effort to deeply understand the patient's subjective experience. Self Psychology argues that interpreting the patient's wishes as unrealistic or distorted only causes more injury to the nascent self. The analyst also does not confront the patient with the workings of their relationship. The analyst strives to identify and maintain attunement to whichever transference is activated. Again, it is through the inevitable failures of the analyst's attunement that the patient gradually builds up the internal strength that is seen in healthy narcissism.

Psychodynamic Approaches

David Brandwein
Kean University, Union, NJ, USA

Synonyms

Insight-oriented approaches

Definition

Psychodynamic approaches refer to psychotherapeutic techniques that derive from Sigmund Freud's psychoanalytic theory. These approaches focus on unconscious processes as they are manifested in the patient's current behavior. The goals of psychodynamic approaches to psychotherapy are for the patient to develop self-awareness and understanding of the influence of the past on present behavior.

A variety of different approaches to psychodynamic psychotherapy have evolved from Freud's psychoanalytic theory, and they have been clinically applied to a wide range of psychological disorders. There is a body of research that generally supports the efficacy of these approaches.

Description

Psychodynamic approaches to psychotherapy are rooted in psychodynamic therapy, the forerunner of modern therapeutic approaches. Freud's psychoanalysis is a type of psychodynamic therapy, and is based in a highly structured and layered theory of human development and interaction. Later psychodynamic theorists (Anna Freud, Heinz Kohut, Melanie Klein) studied Freud's original and later conceptions of psychoanalytic psychotherapy and formulated original therapeutic approaches based upon, but differing from, Freud's original ideas. More recently, approaches such of Brief Psychodynamic Therapy and Relational Psychodynamic Therapy have evolved to bring Freudian ideas into the twenty-first century.

There are four major schools of psychoanalytic theory, each of which has influenced psychodynamic approaches to psychotherapy. The four schools are: Freudian, Ego Psychology, Object Relations, and Self Psychology.

Freudian psychology is based on theories formulated by Sigmund Freud in the first half of the twentieth century, and is based on the idea that people are basically determined by psychic energy (drives) and by early childhood experiences. The essence of Freud's theory is that sexual and aggressive energies originating in the id (or unconscious) are central in present behavior. These energies are modulated by the ego, which is a set of functions that moderates between the id and external reality. Defense mechanisms parts of the ego that operate to minimize pain and to maintain psychic equilibrium. The superego, formed during latency (between age 5 and puberty), operates to control id drives through guilt. Early development is of critical importance because later personality problems have their etiology in repressed childhood conflicts created by fixation at one of five psychosexual stages of childhood. Erik Erikson, an ego psychologist, expanded on Freud's notion of child development through stages, but focused on interpersonal and social, rather than sexual, development while maintaining the idea that fixation led to personality conflicts.

Ego Psychology derives from Freudian psychology. Its proponents focus their work on enhancing and maintaining ego function in accordance with the demands of reality. Ego Psychology stresses the individual's capacity for defense, adaptation, and reality testing. Leading ego psychologists who added to the theoretical model of psychoanalysis include Anna Freud (daughter of Sigmund Freud), Heinz Hartmann and Erik Erikson. Anna Freud was instrumental in introducing psychoanalysis into the treatment of children and further developed her father's conception of ego defense mechanisms. Heinz Hartmann addressed the function of the ego in psychoanalytic theory by stressing its autonomy and its ability to adapt in its dealings with the external world. Hartmann proposed a part of the ego that existed in a sphere free of conflict with the id and the superego. Erik Erikson widened the concept of life stages into adulthood and introduced social and non-sexual motives to the stages.

Object Relations psychology was first articulated by several British analysts, among them Melanie Klein, W.R.D. Fairbairn, and D.W. Winnicott. According to this theory, human beings are shaped in relation to the significant others surrounding them. Our struggles and goals in life are based on maintaining relations with others, while at the same time differentiating ourselves from others. The internal representations of self and others acquired in childhood are later played out in adult relations. Individuals repeat old object relationships in an effort to master them and become free of them.

Self Psychology was founded by Heinz Kohut, M.D., in Chicago during the 1950s. Kohut observed that the self refers to a person's perception of his experience of his self, including the presence or lack of a sense of self-esteem. The self is perceived in relation to the establishment of boundaries and the differentiations of self from others (or the lack of boundaries and differentiations).

Each of the above schools presents separate theories of personality formation, psychopathology formation and change, techniques by which to conduct therapy, and indications and contraindications for therapy. However, they all share similar therapeutic goals: to make the unconscious conscious, to reconstruct personality, to assist the client in reliving earlier experiences and working through previously repressed conflicts, and to achieve intellectual and emotional awareness [1].

These schools also have a similar approach to the therapeutic relationship, with the analyst remaining anonymous, enabling the client to develop projections toward him or her. The focus is on reducing resistances that occur when working with transference and on establishing more rational control. Clients usually undergo long-term analysis, engage in free association to reveal conflicts and gain insight by "working through." The analyst makes interpretations to teach clients the meaning of current behavior as it relates to the past.

Contemporary psychodynamic approaches, such as Brief Psychodynamic Therapy and Relational Psychodynamic Approaches have challenged many of the traditional assumptions about traditional psychodynamic theory and treatment.

A brief psychodynamic approach, such as Messer and Warren's [9, 10] Brief Psychodynamic Therapy (BPT), enables the client to examine unresolved conflicts and symptoms that arise from past dysfunctional relationships and do so in an expedited fashion. It is believed that an initial brief intervention will serve as a catalyst to an ongoing process of change without constant involvement of the therapist. A central idea of brief therapy is that there should be one major focus for the therapy rather than the more traditional psychoanalytic practice of allowing the client to associate freely and move from issue to issue. In brief therapy, the therapist and the client agree upon a central focus during the first or second session. The central focus singles out the most important issues and thus creates a structure and identifies a goal for the treatment. In brief therapy, the therapist is expected to be fairly active in keeping the session focused on the main issue. Having a clear focus makes it possible to do interpretive work in a relatively short time because the therapist only addresses the circumscribed problem area. Due to societal

pressures and the influence of managed-care companies, there is a greater demand for time-limited therapies and evidence-based practices in order to provide accountability and cost-effectiveness, and it seems likely that briefer forms of psychodynamic treatment will remain in vogue.

Relational psychodynamic approaches, such as the model developed by Steven Mitchell [11, 12], take the Freudian "one-person" approach and revise it to a "two-person" approach by re-conceptualizing the nature of the analytic relationship. The relational model is based on the exploration of the complex conscious and unconscious dynamics at play with respect to both therapist and client, and this is in contrast with the Freudian approach, which pays attention primarily to these dynamics in regard to the client. Mitchell's relational model integrates object-relations theory, systems theory, and interpersonal theory to show the various ways in which people seek attachments with other people, especially early caregivers. A relational psychodynamic approach to psychotherapy is based on the idea that therapy is an interactive process between therapist and client. This model conceptualizes counter-transference differently than the traditional Freudian model, and sees it as a rich source of information about the client's character and dynamics. Mitchell also adds a cultural notion to psychodynamic approaches by noting that the caregiver's qualities reflect the particular culture in which the person lives. He added that people are deeply embedded in their cultures, and since different cultures maintain different values, Freud's notion of universal biological drives alone may not be sufficient to explain psychic development. The lack of cultural relativity and the notion of universal biological drives are often cited as criticisms of the traditional Freudian approach.

The number of professionals who practice an exclusive form of psychodynamic therapy today is a small percentage of psychotherapists. Many psychotherapists use components of psychodynamic theories, however, in their formulation of a client's issues, while employing other types of psychological techniques (most often, cognitive-behavioral techniques) to affect change in the individual.

Sharf [13] points out several strengths of psychodynamic approaches, including the exploration, in depth, of early childhood and past as they affect current functioning, the presentation of mechanisms to understand resistance, anxiety, and ego defense mechanisms that relate to an individual's psychological functioning, the development of a framework (in the case of object-relations and self-psychology) to understand psychological disorders, and, with brief approaches, the availability to those patients who could not afford long-term therapy or psychoanalysis.

Weaknesses of psychodynamic approaches, according to Corey [1], include lengthy training for therapists (psychoanalysis only) and much time and expense for clients (Brief approaches seem to address this weakness), neglect of social, cultural, and interpersonal factors (this has been partially addressed through relational, "two-person" approaches), ineffectiveness at solving specific daily life problems of clients, lack of a multi-cultural focus, and many clients lack the ego strength needed for reconstructive past-oriented psychotherapy.

Psychoeducational Assessment

Elizabeth Levin[1], Dorothy Olfert[2]
[1]Laurentian University, Sudbury, ON, Canada
[2]Rainbow District School Board, Sudbury, ON, Canada

Synonyms

Psychoeducational evaluation; Psychoeducational testing

Definition

A psychological assessment performed for use in a school setting, which is typically used to identify, for educational or diagnostic purposes, a student's academic strengths and weaknesses.

Description

Psychoeducational assessments are primarily conducted by school psychological staff and/or external, clinical psychologists for usage within the school context. Results of the assessment can be used to make educational identifications, e.g., academic giftedness and/or formal diagnoses, e.g., reading disability. The results can assist school staff and parents in obtaining a better understanding of a student's individual learning strengths and needs, and providing educational programming accordingly.

A typical school based referral for a psychological assessment includes the administration of a number of standardized tests. Standardized tests allow the child to be compared to broad based normative populations to evaluate the child in comparison to a group of peers [3]. The results of the testing, which may be conducted by psychometrists, are evaluated by the psychologist, along with previous test results, past history, school report cards, parent and teacher checklists and/or interviews and direct observation yielding the final assessment which may come in the form of a diagnosis of a disorder and suggestions for treatment and program planning [1, 2].

Generally, psychoeducational assessments investigate student learning difficulties, as well as evaluate other factors such as social, emotional and behavioral issues which may be contributing to the student's academic problems and/or the student's intellectual and academic learning potential [2]. At a minimum, such assessments typically involve an ethical process of obtaining informed parental consent, gathering student developmental background and academic history, as well as a formal assessment of the student's intellectual ability and academic skill development using standardized intelligence and academic achievement tests. A typical assessment will also include further testing to investigate potential areas of deficit such as memory, rapid automatized naming or fluency issues, phonological awareness, attention or executive functioning [1]. Standardized self-report questionnaires might also be used to further support test results and/or obtain quantitative data to substantiate qualitative reports from parents, teachers and the students themselves. For instance, rating scales can be used to obtain teacher, parent and student's own assessments of emotional and behavior issues, can be utilized to support areas of executive functions deficits reported by teachers and parents, and can explore student's own strengths and weaknesses in coping with challenges.

Psychoeducational assessments yield a view into a student's current intellectual functioning and development of academic skills. In this basic view, these assessments can reveal a student's individual learning styles and/or areas of intellectual and academic strengths and weaknesses, which in turn can assist school staff and parents in not only understanding but in effectively addressing the student's individual academic and intellectual learning needs and/or providing differentiated learning instruction towards optimal academic success. A standard assessment will typically reveal a student's level of higher-order intellect or verbal and nonverbal thinking and reasoning abilities [2]. Information will also be obtained on lower level cognitive processing such as auditory working memory and visual-motor processing speed. The assessment also indicates the student's academic achievement in reading, writing and math skills. Taken together, the assessment can demonstrate whether the student is functioning academically at the expected level, given the child's current intellectual ability. Discrepancies found between academic skill expectations and the student's intellectual functioning are useful data for teacher and parents, and can also highlight the need for further investigation into

potential learning issues [2]. It is not unusual for students who have learning disabilities to also be diagnosed with co-morbid disorders, such as with attention problems or mental health issues such as anxiety and depression.

The assessment data can be used to predict a student's academic learning potential and/or future intellectual and adaptive functioning. In this case, more involved testing and/or gathering of qualitative data is usually required to ensure the student meets appropriate formal diagnostic criteria (DSM-IV). The most common formal diagnostic outcomes related to psychoeducational assessments include: Specific Learning Disabilities and Global Developmental Disabilities. However, psychoeducational assessments can result in and/or contribute valuable data for diagnoses of numerous other disorders such as Autism Spectrum Disorder, Pervasive Developmental Disorders, Generalized and Specific Anxiety Disorders, Attachment Disorder, Tourette's Disorder, Attention Deficit/ Hyperactivity Disorder, etc. In these cases, more specific testing related to the diagnosis will be conducted. It is important to note that, more complex assessments, such as those involving a formal diagnosis, ideally include more elaborate testing and/or collaboration with appropriate school staff and other professionals such as speech-language pathologists, occupational therapists, pediatricians, child and youth workers, mental health professionals, neuropsychologists, medical doctors, etc.

By law, if a child has a documented disability, the child is entitled to a free, appropriate public education [1]. Once a child has been identified with an exceptionality, the child is entitled to special education services. While children may receive some special services without the identification provided via the psychoeducational assessment, the assessment is required to qualify for specialized services. An ►individualized education plan (IEP) may be developed to specify the services to be provided.

Psychology of language

Definition

Psycholinguistics is the scientific discipline that aims to understand all aspects of the use of human language, including how language is acquired, how language is produced, and how language is comprehended.

Description

Psycholinguistics is a branch of cognitive science that focuses specifically on the psychological and neurobiological processes involved in the acquisition, production, and comprehension of human language. The field of cognitive science focuses broadly on the study of the mind and intelligence, embracing multiple disciplines, including computer science, psychology, neurobiology, linguistics, philosophy, and communication [1]. The field has grown in importance over the last decade, as brain imaging techniques have become widely used and as advances in computer science, information sciences, artificial intelligence and robotics have been made.

The term *psycholinguistics* is a combination of the terms *psychology* and *linguistics*. Psychology is the scientific study of mind and behavior [2]. Linguistics is the scientific study of language [3]. Noam Chomsky, a pioneer in the field of psycholinguistics, used the term *language competence* to refer to the knowledge of language and the term *language performance* to refer to the use of language. He proposed that those who have acquired a language from birth possess *language competence*, which includes knowledge of the rules of language, such as word order rules (i.e., syntax), sound rules (i.e., phonology), and rules

pertaining to meaning (i.e., semantics). In contrast, the performance of language involves putting one's knowledge of language into action using the psychological and biological mechanisms [4, 5]. Following these distinctions, psycholinguistics focuses on issues related to language performance, and linguistics focuses on issues related to language competence.

Relevance to Childhood Development

Healthy children acquire the language(s) of their home rapidly, with little direct instruction from parents and/or caregivers. Some researchers, most notably Noam Chomsky [4, 5] and Steven Pinker [6] have argued that the rapid acquisition of language occurs because some aspects of language knowledge are innate. In contrast, other researchers, such as Michael Tomasello [7], have maintained that the acquisition of language utilizes the same biological processes and mechanisms that are involved in acquisition of other cognitive skills. The debate concerning the extent to which language acquisition may be facilitated by innate knowledge is likely to continue. It is important to note that there are an increasing number of studies showing that some language disorders are heritable and have a genetic component [8].

Psychological Abuse

Lindsay Weymouth, Tasha R. Howe
Humboldt State University, Arcata, CA, USA

Synonyms

Child maltreatment; Emotional abuse; Psychological maltreatment; Verbal abuse

Definition

A persistent pattern of demeaning or humiliating behavior directed at a child by a caregiver.

Description

A type of abuse in which a caregiver degrades, corrupts, berates, belittles, rejects, threatens, ignores, exploits, assaults, spurns and/or terrorizes a child in a repeated pattern [1, 2]. Psychological abuse may also consist of denial of psychological treatment, extreme verbal punishment, unreasonable expectations, and/or lack of responsiveness. This pattern of behavior from caregivers may adversely affect the child cognitively, emotionally, and socially. A caregiver may make a child feel unloved, flawed, or worthless through name calling and/or scapegoating or may be unconcerned with a child's troubles [1, 5]. The presence of psychological abuse may adversely affect later development of the child including symptoms of aggression, depression, emotional dysregulation, eating disorders, substance abuse, and learning disabilities [3, 5].

A child who is being psychologically abused may present symptoms of anxiety, depression, conduct disorder, and/or personality problems. Children who are psychologically abused may also show signs of regression in development, passivity, low self-esteem, social impairment, insecure attachment to caregiver, and/or suicidal behavior [2, 3].

Problems with emotion regulation may lead to alterations in the limbic system of the brain, disrupting the child's ability to self-regulate and interact with peers [6]. Without proper intervention, children who are abused may be affected well into adulthood. As adolescents and adults, they may abuse substances, show symptoms of psychiatric disorders, and engage in criminal behavior [4].

Psychological Age

Douglas K. Symons
Acadia University, Wolfville, ON, Canada

Synonyms

Age-equivalent; Age-related attitudes; Developmental Age; Maturity

Definition

Psychological age refers to the subjective age-equivalent of a person or how old one feels.

Description

Psychological age is how old one feels, acts, and behaves, and is thus not necessarily equal to chronological age, which is age since birth [1]. A person can therefore have a psychological age that exceeds their chronological age if they are mature or at least feel older than they really are. For example, this may be common in adolescence when young teens that feel older than they really are engage in behaviors typical of late teens and early adults. There is some indication that social maturity and achievement motivation in teens which could be associated with an advanced psychological age, for example, is associated with a parenting environment that is authoritative, emotionally warm, democratic, and firm. On the negative side, teens feeling older than they are may get involved in risk-taking behaviors that are appropriate for older individuals, and on the positive side, this may involve taking on responsibilities usually reserved for older people.

A person can also have a psychological age that is less than their chronological age if they feel or act younger than they really are, such as teens who are socially immature and children who go through developmental regression in response to a trauma. Implicit in these examples are expectations that people of different ages typically act in certain ways, and there can be generational differences in hobbies, movie preferences [3], and music that reflect these differences.

Health no doubt contributes to psychological age because the vitality of youth is associated with physical sensations of good health, and "aches and pains" are associated with the elderly. Psychological age should also reflect attitudes that are typical of people of different ages. For example, younger people generally are more positive about computers [2], facile with other forms of technology such as cell phones, and hold more liberal attitudes towards social issues like abortion, same-sex marriage, and gender-equality. An elderly person who is fluent with computer and cell-phone use, holds liberal social attitudes, and dresses like a young person may be said to have a psychological age less than their chronological age.

As these kinds of issues are difficult to quantify, the concept of psychological age is more common in the popular media than in psychological research. But the concept is based on age-related expectations of attitudes and behavior.

Psychological Assessment

David Michalec
Nationwide Children's Hospital/Ohio State University, Westerville, OH, USA

Synonyms

Psychological testing; Psychological evaluation

Definition

Psychological assessment is the process of gathering information about a child to make informed decisions [2]. Interviewing the child (or their caregivers), observing behavior in different settings, and administering standardized tests with the child or their caregiver are all commonly used methods of gathering such information. Psychological assessment can take any or all of these forms for a particular child.

Description

Psychological assessment is vital to the training, practice, and definition of professional psychology [1]. Most psychologists engage in some type of assessment as part of their practice. Sattler [2] discussed the "four pillars of assessment", a model that is typically referenced when describing this practice.

Psychological assessment typically involves observations of the child, often in different environments (school, testing appointment, or with peers). Interviewing the child's primary caregivers is necessary for any comprehensive assessment. Interviews can either be structured or semi-structured, and are designed to guide the conversations with the caregiver to gather necessary data. Interviewing an older child (pre-teen, adolescent) is also a common practice. Administration of norm-referenced tests is an essential facet of psychological assessment. Norm-referenced tests measure a host of skills including cognitive ability, academic achievement, motor functioning, and adaptive behaviors. Finally, gathering data in more informal contexts is also necessary. Reviewing school records, homework, previous assessments, writing samples, and school district testing are all commonly used practices. At times psychological assessment is used to gather information on personality characteristics or emotional states. The use of projective measures or self-report personality scales is useful in this regard.

Upon completion of a psychological assessment, the psychologist writes a formalized report. This report is a document that includes demographic information, the reason for referral, medical history, psycho-social concerns, and formal assessment data. All the data is synthesized and interpreted, which leads to diagnostic formulations. From that interpretation recommendations are made for treatment. The report is then shared with the child's caregivers and is distributed back to the referral source.

Relevance to Childhood Development

Psychological assessments are used in a variety of settings. School districts, medical clinics, mental health centers, and the legal system all utilize psychological assessments. The psychological assessment is then used to solidify diagnoses, initiate services, place children in appropriate educational settings, make recommendations for treatment, and monitor progress over time.

▶Risk Factors

Psychological Disorders

Ashlea Smith
Phoenix College, Phoenix, AZ, USA

Synonyms

Behavioral disorders; Emotional disorders; Mental disorders; Mental health; Mental illness; Psychiatric disorders; Psychopathology

Definition

Psychological disorders also commonly known as mental disorders are terms used to define abnormalities in the brain's chemical functioning (physiological) and the abnormal emotional states (psychological) that impacts one's emotions, cognitions, and behavior that are considered maladaptive, causing distress in all aspects of life (e.g., social, occupational, educational, etc.), and disruptive for both the individual experiencing the symptoms or for others. Additionally, it is important to note that the term, psychological disorders, may be defined quite differently based on cultural implications and culturally defined "norms."

Description

Disorders that occur prior or during the onset of puberty around the ages of 11–12 years to the progression into early adulthood (ages 18–24) are considered psychological disorders of childhood and adolescence with the continuation into early adulthood. Young children and infants can also be subjected to developing a serious psychological disorder. A child may be predisposed genetically to develop a psychological disorder, meaning that the child received hereditary (passed down) traits or genes from the parents which would explain the biological roots. Next, it is important to take into account the concept of both nature and nurture in the development of mental health issues in youth. Many other events such as a child's family or social support network, environment, and culture molds how one develops, displays behavior, and predicts mental health well-being [4].

Family dynamics and interactions play such a large role in the emotional and physical development of children. Every child is born with unique characteristics that ultimately shape them into the person they are genetically meant to be. Children are born with different attachment styles: secure, avoidant, ambivalent, & disorganized–disoriented [1, 2], temperaments such as: easy, difficult, and slow to warm up [5, 12], and tend to

develop cognitively, emotionally, and physically at varying rates. Some more maternal factors that increase the risk for a child to develop a psychological disorder remain in the hands of the mother who decides to use alcohol, drugs, or encounters other teratogens involved in disability or illness during pregnancy. In addition, the family's medical history must be explored to assess the visibility of mental illness to predict the child's chance to also be diagnosed with a mental disorder. Psychological disorders are not always congenital, but may also develop early in a child's life due to suffering an injury, trauma, or illness.

[4] reported that when considering a child's behavior or mental health well-being you must take into account the context of familial cultural practices and traditions. These help mold and define one's values, childrearing practices, the family unit, relationship development, spiritual or religious beliefs, and the roles and rules unique to every family system. Cultural norms vary from culture to culture; hence it is vital to understand the child or adolescent's perception of how culture impacts one's worldview and the development of the self. However, as [4] noted current empirical studies have shown that no matter what the cultural practices and traditions a child may have experienced or played a key role in development; the ultimate deciding factor to healthy development on how a child or adolescent acts, thinks, and behaves remains to be the relational connection and bond (e.g., attachment) with a caregiver or parent(s). This lack of a healthy connection with a significant other or caregiver which provides both care on a nature and nurture level could implicate one's risk to develop a psychological disorder (s) in the future.

The last factor to be mentioned before the discussion of different psychological disorders, that are more prevalent in childhood or adolescence, is the concept of how environmental factors come into play with a child's mental health. We are all products and producers of our environment. As adults not only do we learn from the media, societal defined norms, and our surroundings, but children are also exposed to learning from the environment. Children learn how to act, think, and behave by observing and modeling others around them in their environment. [4] stated that children who are constantly exposed to violence whether it is in the home, in the neighborhood, or in the surrounding community are more at risk to develop anxiety, difficulty trusting others, lack of social skills, and may also display aggression. This repeated exposure to violence for children increases the risk to also develop a psychological disorder.

Psychological Disorders of Childhood and Adolescence

Attention Deficit and Disruptive Behavior Disorders

Oppositional Defiant Disorder

According to the American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders-IV-Text Revision [3], oppositional defiant disorder is defined when a child displays repeatedly for at least 6 months: aggression, disobedience, and hostile behavior towards adults or other authority figures. This disorder is usually evident around the age of 8 years with 2–16% percent of all children meeting diagnostic criteria for this disorder [11]. Oppositional defiant disorder is more common in boys before puberty, but tends to become equal for both sexes after reaching puberty. The outward signs and symptoms range from throwing temper tantrums, displaying intense anger, to ignoring rules, and quick to point the finger at someone else by blaming others. As one matures in age usually this disorder dissipates and is no longer an issue, if not this disorder tends to lead to a more serious disorder called, conduct disorder.

Conduct Disorder

Conduct disorder is the more severe form of conduct disorder as described earlier. [3] defined conduct disorder as when one repeatedly displays behavior that violates the basic rights of others with rules and social norms being violated. Conduct disorder most represents what we see in adults called anti-social personality disorder, which this disorder in childhood often will lead to anti-social personality disorder in adulthood. The signs and symptoms of children and adolescents exhibiting this disorder would be the following: aggression, cruelty to humans and animals, truancy (e.g., skipping school and runaways), bullying, stealing, and committing crimes. Crimes usually begin with stealing, shoplifting, forgery, but lead to more severe crimes such as breaking and entering, mugging, armed robbery, rape, and homicide. [11] reported that conduct disorder is three to four times more common in boys than their female counterparts, whereas adolescents diagnosed with this disorder frequently instigate fights with peers, teachers, and other authority figures. These children feel as though rules or laws are not applicable to them.

While boys who are diagnosed with this disorder display more outward forms of aggression, females who are diagnosed with conduct disorder usually show a different pattern of behavior of conduct disorder, called relational aggression (RA). [6] defined the term relational aggression

as emotional violence and bullying behaviors focused primarily on damaging or manipulating the individual's relationships within a peer group. These same two authors found that boys are more likely to use physical victimization (e.g., fighting) whereas girls are more likely to use relational victimization (e.g., spreading rumors, teasing, cyberbullying). [13] highlighted the different types of RA:

1. Relational aggression – behavior intended to harm someone's relationships with others
2. Covert aggression – indirect or hidden acts of aggress
3. Peer aggression – physical, verbal, and relational aggression
4. Physical/Overt aggression – direct, blatant acts of aggression, can be physical or verbal
5. Verbal aggression – threats, putdowns, and name calling
6. Reactive relational aggression – defensive response to provocation with intent to retaliate
7. Proactive relational aggression – proactive means for achieving a goal. (p. 3)

For young girls whom experience relational aggression could experience the following long-term effects such as: poor self-esteem, poor relational skills, anger, depression, teen pregnancy, self-injury, and eating disorders just to name a few [13].

Attention Deficit/Hyperactivity Disorder (ADD/ADHD)

This disorder seems to be one that is frequently given to children nowadays that have difficulty sitting still, inability to pay attention, or may display some type of outward aggressive behavior as a quick fix or easy label. [3] defined the following guidelines for someone to meet diagnostic criteria the behavior must be present continuously for at least 6 months, disruptive (e.g., both at home, school, other environments), inappropriate by cultural and developmental standards, and all of these symptoms have an onset before the child is 7 years of age. ADHD is further described as a child having poor attention, easily distracted, inability to sit still, lacks impulse control, tends to talk when inappropriate, and unable to wait his or her turn [4]. On the other hand to be diagnosed as the hyperactive-impulsive type, according to [3] the child must constantly fidget and move around, talks excessively, interrupts others, and has a hard time waiting to be called on as just a few of the many signs of ADHD.

Elimination Disorders

Enuresis and Encopresis

There are two major types of elimination disorders as defined by [3] the first is enuresis (e.g., intentional bed wetting or wetting on oneself) with a diagnostic criterion of:

1. Urinating in the bed on the child's clothing at least twice a week for at least 3 months
2. The accidents cause significant distress
3. The child is 5 years of age or older
4. The wetting accidents are not otherwise explained by another medical condition.

The urinating in one's bed, clothing, or floor occurs at an age when the child should have already mastered the task of potty training. The second encopresis (e.g., defecating in one's clothing, bed, floor) is defined according to the DSM-IV-TR as:

1. Repeated bowel movements in inappropriate places
2. Inappropriate bowel movements occur once a month for at least 3 months
3. The child has an age of four
4. The problem is not otherwise explained by another medical condition.

In the case of a child being diagnosed with enuresis or encopresis it is not uncommon for the parent or sibling(s) to have experienced a similar problem as a child. There is no one cause as a reasoning why children develop these disorders, but it could be concluded that these children have anxiety, emotional conflicts, improper toilet training, a weak bladder, social problems, shame, stress, or embarrassment [4]. Elimination disorders should be addressed with the child's pediatrician to confirm that the disorder is not accounted for by a medical condition before pursuing other therapies. It is also important to include family therapy as discussed earlier family conflicts could be the root of the problem.

Pervasive Developmental Disorders

Autism/Autistic Disorder

Autism or Autistic Disorder is a diagnosis focused on social interaction, communication delays, and repetitive behaviors where a child must have symptoms from each of these three areas that are present before the child turns 3 years of age [3]. When looking at the social interaction piece, children with autism prefer to play by themselves, avoid interactions with others, and seem disinterested in forms of affection such as hugs and kisses. Next, communication delays are displayed when the child has significant language issues such as failure to speak or develop language, or the refusal to use or acknowledge nonverbal forms of communication with peers, teachers, parents, or others. Lastly, children diagnosed with autism often

repeat certain behaviors or mannerisms like flapping hands, twisting arms, rocking, spinning, or making off grimaces. These children appear to be in their own little world as though they have detached themselves from reality, and have extreme difficulty relating to others. It is also commonplace for children, mostly boys, diagnosed with this disorder to induce self-inflicted injury through head-banging, biting, or pulling one's hair. When it comes to play, children with autism have limited play or what we as play therapists would describe as non-imaginative play, which is the inability to incorporate fantasy, real-life scenarios, sequential play (e.g., play with a beginning, middle, and end that flows together), and the ability to play in a variety of ways. Play is typically done by oneself due to the inability to include others utilizing toys that include buttons or lids. The child will then in a sense get lost in their own little world by repeatedly playing with the buttons or the lids by taking the lid off and then replacing it. Children diagnosed with autism have difficulty dealing with change and best adapt to their environments by following daily routines and schedules. If you must create change around these children it is best to give them warnings in different time increments such as 20 min warning, 15 min warning, 10 min warning, and 5 min warning to slowly prepare the child for a change in his or her routine.

Asperger's Disorder/Asperger's Syndrome

Asperger's disorder is quite similar to autism, but with some key diagnostic criteria points that exist to differentiate between the two disorders. [3] defined Asperger's disorder as one with a child having difficulty with peer social interactions, but still remain interested in peers, they do not usually have language and speech delays, are able to develop patterns of behavior such as rituals, and the children do not usually experience cognitive difficulties. It is also quite common for some children with Asperger's disorder to be given the label of gifted intellectually. Children with Asperger's disorders enjoy talking and including others in their conversations, but the child with Asperger's typically takes over the conversation with topics only interesting to them. When interacting with other children it is also at times difficult for children with Asperger's to pick up on nonverbal cues causing a social impairment. These children want to fit in with their peers, but find it extremely difficult to interact with others due to the poor social functioning. As with autism, this disorder causes children to become easily angered or frustrated that could potentially induce self harming behaviors.

Rett's Disorder

Rett's Disorder is often confused with Autistic Disorder due to the appearance of multiple deficits following a period of normal growth and functioning after birth. The Autism Program at Yale School of [8] found this condition occurs primarily in girls at the rate of 3.8 per 10,000 with mutations of the gene MECP2 being indicated as causing the disorder. The typical onset for Rett's is around the first or second year of life, but before the age of four. The disorder is chronic after onset of the symptoms and is generally progressive as one ages. [3] outlined the following criterion for one to be diagnosed: deceleration of head growth, loss of hand skills such as hand-wringing or hand-washing, lack of social engagement, poor gait, and a severe impairment of both receptive and expressive language development.

Childhood Disintegrative Disorder

Childhood Disintegrative Disorder also known as CDD is a rather rare disorder that tends to affect more boys than girls. Symptomatology of this disorder becomes apparent after at least 2 years of normal development including social skills both verbal and nonverbal, ability to form social relationships, and play. As the disorder advances the child will experience a loss of interest in the environment, inability to engage in self-care such as toilet training, and language abilities are lost, which may present as autism. According to [3] a child must experience a loss of at least two previously learned skills such as (a) expressive language, (b) social skills, (c) control of bowels, (d) play, and (e) motor skills. In addition, by the standards of [3] the child must also experience abnormalities in two of the following areas: (a) impairment of social skills and ability to form relationships, (b) impairment in communication, and (c) repeated patterns of behaviors.

Mental Retardation

Down Syndrome

The general definition of Mental Retardation (e.g., MR) is someone with below average intelligence as measured by a standardized intelligence test to calculate an intelligence quotient, better known as IQ. The benchmark for MR is an IQ below 70. There are four subtypes of MR: Mild mental retardation (e.g., IQ ranging from 50–70), Moderate mental retardation (e.g., IQ ranging from 35–55), Severe mental retardation (e.g., IQ ranging from 20–40), and Profound mental retardation (e.g., IQ ranging from 20 to 25 or below). The symptoms of mental retardation have a typical onset before the age of 18. For one to be

diagnosed with MR they must experience concurrent impairment in at least two of the following areas: personal self-care/hygiene, communication/social skills, independent community living, and other areas of life functioning.

Down syndrome is one of the most recognized forms of Mental Retardation. This syndrome is a genetic mutation caused by an extra chromosome on the 21st pair. Everyone whom is diagnosed with Down syndrome has mental retardation in the Mild mental retardation (e.g., IQ ranging from 50–69) to the Moderate mental retardation range (e.g., IQ ranging from 35–55). This syndrome has distinctive facial characteristics associated with children with Down syndrome such as slanted eyes (e.g., oblique eye fissures), folds in the skin around the corner of the eyes (e.g., epicanthic eye fold), a flat nose, protruding tongues, usually short and stocky body type, a short neck, and small ears. It is not uncommon for children with Down syndrome to also have other medical complications such as heart defects and visual and auditory impairments to name a few.

Phenylketonuria (e.g., PKU)

Phenylketonuria also known as PKU is a genetic disorder where the body cannot break down the essential amino acid phenylalanine and as an excess amount of phenylalanine develops leads to mental and physical abnormalities. If this disorder is left untreated it can lead to mental retardation. The known cause is by having two parents that both have the recessive gene for the disorder and if only one parent has the recessive gene they are known as a carrier of PKU.

Fragile X Syndrome (e.g., FXS)

Fragile X syndrome is the most common inherited cause of mental retardation. The syndrome occurs when a DNA series makes too many copies of itself. The mutated gene is unable to produce the necessary protein that is needed in the body's cells especially the brain cells for normal functioning. Fragile X is also associated with some distinctive facial features such as long ears and a long face. It is not uncommon for children with Fragile X to experience behavioral disorders for example, temper tantrums, hyperactivity, irritability, and engaging in self-injurious behaviors.

Fetal Alcohol Syndrome (e.g., FAS)

Fetal alcohol syndrome (e.g., FAS) is the leading known preventable cause of mental retardation for children. When a mother drinks alcohol during pregnancy the alcohol can affect both physical and brain development of the fetus leading to mental retardation and an assortment of birth defects. The University of [10] highlighted some key facial features that make it easy to identify a child with FAS such as: (a) flat forehead (e.g., microcephaly), (b) small eye slits (e.g., short palpebral fissures), (c) flat midface, (d) thin upper lip, (e) pointy chin (e.g., micrognathia), (f) short nose, (g) pointed ears, (h) low nasal bridge, and (i) epicanthal folds. Thus, to avoid this disorder a mother must reframe from alcohol intake during pregnancy.

Cultural-Familial Retardation

In other cases of mental retardation the cause is not directly known. The Psychology Encyclopedia (2010) described another form of mental retardation called, familial retardation, "also called sociocultural or cultural-familial retardation, mild mental retardation attributed to environmental causes generally involving some degree of psychosocial disadvantage" (p. 1). The early signs of cultural-familial retardation typically are not visible until a child begins school and starts having troubles academically in the classroom. According to the Psychology Encyclopedia (2010) a child with cultural-familial retardation usually has an IQ in the range of 55–69 and reported that environmental causes like the mother's prenatal care, nutrition, family size, the spacing of births within a family, illness, and other teratogens from the environment like lead may lead to the development of this form of mental retardation.

Learning Disorders

Mathematics Disorder

Mathematics disorder is another learning disorder often referred to as dyscalculia. The key features of this disorder surround the decreased ability to comprehend mathematical concepts, recognize numerical symbols, and copying figures or numbers correctly. As stated earlier, [3] notes that a child's mathematical ability is significantly below what is expected for the child's age as measured by standardized tests, the difficulty interferes with academic achievement and daily functioning, and there might be an additional sensory deficit present that can further impair difficulties with mathematical abilities.

Reading Disorder

The most common reported learning disorder is called reading disorder or commonly known as dyslexia. Reading disorder affects mostly males at 60–80% of children who are diagnosed with this disorder. This disorder results in a child having significantly lowered reading ability and scores than what is expected for the child according to

the child's age, IQ, and grade level. [3] states that the child's reading achievement needs to be well below what is age appropriate as defined by standardized tests, the reading difficulty interferes with academic achievement, and a potential sensory deficit may be present to intensive the reading difficulties for the child.

Disorder of Written Expression

Disorder of written expression may be better recognized as dysgraphia, is beyond sloppy handwriting, but more related to difficulty composing sentences, frequent grammatical and spelling errors, as well as inability to organize paragraphs that flow logically from one topic to the next. This disorder is frequently found in conjunction with reading disorder or dyslexia.

Feeding and Eating Disorders of Infancy or Early Childhood

Pica

Pica is often seen with Mental Retardation and Pervasive Developmental Disorders, although some studies have found vitamin or mineral deficiencies (e.g., zinc) may account for the development of this disorder [3]. Pica occurs when children eat nonnutritive substances such as paint, paper, hair, leaves, etc. consistently for at least one month. The aftermath of Pica can result in serious medical risks and complications. The disorder is seen across racial and socioeconomic classes, both females and females, and all age groups. [3] reports that a child must exhibit the following: (a) constantly eating nonnutritive items for at least one month, (b) the behaviors exhibited is not appropriate for age and developmental levels, and (c) the disordered eating behavior occurs during the course of another existing mental health problem.

Rumination Disorder

Rumination disorder is a rare pattern of disordered eating when a child repeatedly regurgitates and chews recently eaten food. This type of episodic behavior can occur multiple times a day and may resemble self-induced vomiting, which causes children to be misdiagnosed with Bulimia Nervosas or with GERD (e.g., Gastroesophageal Reflux Disease).

Feeding Disorder of Infancy or Early Childhood

Feeding disorder of Infancy or Early Childhood results when a child fails to eat adequate portions or at all in some instances fails to eat at all, which usually causes one to significantly lose weight or an inability to gain weight. The disorder is not explained by another general medication condition or another mental health problem. It is not uncommon for the disorder to have an onset by the age of one, but may have a later onset at the age of 6 years of age. Children and infants may become irritable during feeding times and difficulties with the mother and child bond may also exacerbate the symptoms.

Motor Skills Disorder

Developmental Coordination Disorder

Developmental Coordination Disorder results in the impairment of motor coordination that is not explained by another general medical condition. The diagnosis is typically made after the motor coordination impacts one's academic performance and ability to engage in everyday activities. This disorder is usually evident when a child attempts to hold a knife or fork, or attempts to run or play a game using equipment.

Communication Disorders

Expressive Language Disorder

The key aspect of Expressive language disorder is the impairment in both nonverbal and receptive language development. These difficulties interfere with one's academics, employability, and impact social areas of an individual's life. The usual signs of this disorder are limited speech, small range of vocabulary, and difficulty with grammar that is apparent around the time a child starts school if not before. It is important to consider cultural implications before diagnosing a child with this disorder due to children growing up in bilingual homes and the context within language is also spoken within the home. The diagnostic criteria largely comes from scores from standardized measures of expressive language development constituting in scores far below what is expected according to age and development. [3] defines this disorder when a child has difficulties with language that interfere in a variety of areas for the child such as educational and social functioning. It is also important to rule out the diagnosis of Mental retardation as language difficulties are commonly associated with MR.

Mixed Receptive-Expressive Language Disorder

The marked feature of Mixed Receptive-Expressive is functional impairment with both receptive and expressive language that may be acquired or developed. Children with this disorder have difficulty recalling and understanding words in conjunction with difficulty expressing ideas. The disorder is detected in children through the use of standardized tests assessing both receptive and expressive language

development. The difficulties cause significant problems for a child academically and with social interaction.

Phonological Disorder

The most common communication disorder with children is Phonological disorder, previously known as Developmental Articulation Disorder. Children diagnosed with this disorder fail to use appropriate speech sounds that are relevant according to the child's age and dialect. The impairment usually follows errors in sound production, use of the speech sounds, and the ability to organize sounds. As with other communication disorders it is also important to rule out Mental Retardation as a factor in causing this disorder. The basics of this disorder include difficulty organizing all the sounds necessary for clear speech, ability to understand and read, as well as the skills necessary for accurate spelling.

Stuttering

The disorder of Stuttering is noted by the frequent repetitions or prolongations of sounds and syllables. A child may not be aware of the problem initially but after a child has been diagnosed increased awareness and anxiety surrounding the issue may develop later on. This disorder is more common in boys than girls at a rate of 3 to 1 and is found more often in prepubertal children (e.g., before the age of ten) than in adolescents [3]. According to [3] a child must experience at least one of the following: (a) repetition of sounds, (b) sound prolongations, (c) interjections, (d) pauses within words, (e) silent blocking, (f) heightened physical tension when pronouncing words, (g) monosyllabic whole-word repetitions, (h) the Stuttering interferes with all areas of life such as educational and social situations, and (i) if a child is already diagnosed with speech–motor difficulties then the speech problems are more extreme.

Tic Disorders

Tourette's Disorder

[9] described Tourette's disorder when a person has multiple motor tics such as facial grimaces or eye blinking or vocal tics such as throat clearing, shouting, or barking. Tourette's Disorder may surface around the early years around the age of two or at the latest by the age of 18. [3] states that for one to be diagnosed both motor and vocal tics must be present although not necessary at the same time and that these symptoms must occur several times a day for one year. It must also be ruled out that the motor and vocal tics are not caused by an underlying general medical condition or the affect of substance use.

Chronic Motor or Vocal Tic Disorder

Chronic Motor or Vocal Tic disorder is very similar to Tourette's disorder except a child or adolescent tends to have either motor movement tics or vocal tics but do not have both of these.

Transient Tic Disorder

Transient Tic disorder is very similar to both Tourette's disorder and Chronic Motor or Vocal Tic disorder in diagnostic criteria except the motor or vocal tics usually last 4 weeks, but not longer than one year (e.g., 12 consecutive months).

Other Disorders of Infancy, Childhood, or Adolescence

Separation Anxiety Disorder

Separation Anxiety Disorder (e.g., SAD) affects both children and adolescents whom have an excessive worry or fear of being separated from their caregiver (e.g., parent, relative, nanny, or other caregiver) or home. The onset of symptoms usually follows a major life change (e.g., starting a new school or a recent move) or a traumatic loss (e.g., death of a loved one). This anxiety is not common for what is appropriate for the individual's age and developmental status. For this disorder to be diagnosed the child must be under the age of 18 and the symptoms must last for a consecutive 4 weeks. When these children are out of touch with caregivers they constantly need to know where they are located by keeping in touch through phone calls or checking in- person with the caregiver. Children may also express fears about being alone, animals, monsters, plane crashes, car accidents, or the fear that someone may break into the child's home. [7] outlined some signs to be aware of in the home, at school, and at the doctor's office:

1. At home:
   (a) Extreme worry about separating from caregiver or the anticipation of separation
   (b) Constant fears that something tragic may happen to the caregiver
   (c) The child may refuse to go to school
   (d) The child may not want to engage in extracurricular activities or spend time with peers due to separation fears
   (e) The child may insist on sleeping in the bed with the caregiver or may experience nightmares about being separated
   (f) The child may begin experiencing psychosomatic symptoms as a result of the excessive anxiety and

worry around being separated from the caregiver such as stomach aches, headaches, and other physical ailments.

2. At school:
   (a) The child may have a difficult time transitioned from the home to the school environment
   (b) The child may insist on staying home or engage in behaviors to avoid going to school
   (c) The child may have difficulty concentrating on tasks in the classroom
   (d) It is not uncommon for the child to have lowered self-esteem
   (e) Continued avoidance of after-school activities or engaging in other activities with peers.
3. At the doctor's office:
   (a) As a child ages the symptoms may change
   (b) Other conditions such as phobias and panic disorder should be ruled out
   (c) Depression is often seen in these children
   (d) The child will complain of various physical ailments
   (e) Children may lack insight into their disorder or avoid talking about the fears of separation
   (f) It will be beneficial for the families to be directed on how to deal with these worries.

These worries and excessive fears of being separated from the caregiver cause severe disturbance for the child socially, academically, and is various other areas of functioning.

Selective Mutism

Selective Mutism formerly known as Elective Mutism is when a child refuses or fails to speak in social situations where speaking is expected and normal. This disorder typically has an onset before the age of five for children, but is not typically noticeable until the child begins school. [3] reported that for a child to be diagnosed with Selective Mutism the following must occur: (a) failure to speak, (b) the mental disturbances cause impairment in functioning of one's academic and social functioning, (c) the failure to speak is not accounted for by the lack of ability to speak, and (d) the disturbance is not otherwise explained by another mental disorder. Selective Mutism is a rare disorder is has been found in "1% of individuals in mental health settings" (APA, [3], p. 126).

Reactive Attachment Disorder of Infancy or Childhood

Reactive Attachment Disorder of Infancy or Childhood begins around the age of five. There are two subtypes inhibited type (e.g., extremely withdrawn and emotionally detached) and disinhibited type (e.g., seeks attention from virtually anyone). It is not uncommon for a child diagnosed with Reactive Attachment Disorder of Infancy or Childhood to have experienced abuse or neglect. Children with this disorder have difficulty forming nurturing bonds with caregivers and others, which ultimately impacts brain growth and development. According to [3] a child must fail to respond appropriately to social interaction or fail to develop selective attachments as well as experience neglect from the caregiver(s) related to the child's emotional and physical needs.

Stereotypic Movement Disorder

In Stereotypic Movement Disorder a child repeatedly makes movements such as hand waving, body rocking, biting self, or head banging to name a few for at least 4 weeks. The disorder seems exacerbated by increased levels of stress. The behavior impairs one's ability to participate in normal activities and may cause medical complications with the self injurious behavior. These behaviors are not otherwise accounted for by another general medical condition and if Mental Retardation is present treatment will focus on the self injurious behaviors.

Relevance to Childhood Development

A child's development is based out of a variety of factors: family, environment, culture, and biology. Each one of these factors can impact not only a child's physical and cognitive development, but more importantly a child's psychological development. Psychological disorders or commonly known as mental disorders do not only affect adults, but many mental disorders actually begin in childhood. As a caregiver, teacher, parent, or clinician it is important to know and recognize the different symptomatology associated with specific disorders, so that the child or adolescent can receive the best care, whether that means therapy, medication, special education plan, or other interventions. It is important for the child to not only be physically healthy, but mentally healthy as well as they progress through the life span.

Psychological Maltreatment

Lindsay Weymouth, Tasha R. Howe
Humboldt State University, Arcata, CA, USA

Synonyms

Child maltreatment; Emotional abuse; Psychological abuse; Verbal abuse

Definition

A persistent pattern of demeaning or humiliating behavior directed at child by a caregiver.

Description

A type of maltreatment in which a caregiver degrades, corrupts, berates, belittles, rejects, threatens, ignores, exploits, assaults, spurns and/or terrorizes a child in a repeated pattern [1, 2]. Psychological maltreatment may also consist of denial of psychological treatment, extreme verbal punishment, unreasonable expectations, and/or lack of responsiveness. This pattern of behavior from caregivers may adversely affect the child cognitively, emotionally, and socially. A caregiver may make a child feel unloved, flawed, or worthless through name calling and/or scapegoating or may be unconcerned with a child's troubles [1, 5]. The presence of psychological maltreatment may adversely affect later development of the child including symptoms of aggression, depression, emotional regulation, eating disorders, substance abuse, and learning disabilities [3, 5].

A child who is being psychologically maltreated may present symptoms of anxiety, depression, conduct disorder, and/or personality problems. Children who are psychologically maltreated may also show signs of regression in development, passivity, low self-esteem, social impairment, insecure attachment to caregiver, and/or suicidal behavior [2, 3].

Problems with emotion regulation may lead to alterations in the limbic system of the brain, disrupting the child's ability to self-regulate and interact with peers [6]. Without proper intervention, children who are maltreated may be affected well into adulthood. As adolescents and adults, they may abuse substances, show symptoms of psychiatric disorders, and engage in criminal behavior [4].

Psychological Testing

►Psychological Assessment

Psychology

Definition

Psychology is the scientific investigation of the way people think, communicate, the study of the mind and mental states. The concept of the study of the consciousness, temperament and behavior is also imperative. The two Greek words psyche and logos, psyche was translated as the soul or the breath of life, and the word logos was the knowledge or study and was originally defined as: the study of the mind.

Description

Psychology involves the scientific study of the conscious experience of mental processes and behavior. These concepts include perception, cognition, emotions, personality, interpersonal, intrapersonal relationship and consciousness. Psychology emphasis is on experimentation and research with animals and humans concentrating on observable and measurable behaviors, biological and neurological processes. It is important to understand how these functions inter play with social dynamics. Psychologists use various statistical assessments essential to scientific methods. The applications include issues that relate to problems in living, including treatment of mental health. There are various concentrations in the field of psychology these are: developmental, social, comparative, cognitive, bio-physiology, health, and organizational.

Relevance to Childhood Development

Clinical psychology is the branch that diagnosis children with psychological problems and treatment. They also can give assessments for cognition, achievement and intelligence (IQ) Psychologists with specialized training in evaluation of cognitive functioning is a Neuropsychologist. They use a battery of standardized assessments developed in diagnosing children with specific cognitive impairment. When the area of impairment is identified recommendations of specific mental exercises are then given to help the child to improvement. An example is Brain training software to help children with brain injury. Also Neuropsychologist have had major success with Bio-feedback for children with Attention Deficit Disorders and various other disorders.

Psychometrics

Marie C. McGrath
Immaculata University, Immaculata, PA, USA

Synonyms

Psychometry; Measurement theory; Test theory

Definition

An area of psychological science focusing on the development, use, and interpretation of theoretically sound, consistent, and valid assessment instruments.

Description

Psychological testing involves the systematic measurement of psychological or educational variables, such as personality, intelligence, or academic achievement. Two major assumptions underlying psychological testing are that individuals demonstrate relative stability of psychological traits across situations and over time, and that the extent to which individuals possess certain psychological traits varies significantly in the population at large. Understanding the extent to which an individual possesses or demonstrates certain psychological traits, and the typicality of those traits in the general population and/or others similar to the individual, can be useful in understanding and/or making predictions about that individual's functioning. Psychological testing attempts to quantify the differences in traits among individuals by systematically assigning scores to items measuring those traits, which in turn permits statistical examination of the relationships among test scores and other variables of interest.

The American Psychological Association's Report of the Task Force on Test User Qualifications [1] indicates that test users' psychometric knowledge must encompass both *classical test theory* (CTT) and *item response theory* (IRT).

Classical test theory is characterized by the assumption that the score received by an individual on a given test, sometimes referred to as the obtained or observed score, comprises both a "true score" that the individual could obtain on that test under ideal circumstances, and some degree of measurement error introduced into the testing process by the test user, the test taker, or the test itself. Since it is not possible to precisely identify and quantify all sources of error, it is also impossible to state the precise difference between the obtained score and the true score. In the CTT model, psychometric statistics are obtained by examining the performance of a sample group on the test as a whole, as well as at the item level. Test consistency is measured by examining score correlations across parallel forms of the test, or among items within the test. Items' levels of difficulty are determined based on the sample's overall performance on each item. In recent years, CTT has been criticized as too simplistic and sample-dependent, since the data obtained from CTT analyzes will vary based on the performance of the individuals in a given sample. Accordingly, the use of IRT, a psychometric approach that examines the links between test-takers' latent abilities and their test performance, has become increasingly prevalent. Through the use of mathematical probability models, IRT permits examination of the extent to which levels of ability or traits of interest (as measured by overall test performance) predict performance on individual test items.

Other necessary test user competencies, as identified by APA [1], include: familiarity with descriptive statistics; knowledge of statistical measures of variation (e.g., standard deviation) and relation (e.g., correlation); awareness of the characteristics of the normal curve; knowledge of types of scales and scores; and familiarity with how these concepts relate to assessing a test's *reliability*, or consistency of measurement, and *validity*, or the extent to which a test measures what it is supposed to measure (*content/construct* validity, or validity of measurement) and predicts performance on some external measure or criterion variable (*criterion* validity, or validity for decision-making).

When used in reference to individual assessment instruments or to types of tests, the phrases "psychometric soundness" and/or "psychometric adequacy" refer to whether the tests demonstrate sufficient levels of reliability and validity for ethical use with clients. The *Standards for Educational and Psychological Testing* [3], which establish standards for test construction, competency and knowledge of test users, and appropriate use of tests, do not "dictate minimal levels of test-criterion correlation, classification accuracy, or reliability for any given purpose" (p.112). As a general rule, however, any tests used in high-stakes decision-making processes should possess high levels of reliability and validity in order to increase the likelihood that such decisions are made appropriately.

Psychomotor Seizures

Matthew J. Holcomb, Raymond S. Dean
Ball State University, Muncie, IN, USA

Synonyms

Complex partial seizure; Temporal lobe seizure

Definition

A psychomotor seizure is a form of epilepsy that is typically limited to the temporal lobe of the brain and results in impairment of responsiveness and awareness to ones surroundings. Patients may act out in a variety of ways while experiencing the seizure but have not recall of it.

Description

Psychomotor seizure is an older term used to describe a complex partial seizure which is seen in its most common forms as either psychomotor or temporal lobe epilepsy. Psychomotor seizures are more complex than simple partial seizures because an alteration of awareness typically accompanies the experience of a seizure. In fact,

about half of all people who experience a psychomotor seizure also experience a concomitant aura [3].

In many circumstances the aura that a person experiences is directly related to the origination of the seizure. In other words, if a person has a visual aura or manifestation (e.g., perceiving objects as getting smaller or larger) there is a high likelihood that the seizure has an origination point, or the abnormal firings of neurons is occurring, in the occipital lobe. Similarly those with frontal lobe seizures might possibly experience motor problems.

Alterations of consciousness can take several forms with a psychomotor seizure. The experience of a seizure may induce a sense of déjà vu ("already seen") or jamais vu ("never seen") with regards to familiar places or situations. Additionally, it is not uncommon for a person experiencing a psychomotor seizure to have a sense of rushed thoughts, nausea, illusions, terror, euphoria, panic, or ecstasy.

Relevance to Childhood Development

Children with seizure disorders are at a high risk for experiencing problems with learning. This is due largely to the high number of missed school days each year that a child with psychomotor seizures will experience. Bailet and Turk [1] found that while some children with seizure disorders may have lower than average IQ's typically it is a difficulty with learning and a lack of educational opportunities that have a detrimental impact of child performance within schools.

In addition to school associated problems, children with seizures in general have been found to have disproportionately high rates of psychological problems. Researchers have found rates between 25% and 60% of children with seizure disorders also display identifiable behavioral disorders [2, 4]. Still other research has shown a link between aggression and depression in children with a seizure disorder [5].

Psychopathology

Chris Leeth
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Mental disorders; Mental illness; Psychological disorders

Definition

Psychopathology is an umbrella term that describes behavior that is significantly dysfunctional or different than "normal."

Description

Psychopathology is a term that encapsulates deviant, dysfunctional, or otherwise abnormal behavior and thought processes. Broken down, "pathology" is a term used for deviance while "psycho" is used to indicate mental or mind-states. Together, "psychopathology" is used to describe deviance in mental status. Schizophrenia, Bipolar Disorder, and Narcissism are all types of psychopathology. The most widely used system in the United States for categorizing, diagnosing, and describing psychopathology is the Diagnostic and Statistical Manual of Mental Disorders, published by the American Psychiatric Association.

Psychopathology can be present in any type of person, regardless of sex, age, and ethnicity. However, different countries may recognize different forms of psychopathology. Further, behavior that may be considered as pathological is based on how different that behavior is when compared to the rest of the population.

Psychopathology can be assessed by a variety of instruments, direct observation, or through self-report. It is important to note that while behaviors may be pathological, people are not. In other words, the person is not pathological, but rather, the person is demonstrating a type of thought or behavior that is pathological.

Psychosexual Stages, of Freud

Jed Yalof
Immaculata University, Immaculata, PA, USA

Synonyms

Oral, anal, phallic, and genital stages; Psychosexuality

Definition

Psychosexual stages of development, observed by Sigmund Freud, the father of psychoanalysis, represent maturational processes by which a child's innate biological drives interact with different erogenous zones to influence personality. Different conflicts emerge in relation to the psychosexual stages of childhood, and these conflicts are reworked during adolescent development in response to hormonal changes and new psychosocial stresses in ways that are unique and characteristic of the individual.

Description

An unusually integrative and creative thinker, Freud's theory of psychosexual development can be best understood in relation to his other ideas about childhood sexuality [11], instincts [12], and the oedipal conflict, superego, and structural theory [14]. Other sources provide an overview of components of Freud's theory [3, 20, 25, 26]. The purpose of this entry is to orient the reader to psychosexuality and some of its key related concepts.

Drives

A neurologist by training, Freud [11] envisioned a biologically based model of psychological maturation in which a primary sexual instinct or drive, and an innate need for gratification and pleasure, interfaced with the highly sensitized nerve endings of the oral, anal, and genital erogenous zones that were in ascension at different points in the child's early development. Freud stated: "The concept of instinct is thus one of those lying on the frontier between the mental and the physical" [11, p. 168]. Drives have an impetus, which reflects a push forward; a source, which is the erogenous zone from which the drive emanates; an aim, as reflected in the desire to gratify the drive; and an object, represented by the person gratifies the drive, though something other than a person could also gratify a drive. Although Freud later added aggression [13] as a second drive, it was the sexual instinct that was primary in his development of psychosexuality as a central concept in personality formation.

Psychosexuality and Personality

The way in which the experience of drive build-up and discharge in psychosexual zones influences the child's personality development [11, 20] is summarized as follows. The erogenous zone – oral, anal – or genital phallic – that is dominant at a particular point in time, and the degree to which these drives are gratified or frustrated by the primary caregiver, help to organize the child's internal and external experience. Rather than think of psychosexual stages as time-limited phenomena in which one stage ends and another begins, it is clinically useful to view psychosexual stages as interactive periods of conflict, adaptation, and development in which there is an unfolding and dynamic tension between stages.

Oral Stage

The oral stage is assumed generally to be dominant from birth through 18 months and centers around sensations associated with feeding, but oral tensions persist beyond this general time frame and continue to find expression in later childhood, adolescent, and adult personality. For example, conflicts associated with alcohol, eating, and physical contact might have their derivatives in the oral stage.

Anal Stage

The anal stage covers the toilet training period up until about age 3 and is focused on sensations associated with retention and expulsion, but adolescents and adults can remain preoccupied with and conflicted about body functions and control.

Phallic-Genital Stage and Oedipal Conflict

The phallic-genital stage, occurring up until about age 5 at which point the oedipal conflict (see below) is in ascension, organizes fantasies of "...penetrating or being penetrated..." [20, p. 331], but phallic-genital conflicts

continue to persist beyond this time frame in the form of locker-room anxiety, or exhibitionism, or conflicted competition.

Illustration

To illustrate the interactive nature of psychosexual stages, assume a child who experiences a relatively uncomplicated oral stage, but has significant frustrations during the anal stage in conjunction with toilet-training. During toilet training there are conflicts related to control and autonomy versus dependency. The child is willful, resistant to parental controls, and angry at being told what to do and when to do it. This same child then enters the phallic-genital stage with an angry disposition characterized by a willful readiness toward controlling and stubborn behaviors, rather than being able to easily comply, cooperate, and enjoy an activity. The former are more conflicted residuals of anal stage conflicts, whereas the latter suggest a less conflicted anal stage. In the classroom, this same child might be messy, controlling, and excessively challenging. This disposition might then carry over to the phallic-genital stage in the form of a "win-at-all-costs" attitude in which cooperative gamesmanship is minimized, and where defeat is experienced as a humiliating loss with acute self-loathing.

Psychosexuality, Structural Theory and Defenses

Freud's ideas about aggression [13] and his structural theory [3, 14] provide important insights into the way in which the constructs of id, ego, oedipal conflict, and superego development interface with psychosexuality and sexual identity [26]. Structural theory presents a tripartite (id-ego-superego) model of the mind in conflict. The unconscious id's primary motivation for tension-reduction operates on a pleasure principle. In Freud's structural theory, the id gradually comes under the control of the ego, which in Freud's theory, emerged toward the end of the oral stage and is concerned with the demands of reality. The ego acts as the part of the mind that represents the id to reality and partners with it, by disguising and channeling the id's sexual and aggressive impulses through various defense mechanisms. The ego's defense mechanisms, outlined by Freud [10], are also unconscious and redirect id impulses toward socially acceptable aims. In terms of defense mechanisms and their presumed psychosexual correlates, one might consider the child's hallucinating of the breast as a defense against periods of frustration during the oral stage; the use reaction-formation against anger and disgust (e.g., over compliance as a defense against anger) as a primary defense mechanism during the anal stage; and repression, undoing, identification, intellectualization as primary defenses during the genital stage. Brenner [4] argues that any psychological activity reflects a compromise between id, ego, and superego, and includes both adaptive and defensive aspects.

Psychosexuality, Ego Psychology, Psychosocial Stages, and Object Relations

Although Freud focused primarily on psychosexual conflict, other prominent psychoanalytic theorists elaborated upon psychosexual theory and emphasized the ego's adaptive capacities, [15], psychosocial conflicts [8], the role of developmentally appropriate separations from the primary caretaker's in the maturation of ego's autonomous functions [17]. An ego-psychological perspective holds that the ego is present from birth with its own autonomous abilities, such as perception, motility, language, anticipation, attention, memory, emotion, that are directed toward adaptation. This idea of the ego as adaptive is different from the idea of an ego that served mainly to direct the id's desires. Erikson's psychosocial theory emphasizes different stages of psychosocial conflict in conjunction with psychosexual stages and extends these conflicts throughout the lifespan. Mahler, Pine, and Bergman's separation-individuation model focuses on the way in which the child's ability to separate from the caretaker supports the development of different skills and independence, and contributes to the internalization of different perceptions of self in relation to other people.

These developmental challenges interact with psychosexuality; for example, the oral stage involves tension and sensation associated with the mouth, including feeding, and biting, but orality also involves being held, comforted, and nurtured, and has implications for the development of a sense of trust versus mistrust [8], and the child's emergent ability to use different skills and feel psychologically safe even when separated from the primary caretaker [17]. Similarly, the anal stage is associated with feelings of internal bodily pressure and control, but also has psychosocial implications for a child's sense of autonomy versus shame and self-doubt as well an object-relational component of predominately self control versus feeling controlled by a demanding caretaker.

Recall that the instinct is gratified by an outside source, and it is this source, typically a caretaker, to whom the child becomes attached interpersonally. Indeed, at each psychosexual stage, the prevailing attitude of parents, which might be timely, frustrating, or over stimulating, influences the type of conflict, but this does not necessarily translate into discrete character oral, anal, or phallic-genital types. Instead, a child who is needy, or greedy, or bossy, or overly

competitive has conflicts that have been influenced to different degrees by the predominance of conflict associated with the oral, anal, and phallic-genital stages. Frustration or excessive stimulation can fixate child character development and complicate maturation through the subsequent psychosexual stage(s). The clinician has to assess the degree to which each stage contributes to conflict, understand its adaptive and maladaptive nature, and appreciate the defenses that are constructed to protect the child from experiencing excessive anxiety and their impact on the parent-child relationship.

Oedipal Conflict and Superego

It is during the genital stage and as outcome to the oedipal conflict that the superego emerges. The superego [14] is the part of the mind that internalizes parental standards, imposes consequences, and, as Schafer [22] notes, also embodies internal ideals that serve as a source of pride and self-love. The oedipal conflict is central to Freud's psychosexual theory because of its intimate connection with psychosexuality and differential clinical implications for boys and girls. In Freud's theory, boys gradually separate from their mother, the initial object of identification and gratification, as genital sensations are differentiated from other feelings. Freud assumed an innate bisexuality, but as a biological evolutionist, viewed heterosexuality as the more desirable outcome of a positive oedipal resolution.

In the oedipal conflict, the boy competes with his father for his mother's affection, but must ultimately renounce these rivalrous feelings because of a fear of castration. Castration anxieties are present because the of the genital excitement associated with the boy's wish to possess his mother in conjunction with the guilt feelings that occur in connection with this wish – he experiences rivalry towards his father, who is bigger and evokes a danger (i.e., castration anxiety) in the boy that becomes centered unconsciously in the genital region. The boy then defensively identifies with his father, ". . .or a suitable substitute and idealizing him, thereby establishing the basic strictures of the superego; prohibitions of both killing and incest" [26, p. 339]. Thus, the drive intensity that colors the boy's identification with his father's values, or the values of a father-substitute, and his own superego, reflect, on the one hand, his aggressive and incestuous desires and, on the other hand, a fantasy of his father's retaliatory power. Likewise, for the oedipal girl, similar to the boy, there is also love for the mother, but disappointment in her lack of a phallus. She feels hostility and turns toward the father as a love object. Rivalry with her mother is renounced and positive identification is effected, under the throes of oedipal pressure. The boy's superego was presumed harsher than the girl's superego because it carries with it the threat of castration, though the superego of both boy and girl emerge under the force of repression of sexual and aggression drive energy directed toward the mother (girl) and father (boy).

Relevance to Childhood Development

Primary drive dispositions that emerge from a child's navigation of psychosexual stage conflicts do not operate in isolation; instead, they build upon each other and shape and the emergent personality in ways that interact with social and educational pressures. Early contributions of psychoanalysis to education discussed the therapeutic role of the school in helping to contain and sublimate drives into positive learning experiences [1, 19] and the way in which psychosexual theory informs learning styles [24]. Psychoanalytic theory also offers insight into school problems in such areas as boredom, impatience, obsessionality, and narcissistic vulnerability [16] as well as a range of learning problems [21]. With respect to intervention, there is an extensive literature on child psychodynamic psychotherapy [5] and psychoanalysis (e.g., [7]) that integrates insights from Freud's psychosexual model with a psychoanalytic treatment paradigm.

Criticisms

Freud's ideas have endured historically, but not without criticisms that touch upon core elements of his psychosexual theory. For example, Blum [2] discussed modifications in Freud's theory of female development. Fast [9] criticized Freud's conception of gender development. Chodorow [6] discussed the narrow nature of potential positive outcomes in Freud's oedipal conflict, and describes both heterosexuality and homosexuality as well as other sexual outcomes as reflecting compromise formations. Boesky [3, pp. 500–504] summarized conceptual challenges to structural theory. Seligman [23] discussed the role of new paradigms of infant observation and research that raise questions about the intrapsychic focus of Freud's psychosexual theory.

Psychosexuality

►Psychosexual Stages, of Freud

Psychosis

Synonyms

Delusional disorder; Depersonalization disorder; Thought disorder

Definition

A loss of contact with reality, usually including false ideas about what is taking place or who one is (delusions) and seeing or hearing things that aren't there (hallucinations).

Description

Psychosis is a term used to describe an array of signs and symptoms suggesting a form of thinking that breaks from reality. Psychosis is not pathognomonic (a sign or symptom specific to a disease or condition) of psychiatric illness. It is a nonspecific cluster of signs and symptoms that may occur in a broad array of medical, neurologic and surgical disorders, or as a consequence of pharmacologic treatment, substance abuse or the withdrawal of drugs and alcohol.

The predominant characteristics of this syndrome are used in determining its classification of either organic or functional mental disorders. Psychosis can be due to organic disorders (like thyroid abnormalities), which cause structural defects or physiologic dysfunction of the brain. There is substantial evidence that there are chemical abnormalities in the brains of people with this problem.

Psychosis is characterized by an adherence to fixed, false beliefs outside the normal range of a person's subculture, or by a hallucinatory experience or by what is known as thought disorder: thinking that does not follow any rational line. False beliefs that cause a person to suffer, produce conflict with others or render a person unable to comfortably adapt to the demands of life, are delusions if they are not relinquished when the person is presented with adequate evidence to the contrary.

A wide variety of central nervous system disease, from both external poisons and internal physiologic illness, can produce symptoms of psychosis. Possible causes may include alcohol and certain drugs; brain tumors, dementia, including Alzheimer's disease; epilepsy; manic depression; schizophrenia; and stroke. Symptoms may include abnormal displays of emotion; confusion; depression and suicidal thoughts; disorganized though and speech; extreme excitement (mania); false beliefs (delusions); loss of touch with reality; mistaken perceptions (illusions); seeing, hearing feeling, or perceiving things that are not there (hallucinations); and unfounded

fear and suspicion. Treatment depends on the cause of the psychosis. Care in a hospital is often needed to ensure the patient's safety. Antipsychotic drugs, which reduce hallucinations and delusions and improve thinking and behavior are helpful, whether the cause is a medial or psychiatric disorder. Treatment can be with neuroleptic medication such as atypical neuroleptics like risperidone (brand name: Risperdal) or older neuroleptics like haloperidol (brand name: Haldol). In cases that do not respond to medication, electroshock therapy (ECT) is sometimes used.

Psychosomatic

Maria-Eva Tsola, Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Synonyms

Psychogenic; Psychophysiological; Psychobiological; Somatopsychic; Somatoform; Somatization.

Definition

Psychological and behavioral factors that influence the onset, exacerbation, course and outcome of physical conditions.

Description

A psychosomatic disorder is a physical condition in which emotional factors play an important part in the causation or maintenance of symptoms. The somatic complaints cause significant distress and interfere with daily functioning [1]. The pain and distress associated with somatoform disorders is not under the individual's voluntary control, and responses take place at a subconscious level. Disabling physical symptoms can arise in the presence or absence of an identifiable etiology and in the presence or absence of other medical or psychiatric disorder [2]. In some cases, however, the functional impairment clearly symbolizes the precipitating stressor.

Somatoform Disorders is the term used in the Diagnostic and Statistical Manual of Mental Disorders [3] to describe a group of disorders characterized by the production of physical symptoms that cannot be fully explained by a neurological or generalized medical or organic condition. Six different subtypes of disorders are subsumed under the Somatoform Disorders class; these are Conversion Disorder; Somatization Disorder; Body Dysmorphic Disorder; Hypochondriasis; Pain Disorder, and Undifferentiated Somatoform Disorder. Somatoform disorders must be differentiated from other psychiatric conditions, including psychosis, malingering, anxiety disorder, Munchausen syndrome by proxy, and undiagnosed organic disease.

There is much evidence to suggest that recurrent, medically unexplained physical symptoms are common in the pediatric age group, and are often associated with other psychiatric symptoms [4, 5]. Recurrent unexplained physical symptoms in children and adolescents commonly fall into four symptom clusters: cardiovascular, gastrointestinal, pain and weakness, and ►pseudoneurological. Somatization can also be poly-symptomatic with diverse somatic complaints in one patient [5].

Several ways have been proposed for understanding psychosomatic symptoms in children. Stress, loss, modeling, prior psychosomatic and physical illness, family communication style, non-supportive family environments, and neuropsychologic abnormalities have all been proposed as potential factors contributing to the development of somatoform disorder.

Etiology

Psychodynamic Theory

Psychodynamic theory postulates that the unconscious operation of psychological defense mechanisms is responsible for medically unexplained pain. According to this model, repressed affect related to psychic conflict is transformed from the emotional realm to the physical one and symptoms are viewed as the direct symbolic expression of an underlying psychological conflict. Primary gain is obtained by keeping the conflict from consciousness and minimizing negative affect. The symptom can afford secondary gain by providing an escape from unwanted consequences or responsibilities as well as

symbolically representing an unconscious form of self-punishment for unacceptable feelings [5].

Learning theory

Classical and operant conditioning approaches highlight the significance of contingent reinforcement in the development of styles of pain behavior and somatization. Physical symptoms have been called a form of body language for children who have difficulty expressing emotions verbally [5]. Social consequences that are valued by the child, specifically increased parental attention, sympathy from others, and avoidance of responsibilities have been found to play an important role in symptom maintenance, predominantly in children with low self-esteem and low academic competence and in children in families who are uncomfortable discussing negative feelings and experience excessive parental pressure to perform and achieve [6, 7]. Systematic reinforcement of pain-related behaviors early on in the course of the illness appears to increase the probability that these behaviors will endure even following elimination of the original painful stimulus. In opposition, pain-related behaviors have been shown to diminish as they are no longer subject to systematic reinforcement [5].

Family Systems

Somatic preoccupation, recurrent pain complaints, alcohol abuse, and psychiatric disorders are factors within families that have been found to be associated with pain disorders. Social learning theory suggests that the pain symptoms are a result of 'modeling' or 'observational learning' within the family. In such cases, the child subconsciously models the behavior of an ill family member. In other instances, focus on the child's illness draws attention away from parental distress, spouse conflict, or other problems within the family. This can subsequently reinforce the child's illness behavior [5]. Symptoms are often precipitated by environmental stressors. Children undergoing stressful situations have been found to report higher rates of somatic symptoms than children who are not experiencing stressful circumstances. High parental anxiety and prior physical or sexual abuse have also been proposed as factors that intensify the probability of somatization disorders.

Types of somatoform disorders diagnosed in children (DSM-IV):

1. Conversion disorder is the most common type of somatoform disorder diagnosed in children. The disorder involves unexplained symptoms or deficits affecting voluntary motor or sensory function that are suggestive of a neurological or other general medical condition, but clinical and investigative findings do not conform to any known anatomic or physiologic disorder. The symptoms result in functional impairment; the symptoms are not feigned (as opposed to malingering); and the onset or exacerbation of symptoms follows a readily identifiable psychosocial stressor.
2. Somatization disorder is characterized by a combination of pain, gastrointestinal, sexual and pseudoneurological symptoms. This chronic, recurrent disorder with multiple complaints is often presented in a dramatic and exaggerated way. The diagnosis of somatization disorder is relatively rare in children and adolescents, partially due to the requirements for several years of complaints and disability and for one sexual symptom [2].
3. Body dysmorphic disorder criteria require excessive concern or preoccupation with a real or imagined defect in body appearance, not better accounted for by an eating disorder or other psychiatric disorder. The disorder causes significant distress or impairment in social, occupational, or other important areas of functioning.
4. Hypochondriasis is the preoccupation with the fear of having, or the idea that one has, a serious disease based on the person's misinterpretation of bodily symptoms or bodily functions.
5. Pain disorder is diagnosed when a patient's predominant complaint is of unexplained physical pain in one or more body parts that causes distress or impairment and for which "psychological factors are judged to have played a significant role in the onset, severity, exacerbation, or maintenance or the pain" [3]. Pain disorder has limited usefulness in children since there are few studies to distinguish it from Conversion disorder.
6. Undifferentiated somatoform disorder is characterized by unexplained physical complaints and distress or unexpected functional impairment lasting at least 6 months, that are below the threshold for a diagnosis of somatization disorder. When somatoform symptoms do not meet the criteria for any of the specific somatoform disorders, a somatoform disorder not otherwise specified is utilized.

Relevance to Childhood Development

Patterns of somatization are thought to develop throughout childhood and to remain fairly stable in adulthood [4], with females more likely to report symptoms. While many physical complaints correspond to transient

symptoms and a number of children make complete recoveries from somatoform disorders, for some children symptoms grow to be disabling and functionally impairing and result in increased health care utilization [5, 8]. Differences in outcomes are accounted for by a variety of factors. The relevant literature identifies variability in the severity of symptoms, nature of treatments completed, comorbid disorders and problems, length of follow-up, or any combination of these as factors that potentially influence the course and outcome of psychosomatic problems in children [2]. Additional factors that have been found to increase the risk for both the onset of new somatoform conditions and for a stable course over time include female gender, lower social class, the experience of substance use, anxiety and affective disorder, as well as the occurrence of traumatic sexual and physical threat events [8]. A number of long-term consequences in personality development have also been suggested. Individuals who had a somatoform disorder as children or adolescents may continue with identified traits such as being harm avoidant, catastrophizing, symptom sensitive, perfectionistic, high achieving, learning impaired, traumatized, socially impaired, dependent, or passive in coping style. In such an individual, difficulties attaining expectations might add to preexisting anxiety and somatic complaints [2]. An injury, illness, or chronic condition might reinforce symptom anxiety and result in subsequent avoidance of the difficult situation, which would prohibit mastery over it. Remediation of underlying deficits or problems might become increasingly difficult over time as such individuals become progressively more dependent.

Psychotherapist

R. Trent Codd III
Cognitive-Behavioral Therapy Center of WNC, Asheville, NC, USA

Synonyms

Child and family therapist; Therapists

Definition

A psychotherapist is a professional who treats psychological disorders and other emotional disturbances with psychotherapy.

Description

A psychotherapist may practice psychotherapy, counseling or both. Technical distinctions between psychotherapy and counseling exist. In contrast to counseling, psychotherapy focuses on personality change, is often lengthier in duration, and deals with more severe forms of psychopathology. Counseling, comparatively, tends to be briefer and deal with problems in living rather than psychological disturbance. Despite these technical distinctions, most practitioners and consumers tend to use these two terms interchangeably, and most psychotherapists practice both counseling and psychotherapy.

Types of Psychotherapists

Psychotherapists vary by academic discipline, governmental regulation (e.g., licensure type) and psychotherapeutic treatments employed.

Psychotherapists come from a variety of academic backgrounds including Psychiatry, Psychology, Social Work, Counselor Education, Rehabilitation Counseling

and Psychiatric Nursing. They possess a variety of degrees, although they typically possess a masters or doctorate degree, such as the following: MD, Ph.D., PsyD, DSW, EdD, MA, MEd, MAEd, MSW, and MS. They may also possess an EdS (i.e., Educational Specialist) degree which is typically defined as 30 graduate hours beyond a masters degree, but is not a doctoral degree. Governmental regulation varies and thus requirements to practice psychotherapy vary across jurisdictions. Although the requirements vary, typically, one must have completed a terminal degree in their field, have completed specified coursework, completed a post-degree or post-coursework supervised experience, completed an exam and attested to a code of ethics. Continuing education is typically required for licensure renewal.

Government entities may issue licenses, certifications or registrations to psychotherapists. Some of the various licensure types include Licensed Psychologist, Licensed Clinical Psychologist, Licensed Clinical Social Worker (LCSW), Licensed Professional Counselor (LPC), Licensed Mental Health Counselor (LMHC), and Licensed Marriage and Family Therapists (LMFT). In addition to regulating who may practice psychotherapy, some jurisdictions also restrict who may use the titles associated with these license types (e.g., only those duly licensed in a jurisdiction may call themselves Licensed Psychologists).

There are a number of psychotherapeutic treatments practiced by psychotherapists.

Psychotropic Medication

Synonyms

Psychodynamic medication; Psychoactive medication; Psychopharmaceutical medication

Definition

A class of medications that crosses the blood-brain barrier and interacts with the central nervous system (CNS) to affect the mind, emotions, and behavior.

Description

There are a number of psychotropic medications that can be prescribed for different disorders and symptoms. Psychotropic medications are also commonly used by individuals for recreational use because of their pleasurable effects on mood and consciousness. The main classes of psychotropic medications are:

Stimulants- Often prescribed to treat attention deficit/hyperactivity disorder (ADHD), narcolepsy, and short-term obesity. It works to speeds up the central nervous system, some examples are nicotine, cocaine, amphetamines, and caffeine.

Antidepressants- Prescribed to treat depression and anxiety, works to fix the imbalance of neurotransmitters such as serotonin, norepinephrine, and dopamine. The most popular antidepressant medications are selective serotonin reuptake inhibitors (SSRIs), including fluoxetine (Provac), citalopram (Celexa), sertraline (Zoloft), paroxetine (Paxil), and escitalopram (Lexapro).

Antipsychotics and atypical antipsychotics- Often prescribed to treat schizophrenia and bipolar disorder. Some of the most commonly prescribed "typical" antipsychotics are chlorpromazine (Thorazine), haloperidol (Haldol), perphenazine, and fluphenazine. "Atypical" antipsychotics are a newer antipsychotic medication that was created in the 1990s. Some examples are risperidone (Risperdal), olanzapine (Zyprexa), quetiapine (Seroquel), ziprasidone (Geodon), aripiprazole (Abilify), clozapine (Clorazil), and paliperidone (Invega).

Mood stabilizers- Commonly prescribed to treat bipolar disorder, they work on stabilizing mood. The most commonly used mood stabilizers are lithium and anticonvulsant medications, such as divalproex sodium (Depakote).

Benzodiazepines- An anti-anxiety medication that is more fast acting than antidepressants. The most commonly used are clonazepam (Klonopin), lorazepam (Ativan), and alprazolam (Xanax).

Beta-blockers- These medications are also used to treat anxiety; however, they aim to block some of the physical symptoms of anxiety, such as sweating and trembling. Some examples are acebutolol (Sectral), atenolol (Tenormin), bisoprolol (Zebeta), carvedilol (Coreg), metoprolol (Lopressor, Toprol XL), nadolol (Corgard), nebivolol (Bystolic), and propranolol (Inderal LA).

Pubertal Development

►Puberty

Puberty

Jill A. Anderson
University of Texas Health Science Center - Houston, Houston, TX, USA

Synonyms

Pubertal development

Definition

Puberty is the developmental period during which a person becomes capable of sexual reproduction.

Description

Puberty (derived from the Latin "to grow hairy") describes the period of rapid physical *maturation* that takes place primarily during *adolescence*. It marks the beginning of sexual maturation and involves a series of hormonal and bodily changes that lead to the achievement of *fertility* and includes the development of *secondary sex characteristics*, such as breast development or hair growth.

Relevance to Childhood Development

The onset of puberty varies among individual adolescents. Puberty usually begins in girls between the ages of 10 and 14 years, and between the ages of 12 and 16 for boys. In most girls, the first sign of puberty is the beginning of breast development, followed by growth of pubic and armpit hair. The onset of *menstruation (menarche)* is typically the last indication of pubertal development and signals fertility. For boys, the first sign of puberty is an increase in the size of the testicles, followed by an increase in the size of the penis, and an increase in pubic and armpit hair. Fertility is achieved in boys near the onset of puberty with a surge of testosterone that triggers the production of sperm (*spermarche*). The sequence of changes that occur during puberty have been classified by sexual maturity rating (SMR) and are referred to as *Tanner Stages*. Tanner stages are determined by the development of secondary sex characteristics and help classify puberty development from Stage 1 (prepubertal) to stage 5 (mature adult type). Other physical changes that accompany puberty include the growth spurt, bone growth and mineralization, changes in the respiratory and circulatory systems, and changes in body fat and muscle distribution. Because puberty occurs during adolescence, it is often associated with various other cognitive, social, and emotional developments that occur during the same period.

Punisher

►Aversive Stimulus

Punishment

Jennifer M. Alexander, Maria G. Valdovinos
Drake University, Des Moines, IA, USA

Synonyms

Discipline; Timeouts

Definition

Punishment is a behavioral process in which a response produces the presentation of an aversive consequence or termination of an desirable stimulus thereby decreasing the future probability occurrence of the response under similar circumstances [1, 3]. This process is most effective when the punisher (i.e., aversive stimulus) is presented contingent upon the response, is presented immediately following the response, is used sparingly, and is greater in magnitude than the stimulus otherwise produced by the response [3]. As with reinforcement, there are two forms of punishment: positive and negative punishment. Positive punishment is a process by which a stimulus is added to the environment contingent on a response which subsequently decreases the future probability of the response. For example, if a child is barefoot at the beach and walks onto hot sand, the pain delivered from the hot sand decreases the likelihood that the child will walk barefoot on sand again in the future. Negative punishment is a process by which a stimulus is removed from the environment contingent on a response which subsequently then decreases the future probability of the response. A common example of negative punishment is time out. In a time out procedure, the child is removed from the desirable activity/location/person contingent on the behavior one wishes to reduce. For example, a parent might place their child in time out when that child engages in aggression with a playmate. The challenge with negative punishment procedures is maintaining an environment that is in sharp contrast to the time out situation (i.e., must have reinforcing time in). Punishment, regardless of it being positive or negative, functions to decrease the probability of a response, be it a desirable or undesirable behavior. Punishment is a quick way to reduce undesirable behavior, but it is often considered to be a procedure of last resort for affecting behavior change as it is associated with side effects [2, 4]. Since punishment procedures rely on the presentation of aversive stimuli or removal of desirable stimuli, an individual develop other maladaptive behaviors (e.g., aggression) to escape or counter the controlling contingencies or an individual may refrain from engaging in the response only in the presence of the punisher or when the punishment contingencies are in effect. In other words, behaviors under the control of punishment are likely to reoccur when the punisher is removed from the environment [5]. Nonetheless, punishment is useful for eliminating dangerous behaviors as immediately as possible.

Purdue Pegboard Dexterity Test

Tracey McLellan
University of Canterbury, Christchurch, New Zealand

Definition

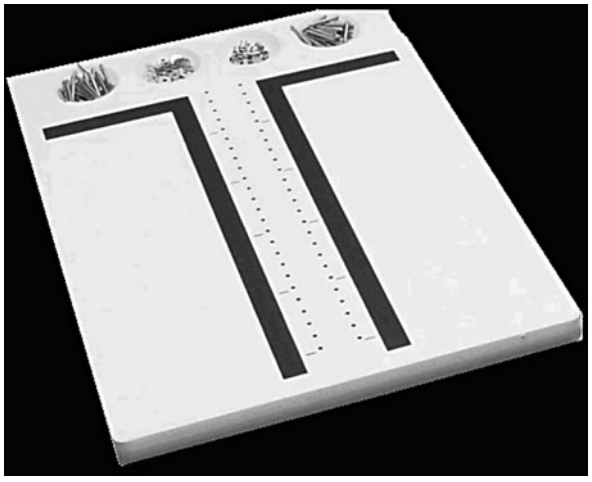
The Purdue Pegboard is a standardized test that measures finger and hand dexterity [4].

Description

The Purdue Pegboard was developed by Joseph Tiffin, Ph.D., in 1948. The test has been used most extensively in personnel selection for jobs that require fine and gross motor dexterity. The test measures the gross motor dexterity of hands, fingers and arms, as well as the fine motor dexterity of fingertips. In addition to being employed in personnel selection, the Purdue Pegboard test has also been used in neuropsychological assessments as it has been found to be sensitive to the presence of brain damage.

The Purdue Pegboard is a board featuring two columns of 25 holes each. At the top of the board are four cups. The pins (pegs) are kept in the outer left and right cups and the collars and washers are kept in the middle cups (see Fig. 1). There are four subtests of the Purdue Pegboard. In the first three subtests, the participant has 30 s to place as many pins as possible in the holes using first their dominant hand, then non-dominant hand, and finally both hands. The participant is required to start at the top of the board and use the right column when testing the right hand, the left column when testing the left hand and both columns when testing both hands. In the forth subtest, the participant has 1 min to construct as many assemblies as possible. Each assembly consists of a pin, a washer, a collar and another washer. The assemblies are constructed using alternative movements of the right and left hands. For example, the participant would pick up a pin with the right hand and then a washer with the left and so on [5].

A demonstration and practice period is provided at the beginning of each subtest. The Purdue Pegboard is scored by calculating the number of pins placed for each hand separately and the number of pairs placed when using both hands. The assembly score is calculated by the number of parts assembled. Normative data are available for males and females ranging from 5 years to 90 years old.



Purdue Pegboard Dexterity Test. Fig. 1 The Purdue Pegboard 32020 (Picture adapted from Lafayette Instrument Company).

Relevance to Childhood Development

Motor skills and co-ordination are basic processing skills that are important to the healthy development of children. In addition, these skills are influential in the development of higher-level cognitive abilities and academic achievement. The Purdue Pegboard is often used to assess fine motor skills and hand-eye coordination in children with a variety of disorders and disease that manifest in childhood and that preferentially effect the development or maintenance of motor skills and co-ordination. For example, Developmental Coordination Disorder (DCD) is characterized by impairment in the development of motor coordination. This impairment interferes with daily activities and often also academic achievements. DCD effects 5–6% of school age children [3]. The Purdue Pegboard assessment can be useful in establishing the severity of the impairment as well as the efficacy of interventions. Similarly, the Purdue Pegboard assessment of the adverse effects of therapy on children with acute lymphocytic leukemia revealed significant slowing of fine motor speed and dexterity [1]. The identification of these side effects of therapy helps researchers to develop interventions that limit the long-term effects of therapy. The Purdue Pegboard can also be employed as part of a neuropsychological test battery to assess the recovery of a child who has experienced traumatic brain injury [2]. Specifically, it is a useful way to establish which skills require more intense remediation.

Synonyms

Barf; Cleaning; Disposal; Elimination; Evacuation; Ejection; Excretion; Expulsion; Heave; Hurl; Pass; Purification; Puke; Regurgitate; Spew; Throw up; Upchuck; Vomit

Definition

Purging is the removal or elimination of impurities or other elements.

Description

The removal of something unwanted or perceived to be impure most commonly associated with the evacuation from the bowels. Cassell and Gleaves [2] characterized the term as the, "forced expulsion of ingested foods and a purification rite as a means to gain self-control by bulimics" (p. 256). These authors further posited that individuals engage in this behavior to regain their sense of self-discipline and to feel as though they are "good persons who are fresh and clean" ([2], p. 256). This process of cleansing and removing impurities is most often associated with eating disorders such as Anorexia Nervosa (AN) and Bulimia Nervosa (BN) as a method of weight control and calorie reduction. However, purging is also regarded as a sign or symptom of Binge eating disorder (BED), and as current research has progressed is also linked to Purging disorder (PD).

The evacuation process is completed by utilizing a variety of methods such as: self-induced vomiting, fasting, over-exercising, or the misuse of enemas, diuretics, or laxatives to expel food. People do also use various objects to induce the purging process for example, the smooth end of a toothbrush or one's finger. Self-induced vomiting is one of the most frequently used methods of purging from a clinical standpoint. According to the *Diagnostic and Statistical Manual of Mental Disorders, 4th Ed., Text Revision* (*DSM-IV-TR* [1]) if an individual meets diagnostic criteria for Anorexia Nervosa (AN), but they also engage in binge eating (e.g., consumption of an excessive amount of calories, some known to digest up to 5,000 calories in a short period of time) and purging behaviors then the diagnosis of Anorexia Nervosa binge eating-purging (ANBP) type is given. Additionally, if an individual meets clinical criteria for Bulimia Nervosa (BN) the disorder will be broken down into either nonpurging type (BN-NP) or purging type (BN-P).

Diagnosis is made when an individual admits to using one or multiple methods listed as a means of purification along with meeting diagnostic criteria as that set by the *DSM-IV-TR* [1] for an eating disorder.

Participating in these behaviors causes serious health concerns and risks such as myocardial infarction (e.g., heart attack) due to electrolyte imbalance, esophageal tears, absence of menstrual cycle (e.g., amenorrhea), dehydration, tooth decay and removal of tooth enamel from repeated exposure to stomach acid, chronic bowel problems, damage to skin and nails, subconjunctival hemorrhage (e.g., broken blood vessels), and at the worst case death. Emotional and social consequences usually follow this type of behavior such as depression, erratic mood swings, anxiety, shame, guilt, suicidal ideation, impairment in psychosocial functioning, and social withdrawal, which in cases can manifest into a full blown psychiatric disorder called, Purging disorder (PD) a newly rediscovered eating disorder [5]. Some may find it difficult to differentiate Anorexia Nervosa (AN), Bulimia Nervosa (BN), or Binge Eating Disorder (BED) with a diagnosis of Purging disorder (PD). Although the idea of "Purging disorder" is something that has been around for over 20 years, Keel [4] recently uncovered more information to support the clinical existence of this disorder. Keel [4] further defined that for one to be diagnosed with Purging disorder they must exhibit the following:

- (a)regularly use self-induced vomiting, laxatives, or diuretics, (b) individuals are not significantly underweight with a minimum body mass index (BMI) above 18.5 kg/m^2, (c) individuals do not have large out of control binge-eating episodes, and (d) individuals have significant body image disturbances. (pp. 1–2)

Continued research on the clinical significance of the diagnosis of Purging disorder (PD) looking at the causes, signs and symptoms, diagnostic criteria set by the *DSM-IV-TR* [1] Diagnostic and Statistical Manual of Mental Disorders, and treatment options is something that is greatly needed for the future. In concluding, purging is the process to get rid of or eliminate, often recognized with clinical disorders centered around eating disorders.

Relevance to Childhood Development

Children as young as four years of age are struggling with body image concerns or wish to be on a diet to lose weight to avoid being labeled fat. With the advent of the world-wide best selling doll, Barbie, on March 9, 1959, 90% of all

girls ages three to ten own at least one Barbie doll with American girls owning an average of 12 Barbie dolls; it is no wonder that she brings in revenue over $1.5 billion dollars annually [6]. For especially young girls Barbie is a "cultural icon of female beauty" and what young girls strive to mimic when it comes to body image, appearance, and body weight which can have detrimental effects on one's self-esteem and self-concept ([3], p. 283). Dittmar, Halliwell and Ive [3] assessed the exposure to images of Barbie doll, Emme doll ([7]; e.g., mirrors the body size of the average U.S. woman), and neutral (e.g., control) images adopted from picture books with five to eight year old girls. [3] found that young girls from the age of five and a half to six and a half experienced a dramatic decrease in body esteem and decreased satisfaction with their current body size making them desire a thinner body like the "thin ideal" Barbie portrays. These researchers also stated that the impact of the images of Barbie was even more pronounced and evident on body esteem dissatisfaction and body image dissatisfaction among those girls age six and a half to seven and a half indicating an even greater risk to the development of eating disorders [3]. The constant exposure of these images to young girls and the strong emphasis society places on these unrealistic thin ideals of what it means to be beautiful may increase the chance that young girls adopt unhealthy strategies such as purging to obtain thinner bodies

Putamen

Chad A. Noggle
SIU School of Medicine, Springfield, IL, USA

Definition

The Putamen is a large nucleus of the Basal Ganglia which, in combination with the other nuclei and structures of this area, participates in the control of higher-order movement.

Description

The Putamen is a large nucleus of the forebrain that with the caudate nucleus forms the Striatum [1]. However, the Putamen is also conceptualized as one portion of the Lentiform Nucleus, in combination with the Globus Pallidus [2]. The Putamen is linked with both groupings as it serves to bridge the caudate nucleus and Globus Pallidus and thus is directly connected with both, while caudate nucleus and Globus Pallidus are only connected to one another by way of the Putamen. All three structures (i.e., Putamen, Caudate Nucleus, and Globus Pallidus) represent parts of the Basal Ganglia. The Basal Ganglia share complex interconnections with other structures and regions of the motor system allowing this grouping to participate in the control of higher-order movement, particularly in starting or initiating movement [4]. Due to the close proximity of these structures it is difficult to differentiate the functional roles each play. Rather, it is their

interconnections that together correspond with their influence on the motor systems. One such pathway is the Striato-Pallido-Thalamic loop, in which the Putamen, as part of the Stiatum, with the Caudate Nucleus, represents the site at which information is received. At this point, information is received from multiple sources of the Neocortex, including the motor system, sensory and higher integrative areas of the cortex, the language center of Broca's and Wernicke's areas, the thalamic nuclei, and the Substantia Nigra [4]. This information is, in turn, projected to aspects of the Thalamus by way of the Globus Pallidus and from there to the motor areas of the cortex [3]. In addition to these links, the Basal Ganglia present with reciprocal connections with the Midbrain, especially the Substantia Nigra, which is a nuclei of the Tegmentum [3]. This connection is essential to as the Substantia Nigra represents a site of origin of the vast majority of Dopamine-containing neurons within the system which demonstrate an excitatory impact thus helping initiate movement [1].

Pygmalion Effect

KC Collins
Nova Southeastern University, Davie, FL, USA

Synonyms

Experimenter bias; Halo effect; Rosenthal effect; Self-fulfilling prophecy; Teacher-expectancy effect

Definition

The Pygmalion effect refers to situations where teacher expectancies of student performance become self-fulfilling prophecies; students perform better or worse than other students based on the way their teacher expects them to perform.

Description

This effect is named after George Bernard Shaw's play, *Pygmalion* (1913), where a phonetics professor is successful in making a bet that he can teach a poor flower girl to act like an upper-class lady. The term Pygmalion originated in Greek legend with Pygmalion, the king of Cyprus, who was a sculptor. Pygmalion fell in love with a beautiful statue of his own creation, which subsequently came to life.

In psychology, the Pygmalion effect, as proposed by Robert Rosenthal and Lenore Jacobson (1968), applies the ideas of Merton's self-fulfilling prophecy (2) to education (1). Rosenthal and Jacobson's landmark Oak School experiment (1968) examined the influence of teacher's expectations on student performance. A student who is expected to perform well, should in fact, perform better than when not expected to perform as well. This self-fulfilling prophecy is referred to as the Pygmalion effect. The Pygmalion effect is a relevant consideration when examining the social, psychological and developmental dynamics between teachers and students in the classroom.

Q

Q-Sort Method Attachment

Shanna M. Williams, Victoria Talwar
McGill University, Montreal, QC, Canada

Definition

The Q-Sort is a measure of attachment used to assess children and toddlers (12–48 months of age).

Description

According to Bowlby's [2] classic theory of attachment an infant's early interactions and experiences with primary caregivers is the basis for the formation of their attachment to parents. Based upon this initial relationship infants come to internalize their attachment to their caregiver. This process was defined by Bowlby [2] as an infant's *internal working model*. In addition to Bowlby's theory several researchers have expanded upon his initial ideas [1, 3, 4].

Through empirical research several different methods of measuring attachment have been developed (e.g., strange situation). One such method is the Q-sort attachment measure. The Q-Sort attachment measure was first introduced through the collective works of Waters and Deane [6]. Since first being developed the Q-sort has been reviewed several times. Based on the initial development of the tool, the Q-Sort attachment measure is composed of numerous cards (75, 90, or 100). A single observer when administering the Q-sort uses these cards. In order to provide accurate ratings these observers require training to administer the Q-sort. A trained observer uses the cards to rate a child or toddler's behaviors after several hours of surveillance. Surveillance can be conducted within varying contexts. Upon each card behaviors are described, which are potentially characteristic of the children being observed. Overall, it is recommended that the child be observed for an average of 3 hours in order to produce accurate rankings. It is recommended that observers collect data over several different time periods. Once the observer has completed their surveillance of the subject the cards are ranked along a continuum. Each item is sorted into one or more piles according to how characteristic it is of the child. Thus, cards are ranked as either very descriptive of the child or not descriptive of the child. Once all of the cards have been ranked the final rankings are compared to the typical rankings of a securely attached child. Rankings can range from perfectly positive score (1.0) to perfectly negative score (−1.0). A perfectly positive correlation indicates that the child is securely attached. In contrast, a perfectly negative correlation indicates that the child is insecurely attached. Scoring does not allow for distinctions to be made among subtypes of insecure children.

Van Ijzendoorn, Vereijken, Bakermans-Kranenburg and Riksen-Walraven [5] performed a meta-analysis of 139 studies on the Q-sort attachment measure. The researchers concluded that measurement of attachment produced through the Q-sort method did converge with attachment measures obtained through the strange situation method. In addition, compared to other attachment measures the Q-sort method allows researchers to measure attachment within varying settings. Thus, permitting researchers with the flexibility to measure attachment outside of the laboratory setting. Since its initial introduction the Q-sort method has been revised several times. Based upon empirical research no differences in effect sizes have been found, to date. Furthermore, researchers have found support for the use of the Q-sort within cross-cultural contexts.

Quetiapine

Synonyms

Ketipinor; Quetiapine fumarate; Seroquel; Seroquel XR

Definition

An antipsychotic drug prescribed for the treatment of schizophrenia, bipolar disorder and used off-label for a variety of other purposes, including insomnia and anxiety disorders.

Description

Quetiapine (pronounced /kwɪˈtaɪ.əpiːn/ *kwi-TYE-ə-peen*) is an atypical or second generation antipsychotic drug marketed by AstraZeneca as Seroquel or SeroquelXR and by Orion Pharma as Ketipinor. Annual sales are approximately $4.7 billion worldwide, and $2.9 billion in the United States. Quetiapine is indicated for the treatment of schizophrenia and as either monotherapy or adjunct therapy for depressive episodes associated with bipolar disorder and acute manic episodes associated bipolar I disorder.

Frequent side effects include headache, agitation, dizziness, drowsiness, weight gain, stomach upset and hyperglycemia. Quetiapine can cause orthostatic hypotension (a drop in blood pressure upon standing that can lead to dizziness or fainting) especially during the first 3-5 day period of treatment, when it is restarted after temporary discontinuation, and after an increase in the dose. The most common side effect of quetiapine is sedation and care should be exercised in any activity requiring mental alertness such as operating a motor vehicle or hazardous machinery. Less common side effects include seizures and hypothyroidism. As with other antipsychotics, long-term use of quetiapine may lead to irreversible tardive dyskinesia, a neurologic disease that consists of involuntary movements of the jaw, lips and tongue. Preexisting conditions or history of liver or kidney disease; heart disease, high blood pressure, heart rhythm problems; heart attack or stroke; low white blood cell (WBC) counts; thyroid disorder; seizures or epilepsy; high cholesterol or triglycerides; diabetes; or trouble swallowing may require dose adjustment or special tests to safely take quetiapine.

Race

Michelle Cox[1], Kenneth Foster[2]
[1]Azusa Pacific University, Azusa, CA, USA
[2]Texas Woman's University, Denton, TX, USA

Synonyms

Ethnicity; Racial identity

Definition

A biological inbreeding, geographically isolated, population that differs in physical traits from other members of the species. Race is a historical categorization system used to make ostensible distinctions among populations or groups, based on a set of physical characteristics. Typically, these characteristics include skin tone or color, hair texture, and facial (cranial) features.

Description

In 1998, the American Anthropology Association published an official statement, noting that "human populations are not unambiguous, clearly demarcated, biologically distinct groups" [1]. Race is viewed by this discipline as a variable concept that is influenced by culture, history, politics and science. Some would even argue that while this taxonomy is useless for humans, it may be a valid and useful model for other species.

The sociological perspective on race is one that focuses on groups who share certain characteristics with their members and the degree to which they interact, i.e., share norms and roles and share a common identity. Despite the fact that many psychologists continue to embrace an essentialist approach and rely on race as a biological fact, the fact remains that it is a mutable variable.

While the term "race" is typically attributed to the period of European imperialism (seventeenth to eighteenth century) and colonization, there exists ample historical evidence that long before this period scientists, philosophers, and rulers were interested in understanding the significance of physical similarity and difference. Ancient Egypt, for example, is credited with the development of some of the original taxonomic concepts that have developed over time, including such categories as "Egyptians," "Asiatics," "Libyans," and "Nubians." Although these categories were based around physical features, they were typically assumed as indicative of sociocultural affiliations and used largely for purposes of making tribal and other distinctions.

Johann Friedrich Blumenbach (1752–1840) is considered the first to systematically study skull features as a method of determining categorical differences among a number of species, including humans. Although he viewed race as about minute variations, Blumenbach's *The Natural Varieties of Mankind* introduced a classification of five varieties of man, including the more commonly used categories of Caucasoid, Mongoloid, and Negroid (his text also identified the categories American Indian and Malayan). Race has been used as a means for demonstrating ostensibly how one race might be innately superior in intelligence (Caucasoid), while another may have greater physical prowess or abilities (Negroid). The European quest for global expansion, including the transatlantic slave trade, provided a major rationale for instituting a categorization system.

Relevance to Childhood Development

Identity is well grounded in the developmental changes that occur from childhood to old age. Identity formation begins early in life, but it continues to develop throughout the lifespan. Racial identity helps shape the attitudes of children and adolescents as well as attitudes about individuals of other racial groups. Racial identity, like any social identity, is a negotiated understanding of who one is and, reciprocally, a negotiated understanding of who others believe one to be. It can be said that while social identity is the generic, racial identity is a case in point, framed by its own unique historical influences which have impacted the ways in which this concept has been viewed and systematically studied.

Race and the role of child development have long been an issue of contention and concern. Developmental outcomes are often moderated by race and other sociocultural factors. In the U.S., for example, the interaction of race and poverty provide for predictably negative outcomes in many cases.

Radical Behaviorism

Josh Pritchard[1], Ivy Chong[2]
[1]University of Nevada, Reno, NV, USA
[2]Florida Institute of Technology, Melbourne, FL, USA

Synonyms

Behavior analysis; Functional behavior analysis; Skinner's behaviorism

Definition

Radical Behaviorism is a philosophy of psychology concerned with a natural scientific approach to the study of behavior. It differs from other types of behaviorism in that it includes as its subject matter both private and public events.

Description

Behaviorism was first mentioned in a lecture in 1908 by the French psychologist H. Peiron. It was further espoused in J. B. Watson's 1913 paper, "Psychology as the behaviorist views it" [3]. Watson insisted that behavior was a worthy subject matter in its own right rather than being seen as epiphenomena of mental events. His behaviorism has been called "methodological behaviorism" and rejected the observation of events that were not available to third-persons, removing thoughts and feelings from the scientific study of behavior.

In his 1938 book, *Science of Human Behavior*, B. F. Skinner expanded the field of study to include these private events, insisting that they were behavior much the same as walking and talking. Skinner, and thus *radical behaviorism*, differed from methodological behaviorism in that radical behaviorism does not rely on third-party objectivity for the inclusion of subject matter. This view states that private behavior is subject to the same influences, principles, and laws as public behavior.

Radical behaviorism poses that while physiology may be of assistance in studying the subject matter of psychology (behavior), it cannot change psychology. This is an important distinction when considering developmental psychology.

Relevance to Childhood Development

Contemporary developmental psychology can be described as a collection of multiple mini-theories without a single overarching unified theory. This is due, in part, to the structural approach to behavior that is taken by many developmental psychologists. One criticism of this approach is that the myriad of mini-theories are focusing on the outcomes of development as their subject matter, often to the exclusion of the study of how the processes occur which lead to these outcomes. While the field of developmental psychology has generated vast amounts of research, there is little unity in the orientation, leading to varying and sometimes conflicting interpretations of the same research results.

Radical behaviorism is the philosophy from which the science of behavior analysis is developed. This offers a single unified natural scientific theory of behavior from which to approach and interpret the results of research.

Behavior analysis posits that the variables determining behavior are found in the environment rather than in the child. By focusing on function rather than structure of behavior, behavior analysts begin to look at the processes responsible for outcomes of development rather than the outcomes themselves.

The behavior analysis of child development began by Sid Bijou and Don Baer in the 1960s in a model that adopted the radical behaviorism and J. R. Kantor's interbehavioral approach. Like many contemporary theories of psychological development, this model had stages (three), however they were neither essential nor explanatory, and most importantly, they were deemed socially determined. As the behavior analytic research into childhood development continued, behavior analysts tended to focus on the behaviors that preceded changes in stages. This was observed by large differences in the child's ability to interact with the environment due to a seemingly small behavior change, and was named a ▶behavioral cusp [1]. At this point, most behavior analysts tended to focus their study on behavioral cusps rather than stages, once again emphasizing the importance of the process leading to outcomes, rather than the outcomes themselves.

Gary Novak and Martha Pelaez took the behavior analytic developmental model and updated it by including a dynamic systems model that resulted in the behavioral systems approach to child development, which provides a comprehensive approach that scales four levels of systems from the basic processes to the societal and cultural levels.

Raphe Nuclei

Chad A. Noggle
SIU School of Medicine, Springfield, IL, USA

Synonyms

Nuclei of the Raphe

Definition

The raphe nuclei represent a cluster of neurons in the posterior regions of the brainstem that is the primary site of serotonin production.

Description

The raphe nuclei is a cluster of neurons that are housed in the pons and medulla within the hindbrain [4]. Functionally, it is the primary site of serotonin production [5]. Serotonin is an essential neurotransmitter of the central nervous system that is found throughout brain regions that play a vital role in regulating aspects of eating, sleep and emotional behavior [2]. Projections of the raphe nuclei may be differentiated based on whether the serotonergic pathway originates from either the rostral or caudal end. The rostral raphe nuclei of the midbrain and rostral pons project to the entire forebrain, including the cortex (e.g., limbic system), thalamus, and basal ganglia [1]. These projections are those that have been most linked with the manifestation of various psychiatric manifestations. Specifically, increased serotonin activity has been related to obsessive-compulsive disorders, tics, and schizophrenia whereas decreased serotonin activity is

linked to depression [3]. Aside from these anterior projections, the caudal raphe nuclei of the caudal pons and medulla project to the cerebellum, medulla, and spinal cord [1]. These projections play a role in pain modulation as well as in aspects of wakefulness [1, 5].

Rapid Automized Naming

Anna Mazur-Mosiewicz, Andrew S. Davis
Ball State University, Muncie, IN, USA

Synonyms

Automized naming; RAN; Rapid naming; Speed naming

Definition

Rapid Automized Naming (RAN) is a cognitive construct referring to the processing speed and executive control in language access, and is related to lexical access and automaticity of verbal encoding and producing verbal information [7, 8]. The RAN function is impacted by naming ability, basic expressive language, processing speed, working memory, association memory, and long-term verbal memory [8].

Description

RAN accounts for sizable variance in reading when phonological awareness and overall level of intelligence are partialled out and is considered an excellent predictor of early reading achievement [2, 9]. RAN has been shown to make a consistent contribution to reading beyond phonological awareness, orthographic processing, and memory [1, 10, 13]. Impairment of the RAN functions is considered one of primary causes of reading difficulties in children [13]. This is supported by studies of reading, which provide evidence that individuals with poor reading skills can be separated into three subgroups, including poor readers with phonological awareness deficit, poor readers with RAN deficit, and poor readers with both deficits. This suggests that reading difficulties are related to the RAN functions and RAN is independent of phonological awareness [13].

RAN is typically measured through speeded naming tasks, which are a common element of neuropsychological and/or psychoeducational tests when language is investigated. RAN assessment typically requires participants to rapidly name the size, shape, and/or color of presented stimuli. Typically, scores on the test are based on the total number of characteristics named correctly for each figure and the time taken to complete the task. Difficulties in RAN performance tasks are related to a number of factors, including poor phonological processing skills or recall ability, impulsivity, and slow processing speed [2, 3].

Relevance to Childhood Development

Research has established RAN is a valid and reliable predictor of reading success in children [4–6, 12]. Types of RAN tasks tend to have different predictive strength; presymbolic types of RAN tasks (colors and objects) outperform symbolic RAN tests (numbers and letters) in the strength of their relationship to reading skills and vocabulary across grades [11]. Yet, symbolic RAN tends to be a key factor in distinguishing between good and poor readers among children with attention deficit hyperactivity disorder (ADHD) [3].

According to a number of studies, it appears that various RAN performances may be able to distinguish between different clinical groups of children, including reading disabilities (RD), ADHD, and combined RD and ADHD. Additionally, specific RAN tasks, including numbers and letters RAN, are better concurrent discriminators, whereas other RAN tasks, such as the color and objects RAN, and better predictors of reading impairments [3]. Poor RAN performance suggests difficulties related to automaticity of naming, processing speed, or naming ability. Children who display difficulties in the area of speed and automaticity of verbal encoding tend to struggle with decoding of the textual information, and their reading is usually laborious and slow. However, they tend to have normal reading and language comprehension skills [13].

RAN performance may be indicative of connection between spoken and written word. Therefore, reduced RAN ability may be an indicator of problems with accessing correct language labels, and related to deficient retrieval of sound-symbol associations, which may be further related to *dysnomia* [8]. Finally, RAN largely depends on attention and motor skills, and children with attention and/or motor problems are likely to perform poorly on the RAN tasks [8].

Rapid Eye Movement Sleep

Kim Guion
Sleep Disorders Clinic, Children's Hospital, Birmingham, AL, USA

Synonyms

Dream sleep; Dream state; REM; REM Sleep; Stage 5 sleep

Definition

Rapid eye movement sleep is one of five stages of sleep and is characterized by dipolar saccadic eye movements, increased central nervous system activity, muscle paralysis (except for breathing and erectile function), and coincides with dreaming.

Description

REM sleep was first described and discovered as a unique sleep state in 1953 by Aserinsky and Kleitman [1]. This relatively recent discovery lead to a reconceptualization of sleep, which was previously thought to be a state of passivity. In contrast, EEG recordings and reports of dreaming during the newly identified REM period indicated a highly active brain state, similar to that of a waking state [1].

Characteristics: REM typically occurs 70–90 min after sleep onset. One sleep cycle, achieving each of the five sleep stages, lasts approximately 90–110 min. Length of REM sleep during each sleep cycle increases as the night progresses. Initial REM periods average approximately 10 min, while REM sleep in the early morning hours may last up to 60 min [4, 6].

REM sleep is initiated by signals in the pons area at the base of the brain. Neural signals then pass through the thalamus and then the cerebral cortex, the outer layer of the brain responsible for complex thinking and reasoning. The pons also initiates motor paralysis by limiting activation to the spinal chord. When this aspect of REM is disrupted, people may demonstrate sleep behavior disorders [4].

REM sleep is often characterized by increased central nervous system (CNS) activation, oxygen consumption in the brain, and increased neural blood flow [4]. Other physiological characteristics include decreased REM sleep propensity at lowered body temperature, decreased muscle tone, and increased heart rate variability, although average heart rate tends to be diminished (by up to 8%) compared with humans' restful waking state [2, 6]. Temperature regulation may also be more difficult during REM, resulting in reports of feeling too hot or too cold when woken during this stage [2–4].

Measurement: REM may be visually identified, though not with clinically sufficient accuracy, by the saccadic eye movements characteristic of this sleep phase. Sophisticated measures of sleep phase include a combination of EEG data, muscle tone, eye movement measurements, breathing and heart rate as measured by electrodes placed on the head, face, legs, fingers, and breathing monitors. Specifically, decreased chin tone, heart rate, and breathing rate are noted during REM in most people. Breathing rate

during REM is also typically more erratic, and oxygen consumption increases [7].

Importance: The importance of REM sleep in maintaining normal daytime functioning is critical, as inadequate amounts of REM sleep or disrupted REM sleep may result in excessive daytime sleepiness. Sleep deprivation studies have shown that consistent REM sleep deprivation may result in experiencing hallucinations, excessive irritability, and diminished reasoning abilities [3]. Diminished REM sleep may also result in decreased immune functioning [7]. REM deprivation studies with rats and other mammals have also shown that abrupt and severe REM deprivation leads to an increased propensity to fall into REM, and eventual organic functions failure and death [5]. Less severe studies with humans have shown fewer ill effects of REM deprivation, however the inclination to fall into REM sleep more rapidly and for longer periods also occurs in humans [2].

Research indicates that REM sleep plays a key role in information processing and procedural memory functioning (compared with declarative) in particular. Increased CNS activation is considered an associated component of these memory functions [4].

The importance of dreaming, which occurs during REM sleep, is largely unknown. Early psychologists, including Sigmund Freud, hypothesized that dream sleep was essential for working through repressed or hidden psychic distress. Other hypotheses suggest that dreaming is the cortex's attempt to organize and interpret random neural firing or that neurological activation is directly related to the previous day's events [2, 6].

Disruptions in REM sleep: Antidepressants suppress REM sleep [7]. Heavy smokers may demonstrate reduced REM sleep, and alcohol consumption may also result in decreased amounts of REM sleep [7]. Although concerns with substance use are less prevalent in pediatric populations, adolescent substance use and psychotropic medications are important factors to consider when assessing disruptions in REM sleep.

Sleep apneaic events tend to occur more frequently during REM sleep, particularly obstructive apnea, which is exacerbated by the decreased muscle tone that is present during REM sleep. Other sleep disorders, including parasomnias, that are also associated with REM sleep are nightmares, sleep paralysis, sleep behavior disorders (moving in sleep), circadian rhythm disorders, and delayed sleep phase syndrome [3, 6]. Nightmares frequently occur in childhood, and are associated with the REM sleep period.

Relevance to Childhood Development

Due to the importance of REM sleep for maintaining adequate daytime functioning, children and adolescents who exhibit REM sleep disorders or experience disruptions in REM sleep due to sleep apnea, substance use withdrawal, psychotropic medication use, parasomnias, etc., often experience significant daytime functioning difficulty. Excessive daytime sleepiness that results from disruptions in sleep quality has a notable impact on school functioning, attention, motor coordination, and mood. Specifically, children who do not maintain adequate amounts of overall or REM sleep often have lower grades, demonstrate attention and behavioral difficulties in school and at home, demonstrate decreased fine motor coordination, have more depressed mood, and are less sociable [3].

Developmental Changes: Sleep in newborns is comprised of approximately 50% REM sleep, a ratio that decreases developmentally. REM composes 30% of overall sleep time in 1–2 year olds, and 20–25% of total sleep time by 5 years of age. This ratio is maintained throughout adolescence and most of adulthood [3].

Rating Scales

Matthew J. Holcomb, Raymond S. Dean
Ball State University, Muncie, IN, USA

Synonyms

Record judgment of qualitative variables; Semi-objective scales

Definition

Instruments designed to have individuals provide quantitative/semiquantitative ratings to variables using a set of numbers or categories. Quantitative judgments are provided or attributed to the raters with the numerical values being available for statistical measures, such as the mean.

Description

Rating scales may consist of a number of categories and/or an array of numbers representing a level of performance. One example is a typical 1–5 Likert Scale which might assign the following variables to each number.

1. Strongly disagree
2. Disagree
3. Neutral
4. Agree
5. Strongly agree

Whereas rating in sporting events may award a number from 1 to 10 to represent the judgment of performance, typically research that uses rating scales asks examinees how they feel or perceive a situation or circumstance. After the numbers are obtained from the rating scale, they are typically considered direct metrics and can, therefore, be used in calculating averages or in statistical analysis. However, statistically a number of assumptions must be made concerning the underlining distribution.

Relevance to Childhood Development

Rating scales are an often used assessment tool when working with children. They allow the examiner to quickly gather information on a variety of subjects. Specific rating scales that are commonly seen when working with children are the *Behavior Assessment System for Children* – second edition and vineland adaptive behavior scales.

The compendium *Assessment Scales in Psychiatry Series*, edited by Alistair Burns (2006) [4] is an excellent work that covers comprehensively the major rating scales used in clinical and research assessment of children. The book contains concise summaries of important information on over a hundred different children's rating scales. The compendium groups the rating scales into three broad categories: (1) general or broadband behavior rating scales; (2) scales for specific problems as seen in the DSM-IV-TR and ICD-10; and (3) impairment scales. Each entry contains a description of the scale including its uses and psychometric properties. Of additional importance, the compendium also includes (with permission) either sample items from each scale or the entire scale itself.

Raymond Dean

Matthew J. Holcomb, Raymond S. Dean
Ball State University, Muncie, IN, USA

Life Dates

1946–Present

Introduction

Dr. Dean is a well-known and influential neuropsychologist whose work has stressed the need for increased

understanding of neurological functioning through the assessment of specific cognitive and sensory motor functioning.

Educational Information

Originally from New York, Dr. Dean graduated with a BA degree in Psychology and an MS degree in Research and Psychometrics from the State University of New York at Albany. Upon graduation he received the Parachek-Frazier Research Fellow and went on to complete his PhD in School/Child Clinical Psychology at Arizona State University. Dr. Dean later completed a neuropsychological internship at Arizona Neuropsychiatric Hospital and postdoctoral training at the University of Wisconsin at Madison. His career and research has been strong influenced by his association and training with noted psychologists Dr. Ralph Reitan and Dr. Richard W. Woodcock.

Accomplishments

Dr. Dean has been a prolific writer in the area of Neuropsychology contributing more than 500 research articles, books, and chapters to the field. He has served as a Distinguished Visiting Faculty at the Staff College of the National Institute of Mental Health. Additionally, Dr. Dean is a past President of the Clinical Neuropsychology Division of the APA and the National Academy of Neuropsychology, and was elected Fellow of the American Psychological Association. Dr. Dean has been recognized for his accomplishments by awards from the National Academy of Neuropsychology, the Journal of School Psychology, and the Clinical Neuropsychology Division of APA. He is a diplomat of the American Board of Professional Psychology. Dr. Dean was the founder and Editor in Chief of the Archives of Clinical Neuropsychology, the Bulletin of the National Academy and the Journal of School Psychology.

Contributions

Dr. Dean research has focused on laterality, cognitive neuropsychology, and neuropsychological tests based in functionality rather than localization. His concerns on the efficacy of traditional neuropsychological assessment have been realized with the growth of radiological scanning techniques such as the MRI and fMRI over the last quarter century. Through his association with Dr. Richard W. Woodcock, Dr. Dean developed the Dean-Woodcock Neuropsychological Assessment System and the Dean-Woodcock Neuropsychological Battery. The latter was published emphasizing functionality in neurological assessment. With its emphasis on the Cattel-Horn-Cantrell Theory of Intelligence (CHC) the Dean-Woodcock Sensory Motor Battery represented a clear departure from the traditional actuarial approaches of neuropsychological assessment. Dr. Dean was both founder and editor for the Achieves of Clinical Neuropsychology and the Bulletin of the National Academy of Neuropsychology.

Current Involvement

Dr. Dean is currently the George and Frances Ball Distinguished Professor of Neuropsychology at Ball State University and Director of the Neuropsychology Laboratory where he has worked since 1984. He continues to teach, publish, and mentor doctoral students and has remained clinically active.

Razadyne ER®

►Razadyne®

Razadyne®

Anisa Fornoff
Drake University, Ankeny, IA, USA

Synonyms

Galantamine; Razadyne ER®

Definition

A prescription medication FDA approved for the treatment of mild to moderate Alzheimer's disease.

Description

This medication is an acetylcholinesterase inhibitor available in a tablet, solution, or extended release capsule. This medication does not cure the disease or stop it from getting worse, but may improve thinking ability.

The recommended starting dose for this medication in the immediate release tablet or oral solution is 4 mg twice a day. The recommended dose for the extended release capsule is 8 mg once daily. Dose increases should be done gradually. Maximum recommended daily dose is 24 mg. This medication should only be taken as directed by a doctor.

Some side effects are listed here: bladder pain, painful urination, nausea, vomiting, diarrhea, dizziness, headache, changes in sleeping, and weight loss.

Relevance to Childhood Development

Razadyne® is not FDA approved for use in children. Use is not recommended.

Reaction Formation

Kevin Regueira
Niagara University Academic Complex, Niagara, NY, USA

Definition

A Freudian defense mechanism in which an individual expresses a strong outward belief about a particular subject when in fact they are internalizing the opposite belief [2].

Description

Reaction formation was first proposed by Sigmund Freud as one of his Ego Defenses. The definition was further refined by his daughter Ana Freud in 1937. In brief, reaction formation is an unconscious psychological defense mechanism aimed to reduce anxiety about an internalized drive, belief, feeling, or behavior which is manifested by an overt behavior or stance that is the direct opposite [1].

Relevance to Childhood Development

An example, particularly in schools, is that when a child glorifies their mother or father, when in fact they have a strong dislike, resentment, or even hatred toward that parent. Or, a mother who outwardly displays a deep affinity toward her child may inwardly feel that she does not want the child. Therapists who recognize reaction formation in their clients may seek to foster an environment of unconditional positive regard and acceptance while helping the client to acknowledge their feelings and inner conflict and to recognize that such coping mechanisms are unhealthy. The ultimate goal is for the client to abandon this exaggerated form of compensation in favor of socially appropriate alternative behaviors or problem solving skills. Since reaction formation purportedly develops from unconscious thoughts and feelings, therapy is often continued until deeper feelings and emotions can be appropriately addressed [3].

Reactive Attachment Disorder

Elizabeth L. Roberds, Andrew S. Davis
Ball State University, Muncie, IN, USA

Synonyms

Disorganized/disoriented attachment; RAD; Reactive attachment disorder of infancy or early childhood

Definition

A disorder characterized by disturbed and inappropriate social interactions across social contexts. Onset must occur before the age of 5 years. Verification of ►pathogenic care must occur before diagnosis can be confirmed.

Description

Reactive ►attachment disorder (RAD) is characterized by disturbed and inappropriate social interactions across social contexts with an onset prior to age of 5. Before a child can be diagnosed with RAD, developmental delay or other disorders must first be ruled out as the cause of the inappropriate social interaction. Additionally, there must be verification of gross pathogenic care, as indicated by at least one of the following: persistent disregard of the child's emotional needs, persistent disregard of the child's physical needs, or repeated changes in the child's primary caregiver that prevents the formation of stable attachment [1]. It is generally presumed that this neglectful and/or abusive care is primarily responsible for the disturbed social interaction in children with RAD. Prevalence is difficult to determine due to the ►comorbid conditions often seen in children with RAD.

Subtypes and Symptoms

Two subtypes of RAD have been identified: inhibited and disinhibited. Individuals with the inhibited subtype do not to initiate social interactions or respond in social situations in ways that are developmentally appropriate [1]. The inhibited subtype may also be referred to as the "emotionally withdrawn" subtype ([2], p. 1209). Children with RAD of this subtype generally do not seek comfort from others in times of distress, and may resist comfort from familiar caregivers. Individuals with the disinhibited subtype exhibit little to no selectivity when choosing attachment figures [1]. The disinhibited subtype may also be referred to as the "indiscriminate" subtype ([2], p. 1210). Children with RAD of this subtype do not discriminate when seeking comfort and may be equally likely to seek physical comfort from a stranger even if their primary caregiver is close by. These children may be described as shallow and attention-seeking [2]. Following common diagnostic guidelines, children must be diagnosed as having one subtype or the other, and cannot be diagnosed as having both; however, some argue that the two subtypes can be simultaneously present [8].

Children with RAD may lack empathy [4], may intentionally harm themselves or others, and may be hypervigilant [7]. Children with RAD have also been observed to exhibit impulsive and self-endangering behaviors [5]. They may generally struggle with emotional and behavioral regulation [6]. Children diagnosed with RAD may have related issues stemming from abuse and neglect that are not part of RAD that also need professional attention. These include unattended medical conditions, as well as trouble with speech or language [2].

Relevance to Childhood Development

There is not a widely-used standard assessment battery designed specifically for children with RAD. Assessment involves direct observation of the child, preferably including observation of the child with their primary caregivers. It is also critical to consider the child's history and past environment [2]. Comprehensive psychoeducational and/or neuropsychological testing is recommended to aid in ►differential diagnosis and determine functional capability. It is recommended that RAD be diagnosed only by a trained mental health professional with expertise in child development and differential diagnosis [3].

Risk factors have been identified for RAD. These include children who have experienced multiple living situations, such as those raised in orphanages or foster care or who have been frequently moved from one caregiver to the next. Another salient risk factor is a history of abuse and/or neglect. It is important to understand that even extreme abuse, neglect, and multiple living situations do not always lead to RAD.

School may be a challenging environment for children with RAD, as inappropriate social interaction and reciprocity extends into this environment and may contribute to behavioral, emotional, and academic challenges [6]. Children with RAD may be rejected by peers [6]. The teacher–student relationship can also be affected by RAD, leading to a variety of problems such as engaging in proximity-seeking behavior with teachers, or seeking help from teachers in inappropriate ways [6]. Teachers familiar with RAD, and who understand emotional and behavioral regulation, will best be able to support students with the disorder [6].

Given the appropriate supportive environment, children with RAD may improve behaviorally and form attachments to caregivers. To promote healthy attachment, caretakers ideally would provide a stable, safe, and predictable environment, and would be sensitive and responsive to the child's needs [3]. Despite an improved environment, indiscriminate social relatedness may continue even after a child has formed selective attachments [1]. Though RAD has not been well researched, it is presumed that without change in environment and care, improvement should not be expected.

Currently, many therapies exist for the treatment of RAD, but most are not evidence based practices, and some

are controversial. Often, both the child and their caregivers are involved in psychotherapeutic treatment, though treatment may involve working with the child or caregiver(s) alone. The scientific community has generally rejected attachment therapy that involves coercion, compression holding, ►rebirthing therapy, or the promotion of regression, as they have not been empirically supported and in some documented cases have caused serious harm and even death to children [2, 3].

Reading

Elizabeth Levin, Leslie Villeneuve
Laurentian University, Sudbury, ON, Canada

Synonyms

Orthographic reading skills

Definition

Reading can be defined as the cognitive process associated with the interpretation of written language.

Description

Reading is a complex learned skill that most people develop without understanding how or why the process works. However, the ability to read is one of the most important abilities needed in order to be successful academically, professionally, and personally [4].

Those who specialize in the study of reading have been unable to come to an agreement on the definition of reading. Some define reading as the ability to sound out strings of letters while others define reading as the process of extracting and constructing meaning from text [7]. Involved in this complex process of constructing meaning are aspects such as word recognition, fluency, comprehension, and motivation. At a minimum then, reading requires knowing the sounds of letters and knowing the meanings of words and groups of words, and being able to put it all together fluently.

The process of learning to read is a relatively long one that begins early in a child's development [5]. A successful reader must learn how to use spoken language and to recognize that spoken language is composed of individual sounds. Along with this develops the knowledge of the names, sounds, shapes, and formations of letters or syllables, and the knowledge that these letters and syllables are what make up written words. Successful readers know the direction in which text is read (note this is dependent on the specific language), recognize words on sight, and can identify novel words using both the rules of written language and the context in which these words are written. Finally, in order to read successfully, a child must learn to do each of the above abilities automatically, freeing up resources to focus on understanding the selection of text.

An individual passes through the following stages while learning to read: the pre-reader and the beginning reader, the emerging reader, the early reader, and the fluent reader.

1. The pre-reader and the beginning reader enjoy looking at books and having books read to them. They learn words by looking at things like picture books, traffic signs, and logos (e.g., restaurant logos), as well as by singing songs and learning rhymes. At this stage beginning readers learn things like where a story begins and ends, and how to use pictures and memory to tell and retell stories.
2. The emerging reader is prepared to be taught about reading, and has learned that text represents a way to

tell a story or to communicate information to others. An emerging reader starts to match written words to words heard spoken aloud, and to notice the relationships between sounds and letters. The child begins to experiment with reading, and will attempt to read aloud when looking at simple texts. At this stage, pictures are beneficial as they allow the child to understand the words being read, and to realize that the written words express a message that is consistent with the pictures displayed in the story.

3. Early readers develop greater confidence in their reading ability and use a variety of methods to identify words. They will be familiar with many words and will be eager to attempt new types of text.
4. The fluent reader reads automatically, and knows many methods for identifying both words and their meanings. The fluent reader can read many different types of text and is able to predict the events in a story. At this stage, the reader is able to relate personal experiences and knowledge to events read about in books.

The majority of children learn the basics of reading by the time they reach the age of seven, although reading proficiency takes many years. Learning to read has its foundation in the language skills that begin to be acquired shortly after birth. For the most part, birth to age three brings the ability to create sounds that imitate tones and rhythms that adults use when they are speaking. In these years, children begin to associate words they hear regularly with their meanings and to react to gestures and facial expressions. They also begin handling objects such as board books in their play and then they gradually move to pretending to read them. They enjoy listening to stories, and naming objects and discussing characters in the stories. Finally, they ask to read or write with adults, and will start paying attention to specific parts of print, such as the first letters of their names [2].

Between the age of three and four, most children continue to enjoy listening to and talking about stories and they are able to identify signs and labels that are familiar to them. They enjoy participating in rhyming games and they begin to identify some letters and to make matches between letters and sounds. Finally, they will utilize letters that they have learned to represent written language, particularly for words that are meaningful to them such as their names [2].

When most children reach the age of five, they develop the ability to sound like they are reading when they are pretending to read. They continue to enjoy being read to and they will attempt to retell simple stories. They make use of descriptive language when explaining things or when asking questions, and they recognize letters and letter-sound matches. At this age, they realize that English text is read from left to right and from top to bottom; and they begin to match words they hear spoken aloud to words they see written on paper or to pictures. Kindergarten children can identify whether words begin or end with the same sounds and recognize some poetry. Moreover, by the age of five most children will attempt to write the alphabet and some frequently used words. This will be followed by an attempt to write stories that contain some readable parts [2].

By the age of six, most children can usually read and retell stories that are familiar to them, and they have learned a number of ways to help them read stories, such as re-reading, asking questions, or using pictures. They can follow simple written instructions. First graders can recognize consonants and vowels. They can identify new words by using letter-sound relationships, parts of words, and their understanding of the remainder of a story. By this age, they have developed the ability to recognize a growing number of words by sight and depend on word families. They also have the ability to sound out words they are trying to spell [2].

By second grade, children can decode an unfamiliar word based on individual letter sounds. They are much better at using contextual cues to identify new words. Their reading is more proficient as they can vary their intonation when reading aloud. In third grade, the reader understands homophones, antonyms and synonyms. Children's reading speed increases and they are better silent readers. Soon after, reading becomes more fluent and automatic. Children who have not acquired basic reading skills by grade three are at risk for future academic and social problems.

There are two main approaches to reading instruction: ▶phonics and ▶whole language. Phonics based approaches emphasize the correspondence of printed letters and words with the sounds of letters and words. Phonics based instruction focuses on ▶decoding and teaches strategies to sound out words. Phonics instruction provides lots of drills and requires lots of practice to sound out words. In contrast, whole language approaches to reading focus on comprehension of written text. Reading and writing opportunities are provided throughout the school day through multiple experiences that emphasize meaning. Whole language learning emphasizes literacy throughout the curriculum and the opportunity to write is incorporated with reading.

Contrary to popular opinion, current research does not support one form of instruction over the other. Most

children learn best with a balanced approach that begins with phonics instruction and then includes whole language approaches to literacy.

Since reading is an effortful activity that children can choose to engage in or not to engage in, it also requires motivation. Therefore, in addition to learning the skills involved in reading, children must also develop and maintain their motivation to read. Children must learn to appreciate the pleasures of reading, and they must learn that reading is a social act that they can share with others, and that it provides the opportunity to explore their interests.

Most children begin learning to read with a great deal of interest and a sense of optimism. However, children who experience difficulty learning to read may quickly develop a sense that they are a poor reader, and their motivation for reading gradually declines [1]. Without the motivation to read, children may decide not to participate in activities involving reading, and consequently, they get little practice and they may fall further and further behind [3]. Since reading plays a central role in so many of the tasks we perform each day, children who do not read well may experience difficulties in other areas as well. Children with reading disabilities require intense phonics instruction that emphasizes letter-sound concordances as a starting point.

Relevance to Childhood Development

In summary, the ability to read does not develop without careful planning and instruction [6], and the proper motivation. Good reading ability is of life-long value. The process of learning to read begins long before children are able to speak and continues with most children learning the necessary skills by the age of seven. From that point on, most children will continue to refine their skills until they become efficient and fluent readers.

Reading Disorders

Becky Stefanko
University of Detroit Mercy, New Baltimore, MI, USA

Synonyms

Developmental dyslexia; Dyslexia; Reading disability

Definition

A reading disorder is characterized primarily by deficit performance in reading, not attributable to sensory deficits or developmental delays, that falls significantly below expectations for an individual's chronological age and measured intelligence in the context of appropriate reading instruction and socio-economic opportunities and has a significant negative impact on academic achievement or daily living activities.

Description

According to the National Assessment of Educational Progress statistics, approximately 34% of fourth grade students and 27% of eighth grade students nationwide fell below the basic level for reading proficiency in 2007 [3]. Reading disorders are the most pervasive form of learning disabilities in the United States, affecting approximately 80% of all children identified as learning disabled [6]. Reading problems are equally pervasive among male and female students, and tend to persist without effective intervention. Problems not identified prior to grade 3 or 4 are difficult to remediate, and have a negative impact on learning across academic content areas. Evidence suggests that reading disorders are more likely to occur in children whose parents have difficulties with reading, children with limited English proficiencies, hearing or language impairments, and/or children from low socioeconomic backgrounds who may have limited opportunities for exposure to rich language and literacy activities [6]. Shaywitz and Shaywitz [5] reported findings from functional neuroimaging technology studies of differences in brain activity between proficient and struggling readers that demonstrate neural system structural changes in the brain in response to effective interventions. This implies that biological and environmental factors work together to influence reading development, and suggests effective interventions can prevent or remediate reading problems.

There are three broad areas of reading disorders, word-level, fluency, and comprehension [1, 2]. Word-level disabilities involve difficulties in word recognition, decoding, phonological processing, and alphabetic principle. Fluency disability is manifested in difficulties in quickly and accurately deciphering print. A comprehension disability involves difficulties in the ability to understand or learn from the text. Problems with word-level reading skills and fluency often lead to problems with comprehension. Children who have difficulty with word-level skills use cognitive resources, such as attention and memory, to decipher words. Once word-level skills become proficient, the child can begin to read fluently, and cognitive resources become available for use in extracting meaning. In other words, children must be able to quickly and accurately decipher words so that they can devote their attention and memory to understanding what they are reading.

Word-Level Disabilities

Word-level problems in reading are synonymous with dyslexia [2], and involve difficulties with an awareness of the phonological structure of language and its relationship to print. The English language contains up to 44 individual phonemes [4]. For example, the word "that" contains three phonemes /th//a//t/. In oral speech, the phonemes overlap in a process called co-articulation to produce one audible sound, "that." Phonemic awareness involves recognition of the individual sounds that comprise words. It is part of a broader process, known as phonological awareness, which includes the ability to identify and manipulate the components of speech such as (a) identifying beginning, middle, and ending sounds; (b) blending individual sounds to form whole words; (c) isolating (segmenting) individual sounds; and (d) deleting, substituting and adding sounds to form new words.

Children with word-level problems in reading may exhibit difficulty naming letters, associating letters to sounds, understanding the difference between sounds in words, or blending sounds into words. They may confuse similar-looking letters, numbers, or words, or they may reverse letter orders in words. They may have poor memory for new vocabulary words and difficulty with spelling. Children with problems at the phonemic level have difficulty recognizing the syllabic structure of words, and must rely on rote memorization skills [6].

Phonological awareness begins to emerge during the preschool years, typically through natural exposure to language, word play, and early exposure to print and print concepts. Activities such as listening to and repeating nursery rhymes, chants, songs, and other alliterations, along with exposure to environmental print (e.g., fast-food restaurant logos, street signs, etc.), and multiple opportunities for interactions with various forms of literature provide opportunities for the development of phonological awareness. Children who have multiple opportunities to interact with language and print in their early years typically develop better reading proficiency than children who are deprived of such experiences [6, 7].

Once children have a developed phonological awareness, they can begin to apply their knowledge of sounds and words to print. The association of letter-sound relationships to print is known as alphabetic principle, and usually occurs sometime during first grade [4]. It differs from phonological awareness in its relationship to graphemes, which are the alphabetic symbols used to represent speech sounds. For instance, the association between the size and shape of the symbol "A" and the sound /ă/ or /ā/ refers to alphabetic principle, whereas a single phoneme, such as the /th/ sound, can be represented by more than one grapheme. Alphabetic principle involves recognition of the size and shape of print, and its relationship to spelling patterns. Children who struggle with alphabetic principle have difficulty identifying letters and/or their

corresponding sounds, and with recognizing and spelling familiar words.

Unlike phonological awareness, which develops largely from natural interactions with language and speech, alphabetic principle requires explicit instruction [1]. Children who do not grasp the alphabetic principle have difficulty decoding, or sounding out, words in print. Poor instruction in alphabetic principle may have lasting effects on overall reading achievement [6]. The National Reading Panel [4] advises that teaching phonological awareness should include explicit, systematic, multi-skilled approaches that include instruction in the alphabetic principle to achieve maximum results. Activities that involve converting letters into sounds, then blending and segmenting them to form recognizable words, identifying and categorizing phonemes in printed words, and manipulating subparts of words and phonemes to form new words are some of the suggested approaches to teaching phonological awareness and alphabetic principle. This type of instruction is generally more effective when delivered before first grade. It is unclear whether explicit phonics instruction is effective for older, struggling readers.

Fluency Disabilities

Fluent reading involves the ability to read text quickly, accurately, and with proper phrasing and prosody. It is dependent upon the ability to quickly and accurately recognize printed words. It is distinguished from automatic reading by oral prosody. Some children can read automatically, but lack appropriate expression when reading aloud; thus, not all children with proficient word recognition become fluent readers [1, 2, 4]. Other cognitive processes, such as processing speed, executive functions, and lexical memory also play significant roles.

Fluency is an essential component of reading, since it frees up cognitive resources for comprehension. This becomes important as older students progress from learning to read to reading to learn. As students progress through school, learning becomes increasingly dependent upon meaning obtained from texts. Students who are still struggling with decoding will not have access to as much material as their proficient peers. They will not be able to read as much material in the amount of time available, and, without intervention, will lag farther behind in learning as the material becomes increasingly difficult.

Children with fluency disabilities read slowly and hesitantly. Their oral reading sounds unnatural and laborious. They may read in a monotone voice, or pause at inappropriate places within connected text. Although fluent readers may exhibit hesitant, labored reading with difficult or unfamiliar texts, non-fluent readers demonstrate problems even with familiar texts at appropriate levels of difficulty.

Research demonstrates that the use of guided, repeated oral reading practice improves not only reading fluency, but overall reading achievement as well [4]. Providing children with multiple opportunities to practice reading familiar text (repeated reading) enhances the automaticity that frees up resources for comprehension, while corrective feedback improves accuracy and prosody.

Comprehension Disabilities

Reading comprehension involves a combination of word-level skills, fluency, and metacognitive processes that help the reader understand, remember, infer, and communicate information to others about the text. Reading is both an active and interactive process. It is influenced by the reader's intelligence, physical and emotional states, the context of reading (e.g., physical location and purpose), and constraints imposed on the reader [6]. The reader is an active participant, applying prior knowledge and experience to construct meaning extracted from the text. The knowledge acquired from reading further enhances comprehension and learning. When the process of reading is difficult and frustrating, it decreases the motivation to read and reduces the number of opportunities to learn.

The role of vocabulary in reading comprehension is significant. A well-developed vocabulary provides the basis for understanding when decoding printed words. Identifying unfamiliar words in print is easier when the unfamiliar word can be associated with a word that already exists in the reader's oral vocabulary. The effect is bi-directional because poor comprehension can result in limited exposure to new words and have a negative impact on continued vocabulary development [6]. Vocabulary becomes increasingly more important in the older reader, when the focus of reading shifts toward texts of a more technical nature. Technical manuals, research reports, and other non-fictional materials gradually replace fictional literature as primary reading sources as students' learning becomes increasingly complex and content-focused. The vocabulary used in these types of texts is often specific to the content, and knowing the technical terms becomes essential for understanding the material. Pre-teaching vocabulary words, and repeated drill practices are effective interventions for building a student's vocabulary skills; however, the National Reading Panel [4] recommends using a variety of instructional methods rather than just one, and exposure to rich contexts for vocabulary learning.

In addition to vocabulary, metacognitive strategies help students monitor and regulate their own

comprehension. Students who struggle with metacognitive strategies have difficulty summarizing, clarifying, and making inferences or predictions based on what they read. They may not understand the relationships between main points and supporting ideas, or appreciate the purpose or organization of the text.

The National Reading Panel [4] has identified seven instructional strategies with empirical support for promoting reading comprehension. Memory strategies, such as mental imagery and mnemonics help children build mental representations that facilitate the ability recall information for later use. Pre- and post-reading activities such as questioning, elaboration, and classroom discussions are useful for assessing, activating, and building background knowledge that forms the foundation for understanding textual material. Comprehension monitoring strategies, such as error detection, recall, and question answering, can help students identify material that requires additional support or strategies for comprehension to occur. Cooperative learning, peer tutoring, facilitates discussion that can provide corrective feedback in a social environment that has the potential to increase the student's sense of control and motivation to read. Graphic organizers help with retention and organization of reading material to enhance understanding. Instruction on the story structure organization aids with questioning, inferring, and prediction. Summarizing improves retention of the material, assists with connecting the main idea with relevant, supporting ideas, and facilitates generalization of the text information.

Reading Skills

Elizabeth Levin, Leslie Villeneuve
Laurentian University, Sudbury, ON, Canada

Synonyms

Comprehension; Decoding; Word recognition

Definition

Two major skills are required for fluent reading: one deals with word recognition or ►decoding, and the other deals with reading for meaning or *comprehension* [6].

Description

The process of reading requires that a number of skills be mastered for proficiency including decoding and *comprehension*. In order to become a fluent and efficient reader, a child must first acquire automatized word-level analysis skills. This requires a substantial amount of reading practice. Once the child has mastered word-level skills, the focus shifts to reading comprehension [6]. Although decoding and comprehension are the two main aspects of reading, several sub-skills have been identified as essential for reading development [10].

The majority of current theories of reading development emphasize the primary importance of phonological skills in learning to read. At a basic level, children who are learning to read in an alphabetic orthography must first establish a correspondence between the letters that make up printed words and the ►phonemes that make up spoken words [8]. Once letters have become linked to individual sounds or phonemes, they become linked to spoken language and thus have been decoded. The developing reader must first recognize that spoken words are made up of phonemes, that is, the child acquires ►phonemic awareness. The next step is to recognize that phonemes are linked to written symbols or letters and when that happens decoding has occurred and the child has taken the first steps to reading.

Learning to read then requires the acquisition of a number of skills. One of the first skills to develop is the ability to name each letter. This is followed by the ability to identify the sound each letter makes.

For vowels, this includes understanding the long and short pronunciations and for consonants, recognizing that there sometimes may be two sound outcomes. Next, children must develop the alphabetic principle, which is the knowledge that written letters and letter combinations represent the sounds in oral language and that these sounds are used to form words [2, 5, 10]. Thus, this letter-sound knowledge is critical for word identification skills [2]. According to Reading and Van Deuren [10], most children are exposed to print at an early age, therefore, many begin kindergarten with knowledge of the alphabetic principle.

Phonemic awareness is another important reading skill. Often, in the literature, the terms ▶phonological awareness and phonemic awareness are used interchangeably, however they do not represent the same thing [1]. Phonological awareness is a more general term and it refers to a child's ability to identify and analyze the sound structure of words and to understand that language can be broken down into smaller units [4]. It is the knowledge that words consist of syllables, onsets and rimes, and phonemes [9]. It has been found to be one of the most powerful factors involved in reading development [4]. Phonemic awareness is a more specific term and has the strongest relationship with later reading. Phonemic awareness is an awareness of the individual phonemes or more specifically, the ability to hear, detect, think about, and manipulate the individual sounds in spoken words [2]. It involves auditory awareness [2, 10], however, it is not necessary for understanding spoken language. Humans have been created to hear oral language and language is heard seamlessly, that is, whole words are heard not individual sounds. The ability to manipulate the individual sounds of a word however is critical for reading and writing success and for second language learning.

Phonemic awareness can be measured using sound comparison skills, that is, identifying and generating words which begin with the same first or last sound. It also includes the ability to segment phonemes. This includes being able to break a word into individual phonemes. Phonemic awareness also includes phoneme blending or the ability to put phonemes together to produce words.

It is well accepted that there is much more to learning to read than simply decoding [8]. Decoding is the ability to correctly pronounce written words by using the knowledge of letter-sound relationships [9], or more simply put, it is the sounding out of words [10]. This understanding allows children to recognize familiar words quickly and to figure out how to pronounce new words [9]. Once a child can decode individual words, the development of fluent and automatic reading skills is the next important goal. While there is a lack of consensus on a single definition of reading fluency, most would agree that it involves the ability to read quickly and accurately. Decoding plays a large role in reading and reading fluency. Good readers do not have to reread words; they efficiently process every word and every letter within a word.

Therefore, once readers understand and become fluent in the mechanics of reading, they can turn their focus to understanding what they are reading. This is known as *comprehension*. In order to understand a selection of text, students must first learn to read for factual information. Then, they must learn to look for and locate the main ideas in a text, as well as to compare and contrast these ideas. Finally, they must develop the ability to analyze and synthesize the information in order to draw conclusions and to make reasonable inferences. This involves integrating existing knowledge with the new information presented in the text being read [7].

The role of vocabulary development in the acquisition of reading skills has not received the same attention as decoding and comprehension strategies, however, vocabulary knowledge is closely linked to comprehension. In order to be a skilled reader, it is important to know the meanings of words, as well as demonstrate the ability to infer and learn the meaning of new words [7], because a well-developed vocabulary represents a critical link between decoding and comprehension [3]. The sources of vocabulary knowledge include home experience, general mental and verbal ability, and education [4]. If a reader has an insufficient knowledge of important words and concepts or if they are not able to determine the meanings of words, they will have a harder time understanding what they are reading [7]. In fact, contrary to popular opinion, teaching poor readers to guess the meaning of unfamiliar words using contextual cues is counterproductive.

When a child exhibits accurate, but very slow decoding, it may not be sufficient to support comprehension. In order to adequately comprehend what has been read, decoded words must be present simultaneously in working memory, so that the relations among them can be processed. If decoding is slow, then important information will have perished by the time later information is decoded. Furthermore, if decoding is effortful, meaning that conscious thought must be devoted to it, then fewer working memory resources will be available for comprehension. Many children with reading disabilities have stronger comprehension skills than decoding skills. They can infer the meaning of what they are reading because their higher order cognitive processes are not impaired, but reading of individual words is laborious. This is one

reason why poor readers benefit from intense instruction in letter-sound concordances.

Good readers share a number of characteristics. They try to interpret the meanings of new words as they read. They make predictions and test these predictions as they continue reading, revising as necessary. They monitor their understanding of what they are reading and adjust as needed, rereading and reinterpreting based on what they have read and what they know. Good readers have different strategies for reading different kinds of materials; this influences whether passages should be reread or skimmed, which parts deserve more attention, etc. Reading is an active process and improves with practice; for example, vocabulary improves with reading and improved vocabulary aids reading.

Reading/Writing Proficiency

►Literacy

Reality Principle

Janet L. Etzi
Immaculata University, Immaculata, PA, USA

Synonyms

Reality testing; Secondary process

Definition

A Freudian concept used to describe one of the fundamental ways in which the psyche develops from infantile, instinctual functioning based on attaining pleasure, the pleasure principle, to a more mature and modulated functioning based on the demands of reality.

Description

The reality principle develops secondarily in relation to the pleasure principle. If the pleasure principle represents the psyche's orientation to attaining pleasure, then the reality principle can be said to represent the psyche's adjustment to the demands of reality, whether or not these demands lead to pleasure or pleasurable experiences. In this sense, the reality principle is the infant's movement towards maturation in that maturity is constituted by the ability to accept and adapt to reality, both frustrating and rewarding aspects of reality. The infant is increasingly able to observe and to accept that reality is not always gratifying or what the infant desires. For example, the parent of reality has both good and bad days, and will be a disappointment to the infant from time to time. The perfect parent, for which the infant might wish, does not exist in reality. The infant's ability to accept and even to love the real parent is the manifestation of the reality principle's influence within the functioning of the mind.

Relevance to Childhood Development

The reality principle as a concept has been relevant to childhood development especially for psychoanalytically or psychodynamically oriented investigators and those working directly with children. It is a concept that can be useful in describing the normal conflict during early childhood in moving from a self-centered, infantile state of existence to a more tolerant and realistic position in relation to primary caregivers. The reality principle is said by psychoanalytic theory to bring with it the ability on the child's part to delay gratification and to tolerate increasing amounts of frustration brought on by normal reality constraints and demands. The reality principle helps the child

take into account the world and experience outside of, or other than him/herself.

As a concept "reality principle" is useful for formulating aspects of inner experience, much of which is outside of everyday, conscious awareness, and inaccessible to infants and small children.

Reality Testing

►Reality Principle

Reality Therapy

Cassandra Means
Capella University, Batesburg, SC, USA

Synonyms

Choice Theory; Counseling; Counseling method; Psychotherapy

Definition

A counseling technique where the client is encouraged to focus on the here and now rather than on the past, complaints or symptoms in order to obtain better control over his or her life.

Description

Reality therapy was developed by *Dr. William Glasser* in 1965 and is based on Choice Theory, once known as Control Theory [2, 4–9, 11]. *Choice Theory* basically theorizes that all behavior is purposeful and is meant to match the pictures we have formulated in our minds of what we want to reality in order to fulfill the five basic human needs: love and belonging, power, fun, freedom and self preservation [4, 6, 7].

Basic Assumptions

The basic assumptions of Reality therapy are that underlying problem is based on relationships that are disconnected or unsatisfactory as well as how the person perceives and feels about him or herself, people are in control of their *behaviors* thus are responsible for the behaviors that they choose to engage in while trying to meet their wants and needs, people have the ability to change, there is no need for the person to wait on others or remain a victim in order to make changes that will lead to a more effective life [4–9, 12]. This is not a sign of mental illness, rather, a purposeful method to get what one wants [6, 7]. Thus, if a person is depressed it is due to the person is choosing to depress rather than evaluate and consider more effective alternative behaviors to get what he or she wants [5, 7, 12].

Counseling Process

The focus or goal of the *counseling* process is for the *therapist* or counselor to assist the client to reconnect with others in a more effective way by acknowledging that no matter what has happened in the past, he or she has control over his or her behaviors and he or she has choices [5–7, 9, 12]. This reconnection is done through the process of the therapist creating a warm, trustful atmosphere for the client, helping the client to understand the concept of total behavior which involves thoughts, feelings, physiology and behaviors or actions, remaining non-judgmental, being supportive while challenging the client to make changes in a non-criticizing manner, helping the client to see and evaluate ineffective behavioral choices, focus on the present and specifically what the client can do and avoid discussing symptoms, complaints, blaming (*transference*) and excuses [5–9]. During the process the therapist will help the client to evaluate and consider five questions that drive the process: what do you want, what are you doing to get what you want, is it working, if not, what are you willing to do and to make a plan that realistically can help him or her to obtain what it is that he or she is wanting [2, 5, 12]. The results include increased self esteem and concept, increased inner strength, improved relationships with others and a plan to live a more effective life [1, 3, 6, 10–12].

Contributions

Reality therapy has contributed to the counseling profession by providing a short term counseling approach that can be utilized with a wide variety of clientele [7].

Limitations

Reality therapy as with all counseling methods has its limitations. These have been identified as limited emphasis on the unconsciousness, avoids issue of transference, can be too confrontational, limited focus on the effects of early childhood trauma, limited focus on feelings, does not take into account role of the past regarding personality, the role of dreams in the therapeutic process, role of social or cultural influences and the role of discrimination as a barrier in a person's life [7].

Relevance to Childhood Development

The technique can be used with children to provide tools for the individual to use in order to cope with problems as well as gain control over his or her life and grow personally [2, 5, 6]. For instance, parents can utilize Reality Therapy techniques in their parenting in order to help the child to learn how to gain control over their lives [4]. This in turn will help to increase the child's self esteem and sense of self worth by being able to successfully meet his/her basic needs of love/belonging, power, fun, freedom and self preservation through effective means [4, 6, 7, 12]. Teachers can also use Reality Therapy techniques in their classrooms to not only help the child to continue to learn to control his/her life and meet his/her basic needs, but also to increase the child's learning of a subject by making the learning process fun thus appealing to the child's need for fun [4]. School guidance counselors can utilize Reality Therapy techniques to help a child with such issues as building positive relationships with peers and teachers, address homework issues, and improve communication with others [12].

Receptive Language

Mysti S. Frazier
University of Texas at San Antonio, San Antonio, TX, USA

Definition

Receptive language is the ability to accurately comprehend what is said, written, or signed by others.

Description

Both receptive and expressive language are important to the understanding of a child's overall language skills [3]. While expressive language refers to the child's ability to produce language, receptive language refers to the child's ability to comprehend language. Typically, children with

severe reading and reading comprehension problems show poor receptive language skills [4], and problems with receptive language also lead to problems with expressive language [3]. In addition to studying the comprehension of the content of language (e.g., words), it is also important to study the child's ability to comprehend other aspects of language, such as syntax and pronouns [3].

Biologically, researchers have identified the location of the brain that is responsible for receptive language processing, in the area between the temporal and parietal cortex very near the angular gyrus [4]. As expected the number of understandable words increases with age; however the development of such abilities is very unpredictable and many factors (e.g., genetics, parent's work with the child on language development, and the overall health of the child) play a role in the child's abilities [3].

There are various ways to assess receptive language abilities. For example, picture-naming abilities have some connection to receptive vocabulary comprehension, because the picture may be a visual representation of a word the child knows [5]. However, these tests do not always provide accurate measures of word identification abilities in children [5] because the picture may be an object or situation that the child has not yet encountered, therefore, he/she is unable to name it. Similarly, in many cases when the child does not understand a word it may simply be due to the child's lack of exposure to the word, not a serious developmental problem. Clinicians can retest the child using other words or pictures to test the child's abilities across multiple stimuli [2].

In a meta-analysis of receptive language interventions, Law et al. [1] found that the duration and administrator of the intervention play significant roles in outcomes. It was found that when parents administered the intervention for more than 8 weeks, children had the most developmental success. However, this study was unable to determine the intensity of the interventions given because the administration varied too much from child to child, meaning that there is a need for more structured research [1].

Receptive Language Disorders

Cassandra Means
Capella University, Batesburg, SC, USA

Synonyms

Communication disorders; Comprehension deficit; Delayed language; Delayed speech

Definition

A language disorder where there is difficulty in understanding what is being said and/or written. The individual also experiences difficulty in retaining, processing and attending to spoken language.

Description

Differing from speech disorders, language disorders such as receptive language disorders include problems with the understanding and use of language to include written, spoken and/or simple systems such as sign language [1]. Referred to as delayed speech or language [5], receptive language disorder is described as being a type of learning disability where the individual struggles with comprehending what another is saying to him or her [4, 6]. The individual also has difficulty with retention of and attending to what is being said to him or her [4, 9]. Receptive language disorders include such disorders as Comprehension Deficit, Aphasia, and Central Auditory Processing Disorders (CAPD) and can co-occur with expressive language disorder [1, 5, 10]. Several language processing centers of the brain are involved in receptive language disorder [6]. According to the classical model that became popular among physicians during the late nineteenth century, the Wernicke's area was identified as being the area responsible for language comprehension [2]. However, recent research has found that a small number of left temporoparietal regions located outside of Wernicke's area as well as the left frontal lobe are the primary locations of language comprehension [2].

Signs and Symptoms

Although each individual will differ in the signs and symptoms, the basic signs and symptoms of receptive language disorder include: presenting as though he or she is not listening to what is being said, repeating back or parroting words or phrases (*Echolalia*), difficulty with following verbal directions, language skills are not age level, repeats a question that is asked first before answering, high activity and not attending to what is being said to him or her, responses to "wh" questions tend to be off or inappropriate along with difficulty answering yes/no and either/or questions, using phrases and sentences that are memorized and unintelligible speech or jargon [5, 7, 10]. Other problem areas that occur with receptive language disorder include *pragmatics* (function of language i.e., joke vs. serious statement), *phonemic awareness* (how language is formed i.e., distinguishing the "f" sound from the "th" sound), *semantics* (meaning of words) *and syntax* (meaning of sentences) [1, 7].

Causes

In most cases, the cause of receptive language disorder is unknown [1, 4, 10]. However, there are cases where the cause of the receptive language disorder is due to a physiological or medical reason (i.e., stroke, brain injury, exposure to toxins during pregnancy, tumor, disease), genetic factors, *congenital syndromes* (i.e., *Down Syndrome, Fragile X Syndrome*), hearing loss, or a developmental disorder (i.e., *Autism*) [1, 3, 5, 10]. It has also been theorized that such factors as how much exposure one has to language and one's overall cognitive and developmental abilities play a role [10].

Diagnosis

The methods used to diagnose receptive language disorder include: a hearing test, vision or eye examination, observing the individual interacting with others, assessing for cognitive problems by a neuropsychologist and comprehension testing [10].

Treatment

Treatment is determined by several factors. These factors include individual's preference and expectations regarding therapies, the how severe the disorder is (i.e., prognosis), if the individual knows that a problem exists and the individual's age [1, 3]. The types of treatment and intervention available include one on one speech/language therapy, group speech/language therapy, mental health intervention to address behavioral issues that stem from frustration, special education classes and educational support to help the child integrate from one grade level to the next [10]. It should be noted that the prognosis for a child with receptive language disorder is not as good as that of a child with expressive language disorder [4, 7].

Relevance to Childhood Development

It is stressed that it is very important that before one can learn how to talk, one must be able to attend to and understand what is being said to him or her [8, 10]. It is estimated that between 3 and 5% of children have a receptive language disorder, expressive language disorder or a mixture of both [10]. It is further estimated that about 7% school age children are found to present with notable language deficiencies [1, 4]. It is noted that being able to attend to and understand language as well as express one's self is the key to success academically as well as socially [1, 4, 8]. Academically, a child with receptive language disorder will struggle with such tasks as learning to read, understanding and attending to directions being given by the teacher, and taking a test thus resulting in not performing academically at grade level [1, 4, 8]. It can further result in the teacher misperceiving the child's capabilities due to the child is unable to effectively express him or herself [6, 7]. Socially, a child with receptive language disorder will experience difficulty with being able to communicate with peers and teachers and making good decisions which can result in the child not liking school thus engaging in avoidant behaviors [1, 4, 7]. These deficits often carry over into adulthood [7].

Amy Burger, Ivy Chong
Florida Institute of Technology, Melbourne, FL, USA

Synonyms

Receptive lexicon

Definition

Receptive vocabulary (vocabulary refers to all the words in a person's language repertoire) refers to words that a person can comprehend and respond to, even if the person cannot produce those words.

Description

Receptive vocabulary refers to all the words that can be understood by a person, including spoken, written, or manually signed words. In contrast, expressive vocabulary refers to words that a person can express or produce, for example, by speaking or writing. In general, receptive vocabulary appears to develop before expressive vocabulary over the course of early language development, and receptive vocabulary is generally larger than expressive vocabulary [3]. However, language development throughout childhood is often more complex, with expressive vocabulary development sometimes exceeding receptive vocabulary and vice versa [3]. For example, a child may produce a word with imperfect understanding of its meaning and later learn through experience the correct definition and usage. Thus, it is likely that both types of vocabulary development occur together and that the development of one is dependent on the development of the other [3].

Receptive vocabulary begins to develop when an infant learns to discriminate speech sounds, and, as children mature, they begin to decode and respond to words based on contextual cues [3]. By approximately 7–12 months of age, the development of receptive vocabulary becomes evident when an infant begins to respond to simple requests and shows signs of recognizing a few words [1, 3]. Children between 1–2 years old begin to show signs of a more advanced receptive vocabulary through activities such as pointing to objects when they are named by another person [1, 3]. Between the ages of 2–3 years, children's receptive vocabulary increases as overall language abilities develop; at this stage, children are able to respond to more complex requests and will attend to longer adult utterances, including stories [1]. After age 5, the child's receptive vocabulary continues to grow as language continues to develop; by age 6, typical children will have a receptive vocabulary of 20,000–24,000 words while their expressive vocabulary will consist of only about 2,600 words. By age 12, typical children on average will have a receptive vocabulary of about 50,000 words [3].

Relevance to Childhood Development

The acquisition of receptive vocabulary in childhood is essential for communicative and social development. Understanding the development of receptive vocabulary can help parents and professionals to develop educational and play activities that are appropriate for children in various age groups. Knowledge of developmental milestones (a developmental milestone is a behavior or physical sign that indicates the progress in a child's maturation [2]) related to receptive vocabulary and receptive language in general can be helpful for identifying language delays and disorders affecting receptive vocabulary development and for understanding various treatments for language delays and disorders.

Recessive Gene

►Recessive Trait

Recessive Trait

Rebekah R. Pender
San Antonio, TX, USA

Synonyms

Recessive gene

Definition

The trait of a dichotomous pair that is not expressed in the phenotype of heterozygous individuals [3]. The weaker of a pair of alleles in heterozygous combination [2]. The recessive gene is the second gene that has no effect [1].

Description

A recessive trait is the weak, unexpressed trait of a dichotomous pair of alleles (dominant-recessive) that has no effect in the phenotype of heterozygous individuals. An example would be a child who has the dominant or expressed trait for curly hair combined with the weak, unexpressed, recessive trait for straight hair and thus would be a child with curly hair [2]. However, if two recessive genes for a particular trait are inherited by a child, such as albinism, the child will be albino [2]. Recessive traits have a definite impact on child development such that children can inherit recessive characteristics ranging from red hair or a straight nose to serious conditions such as hemophilia, color blindness, or congenital deafness.

Recognition

►Recognition Memory

Recognition Memory

Matthew J. Holcomb, Raymond S. Dean
Ball State University, Muncie, IN, USA

Synonyms

Cued memory; Recognition

Definition

Recognition memory is the correct identification of verbal or non-verbal stimuli that have been presented previously.

Description

Recognition memory is often investigated by presenting a subject with lists of words or pictures of items to remember. After various periods of delay, subjects are then presented with a mixture of items that have been present and those that have not. Subjects must identify items presented (targets) and those that were not (foils) [5]. This task is not as difficult as "free recall," in which the subject must recall without a cue. Researchers and clinicians often test both recognition and recall memory, with recall tests presented first (e.g., "please tell me the words that were presented") and a recognition assessment presented following the recall assessment. This approach is useful in that much greater performance in recognition than recall suggests problems in retrieval of information, rather than encoding or input into memory. All subjects do better on tests of recognition memory then recall. The important feature is the difference between the two. Additionally, recognition memory has been considered an important area of study within the field of psychology because it is generally viewed by researchers to be a simple memory task, easily measured, rather than complex like many other forms of memory: serial recall, pair-associate recall, or free recall [1]. Memory is a complex process, and patients said to have a memory disorder may show impairment in any one of a number of factors. Recognition memory does not necessarily require the production of specific information from memory but rather a matching procedure [9].

Much of the research in the area of recognition memory focuses on whether or not recognition is a singular process or the result of multiple factors. Specifically, some in the literature argue for a single-process model of recognition, which is based on the idea of familiarity. Others argue for a multi or dual-process model of recognition, which have focused not only on familiarity but the process

in which we develop and join episodic experiences. Each view is not without its detractors. For example, while many argue that the single-process model of recognition memory is simpler [3] there are others who argue that a single-process model ignores the latency of recognition memory [7]. Dual-process models have been problematic for many researchers due to the models' inability to distinguish between sensitivity and bias [10]. Still other researchers are proponents of the dual-process model because it accounts for a more dynamic process within the brain [2].

Single Process Models

The single-process signal-detection model provides a simple measure of recognition, but it comes up short in its ability to account for the accuracy and the time required for confidence ratings. This is not a major problem for many researchers, as investigations of recognition are interested in accuracy and not confidence or judgments concerning recognition [8].

Dual Process Models

Early dual-process models such as that of Pavio suggested information is encoded in a dual fashion (verbal and nonverbal). By nature a dual processing model assumes more complex encoding than single process counterparts, recognition is performed in two ways: familiarity or recollection, as compared to performance of the individual in recognizing cues. Researchers have therefore, been extremely interested in measuring the relative contributions of recollection and familiarity [4].

Due to the inherently more complex nature of dual-process models there are several competing models within the field on how recognition memory develops. Some models assume that recognition is based on a continuous random variable (familiarity) and a discrete random variable based on threshold principals (or a tipping point in which recognition becomes apparent) [6].

Record Judgment of Qualitative Variables

▶Rating Scales

Redl, Fritz

Jerry Gold
Adelphi University, Garden City, NY, USA

Life Dates

1902–1988

Educational Information

Dr. Redl received his Ph.D. in education from the University of Vienna in 1925. During the decade that followed he completed training in psychoanalysis at the Vienna Psychoanalytic Institute. This dual focus on the education and socialization of children, and on psychoanalytic models of understanding personality development and of the treatment of children, typified his work throughout his career.

Accomplishments

Dr. Redl worked as a teacher in his native Vienna and in 1936 traveled to the United States for what was originally supposed to be a temporary applied research assignment. His stay in the United States became permanent due to the ascendancy of the Nazis in German-annexed Austria.

Dr. Redl soon became a professor at the University of Michigan, and moved in 1941 to the School of Social Work at Wayne State University. It was during his 12 year stay at Wayne State that his most important and enduring work on the psychology of delinquency was conducted.

In his academic career his work was rarely limited to the classroom. Rather, he sought, and succeeded in applying and testing his psychoanalytically informed ideas in camps, schools and residential settings. In 1953 he moved to the National Institute of Mental Health as the Chief of the Children's Research Branch, where he continued his investigations into the causes and treatment of aggressive and anti-social behavior in children and adolescents. He also was a co-founder and president of the American Orthopsychiatric Association, an interdisciplinary society for the mental health professions.

Contributions

Dr. Redl is best known for his practical and theoretical work with impulsive and aggressive children, through which he emerged as a pioneer in the development of group, residential and *milieu therapies* for juvenile delinquents, conduct disorders and other forms of externalizing psychopathologies of childhood and adolescence.

Dr. Redl's most influential published works, written with his colleague David Wineman, are the volumes *Children Who Hate* and *Controls From Within*. In these books, the authors described their work at Pioneer House, a residential treatment center for pre-adolescent boys (ages 8–11) who were referred because of aggressive and anti-social behavior. While such programs had been established previously, Pioneer House was unique at its inception in 1946 because of the theoretical framework that informed and guided the diagnostic and therapeutic efforts of its staff. Specifically, Redl and Wineman introduced concepts from psychoanalytic ego psychology into the study and treatment of juvenile delinquency and anti-social behavior. Their work at Pioneer House was understood to be a clinical experiment in which they and their staff attempted, via selective environmental interventions and interpersonal interactions, to promote the growth and remediation of those ego functions that were lacking or deviant in their young clients.

Dr. Redl's work after the close of Pioneer House in 1948 was a continuation and elaboration of these concerns. He was a leading advocate for the psychological and social needs of children, an influential researcher whose integration of psychoanalytic ego psychology and milieu therapy guided the work of countless programs, and a much sought-after teacher and lecturer. He also is known for the development of the Life-Space Interview, a method for therapeutic intervention with children and adolescents which is employed during and after problematic behaviors are displayed in the patients' interactions with peers and adults.

Regression Analysis

Kristen M. Grabill
University of Florida, Gainesville, FL, USA

Definition

A statistical technique based on the general linear model which uses one or more variables to predict an outcome.

Description

Regression analysis uses a model that predicts values of a dependent variable (outcome) from one or more independent variables (predictors). Regression is a commonly used statistical approach, and encompasses both simple and multiple regression approaches.

Simple Regression [1]

Simple regression examines the relationship between one predictor variable and one outcome variable. It can be represented with the following equation:

$$Y = A + BX + e$$

In this equation, Y (outcome) is the sum of a weighted value (B) of X (predictor) plus starting value (A) and a residual (e). The residual represents variance in the data that is unaccounted for by the predictor. When regression is conducted in research, a commonly reported estimate is R^2, which can be interpreted as the percentage of variance in the outcome that is accounted for by the predictor. Researchers also typically report an F-statistic, which is a figure based on the ratio of variance predicted in the model to variance that is unexplained in the model, and determines whether the model is statistically significant.

Multiple Regression [1]

Multiple regression predicts an outcome based on the combined effects of more than one predictor. It can be used in several ways based on the way predictors are entered into the model. Types of multiple regression include standard, hierarchical, and stepwise.

Standard: Standard multiple regression can be represented with the following equation:

$$Y = A + \Sigma_i BX_i + e$$

Similar to the equation for simple regression, Y can be interpreted as the combined effect of summed, weighted values (B) of more than one X (predictors) plus starting value (A) and a residual (e). The residual (e) represents error in the data that is unaccounted for by the combined predictors. In multiple regression, the weights (values of B) represent the unique relationships between each X variable and Y while controlling for all other variables. In literature using multiple regression, B weights will often be reported because they represent the unique value of each predictor to the model, in original units. Researchers often report β-weights as well, which are standardized versions of B-weights. As with simple regression, an F-statistic and an R^2 estimate are typically reported. However, in multiple regression, R^2 can be interpreted as the percentage of variance in the outcome that is accounted for the combined predictors.

Researchers using multiple regression must be careful that their predictors are not multicollinear. When two predictors are highly correlated with each other, they are considered to be multicollinear, and this is problematic in multiple regression because it renders estimation of regression values inaccurate.

Hierarchical: In hierarchical multiple regression, researchers test whether new variables add anything to a model after predictors are accounted for. Rather than add predictors all at once as with standard multiple regression, predictors are entered into a regression model in a series of blocks based on theoretical rationale. This allows researchers to determine whether there is a significant change in the amount of variance predicted in each subsequent block of the model. In hierarchical multiple regression, researchers often report a change in R^2 estimate for each block of the regression analysis. This reflects the percent of variance accounted for by each individual block of the regression, rather than by all variables in the analysis at one time.

Stepwise: In stepwise multiple regression, researchers decide whether to include or omit predictors based on statistical criteria. There are several methods for conducting stepwise regression, although it has fallen out of use due to criticism for not being a theory-driven approach to data analysis.

Relevance to Childhood Development

Regression is one of the most commonly used statistical analysis tools used in all research fields, including the field of childhood development. For example, PsychInfo search using the terms "child development" and "regression analysis" yields 2,443 results. Therefore, understanding of regression analysis is important for researchers, clinicians, and others work with children to maintain current information about research which informs their fields.

Regulation of Emotion

Anthony R. Artino, Jr.
Uniformed Services University of the Health Sciences, Bethesda, Maryland, USA

Synonyms

Emotion control; Emotion management; Emotion regulation; Emotional self-regulation; Self-regulation of emotion

Definition

Regulation of emotion refers to the processes whereby individuals monitor, evaluate, and modify their emotions in an effort to control which emotions they have, when they have them, and how they experience and express those emotions.

Description

Before discussing regulation of emotion, it is important to first define emotion. Unfortunately, there is no clear consensus among affect researchers as to the one best definition of emotion. Instead, research and theory on emotion have been characterized by much conceptual and definitional confusion [4]. This confusion is due, in part, to the fact that emotion has been studied from a diverse set of disciplinary perspectives, including, for example, psychology, neuroscience, sociology, and philosophy [7]. However, in terms of organization and association with other constructs, emotion is often considered a subset of the more general term *affect*. In particular, affect has been organized into three levels: *affective traits*, *moods*, and *emotions*, with moods and emotions considered two distinct types of *affective states* [11]. Further, the distinction between moods and emotions is often based on intensity and duration, with moods being longer, more diffuse, and without a particular referent; whereas emotions tend to be shorter, more intense, and in response to a particular referent [6, 11]. Using this conceptual framework, then, emotion can be defined as an acute, intense, and typically brief psycho-physiological change that results from a response to a meaningful situation in an individual's environment [11]. Importantly, emotions are experienced from an individual's point of view; that is, they are subjective. Of course, as mentioned previously, not all affect researchers subscribe to this conceptualization of emotion (for alternative perspectives, see [2]).

Using this definition of emotion as a foundation, *emotion regulation* simply refers to the processes involved with managing one's emotions. These regulatory processes can be automatic or controlled, conscious or unconscious [7]. Ultimately, emotion regulation involves processes that change the dynamics of the emotional response [16]. That is, emotion regulatory processes affect the latency, intensity, frequency, and duration of emotional responses in the psychological and physiological domains [5].

Several aspects of this definition of emotion regulation warrant further clarification. First, emotion regulation can involve increasing, maintaining, or decreasing both negative and positive emotions [7, 17]. Second, emotion regulation is generally concerned with regulation of "self" and does not include attempts to influence others' emotions (although some theories of emotion regulation do include consideration for "other" regulation; [17]). Finally, emotion regulation can occur along a continuum that spans from conscious, effortful, and controlled regulation (the prototypical form of emotion regulation) to unconscious, effortless, and automatic regulation [7].

Emotion Regulatory Processes

An essential goal for affect researchers is to better understand the processes involved in emotion regulation. That is, what do people actually do when they attempt to regulate their emotions? Although there are a multitude of emotion regulatory processes one could conceptualize, Gross [7] proposed a parsimonious model that includes five sets of processes: situation selection, situation modification, attention deployment, cognitive change, and response modulation. *Situation selection* involves approaching or avoiding certain people, places, or objects in an effort to regulate emotion. An example of situation selection would be taking a different route to the playground to avoid an altercation with a bully. *Situation modification* refers to efforts aimed at directly modifying the situation to alter its emotional impact. An example would be convincing a schoolmate to play in a different area of the playground to avoid an argument with a bossy

child. *Attention deployment* processes include strategies that change attentional focus away from emotion-inducing situations; for example, distracting oneself from an emotional situation or concentrating deeply on another non-emotional task. *Cognitive change* involves modifying cognitive appraisals to adjust the emotional response. Examples include denial, reappraisal, and optimistic thinking. Whereas situation selection, situation modification, attention deployment, and cognitive change all happen before an emotion is elicited; *response modulation* processes transpire once an emotional response has occurred. As such, response modulation is meant to directly influence psychological and physiological responding. Examples of response modulation include biofeedback, relaxation, and exercise [7].

Theoretical Perspectives

In psychology and education, regulation of emotion has been conceptualized from several different theoretical perspectives. For instance, according to Skinner's behavioral learning theory, emotion regulation is a process in which individuals learn to respond to observable stimuli depending on the antecedents and consequences of actions as they either are reinforced or punished [15]. Although, according to Skinner's behavioral learning theory, emotions have a genetic connotation, the expressions and regulation of emotion depend on the individual's history of reinforcement and stimulus control. In contrast, social cognitive theory conceives emotion regulation as a learning process that occurs largely by observing others [1]. Moreover, social cognitive theory considers cognitive factors, beliefs, values, perceptions, interests, and expectancies as critical aspects of emotion regulation. In this view, emotion regulation is a triadic, reciprocal process whereby individuals control emotions in an effort to influence their environment and their own behavior. In turn, the environment and behavior reciprocate by influencing how individuals experience and express their emotions to ultimately become effective social agents. Finally, from the social cognitive perspective, emotion regulation depends on individuals' *self-efficacy*; that is, their beliefs in their capability to effectively manage particular situations and their emotional responses to those situations.

Relevance to Childhood Development

For children, there are many developmental pathways to effective emotion regulation. These pathways evolve from efforts of external agents to manage the emotions of children, as well as from the child's growing capacity to self-regulate [17]. During childhood, children gradually acquire the emotion regulation skills and strategies necessary to cope with various developmental challenges [5]. In early childhood, the child's ability to regulate emotions is dependent on the caregiver's awareness, flexibility, and responsiveness to the child's emotional needs. As the child ages, her ability to self-regulate grows as she gains independence, control, and an identity of her own [5]. Thus, like other forms of self-regulation, emotion regulation is initially supervised by caregivers and teachers at early stages of skill acquisition, but as children mature, they begin to develop competent emotion regulation by internalizing the regulatory strategies they have observed in others.

The importance of emotion regulation becomes clear as children progress through adolescence. In particular, many adolescents experience emotional conflicts during the transition from elementary to middle school or from middle school to high school [13]. Although most children successfully navigate these stressful transitions, for some the emotional conflicts are not adequately handled and can result in maladaptive behaviors (e.g., school delinquency, overeating, and drug abuse). Consequently, it is important for adults to assist children as they develop and learn to manage their emotions. For example, preadolescents often need assistance understanding that emotions such as anger, fear, and frustration are a natural part of growing up. By simply acknowledging these feelings and helping children identify appropriate strategies for managing their emotions, adults can help children develop adaptive emotion regulatory processes. Ultimately, the hope is that children will learn that although they cannot always control what happens to them, they can control how they think about what happens to them and how they react emotionally [9].

Influences on Learning and Performance

From the perspective of learning and performance, emotion regulation is considered a critical competence [13]. Although affect has historically been deemed important to theories of learning and development, moods and emotions have been largely neglected in educational research [14]. Recently, however, educational psychologists have acknowledged the importance of affective states and their impact on learning in academic and non-academic settings. Accordingly, researchers and practitioners have started integrating emotion and emotion regulation into theories of learning and development. In fact, research conducted within the last decade has made it clear that emotions are intimately involved in virtually every aspect of teaching and learning [14]. As such, understanding the nature of emotions as they unfold and are regulated in

various learning contexts has become an important goal for educational psychologists [10].

In general, emotions are thought to influence learning and performance through several mechanisms. First, emotions affect memory processes such as retrieval and storage of information [10]; that is, memory can be enhanced if the individual's affective state at the time of retrieval matches his affective state at the time of encoding. Second, emotions influence the type and amount of cognitive and metacognitive strategies employed by individuals. For example, positive emotions are generally hypothesized to facilitate the use of flexible, deep processing strategies like elaboration, organization, and metacognitive self-regulation, whereas negative emotions are thought to result in the use of more rigid, shallow processing strategies like simple rehearsal [10]. The third way emotions can influence learning and performance is through an increase or decrease in attentional resources, as well as through general interference with working memory functioning (i.e., excess cognitive load; [10]). Finally, emotions can have an effect on motivational processes, such as self-efficacy beliefs and goal orientations [8]. Although somewhat oversimplified, positive emotions are thought to lead to more adaptive motivational processes, whereas negative emotions are assumed to result in decreased motivation (although some negative emotions, such as fear, may actually increase the *extrinsic* motivation associated with a task; [13]).

It is clear from the dynamic, reciprocal links between emotion and cognition that emotion regulation – under the broad rubric of self-regulated learning – is an essential competency for children to master as they develop and learn across a variety of academic and non-academic contexts. Through effective self-regulation of emotion, children move closer to becoming autonomous, self-regulated learners.

Emotion Regulation and Self-efficacy

Emotion regulation is a hallmark of being human and developing as a productive agent in society. From the social cognitive view, self-efficacy beliefs are essential for the effective development of human agency and are the social foundations of all emotion regulation [1]. With this in mind, caregivers and teachers can help children develop self-efficacy for managing and exercising self-control of their emotions. Adults can also help children develop the willingness and ability to delay gratification in order to postpone immediate impulse behaviors and wait for an appropriate time to express their emotions in socially-acceptable ways [3]. In doing so, caregivers and teachers help children develop *emotional self-efficacy*, which is the belief that they are in control of their emotional experiences [12].

Rehabilitation Act of 1973

Eva D. Sloan
St. Mary's University, San Antonio, TX, USA

Definition

Replaced the Vocational Rehabilitation Act, expanded the requirements of states receiving funding for rehabilitation services, and placed special emphasis on those with more severe handicaps.

Description

This Act was passed by the Senate and House of Representatives of the United States of America on September 26, 1973 and was written to replace the Vocational Rehabilitation Act. The Rehabilitation Act of 1973 provided a framework for the Rehabilitation Services Administration to determine how states would meet the needs of handicapped persons [1]. Section 501 of the Act prohibited discrimination in employment of persons in Federal agencies of the executive branch of the United States government. Section 503 required affirmative action for those persons with disabilities and prohibits discrimination in employment of Federal contractors or subcontractors with contracts worth more than $10,000. Section 504 established the civil rights of handicapped individuals and prohibited discrimination in the employment of handicapped persons among Federal agencies or agencies receiving Federal funding. Section 508 required that electronic information and information technology be made available to individuals with disabilities.

Reinforcement

Jennifer M. Alexander, Maria G. Valdovinos
Drake University, Des Moines, IA, USA

Synonyms

Self-reinforcement

Definition

Reinforcement is a behavioral process in which a response produces the presentation of a desirable consequence or termination of an aversive consequence thereby increasing the future probability occurrence of the response under similar circumstances [1, 2].

Description

There are two forms of reinforcement: positive reinforcement and negative reinforcement [1, 2]. **Positive reinforcement** is a process by which a stimulus is added to the environment contingent on a response which subsequently increases the future probability of the response. For example, when an infant begins to coo and babble, the feedback provided by its caregiver (e.g., verbal response, physical interaction, facial expressions, etc.) reinforces the cooing and babbling increasing the likelihood of future cooing and babbling. **Negative reinforcement** is a process by which a stimulus is removed from the environment contingent on a response which subsequently then increases the future probability of the response. For example, if a child is "bugging" an older sibling and the sibling hits the younger child resulting in the child running away, the hitting has been negatively reinforced by the termination of the nagging. In the future, the older sibling is more likely to hit their younger sibling when he is bugging the older sibling. Reinforcement, regardless of it being positive or negative, functions to increase the probability of a response be it a desirable or undesirable behavior. Reinforcement is often used to teach new behaviors, and to increase desirable behaviors in behavior management interventions.

Reinforcement-Maintained Behavior

►Extrinsically Motivated Behavior

Reinforcers

Jennifer M. Alexander, Maria G. Valdovinos
Drake University, Des Moines, IA, USA

Definition

A reinforcer is a stimulus that generates an increase in the rate of the response that produced it.

Description

Reinforcers can be characterized as either positive or negative [1]. A positive reinforcer functions to increase the future likelihood of behavior **contingent** on the stimulus presentation. A negative reinforcer functions to increase the future likelihood of behavior contingent on the stimulus removal. There are different types of reinforcers: primary and conditioned [3]. Primary reinforcers are stimuli that produce their effects on behavior without any history or prior exposure and are often associated with survival functions (e.g., food) [4]. Primary reinforcers may vary in their magnitude temporarily through deprivation and satiation (i.e., **motivating operations**). Conditioned reinforcers are previously neutral stimuli that come to function as reinforcers because they have been paired with reinforcing stimuli. For example, the word "good" initially upon being heard is neutral; however, through it's pairing with smiles, hugs, and other affection, the word "good" comes to function as a reinforcer for the behavior that produces it [2]. Conditioned reinforcers are often more effective than primary reinforcers as they are more challenging to affect via satiation.

Reitan, Ralph M.

Matthew J. Holcomb, Raymond S. Dean
Ball State University, Muncie, IN, USA

Life Dates

1922–present

Introduction

Dr. Ralph Reitan is often seen as the "Father of Clinical Neuropsychology" with over 250 publications as well as being one of the foremost American psychologists of the last 50 years. His work with Ward Halstead resulted in the development of the Halstead–Reitan Neuropsychological Battery (HRNB). Dr. Reitan's work is viewed as groundbreaking in psychology and neurosurgery, because of its utility in predicting the location of brain lesions. The HRNB remains the most widely used neuropsychological battery in North America.

Educational Information

Dr. Reitan received his doctorate in physiological psychology under the supervision of Dr. Ward Halstead at the University of Chicago.

Accomplishments

Dr. Reitan's interest in neuropsychology was seen early in his studies with Ward Halstead and through his interest in biological intelligence. In an effort to understand normal brain functioning Reitan's early research focused on tests that would predict localized brain-damage. His early research studied World War II veterans. These tests would collectively go on to be known as the Halstead–Reitan Neuropsychological Battery (HRNB).

Reitan spent considerable time in conducting research validating the HRNB at the Indiana University Medical Center. Reitan's major contributions involved an actuarial approach to psychological tests and the use of a fixed battery approach which allowed the collection of predictive data which continued to validate his procedures. In addition to the original validation of the battery, Reitan and others conducted research and validation on the HNRB and its ability to provide a diagnosis, lesion localization and functional impairment. Such work is responsible for the HNRB becoming the most widely used neuropsychological battery in the Americas. Dean [1] reviewed the Halstead–Reitan Neuropsychological Test Battery and indicated that, "neuropsychological assessment in North America has focused on the development of test batteries that would predict the presence of brain damage while offering a comprehensive view of a patient's individual functions. Numerous batteries have been offered as wide-band measures of the integrity and functioning of the brain. However, the HRB remains the most researched and widely utilized measure in the United States" (p. 642).

During his time at Indiana University Medical Center, Reitan also worked with refining the HRNB, adjusting individual tests for use with younger patients (9 to 14 years) in what would become The Halstead–Reitan Neuropsychological Test Battery for Older Children. With its validation it has become an important measure in older pediatric populations. This battery has proven significant in differentiating between normal and brain-damaged children [2]. Although valid with 9–14 year old patients, Reitan decided there was a need for significant changes for younger children. Reitan attempted a functional

developed equivalent for children 5–9 years old which is the Reitan-Indiana Neuropsychological Test Battery for Children. This measure represented a vast change of tests from the HRNB. Related perhaps to the age of the subjects, the typical validity and reliability found with the HRNB has not been demonstrated.

Dr. Reitan has taught at Indiana University, University of Oregon and University Arizona. He has received numerous awards and recognitions, from both the fields of psychology and medicine. Clearly, Ralph Reitan and his work have made major changes in modern psychology, not the least of which is major responsibility for a viable new specialty in psychology.

Rejected Children

Erika Carpenter Rich
Los Angeles Private Practice, Los Angeles, CA, USA

Synonyms

Low-accepted children; Low social status children; Peer rejection

Definition

Rejected children are those that are excluded from the activities of the larger group. Within the peer group, there are varying degrees of acceptance. Peer acceptance is measured through ►sociometrics, whereby peer rejection is defined as being actively disliked by the peer group (e.g., the child's classroom or grade level). Most widely studied in children, peer rejection is linked to a wide array of concomitant difficulties, including academic difficulties, ►aggression, loneliness, depression, anxiety, and juvenile delinquency.

Description

Peer rejection is a phenomenon that cuts across a number of diagnostic categories. Indeed, it is more developmental in nature and a group process than a characteristic of the individual, per se [1]. In order to understand peer rejection, it is important to understand the process of peer acceptance versus rejection as a whole.

Often assessed through classroom-wide peer nomination or sociometric techniques, children are assigned to categories of popular, average, neglected, rejected, or controversial [2]. Popular children are widely liked, neglected children do not tend to be actively liked or disliked, controversial children are both actively liked and actively disliked, whereas rejected children are widely disliked. Approximately 15% of children are rejected by their peers. Peer rejection is remarkably stable, even when the rejected child enters a new peer group. In contrast, children who are neglected by their peers tend to shift into the rejected or more well-liked categories over time [1, 2].

Behavioral Characteristics

What is it about a child that incites widespread levels of dislike among his or her peer group? Rejection is firmly linked to behavior problems such as aggression, classroom disruptiveness, and inattentiveness [1, 2]. Predictive models highlight the ability of peer rejection to predict these difficulties over time.

The well-liked child tends to be cooperative, friendly, and possessing of some particular skill or talent, such as being athletic, smart, funny, or creative. The rejected child is, in contrast, uncooperative, annoying, and does not possess an offsetting skill or ability. This is typically a child who angers easily and is both verbally and physically aggressive. Rejected children might also have an off-putting characteristic, such as being overweight, unattractive, or disheveled. Specific social skills deficits are commonly found in the areas of peer entry, perspective-taking, and social-cognitive processing, such as understanding the motives of another's behavior or being able to accurately read social cues [1–3].

Academic and Psychological Maladjustment

Rejected children also have academic and psychological difficulties [4]. These children are more likely to be truant,

suspended, and/or drop out of school [5]. In addition, rejected children have lower levels of classroom participation and lower academic achievement [6, 7].

Children who are rejected by their peers suffer emotional difficulties, as well. Higher levels of depression, loneliness, and anxiety are related to levels of peer rejection [8, 9]. Oftentimes, these children want to have friends and are lonely as a result of their rejection. However, the existence of just one reciprocal friendship appears to function as a protective factor against loneliness and depression in grade school [8, 9]. Although not considered a symptom of any particular disorder per se, peer rejection has been linked to Attention-Deficit/Hyperactivity Disorder in the research literature [10].

There is a subset of aggressive and rejected children that are likely to affiliate with a deviant peer group [11, 12]. It stands to reason that an aggressive child is more likely to be accepted by a peer group where aggression is more normative. In fact, escalated aggression and antisocial behavior may elevate one's status within that deviant peer group. In this subset, the rejected child is more likely to have difficulties with substance abuse and criminal behavior [4, 11, 12].

A Predictive Model for Peer Rejection

An additive model appears to have the strongest research support and is one that ascribes an independent, partially correlated influence of child characteristics, such as aggressive or withdrawn behaviors, and peer social status on child adjustment. For example, in a longitudinal study of children ages 5–12, researchers found that both aggression and rejection predicted externalizing problems, with the influence of rejection being stronger at earlier points in development [13]. The combination of withdrawn behavior and rejection predicted internalizing problems, with the impact of peer rejection being stronger as the children matured. These findings highlight the complicated nature of peer rejection as a predictor of child outcomes.

It is difficult, if not impossible, to account for all of the variables that influence peer acceptance versus rejection. These variables are contingent on the demographics of the social group, the physical environment, and the developmental context. Many of these variables fluctuate across environments and time periods. For example, there is evidence to suggest that peer acceptance is more valuable to members of the majority group (e.g., Caucasians) than to minorities [4]. Similarly, peer rejection has a larger impact on psychological adjustment for girls than boys [13]. A child's social status, therefore, is a function not only of that child's individual characteristics (i.e., behavioral traits, social support, coping skills) but also of the specific group dynamic.

The influence of peer rejection itself changes over time, taking on a life of its own [14]. For example, a child might initially be rejected by peers in preschool for aggressive, bossy behavior. Because he is rejected by his peers, these peers then identify him as someone to automatically exclude and to also be the target of victimization. These resultant experiences serve to encourage further aggressive behavior in a cyclical fashion. It may very well be this *experience* of peer rejection that results in psychological maladjustment.

Intervention

Due to the complicated nature of peer rejection, intervention efforts are typically only partially successful or yield mixed results [1]. Because peer rejection results from a combination of specific social skill deficits, the presence of inappropriate behavior, emotional dysregulation, and social problem-solving deficits, it is important for an intervention to have a comprehensive focus. The role of the peer group cannot be ignored, either. It is important for children to be able to identify and capitalize on opportunities to move into new social networks.

A reputational bias exists, whereby a child's reputation precedes him in future social interactions [1]. For example, if a child has a reputation for being aggressive, peers are more likely to notice the times when that child is aggressive than instances of friendly, cooperative behavior [12]. As a result, reputation is difficult to change in the peer group, especially at older ages. Therefore, early intervention is preferred, in order to change the rejected child's reputation before it becomes stable.

Peer-mediated interventions may be met with greater success in changing peer reputation. These interventions incorporate peer coaching or are classroom-based. Such interventions not only provide skill training directly to the rejected child, but encourage awareness of behavior change in the peer group and provide specific opportunities for new friendships to form [1].

Rejecting Parenting Style

►Indifferent Parenting Style

Rejecting Parents

►Uninvolved Parents

Rejecting/Neglecting Parents

Tamara Del Vecchio
St. John's University, Queens, NY, USA

Synonyms

Uninvolved parents

Definition

Rejecting/neglecting parents are low on measures of demandingness and responsiveness.

Description

Baumrind [1] and Maccoby and Martin [2] have differentiated four parenting styles based on how high or low parents are on each of two independent factors: demandingness and responsiveness. Variations in these factors produce four parenting styles: authoritative, authoritarian, permissive/indulgent, and rejecting/neglecting. A basic tenet of this typology is the notion that exactly how parents socialize their children and the amount of behavioral control and responsiveness displayed varies across parents. These are considered normal variations in parenting and these four parenting styles are not intended to represent abusive parenting behaviors.

Demandingness refers to the level of behavioral control, demands placed, or discipline parents display in their attempts to socialize their children. Responsiveness refers to the level of warmth and sensitivity parents display in their interactions with their children. Parents high on both demandingness and responsiveness display optimal Authoritative parenting and their children evidence competence academically and behaviorally [3, 4]. Authoritarian parenting is high on demandingness but low on measures of responsiveness, suggesting that these parents engage in less sensitive, coercive parenting. Children of authoritarian parents may fare moderately academically, but may lack behavioral control. Permissive parents are highly responsive but lack in demandingness often resulting in children with poor academic functioning and moderate problem behaviors. Rejecting/neglecting parents lack both demandingness and responsiveness. Rejecting/neglecting parents apply little control and are also less sensitive to their children's needs. Children of rejecting/neglecting parents tend to fare the most poorly with difficulties across all academic, behavioral, and social domains.

Relational Aggression

Kristin D. Sawka-Miller
Siena College, Loudonville, NY, USA

Synonyms

Covert bullying; Indirect aggression; Relational bullying; Social aggression

Definition

Relational aggression is the use of exclusionary and/or other nonphysical behaviors to undermine another person's self-esteem or group status.

Description

Relational aggression involves the intent to harm another person through nonphysical injury to or manipulation of relationships. Relationally aggressive behaviors can be covert (i.e., spreading rumors, gossiping, ignoring, excluding) or overt (e.g., directly telling a peer, "If you don't do what I say, I won't be your friend"). Similarly, relational aggression can be reactive in that it occurs in response to feeling angry or threatened, or it can serve an instrumental purpose in getting what one wants.

Both males and females engage in relational aggression. While it is a commonly held belief that females exhibit higher levels of relational aggression than males, research addressing gender differences in prevalence rates has yielded inconsistent and contradictory results. Specifically, results of some studies suggest more females engage in relational aggression, others have found no gender differences, and some studies suggest the prevalence is higher for males but it is more apt to be underreported [4].

Relevance to Childhood Development

Children who engage in acts of relational aggression typically do so to maintain or improve their position in peer groups. Evidence suggests that relational aggression may cause as much, if not more, damage than physical aggression. Victims are at-risk for negative outcomes such as anxiety, depression, suicidal thoughts and behaviors, school avoidance, peer distrust, and low academic achievement [1]. Children who are frequent targets of relational aggression and/or who experience relational aggression in the context of a close friendship are at greatest risk for adjustment problems.

Research suggests that efforts to reduce relational aggression by intervening with individual students have generally resulted in little to no positive behavior change [2]. Consequently it is recommended that relational aggression be addressed in the context of broader systems-level interventions such as school-wide positive behavior support [3] to create positive and safe social climates and decrease antisocial behavior in general.

Relational Frame Theory

Ian Stewart
National University of Ireland Galway, Republic of Ireland

Synonyms

RFT

Definition

Relational Frame Theory (RFT; [13]) is a behavior analytic theory that analyzes and explains the development of language and cognition in terms of learned, generalized, contextually-controlled patterns of relational responding, referred to as *arbitrarily applicable relational responding* or *relational framing*.

Description

Relational Frame Theory (RFT; [13]) is a behavior analytic approach to language and cognition. Behavior analysis has traditionally been regarded as an extremely effective approach with regard to training non-verbal skills in non-humans and non-verbally able humans but has been seen as deficient in terms of its ability to account for the generative nature of human language (see [6]). Relational Frame Theorists would agree that traditional behavioral accounts such as that of Skinner [22] are theoretically inadequate with respect to this aspect of language. However, they argue that the novel generalized relational operant account provided by RFT successfully overcomes the limitation in this respect of earlier behavioral accounts and empirical evidence to date, some of which will be cited below, bears out this contention. As such, Relational Frame Theory includes the rigor, parsimony and strong empirical foundations of behavior analysis, but goes beyond traditional behavioral accounts to explain the generative nature of language, thus ultimately enabling it to present a comprehensive, theoretically unified, empirically well-grounded and practically applicable psychological account of many aspects of higher human functioning.

Arbitrarily Applicable Relational Responding

The key concept in the RFT account of language is arbitrarily applicable relational responding. This can be explained as follows. Many non-human animals can be trained to respond to physical relationships between objects; for example, they can be trained to consistently pick the biggest object from an array. Humans also can do this from a very early age. However, RFT argues that language able humans show an additional type of relational responding that other animals do not in which they relate objects not based on the physical relation between them but based upon contextual cues that determine which relation is appropriate.

For example, imagine a verbally able child is given an exercise involving the hypothetical characters Mr. A. and Mr. B, in which she is told that "Mr. A is taller than Mr. B". If subsequently asked to say which person is shorter, she will likely say "Mr. B" without needing to be told anything further. This response is based upon the contextual cues "taller" and "shorter" rather than on physical relations. Since the taught relation need not depend in any way on physical relations and hence is arbitrarily applicable to any stimuli no matter what their physical properties, this type of responding is referred to as arbitrarily applicable relational responding.

The Emergence of Relational Framing

According to RFT, there are many different patterns of arbitrarily applicable relational responding or, as it is also known, relational framing. These relational patterns or "frames" are forms of operant behavior that humans learn through multiple exposures to interactions with their native language community in which these patterns feature.

Learning to name objects is perhaps the earliest and most basic form of relational framing. As in the case of most forms of relational framing, naming is learned, according to Relational Frame Theory, through *multiple exemplars* of the pattern to which the child is exposed through everyday language interactions. A parent will often say the name of an object (e.g., "This is an apple") and then reinforce (with smiles, praise etc.) any orientation response (e.g., looking or pointing) towards that object (the actual apple). This teaches "Hear name A -> Look at object B." The parent might also present an object (e.g., the apple), ask for the name (e.g., "What is this?"), model the pronunciation of the correct name (e.g., "This is an apple") and then praise the child for production of the same name, which effectively teaches "See Object B -> hear and say name A" (see [1], for a more detailed discussion of this type of interaction). This will happen with many different objects over time. In the beginning, each such interaction may require explicit reinforcement in order for the child to be able to produce it appropriately. Eventually, however, through multiple exposures to this bidirectional pattern (*Name [A] goes with Object [B], Object [B] goes with Name [A]*), the generalized operant of naming results. At this point the child will be able to respond in accordance with the naming pattern based on

contextual cues alone (e.g., such as the word "is") and will not need to be explicitly taught in both directions. Hence, with a novel object-name combination, the child need only be taught in one direction and will be able to respond immediately and without further training, in accordance with the bi-directional pattern. For example, the child might be shown a novel object (e.g., a pencil) and told "This is a pencil." Contextual cues including the word "is" will cue the bidirectional relational pattern so that later if asked "Where is the pencil?," the child will be able to look at or point to the correct object without being explicitly trained to do so (for more detailed descriptions of the learning processes involved see [1, 2, 11, 12, 14, 15]).

Varieties of Relational Framing

Once the child has learned this 'naming' response pattern then being told the name of a novel object (e.g., "This is a car"), which involves the presentation of contextual cues for this pattern (including the word "is," for example) will bring to bear the relational frame of coordination (sameness) between word and object. Coordination is just one example of a relational frame. There are many other types of framing also learned on the basis of multiple natural language exemplars, each of which, similar to the example just seen, essentially involves learning to produce particular patterns (frames) of responding in the presence of particular classes of contextual cue. Some further examples include responding in accordance with frames of opposition (e.g., "Big is the opposite of small"; the word "opposite" here is the cue for a relational pattern of opposition), difference ("A boat is different from a ship"; the cue here is "different," though other words or phrases such as "not" or "other than" could also cue a relation of difference), comparison (e.g., "An elephant is bigger than a mouse"; the cue here is "bigger"; other words and phrases that might function as cues for comparative relations include "greater," "smaller," "more than," "less than" etc.) and perspective-taking (e.g., "I am here, but you are there"; cues for deictic or perspective relations include words such as "I," "you," "here," "there," "now" and "then"). Furthermore, there is an increasing quantity of empirical support for the existence and development of these and other frames (e.g., [7–9, 20, 21, 23]).

Apart from simply demonstrating the existence of such patterns of responding in the behavior of adults and children, RFT researchers have also used the relational frame concept to empirically model several key aspects of complex human cognition including, for example, analogical reasoning (e.g., [24, 25]), rule following (e.g., [10, 18]), perspective-taking (e.g., [17]) and verbal motivation (e.g., [26]).

Properties of Relational Framing

Despite their diversity, all relational frames ultimately involve three defining features. (a) *Mutual entailment* refers to the fact that a relation in one direction between two objects entails or automatically gives rise to a second relation in the opposite direction. For example, if a verbal person is given two foreign coins and told that coin 1 is worth more than coin 2, then they will derive that coin 2 is worth less than coin 1. In other words, the first relation entails the appropriateness of the second relation and this works whichever of the two is trained first (i.e., it is mutual). (b) *Combinatorial entailment* is the phenomenon in which two relations are combined to form a third relation. For example, given three foreign coins, if coin 1 is worth more than coin 2, and coin 2 is worth more than coin 3, then a "more than" relation is entailed between coins 1 and 3, and a "less than" relation is entailed between coins 3 and 1. (c) *Transformation of stimulus functions* is extremely important as regards the psychological relevance of relational framing since, from an RFT perspective, it is the process according to which language can control our behavior. In technical terms, if two stimuli, A and B, participate in a relation, and one stimulus (e.g., A) has a psychological function, then under certain conditions the stimulus functions of B may be transformed in accordance with that relation. For instance, imagine a verbally able child who is shown a coin and told that now they can buy candy in the store. Telling them that they can buy candy gives the coin value and thus makes it desirable to have it (in technical terms, this gives the coin an "appetitive" function). If they are then shown a second coin and told that this second coin is worth more than the first then the psychological functions of the second coin may be transformed such that it is now more desirable (or more appetitive) than the first and if given a choice between the two coins the child will choose the second.

Relevance to Childhood Development

RFT is an operant account of the development of language and cognition that explains these phenomena in terms of the development of learned patterns of generalized relational responding and the patterns of transformation of psychological functions that these learned patterns produce. As such, it suggests that linguistic and cognitive skills may be trained and it posits important parameters for such training. Indeed, several empirical studies already demonstrate the successful training in young children of relational frames including coordination (e.g., [16]), opposition (e.g., [3]), comparison (e.g., [4]), perspective-taking (e.g., [19]) and analogical reasoning [5].

Based on its potential comprehensiveness as well as its practical utility as an approach to training intellectual skills, Relational Frame Theory is highly relevant to the domain of childhood development. It is a relatively young approach as yet, and thus research based on this approach is only beginning to blossom. However, it offers the potential for a theoretically unified, empirically well-grounded, practically useful conceptualization of a number of core areas of human development including intellectual, linguistic, emotional and moral development. A detailed description of the RFT conceptualization of each these specific areas of development is beyond the scope of this entry but those interested can read further in Hayes et al. [13], and in the empirical citations made above.

Relationships

Douglas K. Symons
Acadia University, Wolfville, ON, Canada

Synonyms

Attachments; Family relationships; Interpersonal processes; Parent-child relationships; Sibling relationships; Teacher-child relationships

Definition

A relationship is an interpersonal process with ongoing involvement over time. In children, relationships are usually classified by whom the relationship is with: parents, siblings, peers, and significant others in a child's life such as a teacher.

Description

Relationships constitute the social landscape within which a child develops. There are many different kinds of relationships that develop and take on different degrees of importance across childhood. Initially, the parent-child relationship is the most important. Then siblings within the family environment are a focus during the preschool period and beyond. Upon school entry, peer relationships become critical, and in adolescence, these are related to the formation of intimate and romantic relationships [1]. At a purely behavioral level, a relationship consists of a history of verbal and non-verbal behaviours which are interdependent between individuals, but this ignores cognitive components of relationships that are also essential. In keeping with this cognitive approach, there are several generalized principles that are helpful to understand what a relationship is [2].

First, a relationship is an entity unto itself, that is, it is an "*organized whole.*" It cannot be predicted simply by knowing the individual characteristics of each member of the relationship. As it may have unique characteristics, the relationship itself can be the unit of focus and analysis. For example, a bullying relationship between peers could arise when one child believes it is okay to exploit others within a relationship and the other child is passive and can be victimized. But predictive models of bullying relationships are not foolproof, so knowing this information about the individual characteristics of two children does not necessarily mean a bullying relationship will arise. Second, relationships exhibit "*coherence and continuity,*" that is, there should be stability across time and across contexts. Surface behavior may change, but the underlying functions and processes remain predictable. For example, a parent who is critical of their young child by teasing them about their appearance may continue to do so into adolescence, or they may be critical of their educational attainment and occupational aspirations instead. What is common is that the relationship is negative and contains parental criticism, even though the surface behavior of this criticism changes. Third, individuals "*internalize relationships,*" usually through representational models of how the self and other behave in relationships. This may include expectations of social behavior, schemas for how relationships function, and internal working models of secure base behaviour. For example, a child may be neglected by parents throughout childhood, and develop the expectation that "I cannot and should not count on others." Others might have received criticism throughout childhood, developed a poor self-image, and thus feel unloved. Fourth, represented relationships are "*carried forward*" and thus affect future relationships. Continuing with the above examples, this child may develop future relationships in which they are emotionally avoidant of others, given their expectation that others are not there to meet their needs in times of stress and/or they themselves are ultimately unlovable.

These general principles are for dyadic relationships between a child and someone else, but can also be used to describe larger networks of relationships, such as within a family. Each kind of relationship mentioned above (e.g., parent, sibling, peer, teacher) has extensive research within and across domains as described elsewhere in this volume.

Reliability

Jeremy R. Sullivan
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Consistency; Dependability; Repeatability; Stability

Definition

Reliability is used within the context of psychological assessment and educational testing to refer to the consistency of assessment results. Reliability may refer to consistency over time, within the individual items on a test, across more than one rater or scorer, or across more than one form of a test. Which of these types of reliability are most relevant will depend on the type and purpose of the psychological or educational test.

Description

Reliability refers to the extent to which scores on a psychological or educational test are consistent or stable. Note that reliability refers to *scores* or *results* obtained on a test, rather than to the test itself (see [2, 4]). This is because indices of reliability may vary from a small to large degree with different samples of people, across different time intervals, and with different gender, age, or ethnic groups. For some purposes or for some scores or for some groups, reliability may be high, while for others reliability may be low. Thus, reliability is a characteristic of the scores obtained with a test rather than a characteristic of the test itself.

Test results provide a limited measure of performance on a limited number of tasks at one particular time. Test users would like to think that such test results are consistent over different testing occasions, different raters, or different samples of items from the same content domain. If a score is stable, rather than fluctuating randomly, users will have more confidence that a score is an accurate estimate of performance or functioning. Score reliability typically is measured quantitatively with a correlation coefficient such as Pearson *r*, with coefficients closer to 0.0 indicating less reliability and coefficients closer to +1.0 indicating greater reliability.

Reliability can be estimated in many different ways, depending on the purpose of the psychological or educational test and types of items and scores included on the test. Four broad categories of methods of estimating reliability are described below. For more detailed discussion of specific reliability analyses, the reader is referred to those resources cited in the References list. For example, see Thorndike [3] for a more mathematical treatment of reliability.

The first method of estimating reliability is internal consistency, which refers to consistency within the items on a test or assessment procedure. High internal consistency coefficients indicate that the items on a test are strongly intercorrelated, suggesting that each item is assessing the same construct. Methods of estimating internal consistency involve administering the test to a sample of people, dividing the items in different ways, and then correlating the scores from different parts of the instrument. For example, the split-half method is often used with power tests, in which test items become progressively more difficult. With the split-half method, test items are divided into two equivalent halves, usually based on odd and even items in order to control for the effect of increasing difficulty. Then the two halves are scored separately, which provides two scores for each individual. Finally, scores on the two halves of the test are correlated across the entire sample, and the correlation coefficient indicates the degree to which consistent results are obtained from the two halves of the test. The correlation will be more meaningful with a larger number of items. One of the limitations with the split-half method is that it tends to result in small correlation coefficients, thereby providing an underestimate of internal consistency. The Spearman-Brown formula is often used to provide a corrected estimate of split-half reliability.

Other commonly used methods of estimating internal consistency are the Kuder-Richardson formula (K-R 20) and coefficient alpha (also referred to as Cronbach's alpha). These methods split all the items on the test every possible way and then provide the *average* of all possible split-half correlation coefficients. The Kuder-Richardson formula is used when responses are scored dichotomously (e.g., correct or incorrect, True or False), and coefficient alpha is used when responses are not dichotomous (e.g., self-report measures using a 5-point scale). Because these methods do not require the user to split the test items, these methods are often preferred to the split-half method in cases where difficulty is not a consideration (e.g., personality and interest inventories, which do not have correct and incorrect responses).

The second method of estimating reliability is test-retest reliability (sometimes called stability), which is used to estimate the consistency or stability of test scores over time. Test-retest analyses involve administering the same test twice to the same group of people with some time interval between administrations. This time interval often ranges from 1 week to 1 month, but shorter or longer intervals are sometimes appropriate for some types of tests. Once scores are obtained for the two administrations, these sets of scores are correlated. If the results are highly stable, each individual will obtain a score on the second administration that is similar to their score on the first administration. Lower correlation coefficients suggest a larger degree of error and more variability in test performance over time.

The time interval between test administrations is an important consideration with test-retest reliability. If the

interval is too short, people may remember their responses from the first assessment and simply give the same answers again, resulting in an inflated correlation coefficient. If the interval is too long, the results will be influenced by developmental changes, interventions, and exposure to subsequent learning experiences. This will result in a smaller coefficient. Thus, test-retest coefficients tend to decrease in magnitude as the time between administrations increases, and it is impossible to evaluate the quality of a test-retest coefficient without knowing the interval between administrations. Reliability analyses of scores on speed tests are likely to employ the test-retest method, as internal consistency methods are likely to produce inflated coefficients.

Another factor influencing test-retest reliability is the theoretical stability of the construct under investigation. For example, with scores on an intelligence test, users would want test-retest coefficients to be very high because intelligence is conceptualized as a relatively stable construct. With scales measuring emotional functioning such as depression or anxiety, users typically allow for lower coefficients, because these constructs are more influenced by changing environmental factors such as stressors and exposure to intervention. Thus, stability coefficients for scores on personality and interest inventories are typically lower than coefficients for scores on cognitive tests.

The third method of estimating reliability is alternate forms reliability (sometimes called equivalence or parallel forms reliability), which examines consistency across two different forms of the same test or assessment procedure. The process of establishing evidence for alternate forms reliability involves giving two different but equivalent (i.e., based on the same content and specifications and the same number of items in the same format) forms of the test to the same group of people, with no time interval between administrations. After administering the two forms, the scores are correlated. High correlations suggest that the two alternate forms are equivalent or similar in terms of the content or behaviors that are measured.

The alternate forms method is frequently used with standardized tests of academic achievement. In this case, test users may want to measure educational progress, but it would be inappropriate to administer the exact same test over and over to the same student due to practice effects. Thus, different forms of the same test can be used to monitor progress, but users need evidence that the different forms are equivalent. As an example from classroom assessment, teachers sometimes develop two or more forms of a classroom test to control for cheating (i.e., students are less likely to look at one another's tests because there are several different forms of the test). In such cases, teachers would want to ensure that the different forms are equivalent in terms of item content and difficulty so that students' scores are not influenced by which form of the test they take.

The fourth method of estimating reliability is interrater reliability, which refers to consistency of scores across two (or more) different raters or scorers; that is, would two people who scored the same test award the same scores? Interrater reliability is especially important for providing evidence for reliability of scores on subjective tasks, where judgment is required by the rater. These types of tasks include essay tests, performance assessments, and projective psychological tests. Test users would like to think that an individual's score on these subjective tests is not influenced by the professional doing the scoring, but rather is an accurate measure of the test-taker's true knowledge, abilities, or perceptions. The process of examining interrater reliability involves giving a set of responses requiring judgment to two or more raters and having them independently score the responses. Then scores are correlated to see how consistent the raters were. Interrater reliability generally is not considered important for objective tests because no judgment is required to score these tasks (e.g., interrater reliability should be perfect for a multiple choice test).

An important influence on the degree of interrater reliability is the quality of the criteria used to evaluate responses. Well-defined scoring criteria and rubrics, and guided practice in using them, generally lead to greater consistency across scorers. Thus, interrater reliability can be improved by making scoring categories more distinct and by training raters in scoring procedures.

Generally speaking, reliability coefficients are influenced by a number of factors in addition to those factors discussed above. For example, reliability coefficients are influenced by the number of assessment tasks or items on a test (in general, more items typically result in more reliable scores) and the spread of scores on the test (distributions with a wide spread of scores typically result in higher correlation coefficients). Reliability is also directly related to measurement error: as measurement error increases, so do the randomness and inconsistency of scores, thereby decreasing reliability.

In light of the multiple factors that influence reliability and the different methods used to estimate reliability, there is no universally agreed upon correlation coefficient that can be used as a cutoff for a minimally acceptable level of reliability. If the results of an instrument could lead to decisions that have lasting consequences or that have a significant impact on a person's life (e.g., tests of

intelligence and scholastic aptitude), then users would want the instrument to have very high reliability coefficients. Users also can compare the reliability coefficients obtained with the instrument they are considering with those coefficients of other instruments in the area to see if they compare favorably. Users also should examine whether reliability coefficients are significantly different for different groups, such as gender, socioeconomic, ethnic, and age groups. Sometimes coefficients will be smaller for different groups, suggesting caution in using the test with these groups.

Conceptually, reliability is a necessary but not sufficient condition for validity. That is, if a test produces scores that are random and inconsistent, the ability of these scores to facilitate accurate predictions and classifications (e.g., clinical diagnosis, special education placement) will be severely compromised [1]. At the same time, score reliability does not guarantee that the score will lead the test user in the right direction with regard to decision making; appropriate uses and interpretations of test scores are issues of validity.

Relevance to Childhood Development

Tests or standardized procedures are often used for clinical decision making, instructional decision making, educational placement, and research purposes. In order to have confidence that the results of these procedures are consistent and stable, there should be evidence of reliability analyses. The more pieces of evidence for reliability that users have available, either in test manuals or in the research literature, the more comfortable they are using these tests and procedures.

Suppose a teacher administers a classroom test designed to assess the extent to which students have met instructional objectives. After administering and scoring the test, the teacher may wonder: "How similar would students' scores have been if I had tested them yesterday, or tomorrow, or next week?"; "How would the scores have differed if I had used a different sample of items or tasks that measured the same objectives?"; or "How much would the scores have differed if a different teacher scored the tests?" Similar questions arise when a psychologist is interested in assessing the social, emotional, behavioral, or intellectual functioning of children and adolescents. These are the types of assessment-related questions that reliability analyses attempt to answer.

Religion

Bady Quintar
Nova Southeastern University (CPS), Fort Lauderdale, FL, USA

Definition

Religion is defined by Webster's dictionary (Unabridged) as the "belief in a divine or superhuman power or powers to be obeyed and worshiped as the creator(s) and ruler(s) of the universe."

Description

Throughout human existence, man has had the need to understand and explain to himself and others the origins and meanings of the common natural phenomena and the wonders of the world around him. Early men, in every known culture, used their creative imagination to make up stories about the natural events such as floods, earthquakes, eclipses of the sun and moon, and the like. Often in their attempt to make their stories credulous, they gave them anthropomorphic qualities. The Greeks, for example, as early as 2000 B.C., created highly imaginative, wise and instructive myths about gods, which were passed from generation to generation by word of mouth long before the invention of the printing press. In fact, they were the first people who created gods and goddesses that looked like real human beings with human characteristics including virtues, vices, cherished values and ideals. They were described as bigger than life, immortal, forever young, beautiful, powerful, and living a life of leisure. Like human beings they were born, grew up, fell in love, got married, and had children. Ordinary people worshipped them, built temples for them, and were always at their mercy. In essence, people were concerned with the impact of the external world's forces on their day-to-day living.

It was not until the teaching of Socrates who lived from 469 to 399 B.C. that the direction of Greek philosophy was changed from concern with the external world to concentration upon man's inner nature. His student Plato who lived from 429 to 347 B.C. rejected the notion that

knowledge is derived mostly from sensory phenomena. He believed that the soul (psyche), unlike the body, is immortal and contains the imperishable ideas which are the basis of our mental activities. For several centuries men struggled with the Platonic dualism of mind and body. During the nineteenth century several thinkers made meaningful advances in the field of social psychology, anthropology, psychiatry, and neurological discoveries. During this century studies concerning the psychology of religion began in earnest.

Religion was not being considered only as a matter of faith, but as an important subject of intellectual and academic inquiry. Religion was conceptualized as a system of communication which has occupied the mind of human kind from the dawn of civilization. Throughout recorded history philosophers, theologians, anthropologists, and religious scholars attempted to explore and answer some of the vexing questions regarding human existence, deity, destiny, life and death, resurrection, salvation, and human suffering. With the dawning of the twentieth century, different approaches to the study of the origins and functions of religions were explored by several original thinkers such as William James, Sigmund Freud, and Carl Justav Jung. James wrote, in his *Varieties of Religious Experiences* (1901–1902) that *individual religious experiences* rather than adherence to dogmas or doctrines of organized religions are the real essence of religious life. Freud in *Totem and Taboo* (1913) drew a connection between primitive men's religious views and practices and the observed behaviors of obsessive-compulsive neurotics. Furthermore, in *The Future of an Illusion* (1927) and *Moses and Monotheism* (1939), Freud advanced the notion that religious ideas stemmed from men's need to protect themselves from the uncontrollable and destructive forces of nature. The need for protection from an external powerful agent is somewhat reminiscent of a helpless child who looks for a powerful father who can protect and comfort him. Freud assumed that men found it necessary to resort to religious beliefs and practices to comfort and protect them. He never altered his idea that religion was an obsessional neurosis. Jung, on the other hand, assumed that the absence of religion was the chief cause of psychological disorders in the adult population. He believed that religion played a significant part in the daily life of every human being regardless of race, ethnicity, social class, and country of residence.

Whether organized or not, religion has been instrumental in the socialization process by preaching cherished values including love, honesty, respect, charity, compassion, and the like. How such virtuous values are transmitted to others in the course of socialization varies from one religion to the other. Thus, the so-called patriarchal religions; namely, Judaism, Christianity, and Islam, including the various subdivisions in each one of them, tend to be authoritarian. God is viewed as the absolute ruler who demands obedience from his followers and who is highly punitive toward those who challenge his absolute authority. Prior to the emergence of the Roman Empire, Christianity was less authoritarian and more humanistic. They offered hope, love, justice, and salvation to the poor, the deprived, the humble, and the hopeless. They followed the simple and profound teachings of Jesus who reassured his faithful followers that the kingdom of God is within them. This humanism reflected in early Christianity is reminiscent of that noted in the teachings of Socrates and Zen-Buddhism who advocated that no knowledge is valuable or meaningful unless it grows out of ourselves.

Relevance to Childhood Development

In the process of socialization, parents typically assume the responsibility of passing on important religious and moral values and beliefs to their children. Harms (1944), after the analysis of data gathered from children who were asked to draw what they thought God looked like and to comment about his nature, distinguished the following three stages of religious growth: (a) The *fairy-tale stage* which included children between 3 to 6 years of age. These children made no distinction between religion and fairy tales. (b) The *realistic stage* covered children from 7 to 12 years of age. These children tended to be matter-of-fact, questioned the veracity of religious stories, and viewed God as an omnipotent anthropomorphic figure with physical features. (c) The *individualistic stage* corresponding to the age of 12 years through adolescence. Harms encountered a variety of views including the one where God is seen as a spiritual being with whom one may have a very personal relationship. It is worth noting that Harm's threefold classification corresponds to the following Piaget's three stages of cognitive development: *preoperational thinking* (2–7 years), *concrete operational thinking* (7–11 years), and *formal operational thinking* (12 years-adulthood).

Remeron SolTab®

►Remeron®

Remeron®

Synonyms

Mirtazapine; Remeron SolTab®

Definition

A prescription medication FDA approved for the treatment of depression.

Description

This medication works by increasing the release of norepinephrine and serotonin in the brain. It is available as a tablet (Remeron®) or as a disintegrating tablet (Remeron SolTab®).

The recommended starting dose is 15 mg taken once a day at night. Maximum suggested dose is 45 mg a day. Dosage increases should be made slowly to prevent side effects. This medication should only be taken as directed by a doctor. It may take 4 weeks before improvement in symptoms is seen. Concomitant use in patients taking monoamine oxidase (MAO) inhibitors is not advised.

Some side effects of this medication include drowsiness, difficulty thinking, constipation, dry mouth, increased appetite and weight gain, dizziness, light-headedness when standing, and abnormal dreams.

Relevance to Childhood Development

Remeron® is not FDA approved for use in children.

A medication guide must accompany this medication containing information related to the increased risk of suicidal thinking and behavior in children, adolescents, and young adults compared to those not taking the medication. Doctors will monitor patients closely for worsening of symptoms, change in behavior, and thoughts of suicide. Patients are strongly encouraged to notify their health care provider to report sudden changes in mood, behavior, thoughts, or feelings.

Resilience

Mysti S. Frazier
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Coping; Protective factors

Definition

Resilience refers to a child's ability to emotionally, mentally, and physically adjust to life after experiencing adversity. Resilience often is investigated in children who have experienced abuse and/or neglect for substantial periods of time in early life. More generally, resilience can be the positive adaptation to one's environment through intelligence, resourcefulness, and good mental health [1].

Description

Resilience is a difficult term to define with precision. Research on such a broad psychosocial construct has led to many different theories and ideas about what developmental influences lead to resilience in children. Overall, the concept of resilience should include many dynamics such as living environment, genetic influence, parenting, coping skills, intelligence, academic achievement, and protective factors. In most cases children are considered resilient only if they have experienced some major life stressor, current or past hazard, or a demonstrable risk [2]. However, children who do not have such traumatic experiences also have shown resilience from ordinary life stressors, such as divorce [1].

Psychologists began researching resilience among children in the 1970s [2]. They began by studying the genetic and experiential differences between children in various adverse situations. These studies helped develop new ideas about the abilities disadvantaged children develop to lead more functional and healthy lives. Current research is focusing on biological factors and psychosocial factors that play a larger role in the development of resilience than was first expected [1, 3, 4].

It is not entirely clear to researchers why some children who have experienced extreme adversity have developmental advantages over others who experience similar situations. One consideration is biological. Adverse experiences are thought to affect neural plasticity, reducing the ability of the brain to function effectively [3]. Also, genetic adaptations are a consideration since it is clear to researchers that some families develop resilience better than others [3]. However, this research is still in its infancy and longitudinal designs must be employed in order to accurately test these relationships.

Examples of environmental risk variables often included in research on childhood resilience include poverty, parental psychopathology, poor parenting skills, negative parent–child interactions, limited maternal education, minority status, stressful life events, and large family size [1]. Interestingly, several researchers are finding that the *number* of risk factors is more predictive of developing psychopathology than the presence of any particular risk factor (e.g., see [1]).

Protective factors that contribute to the development of resilience in children include emotional regulation, formation of positive relationships, intelligence, successful academic performance, positive parenting behaviors, and coping skills [2, 4, 5]. In early life, positive parenting is important to the development of a high functioning individual and research has shown that children who received better parenting had higher self-esteem, better test scores, and greater conscientiousness than those who did not [2]. However, there is a danger in adolescence when youth who have developed strong resilience

participate in risky behaviors because they feel they are invincible to certain problems [5]; that is, they become over-confident in their abilities to combat adversity.

Response Cost

Judah B. Axe
Simmons College, Boston, MA, USA

Synonyms

Loss of privileges; Loss of reinforcement

Definition

A loss of reinforcers following the occurrence of a behavior resulting in a decrease in the future likelihood of that behavior.

Description

B.F. Skinner described the basic principles of behavior and behavior change including reinforcement, extinction, and punishment. Punishment is defined as a consequence of behavior that results in a future decrease of the frequency of the behavior. There are two types of punishment: the presentation of an aversive stimulus and the removal of a positive reinforcer. Response cost is the removal of a positive reinforcer contingent on the occurrence of a behavior and results in a decrease in the future frequency of the behavior [1, 2].

One common situation in which a response cost is used to decrease undesired behavior is in a token economy behavior change system. Tokens are exchangeable for positive reinforcers and delivered to an individual contingent on desired behavior. A response cost is in effect when tokens are removed contingent on the occurrence of undesired behavior.

A commonplace example of a response cost is a ticket issued by a police officer for offenses such as speeding while driving. The removal of money (a positive reinforcer) contingent on the occurrence of the undesired behavior may decrease the future likelihood of the behavior (i.e., speeding).

Response Generalization

Brady J. Phelps
South Dakota State University, Brookings, SD, USA

Synonyms

Response induction; Response variability

Definition

In the operant conditioning of B.F. Skinner, response generalization refers to the spreading of the effects of a behavior strengthening contingency to other responses that are similar to the target response that resulted in the behavior strengthening consequence.

Description

Response generalization is said to have occurred if a procedure that increases the likelihood of a target operant response causes an increase of other responses that resemble the target response [1]. The other responses to which response generalization spreads need not bear physical or topographical similarity to the reinforced operant. The other responses that are strengthened in response generalization are typically members of the same operant response class; an operant response class is a grouping of operants that share a common function such as putting on a coat, folding your arms and rubbing your hands over your arms and stamping your feet; all of these operants serve the same function of trying to keep warm [7]. Rats that were reinforced for running a maze but subsequently put in a water maze showed improved and faster maze swimming; strengthening maze running generalized into strengthened maze swimming [2, 5].

Response generalization has to be distinguished from stimulus generalization; the latter is a process in which reinforcing a response in the presence of a specific stimulus increases the likelihood the same response will occur in the presence of similar stimulus events. In response generalization, the response varies while the stimulus conditions remain unchanged, whereas in stimulus generalization the response stays the same but the stimulus conditions change [6].

Response generalization is one of the sources of variation in responding that is the basis for shaping a novel operant. In general, the more a response is subject to continuous reinforcement, in which every occurrence of the target response is reinforced, the response is strengthened but the response also becomes more stereotyped. That is, a response often shows less variability the more times it is reinforced. But if an operant is then reinforced intermittently or if reinforcement is discontinued as in extinction, operant variability increases. If reinforcement is then made contingent on one of the variations, the new variation is subsequently strengthened and itself shows additional response generalization. After several such periods of reinforcement followed by intermittent reinforcement or extinction, entirely novel behavior is observed [3, 6, 7].

Response generalization occurs after the reinforcement of either animal or human behavior; in particular response generalization as been observed to occur with typical operants such as lever pressing, key pecking and maze running by animals, as noted previously. Among humans, response generalization has been observed in the midst of learning new verbal behaviors [2]. In another instance, a study conducted in 1991 observed response generalization after pizza delivery drivers were given training to increase seat belt use. Training consisted of meetings with drivers in which seat belt use was emphasized and having drivers make an overt commitment to seat belt use. The delivery vehicles were subsequently equipped with monitors that enabled trainers to record seat belt usage and drivers were provided feedback pertaining to the frequency of seat belt use. As expected, the frequency of seat belt use increased as well as the appropriate use of turn signals, which was not part of the intervention. The seat belt training led to response generalization of increased turn signal use, and both behaviors are instances of a response class of safe driving behaviors [2, 4].

Restricted Environmental Stimulation

►Sensory Deprivation

Restrictive Play

Tabitha Bond
Scott Center for Autism Treatment, Melbourne, FL, USA

Synonyms
Limited play; Stereotypic play

Definition
Restrictive play is a category of behavior representative of continuous, preoccupied interaction with a specific object.

Description
Individuals diagnosed with autism spectrum disorders typically exhibit restrictive play skills [1]. These restrictions result in the individual engaging in bizarre and obsessive behaviors while interacting with objects or toys [2]. While engaging in these behaviors, the individual is completely absorbed in the object while all other items, activities, and individuals in the environment are excluded from their attention. Examples include: repeatedly watching the same movie, dismantling objects, lining up items, spinning a block, opening or closing doors, or banging objects [5]. These behaviors are repetitive in nature and do not resemble the appropriate function for the object. Consistently engaging in restrictive play behaviors results in limited verbal and nonverbal exchanges, minimal toy sharing, and solitary play in a social environment. Individuals with restrictive play also exhibit aversions to change in routines and familiar environments [3]. In addition to these behaviors, individuals may engage in other non-restrictive behaviors including ritualistic behaviors, stereotypical behaviors (e.g., hand flapping), and limited joint attention (e.g., concentrating on a common event or object) [6].

Without treatment, individuals with restrictive play develop fixations and obsessions with items or activities and miss opportunities to develop necessary play skills such as parallel, associative, cooperative, sociodramatic, and rough-and-tumble play [2]. Deficits in these skill areas often result in social isolation and rejection from peers [6], thereby increasing restrictive play and creating an ongoing cycle.

Behavioral interventions are an effective course to treating the repetitive and obsessive behaviors present in restrictive play. Treatment for these behaviors includes redirecting, prompting and modeling procedures [5]. Repetitive, inappropriate behaviors exhibited are replaced by physical support through modeling and prompting the individual to engage in the correct pretend play behavior. For example, banging a toy car onto the ground is replaced by hand over hand guidance in rolling the car over the ground. Visual support procedures – utilizing physical examples of the behavior paired with pictures, icons, or words – are also effective [4]. Peer models can also be introduced to engage the restrictive play individual in appropriate play skills through imitation and modeling.

Retardation, Degrees of

Lauren Alexander, Angela Waguespack
Nova Southeastern University, Fort Lauderdale, FL, USA

Synonyms

Severity of mental retardation

Definition

"Degrees of retardation" is a term used to describe the current and/or predicted functioning level of an individual with mental retardation. The most widely used classification system in the professional literature describes four levels of mental retardation: mild, moderate, severe, and profound. Educators historically have used a classification system that includes terms such as educable mentally handicapped (EMH) or trainable mentally handicapped (TMH); however, these terms have generally been eliminated in special education.

Description

Mental retardation is a condition manifested in the developmental period which consists of two necessary components: subaverage general intellectual functioning and concurrent deficits in adaptive functioning in areas such as communication, self-care, functional academic skills, social/interpersonal skills, etc. The term "mental retardation" has been replaced with the term "intellectual disability" in some professional communities. Degrees of mental retardation describe the level at which an individual would be expected to function given the extent of impairment. More recently, less emphasis has been placed on the degree of impairment and more on the level and amount of support needed for daily living of individuals with this condition.

Mild retardation describes approximately 85% of individuals affected by mental retardation. The expected subaverage intellectual quotient (IQ) range is 50–55 to approximately 70. Individuals within this range often acquire the skills comparable to those of a typical sixth grader and some may be able to complete education through high school at a decelerated pace. They are likely to be able to complete activities of daily living (ADLs) and may be able to live independently with the appropriate support.

Moderate retardation describes approximately 10% of individuals affected by mental retardation. The expected IQ range is 35–40 to 50–55. Individuals functioning at this level often acquire communication skills in childhood and attend to their own personal care (with moderate supervision); however, they function well below peers in terms of academic skill attainment. These individuals typically benefit from living in a supervised setting and can perform semiskilled work under appropriate supervision.

Severe retardation describes approximately 3–4% of individuals affected by mental retardation and includes individuals whose cognitive functioning is measured to be within the range of 20–25 to 35–40. The school curriculum for individuals functioning within this range often includes functional academic skills, as well as life skills which support a meaningful transition from school to adult living. These individuals may be able to master some basic self-care skills; however, they typically require a supervised living situation.

Profound retardation describes approximately 1–2% of individuals affected by retardation. The expected IQ

range is 20–25 and below. Individuals with this designation typically have an identifiable cause for their retardation and have other health conditions and/or disabilities as well. A highly structured environment with supervision and assistance in daily living skills is generally necessary in fostering optimal quality of life for these individuals.

Relevance to Childhood Development

Mental retardation is an enduring condition and although adaptive functioning generally improves in all but the most impaired individuals, the disability is often evident throughout an individual's life. Age of identification, etiology, and developmental progress varies depending on the severity of impairment. An individual's level of impairment will become more evident as he/she advances in age and the gap between his/her functioning and that of same-aged peers widens.

Typically, a child with mild mental retardation will not be identified as such until approximately the first or second grade, when academic expectations are sharply increased. Accordingly, children with moderate mental retardation will likely be identified before ever beginning school since their impairments are more severe than those with mild mental retardation. Children with severe and profound mental retardation will likely be identifiable as such well before early childhood, typically between birth and toddlerhood.

As the degrees of mental retardation progress from mild to profound, so does the likelihood that an identifiable cause for the disability is known. For instance, only about 50% of individuals with mild mental retardation have a known cause for their impairment while almost all individuals with severe to profound mental retardation have a known cause for their condition. Factors such as genetics, including chromosomal abnormalities, acquired syndromes, developmental factors, and the influence of the environment and sociocultural context can all play a role in the etiology of any degree of mental retardation.

Infancy, toddlerhood, and early childhood will be most prototypical for a child with mild mental retardation and less so for a child with more severe forms of mental retardation. In fact, the stages of development for a child with mild mental retardation typically progress similarly as a child without mental retardation. These children often communicate and play like other children and tend to display similar levels of developmental functioning. It is not until entering school that these children are identified because academic and social demands increase significantly at this time. Adolescence often proves to be a challenging stage of development for children with mild and moderate mental retardation because their impairment is such that they often cannot perform the academic and social tasks demanded of them, but they are skilled enough to recognize that they are academically and socially delayed relative to their peers.

The entire lifespan is likely to be recognizably impaired for an individual with severe or profound mental retardation. There may be sensorimotor difficulties, significantly delayed speech and language skills, and significantly impaired social interactions. These children may never participate in a regular education classroom environment, instead beginning specialized education and training suited for their needs at a young age and continuing throughout life.

Retention

Jill Driest
Nova Southeastern University, Davie, FL, USA

Synonyms

Memorization; Non-promotion

Definition

Retention is the process where students are held back from advancing to the next grade level and are required to repeat the grade just completed.

Description

Retention requires that a student repeat a grade rather than being promoted to the next grade level. Most commonly,

students are retained for failure to pass a standardized assessment measure, learning difficulties, or emotional immaturity. The assumption is that the act of retention will remedy any academic deficits or emotional immaturities found in these students [2].

Retention is most commonly regarded as an alternative to social promotion. Social promotion is a process by which children are promoted to the next grade level regardless of their ability to succeed academically. Both of these practices are heavily debated in the literature [1].

The majority of research on retention suggests that the practice is neither a beneficial nor an effective practice [2]. In fact, retention may actually harm academic and social adjustment. Studies demonstrate that those students who are retained are more likely to be retained again, drop out of school, and have problems with peer relationships and self-esteem. Likewise, these students are also more likely to engage in risk-taking behaviors including abusing drugs and alcohol, violence, and promiscuous sexual activity [3].

Some studies suggest that retaining a student early on in their academic career allows for positive effects socially and academically. However, these benefits seem to be only temporary, as only a few years after the retention these benefits are no longer apparent [5].

Relevance to Childhood Development

Despite the controversy associated with retention, the practice is still widely used and accepted in the United States. In fact each year, approximately 15% of students in the United States are retained. Of these students, males, minorities, inner-city children, and those from low socioeconomic status are more likely to be forced to repeat a grade [3, 4].

Reticular Activating System

Edalmarys Santos[1], Chad A. Noggle[2]
[1]Middle Tennessee State University, Murfreesboro, TN, USA
[2]SIU School of Medicine, Springfield, IL, USA

Synonyms

Reticular Activating System (RAS); Reticular formation

Definition

The RAS refers to a network of nerves and connections that originate in the superior portion of the brainstem which together serve the purpose of modulating attention and arousal [3].

Description

The RAS, also known as the reticular formation, refers to a network of nuclei and fibers that extend throughout the central portion of the brainstem from the medulla to the midbrain [1, 2]. While the RAS is described as the primary source/ site of brain activation (e.g. [4]), this is just one portion of the functional role the RAS plays. The superior portion of the RAS, which is based in the upper pons and extends into the midbrain, regulates arousal level and consciousness [1]. In contrast, the inferior portion of the RAS, which lies in the lower pons and medulla, tends to be primarily involved in motor and autonomic function [1].

Due to its direct and indirect connections throughout the system, lesions of the RAS may vary tremendously in terms of functional impact. Specifically, lesions of the RAS may lead to manifestations ranging from dysregulation of sleep in wakefulness and impaired attention to lethargy and/or coma and even death.

Rett Syndrome

Rania D. Hadjicosta,
Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Definition

Rett Syndrome (RS), according to the American Psychiatric Association (APA) [1], is a Pervasive Developmental Disorder (PDD) and as such it is characterized by substantial and pervasive reciprocal, social, communicative and behavioral impairments, which are qualitatively deviant based on the child's developmental level and mental age. The most notable difference between RS and the other PDDs, including Autism, Asperger's Disorder, Childhood Disintegrative Disorder, and PDD Not Otherwise Specified is that RS appears almost only in girls and is not evident from birth [1].

Description

Rett syndrome (RS) is a neurodevelopmental disorder that contributes significantly to severe intellectual disability in 1:10,000 to 1:23,000 females worldwide [2], making RS the second major cause of mental retardation in females, following Down syndrome [3]. RS was first recognized in 1966 by the pediatrician Andreas Rett [4], but increased awareness about the disorder in the English medical literature was brought by Hagberg and colleagues in 1983 [5].

In RS, deficits develop following a normal prenatal and perinatal period and after a period of apparently normal development from birth and until, at least, the fifth month of age. The onset after the fifth month of age is provided by the criteria set in the Diagnostic and Statistical Manual of Mental Disorders, fourth edition, text revision (DSM-IV-TR) [1], even though others have estimated the onset of the disorder to be at the sixth [6] or even the seventh month of age [5].

Generally the onset of the disorder is estimated to be before the age of 4 years, indicated by a deceleration in head growth, usually leading to microcephaly [1]. Other notable features of RS are the loss of purposeful and intended hand movements and hand skills between the 5th and the 13th month of age and the development of repetitive, stereotyped hand-washing, hand-wringing, clapping, flapping, or mouthing gestures. Interest in the social environment deteriorates, as well, within the first years of onset; deficits in the child's gait and trunk movements are also present [1]. Finally, impairment in expressive and receptive language development along with severe psychomotor retardation are also characteristic [1].

In addition, according to Hagberg and colleagues [5], developmental stagnation after a period of apparently normal development is followed by a rapid deterioration of the mental status of the child, leading to dementia with autistic features. However, a period with a relatively stable mental status follows after the onset of RS, but it is marked by the emergence of other neurological abnormalities, including spasticity of the lower limbs and epilepsy [5].

Additional supportive criteria for the diagnosis of RS, which were developed to assist the diagnosis and describe the phenotype of the condition, include: breathing dysfunctions such as episodic hyperventilation or breath-holding [7], EEG abnormalities, seizures, peripheral vasomotor disturbance, scoliosis or kyphosis, growth retardation, and hypotrophic small feet [4, 6]. Furthermore, bruxism, impaired sleeping patterns, air swallowing or abdominal bloating, changed sensitivity to pain, inexplicable episodes of laughing [7], as well as other neurological abnormalities, such as dystonia and Parkinsonism [8] might be present .

Finally, the diagnosis of RS is excluded if there is evidence of a storage disorder, retinopathy, cataract, or optic atrophy, an identifiable metabolic or neurodegenerative disorder, an acquired neurological disorder, evidence of perinatal or postnatal brain injury [6] due to anoxia, ischemia or trauma [10], infantile autism [9, 10], Angelman (or Happy Puppet) syndrome, congenital metabolic defects [10], or untreated phenylketonuria or tuberous sclerosis [9].

Suggested Staging System

Hagberg and Witt-Engerström [9] suggested a four-stage model of describing the developmental course of RS, in order to facilitate the description of the disorder from infancy to adolescence. According to their staging system, Stage I, named the "Early onset stagnation stage", starting

between the 6th and the 18th month of life, is characterized by delayed developmental progress following an apparently normal prenatal, perinatal and early psychomotor development. During this stage decelerating head growth, and diminished play, communication, and eye contact are evident. The symptoms during this period, however, are nonspecific, and diagnosis is usually not made before Stage II, the "Rapid destructive stage", when stagnation of development is more obvious [9].

Stage II typically covers the ages between 1 and 3 or 4 years of life and during this phase individuals experience rapid personality change [7], rapid loss of social interaction, communicative skills and loss of acquired language [9]. Loss of hand skills, development of hand stereotypies, and emergence of autistic symptoms, dementia, irregular breathing, and seizures are also characteristic features of Stage II [9].

In Stage III, the "Pseudostationary stage", which covers the preschool to the early school years, communicative skills improve, autistic features tend to resolve and mood stabilizes [7]. However, neuromotor problems slowly worsen, rigidity becomes more obvious, significant hand dyspraxia develops and during this stage even more females develop epileptic seizures. It is, nevertheless, noted that some individuals may remain in this stage most of their lifetime [9].

For those who will move to Stage IV, the "Late motor deterioration stage" covering the teenage to early adult years, however, motor deterioration is the main feature. Individuals who were able to walk now lose this ability and some become wheelchair-bound. Scoliosis becomes severe and trophic foot disturbances associated with persistent growth retardation become apparent. On the other hand, during Stage IV epilepsy may become less problematic and emotional contact may show some improvement, but intellectual disability becomes more severe [9].

Etiology

Approximately 99.5% of RS cases are sporadic, not following a familial pattern of occurrence, thus making the identification of the cause of the syndrome difficult to establish. Initial observations indicating the inheritance through maternal lines, however, associated with the findings of nonrandom patterns of XCI in obligate carrier females suggested that RS is an X-linked dominant condition caused by mutations in a gene that undergoes X-inactivation [8].

In 1999, Amir and colleagues [11] were the first to denote that RS is caused by mutations in X-linked *MECP2,* encoding methyl-CpG-binging protein 2; further research showed that the majority of RS cases (approximately 90–95%) involve such mutation in the *MECP2* gene on the x-chromosome [2, 4, 6, 11]. This mutation appears to give a growth disadvantage to neuronal and lymphoblast cells, which leads in skewing of X-inactivation, something which also contributes to the large degree of phenotypic variation. Also, recent evidence collected from studies on mice and rat models suggests that *MECP2* may have a role in regulating neuronal activity dependent expression of specific genes such as Hairy2a in Xenopus and Bdnf [6]. However, consistent with the sporadic occurrence of RS most mutations occur de novo, making the investigation of the exact mechanism by which the mutation occurs in the DNA of RS individuals, but also the mechanism by which loss of *MECP2* function results in the pathogenesis of RS, even more difficult [12].

In addition to the mutation in *MECP2*, it seems that at least a small proportion of atypical cases may result from mutations in the X-linked gene cyclin-dependent kinaselike 5 (*CDKL5)*, alterations in which were found to cause early-onset epilepsy and infantile spasms with severe mental retardation. Nonetheless, the relationship between *MECP2* and *CDKL5*, and whether they cause RS through the same or different mechanisms is yet to be established [6].

RS in Males

Although RS was initially thought to be a disorder exclusively affecting females, a number of males with a Rett-like phenotype have been reported, including males who have a XXY karyotype, who are mosaic for severe mutations, and who may have milder mutations. For example, Dayer and colleagues [13] report a case of one male displaying RS symptomatology, providing detailed developmental descriptions of the child's condition, whose mother, however, was heterozygous for the mutation in the *MECP2* gene while having normal intellectual ability and no evident neurological symptoms.

MECP2 mutations that cause classic RS in females typically lead to neonatal encephalopathy and death in the first year of life in males with a normal karyotype. However, the same mutations may result in an RS phenotype in males with Klinefelter syndrome (47, XXY) or somatic mosaicism. Moreover, some of these mutations have been reported in males with classic RS and a normal karyotype, suggesting that genetic modifiers suppress the infantile lethality typically seen in males with loss-of-function *MECP2* mutations. On the other hand, some *MECP2* mutations that do not cause RS in females can cause moderate, nonspecific to profound mental retardation or other psychiatric disorders in males. Deficits in

language and motor skills, obesity, autistic features, and epilepsy are also common in this category of mutations [3, 13]. There are also rare occurrences of *CDKL5* mutations in males suffering from severe mental retardation, infantile spasms, or early-onset epilepsy [14].

Management

RS is a lifelong condition with no treatment protocols currently available, thus planning appropriate management protocols is warranted. Thorough assessment of RS children by a multidisciplinary team should be the first step in the preparation of efficient and individualized management plans, taking into consideration the specific phenotypic and personal needs of every RS child.

Management interventions should include psychosocial support for the families, development of appropriate education plans, and assessment of available community resources. In addition, along with the pharmacological treatments, which may lead to an improvement in the person's wellbeing and quality of life, reduction in the episodes of hyperventilation, and improvement of sleep dysfunction, some other practical strategies should also be applied with an aim to minimize, to the degree possible, further deterioration [6].

For example, decreasing repetitive purposeless hand movements can be achieved by the use of arm restraints, such as soft elbow splints, which can also be helpful in training specific hand skills, such as self feeding. These methods can also be helpful in decreasing agitation and self injurious behavior. Regarding verbal expressive language, alternative forms of communication may be used, including communication boards, technical devices, and switch activated systems. These can also be used for making choices and facilitate environmental access.

Relevance to Childhood Development

RS is a disorder usually first diagnosed in childhood [1]. The severity of symptoms is evident across cognitive, communication, motor, orthopedic, gastroenterological, respiratory, and sleep domains; and research has shown that great heterogeneity in symptoms occurs, not due to genetic/physiological differences alone but due to life experiences as well. Genetic testing alone is not sufficient to fully describe each person's unique phenotype. Thus, genetic assessment should be supplemented with a battery of measures that not only assess observable behaviors but that can be linked back to assessed gene expression. In addition, measures of communication, social skills, adaptive skills, and communication are warranted and should constitute parts of an overall multidisciplinary RS assessment protocol [14].

Revised Children's Manifest Anxiety Scale: Second Edition

Jessica R. Gurley
Argosy University, Arlington, VA, USA

Synonyms

Anxiety; Symptoms checklists

Definition

The *Revised Children's Manifest Anxiety Scale: Second Edition* (RCMAS-2) is an update to the Revised Children's Manifest Anxiety Scale (RCMAS). It is used to help mental health professionals identify children and adolescents between the ages of 6 and 19 who are experiencing symptoms consistent with anxiety disorders [1, 3].

Description

The RCMAS-2 is a 49-item self-report measure of anxiety for children and adolescents between the ages of 6 and 19. It was written at a second grade reading level and there is an audio version available. The items on the RCMAS-2 can be used to calculate a Total Anxiety Score, three scale scores, and two validity indices. One of the validity indices – Inconsistent Responding Index – assesses whether or not the child/adolescent attended to the items on the RCMAS-2. The other validity index – Defensiveness – is an update to the RCMAS Lie scale [3]. It was designed to assess whether the examinee was presenting him or herself in an overly positive manner [1, 3]. The three scales – Physiological Anxiety, Worry, and Social Anxiety – assess different subtypes of anxiety [1, 4].

In addition to the standard form, the RCMAS-2 has a short form. The short form consists of the first ten items of the RCMAS-2 and can be used to screen children and adolescents who may benefit from additional evaluation or intervention [3].

The RCMAS-2 was recently published; consequently, there is little research on it. In the manual for the RCMAS-2, the authors report there is a high correlation between the RCMAS-2 and the RCMAS, so the research on the RCMAS may extend to the RCMAS-2 [3].

Scoring & Psychometrics

The RCMAS-2 can be scored by hand in less than 10 min. The raw scores for the Total Anxiety Scale are transformed into T scores while the raw score for the scale scores are transformed into scaled scores. There are three sets of norms, each representing different age groups [1, 3].

The RCMAS-2 was standardized on 2,300 children and adolescents between the ages of six and 19. Approximately 50% of the children in the standardization sample were female [3].

Relevance to Childhood Development

The RCMAS-2 can be used to screen children and adolescents for symptoms of anxiety. It can also be used as part of a comprehensive psychological evaluation.

Rey Complex Figure Test

Audrey McKinlay
University of Canterbury, Christchurch, Canterbury, New Zealand

Synonyms

Complex figure; Rey figure; Rey-Osterrieth

Definition

A neuropsychological test used to assess visuospatial/constructional ability and visual memory.

Description

The complex figure task devised by Rey in 1941 [1] is considered to be one of the most widely used neuropsychological tests because of its ease of administration and the variety of cognitive processes which it can potentially be used to assess. The original purpose of the test was to assess visuospatial/constructional ability and visual memory ability in brain injured individuals. However, it is commonly used to assess a broader range of cognitive abilities including planning, organization and fine motor skills. Since the original drawing, there have been a number of elaborations of the test, the most commonly

known of these is the Rey-Osterrieth Complex figure and the Taylor alternate version [2].

Administration

Each version of the complex figure test is administered using the same general format. The individual is shown a card with the figure printed on it and asked to copy the figure as carefully as possible on to a blank piece of paper. Then, after a 2 min delay and again after a 30 min delay, and without prior warning, the participant is asked to reproduce the figure from memory [3]. It has been reported that minor variations in length of delay does not have a significant effect on the production of the figure [3] because, for most people, the amount of detail that is forgotten occurs in the first few minutes following the initial copying of the figure [3].

There are various methods of scoring for the ROF depending on the particular version that has been used, and these are outlined in Spreen and Struss [2]. However, for the traditional ROF, each of the figures produced is scored separately on 18 different scoring units [2]. Each unit receives a score between 0–2 and is considered both in terms of accuracy and position relative to the whole design. For example, two points are given if the unit is totally correct and placed correctly, one point is given if the unit is correct but incorrectly placed, or distorted but correctly placed, half a point is given if the unit is poorly place and distorted and no points are given if the unit is missing [2]. Total score ranges from 0–36. Some researchers use an administration system in which they hand the participant a different colored pen to use every 30 s. This is done so that they can see the order in which the different units of the figure were completed. This system of administration can be used as a measure of planning.

Age and intellectual ability influence the performance on the ROF [2]. Therefore, the ROF can be use in adult populations to assess brain impairment. For example, patients with frontal lesions have been reported as having more difficulty planning the task. On the other hand, patients with hemineglect may only partially copy the figure. (Hemineglect refers to an impairments in functioning that may occur after damage to one side or hemisphere of the brain, resulting in a deficit in attention to, and awareness of, one side of space. This is lack of attention or awareness is usually contralateral to the side of damage.)

Relevance to Childhood Development

The ability to produce the ROF systematically develops with age [4]. Younger children tend to draw the figure in a piecemeal manner based on copying around the perimeter of the figure, rather than reproducing the base rectangle as the starting point. However, by about 13 years of age, a more holistic approach to the copy of the figure is evident, with the rectangle as the base strategy being utilized [4]. By age 9 most children are able to accurately complete the ROF and reproduce it with about 75% accuracy [4]. Because the ability to produce the ROF systematically develops in normally functioning children, the ROF is able to be used in clinical contexts with children who have difficulties, including developmental delays or medical conditions. For example, children with closed head injury are likely to make many more mistakes than those without head injury, and are also more likely to use a piecemeal approach [4]. Studies on children with Attention Deficit Hyperactivity Disorder indicate that their productions of the ROF are often poorly organized, and they perform poorly on recall of the figure [4].

Reynolds Adolescent Depression Scale 2

Jenna J. Barry
Humboldt State University, Arcata, CA, USA

Synonyms

RADS; RADS-2

Definition

The Reynolds Adolescent Depression Scale 2 (RADS-2) is an updated version of the original RADS, a paper-and-pencil self-report measure of the severity of depressive symptoms in adolescents [1].

Description and Relevance to Childhood Development

Adolescence is a time of social and physical development and self-discovery, but for some, it is an arduous transitional period. Social and academic pressures can overwhelm some adolescents, and can sometimes lead to a decrease in self-esteem and an increase in emotional disturbances. Depression is one of the most frequently diagnosed mental disorders in the United States [4], with about 20% of adolescents experiencing a depressive episode before they reach adulthood. Depression ranges from mild to severe and can include feelings of sadness, crying, loneliness, dysphoria, somatic complaints, suicidal ideation, loss of motivation and/or pleasure, and apathy. Awareness of these variations in depressive symptomatology is important for all professionals working with children and adolescents. If left untreated, depression can lead to serious and sometimes fatal consequences [3].

Psychologist William M. Reynolds began the development of the Reynolds Adolescent Depression Scale (RADS; [2]) in 1981 in order to assess the severity of depressive symptoms in adolescents in both clinical and school settings. Prior to the RADS, there was no scale measuring the severity of depressive symptomatology in adolescents. The RADS-2 [1] expands the initial RADS by defining four factorially-derived subscales to explain various components of depression (Dysphoric Mood, Anhedonia/Negative Affect, Negative Self Evaluation, and Somatic Complaints). The second edition also extends the age range, is restandardized (n = 3,300) based on census data from the year 2000, includes a representative number of the Hispanic population, provides standard T scores and percentile ranks for comparison, includes a test booklet for hand scoring, and has an updated manual with extensive psychometric information and interpretive guidance. It is important to note, however, that the RADS-2 is not a formal classification measure; therefore, it does not assess other types of psychopathology often comorbid with depression, such as suicidal ideation [1, 5].

The RADS-2 is a 30-item, easily administered paper-and-pencil screening measure evaluating broad domains of depressive symptoms. The test requires a third grade reading level and is used with adolescents 11 to 20 years old. Sentences are short and easy to read. Each item measures the frequency of a specific symptom of depression. Adolescents are asked to endorse how they "usually feel" using a 4-point Likert response format, where *1 = almost never, 2 = hardly ever, 3 = sometimes,* and *4 = most of the time.* Seven items are reversed scored to reduce response bias. Scores range from 30–120, with high scores on the Depression Total scale indicating a higher frequency of depressive symptoms. The RADS-2 does not provide a formal diagnosis of depression; however, the items are consistent with current *DSM* and *ICD* diagnostic criteria, and the measure provides an empirically based score that indicates the clinical severity of depression symptoms in adolescents [1]. Each of the subscales can be totaled for a more detailed picture of the symptoms in each of the four domains. The Dysphoric Mood subscale on the RADS-2 contains eight items that evaluate sadness, crying behavior, loneliness, irritability, worry, and self-pity. The Anhedonia/Negative Affect subscale contains seven reversed-scored items that appraise affect and engagement in pleasurable activities. The Negative Self-Evaluation subscale contains eight items evaluating feelings of low self-worth, self-denigration, thoughts of self-harm, and thoughts that no one cares. The Somatic Complaints subscale contains seven items and assesses somatic (i.e., physical) complaints about the self such as anger, stomachaches, feeling sick, fatigue, sleep disturbance, boredom, and dissatisfaction. High scores on any of the subscales represent a higher level of pathology.

The RADS-2 demonstrates excellent psychometric properties as evidenced by high internal consistency, test-retest reliability, and validity estimates [1]. Internal consistency reliability for the RADS-2 total scale was .93 for the total school sample; internal consistency for the subscales of the RADS-2 ranged from .80 to .87 [1]. Test-retest reliability for the Total Scale was reported to be .85, with the subscales ranging from .77 to .84. Validity has been established for the RADS-2 as evidenced by strong relationships between the RADS-2 and clinical measures of depression (e.g., Hamilton Depression Rating Scale), moderate relationships among the RADS-2 and related constructs such as anxiety and loneliness, and weak relationships among the RADS-2 and measures of intelligence, social desirability, and school achievement.

RCDS

Definition

The Reynolds Child Depression Scale (RCDS) is a 30-item self-report paper and pencil survey assessing the frequency of depressive symptoms in children ages 8–12.

Description and Relevance to Childhood Development

Depression is one of the most frequently diagnosed mental illnesses in the U.S. [3, 4], with nearly five percent of children and adolescents suffering from depression at any one point in time [2]. This disorder can often go without notice, as it is often conceptualized as a quiet disorder with symptoms such as sadness and social withdrawal, unlike other childhood disorders (e.g., ADHD) that may present with overt behavioral problems. However, some children suffering from depression will act out in school or at home, so it is important to pay close attention to the child's overall behavior in order to know if they are suffering from depressive symptoms.

Like adolescent and adult depression, childhood depression is more than just feeling down once in a while. Rather, it is characterized by symptoms such as frequent sadness or crying, feelings of hopelessness, social withdrawal or isolation, low self-esteem, and stomachaches or headaches. Depression varies in level of severity, with some people reporting mild depressive symptoms (e.g., feeling down), and others reporting more severe symptoms (e.g., suicidal ideation and self-injurious behaviors; (2)). However, if left untreated, mild symptoms can lead to more severe symptoms, highlighting the importance of assessment and treatment in the presence of any type of depressive symptoms.

The Reynolds Child Depression Scale (RCDS; 1989), developed by William Reynolds, is a 30-item self-report measure of depression that can be used to assess frequency of depressive symptomatology in children. The scale was developed based on the symptom criteria as delineated in the DSM-III and the research diagnostic criteria (RDC; [1]). Item criteria were also checked against the DSM-III-R upon its release. The scale uses a Likert-style response format (*1=almost never, 2=sometimes, 3=a lot of the time, 4=all the time*) for 29 of the items, and a 1 through 5 scale using faces representing a range of emotions, from sad to happy, for the final item. There are seven reverse-scored items (e.g., I feel happy). Children are asked to answer the questions based on how they have felt in the past two weeks. A high score on the RCDS is representative of higher depressive symptomatology, with scores ranging from 30 to 121. The scale is written at a second-grade reading level, takes about 10 min to complete, and is primarily used for children in grades 3 through 6 (ages 8 through 12); however, it is recommended that children in grades 3 and 4 (ages 8 and 9) have the items read aloud to them [1].

The RCDS is not a diagnostic tool as it merely provides information regarding the frequency of the child's depressive symptoms. It does provide a cutoff score that can be used to identify a child as depressed or non-depressed; however, this score should not be used alone for diagnostic purposes [1].

Critical items are said to distinguish depressed children from non-depressed children. The six critical items on the RCDS resulted in significantly different responses for depressed versus non-depressed children. Depressed children were more likely than non-depressed children to endorse the critical items (to answer *all the time* on items 6, 9, 12, 13, and 20, and *a lot of the time* or *all the time* on item 14). These six items focused on withdrawal, isolation, self-injurious thinking, and disliking one's self, all symptoms of major depression [1].

This scale was subjected to rigorous field testing throughout the 1980s in order to obtain evidence for psychometric properties. Internal consistency has been shown through Cronbach's alphas of 0.88 and above, found consistently in studies across the world [1, 5, 6]. The measure is shown to be psychometrically sound and content valid due to high item-total scale correlations (most items in the 0.40–0.50 range; [1]). Test-retest reliability coefficients have ranged from 0.66 in one study with students from Barcelona [5] to 0.82 in another study with students from the Midwest [1]. Criterion-related validity was shown through a correlation of 0.84 between the RCDS and the

Children's Depression Rating Scale-Revised [1]. Convergent validity was shown through moderately high correlations between the RCDS and other measures of depression, self-esteem, and anxiety. Discriminant validity was evidenced by a lack of relationship between depression and measures of academic achievement and ability [1].

The RCDS provides researchers with an easily understood self-report measure of depression that has been validated through research studies across the world. This scale is a valuable tool for clinicians and researchers alike, as it can identify the frequency of depressive symptomatology in children, and help distinguish between depressed and non-depressed children (although a formal interview would be needed for a final diagnosis of depression).

Right Hemisphere Learning Disability

►Nonverbal Learning Disability

Right Hemisphere Syndromes

David Morrison, Mary Joann Lang
Azusa Pacific University, Azusa, CA, USA

Definition

Knowledge of prevalence and patterns of right hemisphere deficits appears to be incomplete. In fact, a descriptive definition of right hemisphere syndrome and consistent terminology would assist in enhancing communication and providing services for this set of signs and symptoms. The most common right hemisphere syndromes include right hemisphere dysfunction, nonverbal learning disabilities, and Asperger's syndrome.

Description

The right hemisphere is responsible for visual data storage, recognition of shapes and forms, spatial perception, and copying and drawing geometric shapes and representational pictures. It also excels in metric angle judgments and linear arithmetic problem solving [6]. While it may appear to be superior to the left hemisphere in regard to attention capacity, this is merely due to the right hemisphere's ability to integrate complex, nonlinear information quickly. Right hemisphere syndromes include right hemisphere dysfunction, nonverbal learning disabilities, and Asperger's syndrome.

Right Hemisphere Dysfunction

Ardila and Ostrosky-Solis [1] first presented the concept of right hemisphere dysfunction in the mid-1980s. The authors indicated that the right hemisphere dysfunction produced additional symptoms not usually seen in nonverbal learning disabilities. They indicated that there were deficits related to the rhythm, stress, and intonation of connected speech. These authors also indicated that patients may have more significant deficits in frontal lobe functioning with regard to planning and organization, as well as tactile and spatial deficits.

In 1989, Pimental and Kingsbury looked at the many different classifications that had been presented for right hemisphere dysfunction [7]. The main features of right hemisphere dysfunction include: Fluent speech that appears illogical and loosely generalized; difficulty ordering, organizing, and understanding complex situations; verbal comprehension may be poorly developed as a result of literal interpretation; difficulty dealing with speech intonation resulting in monotone speech; failure

to stay alert; perceptual deficits; spatial organization, as well as visuo-spatial memory, and slowed reaction times.

Many descriptions have been given of children with social and emotional issues. These descriptions associate the child's lack of social navigational skills and their poorly developed spatial and mathematical skills. Researchers have taken many different approaches to understanding these deficits and have come up with many different classification terms such as, "minimal brain dysfunction," "nonverbal learning disability," "developmental learning disability of the right hemisphere," "social and emotional learning disability," and "developmental right hemisphere syndrome" [10]. All of these terms have been developed under the context of right hemisphere dysfunction.

Two syndromes discussed in the literature related to right hemisphere dysfunction are nonverbal learning disability syndrome and Asperger's syndrome.

Nonverbal Learning Disabilities

Nonverbal Learning Disability (NLD) is a more recent syndrome being researched. Although a few publications have been done on the syndrome, many mental health professionals are unfamiliar with it. The syndrome is not recognized by federal special education law, which, more than likely, classifies children with the specific symptoms as "Other Health Impaired" [8]. Some children may also be more specifically classified as orthopedically handicapped, learning disabled, or emotionally disturbed. These classifications are appropriate for children who have neurologically acquired NLD syndrome, but those who have acquired the syndrome through more common developmental cases may need a different classification.

Byron Rourke, in the early 1980s, identified a learning disability based on the right and left hemisphere functions. His model was expanded and revised in order to document the range and diversity of deficits in this disorder. Rourke [9] grouped the deficits into three major areas: Neuropsychological, academic, and social emotional/adaptive. Rourke believes that nonverbal learning disability syndrome is present, "at birth or shortly thereafter, and is not complicated by subsequent neurological disease, disorder, or dysfunction" ([9], p. 6).

A summary of the content and dynamics of NLD syndrome was summarized by Rourke in an edited text titled, "*Syndrome of Nonverbal Learning Disabilities*" in 1995. The model that represents these dynamics is shown on the following page:

Intellectual Functioning

On formal measures of intelligence, children with NLD syndrome will normally score higher on Verbal IQ than Performance IQ. This shows the incongruity between verbal, language-based cognitive abilities and nonverbal, visual-spatial cognitive abilities [8]. The greater the difference between scores, the more likely the diagnosis; small point differences can still be significant if there is evidence of the disorder in other domains.

Executive Functions

One of the primary impairments in NLD syndrome is executive functioning. This includes abstract reasoning, logical analysis, cognitive flexibility, and the ability to focus attention and/or redirect it [8]. Executive functioning deficits tend to be more prevalent in severe cases of nonverbal learning disabilities syndrome.

In addition, children with NLD syndrome have significant difficulties with cause-effect relationships and have deficiencies in appreciation of incongruities [10]. These problems tend to persist and only get worse as the child gets older.

Memory Functions

Children with NLD syndrome tend to have lower levels of nonverbal memory ability. Nonverbal tasks that are less complex, such as rote verbal capacities and rote verbal memory skills, tend to be well developed. Children who struggle with remembering complex verbal material probably did not understand the material when it was first presented. Those that struggle on more difficult memory and learning tasks support Rourke's hypothesis that children with NLD syndrome will be able to perform well only on memory and learning tasks that are confined and simple [8].

Language Functions

Receptive and expressive vocabulary measures usually see high performance levels from children with NLD syndrome. Children with right hemisphere dysfunction will perform poorly on measures of speech prosody and intonation [8]. Friends and peers will often complain that the child will dwell on boring topics; this is because the child relies on verbalization to carry them through their social interactions. With simple and repetitive speech, the child is seen as having restricted interests, which is one of the common features of Pervasive Developmental Disorders.

Visual-Spatial Abilities

Children with NLD syndrome perform low on measures of visual processing and visual-spatial abilities. They have difficulties with visual perception, visual-spatial cognitive abilities, and visual processing. Children with NLD syndrome will exhibit difficulties drawing or copying images and have poor handwriting skills. Despite the difficulties

that are manifested at first, as time passes and these difficulties are worked on, children with NLD syndrome will be able to improve their handwriting, ability to copy simple shapes, coloring, and pasting [10]. While simple visual-spatial abilities may improve, the more complex skills will only get worse as the child ages.

Sensory-Perceptual Ability and Motor Functioning as Related to the Left Side

Children with NLD syndrome will demonstrate difficulties with tactile discrimination, haptic discrimination (involves touch), and fine motor coordination [10]. Their fine motor skills and sensory skills are worse on the left side of their body, when compared to the right side. In addition to fine motor skill difficulty, children with NLD syndrome perform low on gross motor activities, such as playing sports. They lack the athleticism that their peers may possess and have a difficult time playing competitive games.

Educational and Academic Performance

Spelling and word recognition are easier than math for children with NLD syndrome. Math relies primarily on spatial and nonverbal concepts, which, as mentioned earlier, are areas in which children with NLD syndrome struggle. The more basic, mechanical aspects of academics are better understood than areas of academia that require more applied aspects. Reading comprehension and mathematical reasoning abilities are weaker than spelling, vocabulary, and simple math calculation abilities [8]. It is difficult for children with NLD syndrome to generate their own ideas, making it hard for them to write meaningful essays and papers.

Children with NLD syndrome also have poor time management skills. They tend to have a distorted sense of time when engaging in common activities. They may be unable to estimate the amount of time that has elapsed in a given activity, as well as the time of day.

Social Performance

NLD syndrome can significantly impair a child's social skills because they have poor "body language," facial expressions, and tone of voice abilities. Children with NLD syndrome tend to miss important social cues, further leading to deficits in social perception. They are unable to perceive social situations accurately and often respond incorrectly when spoken to. If the topic changes, they have problems adapting to the change in circumstances. Additionally, they have deficits in reasoning and generalization of knowledge.

Problems forming close relationships and meaningful friendships may not be perceived until late childhood or early adolescence. Establishing intimacy is very difficult for individuals with NLD syndrome, and Rourke [9] stated these problems are related to a lack of "tactile-perceptual and psychomotor prowess required for smooth affectional encounters" (p. 17).

When the child is young, they may often be seen as hyperactive. As the child ages, however; they move towards hypoactivity, which involves social withdrawal and social isolation. This increases the risk of the development of psychosocial disturbances, especially when related to internalization, in older childhood and adolescence [10].

The Relationship Between Nonverbal Learning Disabilities Syndrome and Asperger's Syndrome

There is evidence of a significant overlap in symptoms between NLD syndrome and Asperger's syndrome (AS). Children with either NLD syndrome or AS experience the same basic difficulties in nonverbal social interaction, and tend to rely heavily on language as a means of learning about themselves and the world around them. This reliance on language is appropriate for telling of categorical information, but not appropriate for conveying direct experience. The neuropsychological assets and deficits of NLD syndrome are also very characteristic of AS.

Children with NLD syndrome or AS are unable to form representations of their world and do not have the ability to code and represent each novel experience they have. As a result, these children will tend to be more interested in the rule-based aspects of learning and have major difficulties with abstract reasoning and generalizing ideas. When processing new information, children with NLD syndrome or AS will rely primary on their poorly developed deductive reasoning, while completely discarding inductive reasoning.

A variety of researchers identified an impairment pattern in individuals with AS. This pattern suggests possible dysfunction in the right hemisphere**.** Through case reports, Ellis and Gunter [3] found AS to be a result of right hemisphere dysfunction due to incomplete and/or dysfunction of white matter. More recently the focus is also placed on the role of the right hemisphere in both NLD syndrome and AS. This focus, however, has been applied more widely. Consideration is focused on two basic processes, including cognitive development and brain maturations. These mental processes promote brain integration and adaptability. Children with either NLD syndrome or AS are impacted by these mental processes.

Primary neuropsychological assets Auditory perception simple motor rote material	Primary Neuropsychological Deficits Tactile perception Visual perception Complex psychomotor Novel material
Secondary neuropsychological assets Auditory attention verbal attention	Secondary Neuropsychological Deficits Tactile attention Visual attention Exploratory behavior
Tertiary neuropsychological assets Auditory memory verbal memory	Tertiary Neuropsychological Deficits Tactile memory Visual memory Concept formation Problem solving
Verbal neuropsychological assets Phonology Verbal reception Verbal repetition Verbal storage Verbal associations Verbal output	Verbal Neuropsychological Deficits Oral-motor praxis Prosody Phonology>Semantics Content Pragmatics Function
Academic assets Graphomotor (late) Word decoding Spelling Verbatim memory Socioemotional/Adaptive assets	Academic deficits Oral-motor praxis Reading comprehension Mechanical arithmetic Mathematics Science Socioemotional/adaptive deficits Adaptation to novelty Social competence Emotional stability Activity level

Asperger's Syndrome

Asperger [2] indicated that early development of children with AS would be normal. Their language development is quick and they show a high interest in language. Asperger focused on this for quite some time, until he began to also recognize the preservation of formal language skills, such as phonology and syntax, rather then the pragmatics of language. Attachment and early social skills are not extremely unusual, but the absence of deviant language may impede recognition. Children with AS have unusual interests, which affect how they acquire normal skills.

Motor Functioning Praxis

Children with AS have delayed motor skills and motor coordination. These motor delays are listed in the DSM-IV as diagnostic criteria for AS. Young children with AS might not have major motor skill impairment but, as they age, they become more dependent on developmental aspects other than simple motor capacities [11]. Some areas in which a delay in acquisition of motor skills is evident are: Pedaling a bicycle, catching a ball, opening jars, climbing monkey bars, etc. [5]. They have visibly poor posture and appear to have significant visual-motor coordination deficits.

Social Functioning

Although children with AS have identifiable social isolation, they are usually aware of and interested in others. They are often eager to relate to others and understand them. Children with AS have difficulty approaching others and engaging them in conversation. Their conversations are usually long-winded and often meaningless. They fail to realize when a person is losing interest and is seemingly uncomfortable with the conversation. As the child ages, they have problems with spontaneous social interaction. The constant social rejection can have a profound effect on the child's mood and mental state.

The child may respond inappropriately to the context of affective social interaction. They appear to be insensitive or disregarding emotional expressions. While the child with AS may be able to formally explain a person's emotions and intentions, they are unable to do so while in a continuing conversation without a period of rest to gather their thoughts.

Communication

Speech development is not a main concern in a young child with AS. Their language and speech develop improperly as they age and, as a result, they experience significant difficulty in pragmatic or conversational skills. In 1994, Klin identified three distinct ways of communication in children with AS [4]:

- (1) They use a minute number of inflection patterns and do not adjust them based on what they are trying to communicate; (2) Conversation is egocentric and one-sided as they try to verbalize every thought without filtering what actually needs to be said aloud; (3) The child with AS tends to focus only on what they know and are interested in, which may result in a long list of facts without a conclusion.

The fixation on one topic is known as restricted and repetitive behavior, as the child with AS is unable to move on to topics which they know nothing about. They have a vast array of knowledge about random facts, such as snakes, names of stars, and railway schedules.

Conclusion

There is strong evidence pointing towards major similarities in characteristics between children with AS and children with NLD syndrome. This similarity may aid in distinguishing AS from higher functioning autism. AS is a newly researched syndrome and will become better understood as years pass and more researchers gain interest in focusing on its unique characteristics.

Risk

Lisa M. DeBellis
Fordham University, Bronx, NY, USA

Synonyms

Risk factors; Threat; Vulnerability

Definition

A risk is a harmful circumstance or attribute which can cause developmental threat or assault.

Description

Risk factors are defined as stressors or conditions that predict negative outcomes on a person's development. Risk is an especially important component of Resilience Theory, a popular framework used in both applied and basic psychological research. Individuals who have exhibited resilience are viewed as achieving normal functioning despite the adverse conditions they have faced. The emphasis is placed upon the process of bouncing back after exposure to risk; in other words, the term does not attempt to explain or describe a characteristic an individual child possesses. Because many risk factors seem to occur together and their effects seem to accumulate over time, such as school dropout and poverty, researchers have recently begun to study cumulative risk, which is studied by pooling or aggregating information related to the risk factors. For example, a student who lives in a single parent household may not be considered at risk for substance abuse; but, a child who lives in a single parent household and has been retained in school may be at risk for substance abuse. Protective factors keep individuals safe from the threat or assault associated with exposure to different risk factors, and may assist individuals to overcome risks. In the example provided above of the child at risk for substance abuse, a positive relationship with a school teacher may serve as a protective factor in his or her positive development over time. An extensive review of popular protective factors found in resilience literature shows that protective factors generally tend to fall into one of three categories including individual attributes, family qualities, and supportive systems outside the family. Risk and protective factors are central concepts in the Developmental Psychopathology framework used to study normal and abnormal development among children and adolescents.

Risk Factors

Aaron R. Schantz, Andy V. Pham, John S. Carlson
Michigan State University, East Lansing, MI, USA

Synonyms

Associated factors; Early predictors; Psychological correlates; Risk

Definition

Risk factors are variables within the child or the surrounding environment that correlate with an increased probability of the child experiencing negative outcomes.

Description

Risk factors are areas of considerable interest to professionals who work with children. These characteristics of a child's life consist of various issues that reside in the community (e.g., public violence), the family (e.g., parent's educational attainment), the school (e.g., teacher education), and within the child (e.g., temperament).

The more risk factors present in the life of a child, the more likely the child will experience negative outcomes. Development of physical or mental health problems, substance use disorders, difficulties in academic functioning, unemployment, teenage pregnancy, violence, and juvenile delinquency are some of the most common outcomes associated with risk factors experienced in childhood.

The link between risk factors and potential outcomes is identified when researchers statistically correlate the presence of a factor in the past and whether the negative outcomes were experienced. Because these studies are correlational, it cannot be said that the presence of the risk factor *causes* the later problems in functioning, only that a higher probability exists. For instance, certain demographic variables such as low parental income are considered risk factors in pediatric mental health because children in these homes may have fewer available supports. For example, the cost of hiring a tutor or consulting with a psychologist may be unaffordable.

Effects of risk factors are experienced as a manifestation of the child's biology (including genetic predispositions) and environment. As a result of this interplay of nature and nurture, two children with the same risk factor in dissimilar environments could experience different impacts on their development. A child who was exposed to alcohol in utero (a biological risk factor) may be at a greater risk for disruptive behavior disorders later in life; however, if the child were raised by parents with strong parenting skills, the negative outcomes of the alcohol exposure could be reduced. If a child lives in a household with parental discord (an environmental risk factor), but has strong academic skills, the child is on a more positive developmental trajectory than a child with parental discord and poor academic skills.

Risk factors can have a cumulative effect. In the example above, parental discord at home could likely make it more difficult for the child to pay attention in school, and the emotional troubles could lead to externalizing behaviors. For a child already struggling with academics, the effects on school performance can seem to multiply. A child with prenatal alcohol exposure, if raised by a parent with alcohol dependence, may additionally experience emotional or physical neglect. These and other risk factors increase the child's likelihood of developing a behavior disorder.

Prevention programs are often initiated by screening a group of children in a particular school or community for the presence of risk factors. Once identified, the risk factors become the target of intervention to avert the foreseen negative outcomes for the child. Perhaps the most widely known prevention program is Project Head Start. Head Start identifies children with economic disadvantages and offers educational interventions to improve the child's academic performance. Prevention programs like Head Start are designed to build upon the child's strengths and supports. Selection of appropriate early intervention strategies can mitigate or perhaps eliminate the effects of the risk factor and positively affect the child's developmental trajectory.

Risley, Todd R.

Derek D. Reed[1], James K. Luiselli[2]
[1]University of Kansas, Lawrence, KS, USA
[2]The May Institute, Inc., Randolph, MA, USA

Life Dates

(1937–2007)

Introduction

Dr. Risley was a pioneer in the field of applied behavior analysis whose research in speech shaping, language

acquisition, time out procedures and incidental learning has influenced the broader fields of education, child development, and psychology. Dr. Risley's motto, "do good and take data," is evidence of his lifelong commitment to finding socially valid, empirically supported approaches to education and rehabilitation [1, 5].

Educational Information

Dr. Risley obtained his B.A. from San Diego State College, where he was mentored by Virginia Voeks, who ultimately encouraged him to pursue the study of learning and child psychology at the University of Washington's Institute of Child Development [5]. While obtaining both his M.S. and Ph.D. at the University of Washington, Dr. Risley worked alongside many child psychology and development leaders, such as Ivar Lovaas and Montrose Wolf – both of whom were post-doctoral fellows – and studied under the advisement of Donald Baer, an internationally renowned researcher and professor in the area of child psychology, development, and applied behavior analysis [2, 4, 5]. Dr. Risley and his colleagues from the University of Washington would ultimately shape the field of behavior analysis away from strict animal experimentation to the direct application of Skinner's behaviorism to the improvement of social problems, culminating in the creation of applied behavior analysis.

Accomplishments

Dr. Risley was a founding Editor of the *Journal of Applied Behavior Analysis* from 1971 to 1974, and served as an Associate Editor for the *Journal of Positive Behavior Interventions*. In addition, Dr. Risley served as the President of both the Association for the Advancement of Behavior Therapy (1976–1977) and the Behavior Analysis Division of the American Psychological Association (Division 25). Dr. Risley also served as Director of Alaska's Division of Mental Health and Developmental Disabilities from 1988 to 1990 [4]. Dr. Risley's book *Meaningful Differences in the Everyday Experiences of Young American Children* [3], was nominated for the Pulitzer Prize.

Contributions

During Dr. Risley's illustrious career in child psychology, he was directly involved in the formation and implementation of 16 major human service organizations and settings. From these endeavors, Dr. Risley contributed to the science of child behavior and development with the publication of more than 50 scientific works [5]. Dr. Risley's 12-year longitudinal study with Dr. Betty Hart on the development of language in young children found that the degree to which parents talked to their children during the early years of their lives predicted academic performance and intelligence test scores later in life [3]. Later in his career, Dr. Risley devoted his time to training parents how to raise their children using the information obtained from his lifelong research career.

Risolid

►Chlordiazepoxide

Risperdal – M-Tab®

►Risperdal®

Risperdal®

Anna L. Lopez
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Risperidone; Risperdal – M-Tab®

Definition

Risperdal® is the brand name for Risperidone, an atypical antipsychotic agent. It is FDA approved for the treatment of shizophrenia in adults and youth ages 13–17. Risperdal® is also FDA approved for the treatment of Bipolar I disorder in children and adolescents

10–17 years of age as well as for treatment of irritability associated with autistic disorder in children and adolescents ages 5–16.

Description

This medication is an atypical antipsychotic, commonly used for acute and maintenance treatment of schizophrenia related psychotic disorders. Risperdal® is available in tablet (0.25, 0.5, 1, 2, 3, and 4 mg), liquid (1 mg/mL), and disintegrating tablet, known as Risperdal M-Tab® (0.5, 1, 2, 3, and 4 mg). Risperdal Consta®, the long-acting injectable form, has not been studied in the pediatric population.

Recommended initial dose for treatment of Bipolar mania in children and adolescents is 0.5 mg/day with an effective dose range of 0.5–6 mg a day. For treatment of irritability associated with autistic disorder, initial dose recommended is 0.25 mg a day with an effective dose range of 0.5–3 mg a day.

When using Risperdal® with children, careful monitoring of both weight and liver function is recommended. Most common side effects include sedation and weight gain. Other reported side effects include loss of appetite, fatigue, upper respiratory tract infection, vomiting, coughing, constipation, fever, increase in saliva, dystonia, abdominal pain, anxiety, nausea, dizziness, dry mouth, tremor, dyspepsia, rash, and akathisia. Long-term side effects associated with atypical antipsychotic use include withdrawal, tardive dyskinesia, parkinsonism, and neuroleptic malignant syndrome.

Relevance to Childhood Development

Risperidone is the only FDA approved medication for treatment of irritability associated with autistic disorder in children and youth ages 5–16. In previous studies, Risperdal® was found effective when used for the treatment of pediatric bipolarity. Previous research supports that Risperdal® may also help with aggression in children and adolescents diagnosed with Conduct Disorder.

Ritalin

▶Stimulant Medications

Ritalin®

Anna L. Lopez
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Methylphenidate; Ritalin-SR®, Ritalin-LA®

Definition

Ritalin® is a stimulant medication FDA approved for children 6 and older for the treatment of ADHD and narcolepsy.

Description

Ritalin® is a central nervous system stimulant used for the treatment of impulsiveness and hyperactivity in children with ADHD. It is also used in the treatment of narcolepsy.

Similar to most other stimulant medications, the active ingredient in Ritalin® is methylphenidate. Ritalin® is available in three forms: Ritalin® immediate release tablets (5, 10, 15, or 20 mg), Ritalin SR® slowly absorbed tablets (20 mg), and Ritalin LA® extended release capsules (10, 20, 30, or 40 mg). Ritalin® and Ritalin SR® tablets

should not be crushed or chewed and must be taken whole. Ritalin LA® capsules may be opened and contents may be sprinkled on apple sauce.

Common side effects include headaches, stomach aches, difficulty sleeping, nausea, loss of appetite, and nervousness. Other side effects including abdominal pain, weight loss, and tachycardia may occur more frequently in children. Note that there are various stimulants believed to have the same treatment effect on ADHD; however, individual reactions may be different to each of these agents.

Relevance to Childhood Development

Methylphenidate, the active ingredient in Ritalin®, is the most commonly used stimulant prescribed for children with ADHD. Beneficial effects of psychostimulants may include reduced hyperarousal, reduced motor restlessness, enhanced concentration, and less aggressive and antisocial behavior. Ritalin® is not FDA approved for children under the age of 6.

Rogerian Psychotherapy

►Client-Centered Therapy

Rogers, Carl

Jennifer Becker
University of Tennessee, Knoxville, TN, USA

Life Dates

1902–1987

Educational Information

Carl Rogers was one of six children born to Walter and Julia Rogers, both from wealthy families with college degrees, at a time when college education was not prevalent. He was born and raised in Oak Park, Illinois until 1914, when his family moved away from the city to a farm outside of Chicago, which allowed him to develop an interest in science and experimentation at a young age. All throughout high school, Rogers collected, studied, and experimented with *Cecropia* caterpillars and moths. As he continued his education, he followed in his father's footsteps majoring in Scientific Agriculture at the University of Wisconsin.

Midway through completing his college degree, Rogers traveled through China, switching his major to History in hopes of pursuing a career in the Christian ministry. Roger's poor health as a child and throughout his life forced him to return home from China and brought about unexpected consequences in several areas of his life. With his return to the United States and the University of Wisconsin, Rogers became active in university life, joined the fraternity, *Alpha Kappa Lambda*, and developed a relationship with another student, Helen, who went on to become his wife in the summer of 1924 after his graduation from college.

Rogers was still determined to become a minister and continued his education at Union Theological Seminary, where he also took courses at the neighboring Teachers College of Columbia University. While attending Teachers College he took a course in clinical psychology taught by

Leta Hollingworth, after which he once again changed career paths, leaving Union to continue doctoral studies at Teachers College. He graduated with his Ph.D. from the Clinical Psychology program at Columbia University in 1931.

Accomplishments

Carl Rogers is one of the founders of the Humanistic approach to psychology, which in combination with Psychoanalysis and Behaviorism makes up the big three forces in psychology. Humanism is a system of thought that accepts an optimistic view of human nature with a focus on human values, needs, worth, and well-being. On December 11, 1940, out of the school of Humanistic Psychology, Carl Rogers held a lecture entitled, "Newer Concepts in Psychotherapy." This event marked the beginning of Rogers' clinical approach known as Person- or Client-centered therapy, which is his most celebrated achievement in the field of psychology. This approach was revolutionary at the time because his therapy was non-directive, emphasized the importance of the therapeutic relationship, and involved face-to-face contact with clients.

Rogers' Client-centered therapy was based on a method involving release, insight, and positive action and this approach is centered on the therapist allowing the client to guide their own way through therapy. The Client-centered approach is composed of three facilitative conditions known as the core conditions: congruence, unconditional positive regard, and empathy. The end point of Client-centered therapy comes when the client becomes a fully-functioning person. In his book *Client-Centered Therapy* (1951), Rogers defines a fully-functioning person as one who is open to experience, able to accept the self, able to cope with life, and able to love and be loved.

Carl Rogers published many books throughout his lifetime, including: *The Clinical Treatment of the Problem Child* (1939), *Client-Centered Therapy* (1951), *On Becoming a Person* (1961), and *A Way of Being* (1980), along with many others. His success led to a professorship at the University of Ohio in 1939 where he remained for 4 years. In 1946 he was elected president of the American Psychological Association (APA). In 1957 he left Chicago to return to the University of Wisconsin to work in both the Psychology and Psychiatry departments. The publication of his book, *On Becoming a Person,* which explored the application of Client-centered theory to all aspects of life, gained him overnight success and influence he had never imagined. The success of this book led to his resignation from the University of Wisconsin and the beginning of his work at the Western Behavioral Sciences Institute (WBSI). After leaving WBSI, he and a group of colleagues left to create the Center for Studies of the Person (CSP), an organization which is still alive today. Rogers continued his work there for 20 years and remained a resident fellow at CSP until his death.

Contribution

Carl Rogers is world-renowned and one of the most notable and influential American psychologists. In his final years, Rogers considered the application of his person-centered approach to world problems and issues. Carl Rogers is less known in the field of psychology for his work with world peace and political issues, nevertheless it remains one of the most significant contributions in his life. In particular, Rogers was interested in helping people from different countries to learn how to cross cultural and racial boundaries by learning and understanding how to respond to others in a person-centered way. In 1985, Rogers led a conference on the "Central American Challenge" that brought together leaders from 17 different countries. This conference, held in Austria, displays the dedication and commitment of Rogers to the preservation of world peace and other political issues. Rogers died in 1987, ironically right before being nominated for a Nobel Peace Prize. From Rogers' client-centered approach and its applications in therapy and psychology to his work toward world peace, he is a distinguished and remarkable man whose contributions remain important today.

Role-Playing

David Hackett
Argosy University, Atlanta, GA, USA

Synonyms

Behavior rehearsal; Psychodrama

Definition

Role-playing is a technique, most often utilized in psychotherapy and skills training, whereby the child is instructed to reenact a response encountered in a specified situation. Widely used in the assessment and treatment of maladaptive behaviors characteristic of childhood disorders, the use of role-play provides an efficient means of sampling the child's behavioral skills and/or deficits [3, 2].

Description

Psychotherapy

Role-playing is a relatively nonthreatening technique used as a means of assessment, intervention, and engagement of children in psychotherapy. In general, due to the indirect and contrived nature of this technique, role-play can be used as an effective substitute to traditional "talk therapies," particularly with those children who present as suspicious, guarded, fearful, or depressed as it provides a mode of interaction wherein the child is partially removed from that which he or she may be avoiding; dolls or puppets can also be used to further "remove" the child from direct involvement [1, 4]. Role-playing provides an opportunity for the child to act out a problematic behavior while serving as a performance base for later interventions [3]. A typical role-play involves at least two individuals engaged in the reenactment of a given scenario, either hypothetical or real. Ideally, the role plays should be as realistic as possible so as to evoke the feelings associated with the identified problematic situation. In the case in which the therapist is playing an individual known to the child (e.g., a teacher, parent, or friend), relevant information about that character, such as examples of what that individual might say, mannerisms they may use, or how they typically react would need to be gathered through systematic questioning in order to provide information about that individual as well as to enhance the realistic quality of the interaction [2]. Role-play, as a therapeutic tool, provides valuable insight as to how the child views his or her environment, as well as the dynamic interplay between the environment and the child. Furthermore, role-playing can provide a wealth of information about the nature and quality of the child's interpersonal functioning [4, 2]. As an experiential technique, role-playing is often used in the treatment of trauma whereby affective states related to a trauma are aroused so that the child is able to reinterpret an earlier, traumatic experience through reenactment [1, 4].

Skills Training

Role-playing is commonly used in skills training to improve assertiveness, anxiety, social skills, aggression, and other interpersonal difficulties. Role-playing is a technique typically employed in behavioral and cognitive-behavioral interventions to treat dysfunctional and maladaptive behaviors exhibited by children with clinically significant behavioral difficulties that impair one or more domains of functioning [4]. Thus, interventions that typically employ role-playing, within the realm of skills training, may involve for example, teaching socially phobic children how to interact in social or performance-based situations that invoke considerable distress. Role-playing is used to simulate problematic social. Typically in these sessions a deficit in some domain of functioning is identified and role-playing is often indicated to remediate such deficits. In this setting, adaptive behaviors are rehearsed through role play with the therapist acting as both teacher and model. This allows the therapist to monitor the child's performance while offering immediate corrective feedback [1, 3].

Relevance to Childhood Development

Psychotherapy with children differs from adult psychotherapy as children typically lack the cognitive abilities to comprehend and assimilate that which is primarily language oriented [4]. Following a Piagetian model of cognitive development, a child whose cognitive capacities are characterized by the concrete operations stage cannot yet engage in ►metacognition. As such, it is likely that children in this stage of cognitive development struggle with the expression of emotional concepts. Often a child may have difficulty expressing his own feeling states, yet he is able to talk of them when speaking in the third person. For these reasons, role-playing is often used within the context of psychotherapy with children [2, 4].

Rorschach Inkblot Method

Edward B. Jenny
Immaculata University, Immaculata, PA, USA

Synonyms

Inkblot test; Rorschach test

Definition

The Rorschach Inkblot Method is a performance-based personality assessment measure. The test consists of ten inkblots. Five inkblots include only shades of grey and black, two include red pigment along with the grey and black and three inkblots have a variety of colors. Test-takers are shown each inkblot, one at a time, and asked "What might this be?"

Description

The Rorschach Inkblot Method was developed by Hermann Rorschach in 1921. From the start Rorschach viewed his method as a perceptual task rather than an association or projective task. His great insight was to propose a method for coding how respondents formed percepts, that is, using color, shape, etc. Due to his untimely death from appendicitis, we will never know in what direction Rorschach might have taken his method. Although there have been numerous approaches proposed for scoring and interpreting the Rorschach, in 1974 John Exner introduced the Comprehensive System utilizing the most robust and best researched scoring categories and introducing several new ratios and scores. Although criticized as lacking validity and reliability by some researchers [6], others point to extensive positive findings that place the Rorschach on par with other personality instruments such as the MMPI-2 [4].

There are two components to the standardized administration of the Rorschach. In the free association phase respondents are given each of the ten inkblots sequentially and asked "what might this be." Responses are taken down verbatim by the examiner. In the second, or inquiry phase, the responses are repeated back to the respondent with the instruction to indicate where on the inkblot they saw the percept and what about the inkblot makes it look like that. In this way a record of the responses is collected with enough data to consistently translate the responses into a form that can be coded and interpreted.

Coding of Rorschach responses involves describing each response in terms of location (where on the inkblot the response was perceived), determinants (what aspects of the inkblot contribute to the response) and contents (categories of items perceived). In terms of location, a response might utilize the entire inkblot (W or whole), a commonly reported region (D) or an unusual detail (Dd) that is utilized by fewer than 5% of the normative sample. In addition to these three location codes, if a respondent incorporates the white space areas of the inkblot, an S is added to the location code (WS, DS, DdS).

Determinants describe what aspects of the inkblot the respondent attended to in creating a response. For example the outline or shape of an inkblot might be the dominant contributor to one response whereas another might take into account the color or shading features of an inkblot.

Each response is then scored for its conformity to the actual contours of the inkblot. Percepts that "fit" the area to which they are ascribed are seen as better integrated and connected to the reality of the blot whereas less well-fitting percepts are thought to represent greater use of internal fantasy at the expense of the real features of the stimulus.

Research has shown that respondents perceive many more things in the inkblots than they report to the examiner. The selection of some percepts and rejection of others is largely a function of personality dynamics. The respondent attempts to complete the task of saying what the blot might be to the best of his or her ability according to the perceived demands of the examiner.

Relevance to Childhood Development

Although the Rorschach has a long history of use with children there is some controversy over normative data for this population. A normative sample of 1,390 children aged 5–16 has been published [2] but is largely based on data collected from 1973 to 1986. More recent samples have suggested different values for some structural variables in the Comprehensive System [3], however these results have been challenged on methodological grounds [5].

Rorschach Inkblot Test

►Rorschach Test

Rorschach Test

Steven R. Smith
University of California, Santa Barbara, CA, USA

Synonyms

Inkblot Test; Rorschach Inkblot Method; Rorschach Inkblot Test

Definition

A performance-based personality assessment measure for ages five and older.

Description

The Rorschach Inkblot Test (RIT) is a semi-structured, standardized, personality assessment for use with individuals 5 years and older. The RIT stimulus consists of ten inkblots; five are black-and-white (and shades of grey), two are bi-chromatic, and three are multicolored. They are presented in a standard order according to a structured administration procedure. Although several systems for administration and scoring have been used throughout the history of the test, the most common system is that of Exner [1]. Recent surveys have shown that the Rorschach is one of the most commonly used personality assessment measures by psychologists working with children and adolescents.

Administration

The standardized administration consists of two steps. In the first step, the client is shown, one at a time, the ten blots and asked what the images might be. The client is allowed to respond how they see fit provided they give enough responses for scoring purposes. In the second phase, the client is shown the blots again, but asked to elaborate on what aspects or features of the blot were the most salient in forming their responses. The clinician is limited in what aspects of the client's response can be queried and the types of questions that can be asked. For example, clinicians are forbidden to use leading questions or questions that might give the client a new vocabulary for describing features of the blot.

Scoring

Like all standardized psychological tests, the RIT makes use of a norms-based scoring procedure. The client's verbal output is transcribed verbatim and this output is then scored based on several different aspects of their response. Specifically, each response is coded for location, complexity, integration, content, and use of space, color, and shading. In addition, responses can be coded for "Special Scores," which are aspects of a client's response that might signal cognitive slippage or psychopathology. Together, scores are summed and compared to age-matched normative samples in order to generate clinical hypotheses.

Norms and Psychometrics

Exner's normative samples for children and adolescents are dated and some have questioned their validity with current populations. Although some other normative samples are available for child and adolescent populations, it is advisable to use the norms available in the 2003 manual. However, Meyer and Viglione [7] recommend that adjustments be made according to irregularities found between Exner's samples and a large number of international normative samples. A number of studies have supported the reliability of the Exner system, both in terms of internal consistency and inter-rater agreement [2–10]. Validity for any test is contingent upon sample, referring question, setting, and use. The RIT has been shown to be particularly useful in the assessment of thought disorder, aggressive tendencies, personality disorder, treatment outcome, and cognitive dysfunction. Interested readers should make use of the number of recent summaries of this work; clinicians should remain abreast of the most recent research because Rorschach research is quite active at the moment.

Domains of Assessment

According to available research, the RIT appears to be particularly useful for the assessment of personality and emotional functioning. Like other performance-based (projective) techniques, the Rorschach allows for the examination of spontaneously-generated behaviors that serve as in vivo demonstrations of personality or personal characteristics. The RIT appears to be particularly strong for assessing problem-solving, thinking styles, reality testing,

and perceptual soundness. The measurement of interpersonal expectations and orientation, dependency, and aggression has been supported by research. Although research evidence exists to suggest that the RIT is effective in measuring depression and anxiety in adult samples, such evidence is less well-established with child samples.

Rorschach, Hermann

Edward B. Jenny
Immaculata University, Immaculata, PA, USA

Life Dates

1884–1922

Introduction

Hermann Rorschach is best known for developing the Rorschach Inkblot Test, a performance-based measure of personality dynamics. The Rorschach inkblot Method is one of the most frequently used assessment measures in clinical practice.

Educational Information

Herman Rorschach was born 1884 in Zurich Switzerland. His father studied art and moved to Schaffhausen where he taught painting. Rorschach was himself recognized as a talented artist in his own right and was known for his detailed drawings of patients in their hospital charts. In 1897 Rorschach's mother died from complications of diabetes and his father died in 1903, apparently the result of exposure to lead contained in his paints.

Rorschach studied medicine at the University of Zurich from 1904 to 1909, obtaining his medical degree in 1909 and specializing in Psychiatry. In 1910 he met and married Olga Stemplin, a Russian national, lived for time in Russia and joined a lucrative practice but returned to Switzerland out of attachment for his homeland. Although he intended to return to Russia he never did.

Accomplishments

Rorschach served as an assistant at the asylum in Munsterlingen from 1909 to 1913. In 1914 he served as assistant at the Waldau psychiatric hospital. His wife, who had been living with family in Moscow since late 1913 was detained and unable to return to Switzerland until 1915 as a result of wartime tensions. In 1915 Rorschach accepted the position of Assistant Director at the Herisau Asylum in Appenzell.

Contributions

Inspiration for Rorschach's inkblot test came from at least two sources. Between 1900 and 1914 the University of Zurich's psychiatric hospital, the Burgholzli, became an active site of innovation in the humane treatment of the mentally ill. In 1898 Eugene Bleuler took over as head of the hospital and appointed Carl Jung as the assistant director. The Burgholzli became famous for its work on word association and the study of schizophrenia (then called dementia praecox). One explanation of schizophrenia arising from this work was that it was a disturbance in associational ability.

A second source of inspiration came from a common parlor game at the time called *Klecksographie*. In this game blots of ink are applied to blank paper which is then folded over to create a symmetrical image. Players compete to name as many possible images seen in the inkblots. It is rumored that Rorschach was so enamored of this game that he earned the nickname *Klex* [1].

Rorschach experimented with a large number of inkblots, modifying them so as to create images that elicited complex responses from subjects. He selected ten inkblots and administered them to 288 hospital

patients and 117 nonpatients giving them the simple instruction "what might this be?" The results of this investigation were published in a 1921 monograph entitled *Psychodiagnostics*.

Although commonly referred to as a projective instrument, Rorschach's real innovation lay in his description of the manner in which respondents utilized various attributes of the inkblots to form their perceptions. In *Psychodiagnostics* Rorschach proposed an elegant system for coding and interpreting the limitless possible responses provided by examinees.

Unfortunately, Rorschach did not live long enough to complete his work. He died in 1922 at the age of 37 from peritonitis secondary to a ruptured appendix. After Rorschach's death the monograph languished but was kept alive by close friends of Rorschach including Emil Oberholzer who would play a role in introducing the work to American psychiatrists who came to Zurich to study. The Rorschach inkblot method continues to be one of the most commonly administered personality assessment instruments.

Satz, Paul

Tracey McLellan
University of Canterbury, Christchurch, New Zealand

Introduction

Dr. Satz is an internationally-renowned clinical neuropsychologist who has devoted many years to advancing our understanding of human brain injuries and how effective therapeutic strategies can enhance recovery of function. His varied research interests also include dyslexia, learning disabilities, brain laterality and remediation in schizophrenia [1, 4].

Educational Information

Dr. Satz received his doctorate of philosophy in clinical psychology from the University of Kentucky, College of Medicine, in 1963. His dissertation on the block rotation task won the Creative Talent Award given by the American Institute of Research.

Sam Goldstein & Jack A. Naglieri (eds.), *Encyclopedia of Child Behavior and Development*, DOI 10.1007/978-0-387-79061-9,

Accomplishments

While at the University of Florida, Dr. Satz developed the first neuropsychology research laboratory as well as the first neuropsychology clinical service. Many prominent clinical researchers have been mentored by Dr. Satz at these facilities and he also helped establish the Association of Post-Doctoral Programs in Clinical Neuropsychology [5]. In addition, Dr. Satz was one of the early founders of the International Neuropsychology Society, helped develop Division 40 of the American Psychological Association (APA), and he was awarded the APA Award for Distinguished Professional Contributions.

Contributions

Dr. Satz has made an invaluable contribution to the development of neuropsychology as a distinct research and professional discipline. He has been one the most productive researchers in neuropsychology as evidenced by more than 300 publications that he has authored and coauthored. Dr. Satz has also coauthored several books including *The Disabled Learner, Middle Childhood: Development and Dysfunction,* and *Neuropsychology of Human Emotion* (e.g., [2, 3]).

Current Involvement

Dr. Satz is currently Professor Emeritus and Chief of the Neuropsychology program at the David Geffen School of Medicine at UCLA.

Scaffolding

Bryan Rotella
Niagara University, NY, USA

Synonyms

Dynamic assessment; Peer-tutoring; Zone of proximal development

Definition

A learning process by which interaction with another individual occurs, resulting in higher competency.

Description

The term instructional scaffolding is a metaphor referencing its original meaning in construction; a temporary framework to support building. Related to instruction, scaffolding is a tool (i.e., assistance from others) for an individual to reach another level of knowledge or skill that could not have been gained without assistance.

Wood, Bruner, and Ross first developed the term for pedagogical purposes, in their 1976 article, "The role of tutoring in problem solving" [6]. They described the term as a means of one on one learning through a tutoring model. This social dynamic later coined as "scaffolding" was a critical component of Lev Vygotsky's Zone of Proximal Development (ZPD) theory. ZPD is a process by which a learner gains knowledge from interactions with their surroundings. Social interactions and their influence on a learner's education are an important part of ZPD. Comparatively, the concepts of ZPD and scaffolding are both based on the assertion that the individual learner will acquire more knowledge through more dialectic interactions than they would if attempting to learn in isolation.

In scaffolding, speech (discourse) is a critical tool and is typically thought of as facilitating intellectual growth. However, the social process of scaffolding also facilitates the development of other intrapsychological processes that promote successful learning such as motivating the student, managing frustration, and regulating attention. Scaffolding is expected to be temporary with supports (surrounding individuals who are more knowledgeable) and should move in the direction of higher competency [4]. Scaffolds (the more knowledgeable individuals) are not limited to school teachers. They can be parents, mentors, peers, tutors or anyone who will facilitate growth in a skill or ability [2].

Relevance to Childhood Development

Tanner and Jones [5] showed that scaffolding in teaching styles effectively accelerated metacognitive skill development. Comparatively, in free play, children may be able to solve a problem without assistance but may not be aware of the relationship between the actions that created the solution. This suggests that there will not be a solid understanding of procedures for the solution of the task, which would result in the inability to use it for future tasks. Studies also show that scaffolding results in children becoming self-regulating and independent of adult help [1, 3].

Schemas

Stephanie A. Grote-Garcia
University of the Incarnate Word College of Education, Texas A&M University-Corpus Christi, Corpus Christi, TX, USA

Synonyms

Schema (singular); Schemata

Definition

Schemas refer to theoretical mental structures that assist individuals in simplifying and organizing knowledge. Phrases used to describe schemas have included the following: mental frames, global knowledge structures, building blocks of cognition, organized knowledge of the world, organized memory structures, and packaged units of knowledge.

Description

Included in schemas are the prior experiences, established knowledge, and abstract representations of events, objects, and relationships in the world of an individual. An individual's schemas tend to influence what he or she perceives, understands, infers, remembers, and comprehends.

The schemas of an individual are not stagnant. As an individual lives through different experiences and gains additional knowledge, his or her schemas continue to develop. Similarly, the more experience and knowledge

an individual can add to a particular schema, the more complex that schema becomes. For example, due to the magnitude of their experiences, professional-culinary chefs hold a more complex schema for cooking gourmet meals than do inexperienced cooks.

Relevance to Childhood Development

The term "schema" is significant to the field of childhood development because it has influenced learning theories, teaching methods, and curriculum design. Two lines of work associated with childhood development and influenced by the notion of schemas are *cognitive constructivism* and *cognitive-developmental constructivism*. These two theoretical lines of work share the idea that individuals generate knowledge and meaning from their experiences. They have also been associated with the ideas of Jean Piaget [1] who focused on child-centered learning. Piaget's belief in child-centered learning was directly related to the theoretical idea of schemas.

In addition to learning and remembering, schemas have also been linked to achievement in reading comprehension [2, 3]. A reader is able to comprehend at a higher level when he or she has a well-developed schema that relates to the content being read. In addition, a reader with schemas that are less complex is likely to find the reading selection to be difficult to comprehend. The relationship between prior knowledge and reading comprehension is explored within the realms of *schema theory*, which is associated with Rumelhart [3].

Not only has the idea of schemas influenced learning theories, it has also assisted in designing effective teaching methods and learner-centered curriculum. With these multiple areas of influence, it is clear that the theoretical idea of schemas has played an important role in child development.

Schizophrenia

Steven L. Proctor
Louisiana State University, Baton Rouge, LA, USA

Synonyms

Childhood schizophrenia

Definition

Schizophrenia is a chronic and debilitating psychiatric illness that represents a profound disruption of the most fundamental human attributes which include, emotion, language, thought, and perception.

Description

The term *schizophrenia* was first coined by Swiss psychiatrist Eugene Bleuler in 1908 following psychiatrist Emil Kraepelin's distinction between what he called "dementia praecox" and other forms of madness. The term schizophrenia comes from the Greek words *schizo* (split) and *phrenos* (mind) [2]. Schizophrenia is a psychiatric diagnosis denoting a mental illness in which component processes are in a state of dysregulation. These processes include neurotransmitter systems, attention and memory, formation of beliefs and abstract thinking, and performing behavioral activities in a socially meaningful context.

Schizophrenia is characterized by impairments in social functioning (e.g., work, home, school) and difficulties in caring for oneself (e.g., poor hygiene). In addition to problems in daily living, individuals with schizophrenia experience a wide range of symptoms including positive symptoms, negative symptoms, cognitive impairments, and problems dealing with the regulation of mood. Positive symptoms refer to features which are present or *added*

to an individual's typical presentation (e.g., delusions; hallucinations; bizarre, disorganized behaviors). Delusions, in particular, can be broken down into smaller subsets; persecutory delusions, delusions of being controlled, thought broadcasting, thought insertion, thought withdrawal, delusions of guilt or sin, somatic delusions, and grandiose delusions. Negative symptoms refer to features which are absent or *taken away* from an individual's typical presentation (e.g., alogia, avolition, psychomotor retardation, flattened affect, anhedonia). Positive symptoms appear to be more responsive to psychopharmacological treatment whereas negative symptoms tend to be more treatment-resistant and follow a more chronic and stable course. Cognitive impairments include difficulties with memory, planning, and abstract thinking, while problems dealing with the regulation of mood include depression, anxiety, and anger [1].

Schizophrenia has been observed across a wide range of different populations and cultures with prevalence rates among adults ranging from 0.5 to 1.5% [1]. The onset of schizophrenia typically occurs between late adolescence and early adulthood. Schizophrenia affects men and women with equal frequency although men typically present earlier (between 18 and 25) than women (between 25 and the mid-30s). Studies suggest that urban-born individuals are at an elevated risk of a formal diagnosis of schizophrenia compared with rural-born individuals [2]. Although rare, the onset of schizophrenia may also begin later in life (e.g., after age 45). For this particular cohort, the proportion of affected women is significantly greater than that of men. The risk for schizophrenia of first-degree biological relatives of individuals with schizophrenia is 10 times greater than that of the general population [1].

The course and prognosis of schizophrenia follows the "Law of 1/3's" which states that about one third of people have nearly complete remission with only mild relapses and little disruption to their daily lives, one third has a variable pattern of symptom exacerbation with more interruption to daily functioning, and the final third has chronic symptoms that impair most aspects of daily life. The life expectancy of individuals with schizophrenia is shorter than that of the general population due in most part to suicide. Approximately 10% of individuals with schizophrenia commit suicide and between 20 and 40% make at least one attempt over the course of the illness [1].

Currently, treatments in schizophrenia are not viewed as a "cure" for the illness, but rather as strategies which help manage the illness and minimize disruption in life. Psychiatric rehabilitation has emerged as an approach to organizing a diversity of treatments for the purpose of overcoming disabilities [2]. Psychiatric rehabilitation efforts, in general, target multiple levels of functioning to optimize treatment outcome and prevent relapse.

Relevance to Childhood Development

The essential features of schizophrenia are the same in children as they are for adults, although a formal diagnosis of schizophrenia may be particularly difficult to make for this age group. Delusions and hallucinations may be far less elaborate in children than in adults and visual hallucinations may be more common. The presence of disorganized speech may also present complications in assigning a formal diagnosis of schizophrenia in children. A number of childhood disorders possess symptoms comparable to those of disorganized speech (e.g., Communication Disorders, Pervasive Developmental Disorders) as well as disorganized behavior (e.g., Attention-Deficit/Hyperactivity Disorder) [1]. These symptoms should not be attributed to schizophrenia without further consideration of these more common childhood disorders.

SAT

Daniel Patanella
New York City Department of Education, New York, NY, USA

Synonyms

SAT-I; SAT reasoning test; Scholastic achievement test; Scholastic aptitude test; Scholastic assessment test

Definition

The SAT is a standardized, high-stakes college entrance examination widely taken by students throughout the United States. It consists of three distinct parts: a mostly multiple-choice verbal section, a multiple-choice mathematics section and, as of 2005, an essay section.

Description

The SAT Reasoning Test is a standardized, high-stakes college entrance examination widely taken by students throughout the United States. It is nearly a century old, being first administered in 1926 and initially largely developed by Carl Campbell Brigham (1890–1943) who had earlier worked on the Army Alpha and Beta intelligence tests. The test itself was originated for and is owned by the College Entrance Examination Board, and is administered by the Educational Testing Service (ETS). The chief rival of the College Board is American College Testing, who publishes the ACT test; traditionally the SAT was taken primarily by students on either coast of the United States and the ACT was taken by Midwesterners. Until 1990, the SAT was known as the Scholastic Aptitude Test; between 1990 and 1993, the test was known as the Scholastic Achievement Test. Currently, the College Board does not attach any official meaning behind the acronym "SAT" although the test is still sometimes referred to by an earlier name such as the Scholastic Achievement Test in the research literature. The SAT Reasoning Test stands apart from the various SAT subject tests that are also offered by the College Board.

Neither the College Board nor ETS describe the SAT as an intelligence test, although research does indicate high correlations between SAT scores and overall general intelligence or *g*. The College Board currently describes the SAT Reasoning Test as an assessment of critical thinking skills. Since the 1960s, the College Board has released descriptive data on every SAT as a public service, which has led some researchers to use SAT scores as an estimate of the quality of overall high school education throughout the United States; this unintended use may not be valid. Regardless, both the College Board's research and research done in academia agree that the SAT is a predictor of college grade point average, making the SAT a heavily-weighed factor in most admissions processes. The new SAT Reasoning Test's predictive ability is about the same as the older versions.

The current version of the SAT Reasoning Test contains three components, each worth between 200 and 800 points, and with a mean of about 500. Each of those components, in turn, consists of three sections. There is also an unscored section consisting of new items that are being piloted for potential future use. Thus, the final SAT score ranges from 600 to 2,400, based on the nine scored sections of the test. Aside from the first and last sections of the test, the sequence of the remaining sections is jumbled. The SAT is a timed test, taking a total of three-and-three-quarters-of-an-hour for the student to complete (not counting time spent receiving instructions). Students within the United States and its territories may take the SAT at seven different times of the year, whereas students elsewhere may take it at six different times.

The critical reading section of the current SAT replaces what was formerly known as the verbal section of the test, and is largely concerned with answering questions based on reading passages instead of the analogy-type questions that used to appear on the SAT. The mathematics section of the current SAT includes higher-level questions than did the older SAT, which did not require more than basic algebra, and omits the quantitative comparison-type questions in favor of more straightforward items. The writing section of the current SAT is similar to the old SAT writing subject test and consists of both an extended essay as well as multiple choice items directed toward issues related to fluent writing and revision techniques. The essay topic itself is broad enough to be accessible to the widest possible variety of students' socioeconomic background and, in fact, many of the changes made to the SAT Reasoning Test in general seem to reduce the possibility of ethnic and racial bias that some researchers reported in earlier editions.

As colleges overall expanded their pools of applicants and the demographics of the average group of students taking the SAT changed, the average SAT score declined from the 1960s to the 1980s. This decline, coupled with concerns over the thresholds needed for admission to select colleges, has partially led to two distinct trends. The first is the rise of the test-prep program; companies such as the Princeton Review and Kaplan offer courses which, some research shows, increase students' scores on tests like the SAT. The second is the trend within some

mostly liberal arts schools to diminish the importance of SAT scores in favor of high school grade point averages and other, more subjective, criteria.

Relevance to Childhood Development

The SAT has provided a rite-of-passage for generations of American adolescents as they prepare to transition to an adult life beyond their high school experience. Given its status as a rigorously designed standardized test developed by a premier testing company, the SAT was (and still is) a key component to acceptance into competitive college programs and thus the results of the test are extremely high-stakes. Long before the standardized testing boom that emerged in response to the *No Child Left Behind* act, both the SAT and the stress accompanying preparation for it, were well known to both parents and children. As perhaps the highest-profile standardized test taken by the greatest number of Americans, the literature concerning the SAT exemplifies the strengths, weaknesses, and controversies surrounding standardized educational tests.

School Climate

Michael Block
Azusa Pacific University, Azusa, CA, USA

Synonyms

Classroom climate; School culture

Definition

School climate is often referred to as the social atmosphere of a setting or learning environment in which students have different experiences, depending upon the protocols set up by the teachers and administrators.

Description

There are many key components that make for a positive school climate. It may be described as an orderly environment in which the school family feels valued and able to pursue the school's mission free from concerns about disruptions and safety. Providing a caring and safe atmosphere are two essential factors that are often mentioned. Research on school climate often indicates several environmental conditions as being critical in establishing a positive school climate. These include the following:

- A physical environment that is welcoming and conducive to learning
- A social environment that promotes communication and interaction
- An affective environment that promotes a sense of belonging and self-esteem
- An academic environment that promotes learning and self-fulfillment

Research shows that school climate can affect many areas and people within schools. For example, a positive school

climate has been associated with fewer behavioral and emotional problems for students. Additionally, specific research on school climate in high-risk urban environments indicates that a positive, supportive, and culturally conscious school climate can significantly shape the degree of academic success experienced by students. Furthermore, researchers have found that positive school climate perceptions may supply high-risk students with a supportive learning environment yielding healthy development, as well as preventing antisocial behavior. School climate research suggests that positive interpersonal relationships and optimal learning opportunities for students in all demographic environments can increase achievement levels and reduce maladaptive behavior.

Regarding the roles of teachers and administrators, it has been found that a positive school climate is associated with increased job satisfaction for school personnel. Finally, student perspectives are important during the transition from one school level to another. Attending a new school can be frightening for students and this apprehension can adversely affect students' perceptions of their school's climate and learning outcomes. Therefore, research has shown that providing a positive and supportive school climate for students is important for a smooth and easy transition to a new school.

Educators and parents have multiple options to enhance school climate and students' overall educational experience. The following is a sample list of possible interventions to improve school climate:

- Increased parent and community involvement
- Implementation of character education or the promotion of fundamental moral values in children
- Use of violence-prevention and conflict-resolution curricula
- Peer mediation
- Prevention of acts of bullying
- Teachers and principals treat students fairly, equally and with respect
- Implementing programs that encourage a safe environment for staff and students
- Personalization through adopt-a-kid programs, honoring most-improved students, and block scheduling

Many researchers have developed measures of school climate. Examining these measures and the attributes specifically assessed provides further detail into the nature of school climate. These assessments consider multiple factors and individuals within the school system using direct measures, such as surveys and interviews, and indirect measures, such as disciplinary and attendance records The School Climate Survey contains seven dimensions of school climate and specifically assesses students' perceptions in the following areas:

- Achievement motivation
- Fairness
- Order and discipline
- Parent involvement
- Sharing of resources
- Student interpersonal relationships
- Student–teacher relationships

The Charles F. Kettering Ltd. (CFK) School Climate Profile is also widely used to measure school climate. This survey is comprised of four sections and is given to teachers, administrators, and students. Part A, the General Climate Factors, is comprised of the following eight subscales [9]:

- Respect
- Trust
- High morale
- Opportunity for input
- Continuous academic & social growth
- Cohesiveness
- School renewal
- Caring

Relevance to Childhood Development

School culture and school climate are useful terms for the intangibles that can affect learning. As such, they deserve serious attention in the effort to improve performance. Comprehensive models that have been developed for school reform have invariably included change in school culture and school climate.

School Dropout

Latoya S. Stewart, Andy V. Pham, John S. Carlson
Michigan State University, East Lansing, MI, USA

Synonyms

School leaving

Definition

School dropout is defined as leaving school without a high school diploma.

Description

School dropout is of great concern in the United States as a significant number of students leave before earning a diploma. Current estimates place the overall dropout rate at 9.4% [14]. This estimate is even higher among students with disabilities, as well as low income and ethnic minority students [8]. For example, in 2000–2001, 41.1% of students age 14 and older with disabilities dropped out of school [13]. Low income students are more than twice as likely to leave school early when compared to middle-income students and about ten times more likely than students from high-income families [4]. In 2005, the dropout rates for Hispanic and African-American students were 22.1% and 10.4%, respectively [14]. Compared with individuals who complete high school, dropouts have fewer employment opportunities and, if employed, earn significantly less [3]. Further, school dropout negatively affects the economy, as billions are spent on welfare, unemployment, and crime prevention to support school dropouts who are more likely to be unemployed, receive public assistance, and be imprisoned [7]. Given the prevalence and negative consequences of school dropout, legislation such as No Child Left Behind (NCLB) was put in place to hold schools accountable for student achievement and success. NCLB requires all school districts to provide a yearly report of students' performance and statewide assessments as well as school dropout and graduation rates.

Individuals usually decide to drop out of school by tenth grade when they are at the age of 16 to legally make that choice. Numerous risk factors involving the individual student, student's family, school, and community typically result in the decision to leave school. Such risk factors may be placed in three broad categories: (1) social background including factors such as race/ethnicity, gender, socioeconomic status [SES], family structure, and inner-city residence; (2) academic background including factors such as ability, test scores, history of grade retention, school engagement, school grades, course failures, truancy, and behavioral problems; and (3) school characteristics including structure and school social organization [9].

Social Background

School dropouts are more likely to be boys than girls, and more likely to be individuals from racial and ethnic minority groups, low-income families, single-parent households, highly stressful (e.g., divorce, death, marriage) households, born to teenage mothers, and from families in which one or both parents also did not complete high school [10]. Among these factors, parents' educational level seems to have the most consistent effect on school dropout. Specifically, low parent educational level seems to increase the likelihood of school dropout because such parents are less likely to be able to teach their children basic prerequisite skills for learning. Children who start school without the basic skills for learning tend to perform poorly in school. Low academic achievement tends to increase students' alienation from school, leading to absenteeism, which in turn increases the risk for school dropout [12].

Academic Background

Poor academic achievement is one of the strongest predictors of school dropout. Specifically, students who eventually drop out of school typically have a history of failing courses, receiving low grades even as early as the first grade, taking lower level courses in middle and high school, being retained at least one year and receiving special education services. They also typically have

a history of behavioral problems, low engagement in classroom via frequent absences, lack of classroom participation, inattention, and disengagement in school functions and extracurricular activities [5].

School Characteristics

The school's structure and social organization have been linked to school dropout. Schools are organized in a way that "push" out some types of students, particularly those who manifest the social and academic characteristics mentioned above [9]. School structure, which includes sector and enrollment, is an important factor related to school dropout. For example, private schools (e.g., Catholic schools) and schools with smaller student population have been found to have lower rates of school dropout than public and urban schools [11] as the former are often described as more favorable learning environments for students. Interviews with individuals who have dropped out of high school revealed that a large number often leave school due to negative relationships with teachers and/or peers; they believe their teachers do not care about them or their progress in school, and are unwilling to support them when problems arise [5].

Among the various characteristics within the three broad categories associated with school dropout, poor academic performance, low SES, and behavioral problems seem to be the three main risk factors [10]. Further, the combination of two or more risk factors increases the likelihood of school dropout [5].

Relevance to Childhood Development

School dropout is a serious problem that has profound consequences for the individual student, the school system, the community, and society at large. The decision to leave school does not happen overnight and is often the end product of a combination of multiple social, academic, and school risk factors that begin early in life [2]. Some risk factors are present as early as the first grade (e.g., receiving low grades, behavior problems, receiving special education services), while others are present even before school enrollment (e.g., single-parent households, low parent educational level, poverty, and ethnicity). Therefore, prevention and intervention programs across different settings (i.e., school, family/home, and community) targeting school dropout risk factors should be in place from early childhood and sustained throughout the school years, in order to prevent and reduce the likelihood of school dropout in later years. Some school-level programs that have been advocated include: (1) eliminating grade retention; (2) individualizing school programs to meet students' needs; (3) providing counseling services; (4) providing supportive learning environments that allow students the opportunity to be successful; and (5) providing a balance of academic and extracurricular activities [6, 10].

School Psychologist

Jackie Kibler
University of Montana, Missoula, MT, USA

Definition

A psychologist trained in psychology and education whose aim is to enhance the potential of children.

Description

School psychologists are professionals who have completed graduate study in the areas of psychology and education. The training of school psychologists is guided by *Blueprint III*, a statement on the training and practice of school psychologists developed by leading experts in the field [3]. The field of school psychology works to enhance the academic, emotional, and social potential of children [2]. School psychologists assist with the development and implementation of prevention and intervention efforts for children. School psychologists use consultation and assessment measures to assist in these efforts. Many times school psychologists are employed to work within schools to accomplish these goals. However, school psychologists may work in other settings such as hospitals, health centers, private practice, and university settings. School psychologists work with educators, parents, community advocates, school administrators and others to enhance the learning environment for students. The National Association of School Psychologists is the professional organization for the field of school psychology. Division 16, the Division of School Psychology, of the American Psychological Association has also helped to develop the profession of school psychology through research activities and advocacy. Both organizations have developed a code of ethics to help guide the profession [1].

School Psychology

Katherine R. Krohn
University of Tennessee, Knoxville, TN, USA

Definition

School psychology is a field of study and professional practice focusing on the educational and psychological needs of children, youth, and families. Although closely related to many other fields such as clinical and counseling psychology, developmental psychology, applied behavior analysis, special education, education, and school counseling, school psychology is a unique discipline. It requires training in child development, learning, behavior, motivation, and mental health, to name a few, as well as in the assessment, consultation, and intervention of these domains.

Description

School psychology is a relatively young field that is rooted in child development, clinical psychology, and special education. The origin of school psychology is generally traced to Lightner Witmer's establishment of the first psychological clinic at the University of Pennsylvania in 1896. However, development and use of the terms *school psychology* and *school psychologist* did not emerge until approximately two decades later when Arnold Gesell was first appointed to the position of *school psychologist* [1]. The first comprehensive picture of the field was assembled at the Thayer Conference of 1954, during which the training, credentialing, and practice of school psychology were delineated [3]. Descriptions of and practices within the field have evolved substantially, accompanying economic, social, and legal impetus. Currently, the two most influential bodies in the field are the National Association of School Psychologists (NASP) and the Division of School Psychology (Division 16) of the American Psychological Association (APA).

With clear ties to both psychology and education, APA and NASP have similar descriptions for the profession of school psychology. Both emphasize concern for the development, mental health, and education of children and

adolescents; collaboration and consultation with parents, educators, and other professionals; and the provision of services within the context of educational settings, although school psychologists are not limited to those settings [3]. However, NASP and APA currently disagree on the minimum requirements for becoming a school psychologist, with the former advocating a specialist degree and the latter a doctorate degree. Additionally, APA regards school psychology as a specialty within the broader field of psychology rather than as a separate profession. This distinction is reflected in the beginning of APA's archival definition of school psychology found on their website: "a general practice and health service provider specialty of professional psychology that is concerned with the science and practice of psychology with children, youth, families; learners of all ages; and the schooling process."

Another approach to defining the field of school psychology is to examine the roles and responsibilities of a school psychologist. According to NASP, the major roles assumed by most school psychologists include consultation, evaluation, intervention, prevention activities, research, and planning. School psychologists collaborate with parents, educators, administrators, and other service providers in order to develop interventions for particular student problems and to strengthen communication and relationships between all parties involved. Assessments are conducted in order to evaluate eligibility for special education services, current academic skills (e.g., achievement testing, curriculum-based testing), aptitude for learning (e.g., intelligence testing), behavioral and social-emotional status, and school and classroom environments. Assessment results are linked to appropriate interventions, which may be designed for individual students, groups of students, or families. Interventions may involve counseling, crisis responses, implementation of behavior management plans, and the allocation of more intensive and individualized academic support. Preventive efforts largely center on the delivery of training to parents and school personnel, the development of programs to improve the physical and psychological health and safety of students, and the effectiveness and efficiency of instructional delivery.

Specific responsibilities of school psychologists vary widely and depend on a number of factors: where school psychologists work, academic preparation and specialization, degree (e.g., specialist versus doctorate) and licensure obtainment, size and location of the employment setting, and state laws governing educational practices and services. Although the majority of school psychologists work in public and private school districts, many are also employed in clinics and hospitals, universities, residential settings, and private practice. Some responsibilities performed by school psychologists working in school districts (e.g., serving on Individualized Education Plan team meetings) are not likely to be performed in other settings. Academic preparation (e.g., extent of counseling focus), specialization in a particular area of study (e.g., autism, behavior disorders), and the obtainment of a certain degree or license may impact a school psychologist's employment setting and job description. For example, a doctorate degree is the minimal requirement for employment in private practice.

School psychology practices are guided by federal legislation, state legislation, and case law; thus, variability exists between states. All school psychologists are impacted by a prominent federal special education legislation known as the Individuals with Disabilities Education Improvement Act (IDEIA), among others, although states may make even more stringent requirements as they are permitted some flexibility in how they implement the federally mandated services. For example, IDEIA requires that assessments be conducted in a multifaceted, multi-informant, and nondiscriminatory nature, yet school districts differ in their current assessment practices for identifying learning disabilities (i.e., some administer traditional standardized testing while others use brief, repeated measures of performance to monitor students' responsiveness to appropriate and increasingly intensive interventions).

Differentiating school psychology from related fields in education and psychology is particularly important due to overlap that exists between services provided and academic preparation, as well as the widespread tendency to equate school psychology with school counseling. Compared to school counselors, school psychologists tend to receive more training in individual assessment methods and intervention techniques, have historically focused more on students with disabilities, and often have more schools and larger numbers of students to serve. Although the terms *educational psychology* and *school psychology* are sometimes used interchangeably, they have separate divisions within APA (15 and 16, respectively), with the former placing a greater emphasis on research and the latter on applied practice. School psychology programs are often found in university departments of education, although occasionally they are enveloped in psychology departments. School, clinical, and counseling psychology are collectively considered the three health care areas of professional psychology, all of which can lead to the title of board-licensed psychologist. Despite the similar focus on working with children, adolescents, and families, clinical

and counseling psychology generally do not prioritize school and educational issues.

Changes in the field of school psychology are continually occurring, enhancing the effectiveness of the field by identifying demands on the profession and assessing the current ability to meet those demands. One major trend is the shift from the focus on assessment practices for purposes of identifying students for special education eligibility (leading to school psychologists being described as "gatekeepers" to special education services) to a tiered-model of preventive service delivery. Specifically, primary prevention activities (directed at entire classes, schools, or districts), or at least secondary prevention activities (i.e., early identification and intervention of academic, social, and emotional issues), are being stressed to reduce the need for more individualized, intensive, costly, and potentially stigmatizing interventions later [5]. Also, the emphasis on training culturally and linguistically diverse school psychologists, or at least preparing psychologists that are knowledgeable and sensitive to cultural issues that impact child development, family functioning, and academic skill acquisition, continues to increase, especially in response to the growing population of students who are bilingual and monolingual enrolling in public schools in the United States. As Reschly and Ysseldyke [4] contend, "the past is not the future" for school psychology, especially considering the current paradigm shift toward increased problem-solving, accountability, and practices designed to make improvements in the lives of children rather than mere predictions. Substantial changes are expected to occur on an international level, considering that school psychology is still in its infancy in many countries [2].

School Readiness

Stacy L. Bender, Andy V. Pham, John S. Carlson
Michigan State University, East Lansing, MI, USA

Synonyms

Academic readiness; School adjustment; School transition

Definition

School readiness refers to the competencies a child possesses upon school entry that are essential to academic and social development.

Description

School readiness has been emphasized as early as 1836, after compulsory education laws were passed which mandated all children to attend formal education. During the past 40 years, there has been an increase in early childhood programs as well as research literature investigating school readiness. Programs began to foster and teach academic and social skills that are necessary for all children to develop in order to succeed in school. During this time, early childhood programs were targeted at low-income children in hopes of enhancing their development through educational, health, and family services. The rising concern and awareness of the importance of young children entering school with adequate skills have been a result of initiatives and policies such as the National Education Goals (2000), the National School Readiness Indicators Initiative (2004), and the reauthorization of the School Readiness Act (2005). These policies support individual success of young children around the country and require quality standards for early childhood programs.

Although school readiness has varied definitions, five areas of development are considered to be the most significant domains of a young child and should be assessed by educators and families upon school entry: (1) physical well-being and motor development, (2) social and emotional development, (3) approaches to learning, (4) language development, and (5) cognitive development and general knowledge.

Physical well-being and motor development include the child's physical health status, disabilities, and motor abilities, such as gross and fine motor skills. Social and emotional development refers to the child's ability to interact appropriately with others and self-regulate their emotions and behaviors. This type of development allows the child to interpret and express their own feelings as well as understand feelings of other people. Approaches to

learning refer to the child's utilization of skills and knowledge, such as persistence and enthusiasm as well as the learning styles and habits a child uses to approach learning. Language development refers to the child's communication skills, such as speaking, and the beginning stages of literacy, such as print awareness and letter-sound associations. Lastly, cognitive development and general knowledge relate to the child's ability to develop thinking and problem solving skills which includes mathematical knowledge and imagination. All of these domains are considered complementary to one another and are taken together in order to understand how the child is developing.

Relevance to Childhood Development

The first five years of childhood are vital to development. Children are exposed to many experiences and environments, which set the stage for future development and learning opportunities. These experiences also shape the brain development of the child, given the rapid brain growth and neuronal connections during these years. Therefore, it is important to provide early opportunities for children to develop academic and social skills that will assist them to become ready for school. In addition to schools, children's families and communities help prepare them for school entry by providing enriched environments which support the child's development in the physical, social, emotional, language, literacy, and cognitive domains.

Researchers have investigated children attending high-quality early childhood education programs (e.g. Pre-Kindergarten) and have found various benefits. These include increased cognitive and language development, increased reading and math achievement, and the promotion of social and behavioral skills in children. These skills, when present at school entry, are likely to have positive, long-term effects which persist into elementary school and are strongly correlated with later skills. Low-income children, who are typically considered to have unfavorable educational outcomes, also benefit from attending high-quality early childhood education programs. These programs build a strong foundation of learning and teach necessary skills for school entry.

Secular Trends

Robert Sean Bannon
Emporia State University, Emporia, KS, USA

Definitions

Marked changes in physical development that have occurred over generations.

Description

Secular increases in height, weight and early maturation are currently the subject of multiple studies. Childhood growth rates have increased dramatically over the past 50–100 years. Advancement in medicine and technology as well as marked increases in standard of living and nutrition have been cited as core factors in secular trends over the past century. Secular increases in the areas of *maturation* and *growth* have been observed in developed countries, while underdeveloped countries have exhibited modest to no alteration in these areas. Improved environmental conditions within a general population have resulted in secular increases, while delayed size and maturation may be attributed to the presence of negative or adverse conditions. Industrialized and developing countries are also witnessing an increased elderly population, increased life expectancy and decline in mortality.

Relevance to Childhood Development

The most important and widely studied aspect of secular trends is the age of onset of *puberty* in girls. Recent comparison studies of the United States and other countries have provided conflicting data regarding the decreasing of the age of onset of puberty and the development of *secondary sex characteristics* in young girls. Factors affecting the age of onset include environmental conditions, ethnicity, geographical location, nutrition and race. According to studies, the age of puberty onset in American girls over the past 40 years has decreased from 0.5 to 1.0 years, with African-American girls maturing 0.5–1 year earlier than Caucasian girls. Studies suggest 1 in every 7 Caucasian American girls and 1 in every 2 African American girls develop breasts and pubic hair by the age of 8. Additionally, data suggest that the age of first menstruation of girls from the United States has decreased from 17 to 13. Data suggesting the decrease in puberty age of onset were supported during a study of Chinese schoolgirls in Hong Kong, where the sexual maturation median age is one of the earliest in the world; the median age of puberty onset was 9.78 years, pubic hair development was 11.6 years and menarche was 12.4 years. While the United States and other countries have displayed a decrease in age of onset of puberty, the trend was not supported during an evaluation of Northern European countries. Several theories have been purported to explain the decrease in puberty onset age including weight gain, hormones in meat and milk, and sexualized images provided by the general media. Additional theories are being considered, but possess insufficient data and further research is required.

Selective Attention

Mei Y. Chang, Raymond S. Dean
Ball State University, Muncie, IN, USA

Synonyms

Focused attention

Definition

Selective attention refers to the ability to maintain a cognitive set in the presence of background noise or distraction [1]. Selective attention acts like a filter that blocks some channels while allowing others to be processed [2]. While Sohlberg and Mateer [7] distinguished between focused and selective attention by relating the "ability to respond discretely" to specific stimuli to the focusing aspect of attention and the capacity to avert distractions to selective attention, Miller [4] suggested that selective attention has been used as an interchangeable term for focused attention in the neuropsychology literature.

Description

Models of attention commonly divide attention into component processes such as alertness/arousal, selective or focused attention, divided attention, alternating attention, and sustained attention or vigilance, of which selective/focused attention is one of the most studied aspects in attentional functioning [3, 8]. Vanderploeg [10] additionally indicated that there is a great deal of overlap among the various attentional models built; selective attention or an attentional focus is one of the six basic factors appearing to encompass the components described by the different researchers. Other basic factors of attention proposed include arousal, capacity, control of the attentional capacity system, sustainability/vigilance, and appraising of stimuli.

Selective attention involves initial concentration directed toward a particular activity and then execution of inhibition of responses to some stimuli over the targeted activity; it enables an individual to choose to pay attention to a specific stimulus and ignore potential external and internal distracters [4]. Mirsky [5] illustrated the ability to scan an array of stimuli and selectively respond as focus-execute, in which focused attention is the perceptual ability to scan a stimulus array, while the execute component is the ability to make a response. Similarly, Lezak [3] refers to selective attention as the capacity to highlight important stimuli or ideas being dealt with while holding the awareness of competing distractions in check. Such capacity is commonly referred to as concentration.

Neuroanatomy of Selective Attention

According to Mirsky and his colleagues [5], the brain structures involved with the regulation of selective/focused attention are the superior temporal cortex, the inferior parietal cortex, and the corpus striatum structures (including the caudate, putamen, and globus pallidus). Posner and Peterson [6] believed that selective attention was linked to the functions of the anterior cingulate and the supplemental motor areas.

Relevance to Childhood Development

Most investigators conceive of attention as a system in which processing occurs sequentially in a series of stages within different brain systems involved in attention. Disorders of attention may arise from lesions involving different points in this system. An attention task requires a focused, selective, sustained, and effortful performance; therefore, assessing the performance of the various points in the attention system will be imperative in indicating aspects of impairments in attentional functioning. Examples of neuropsychological tests that measure selective attention include the Auditory Attention subtest of the Woodcock-Johnson III Tests of Cognitive Abilities (WJ-III) [9] and the Stroop Color-Word Test (SCWT). On the WJ-III, the examinee must overcome the effects of auditory distractions (background noise) to understand oral language. On the SCWT, the examinee is required to selectively attend to the color of the ink that the word is printed in and name that color while ignoring the word itself that actually names a color that is different from the color of the ink [4]. Slow or hesitant performance on this part of the Stroop task may be indicative of difficulty concentrating and warding off distractions, which may suggest impaired selective attention [3].

Selective Mutism

Angela D. Mitchell[1], Heidi King[1], Emily L. Sportsman[2], Andy V. Pham[2], John S. Carlson[2]
[1]Texas Woman's University, Denton, TX, USA
[2]Michigan State University, East Lansing, MI, USA

Synonyms

Aphasia voluntaria; Elective mutism; Functional mutism; Mutism; Reluctant speech; Voluntary mutism

Definition

Selective mutism is a type of childhood anxiety disorder in which a child does not speak in certain social situations where speech is expected despite speaking in other situations. The child's mutism must persist at least 1 month (not including the first month of school), and the mutism cannot be due to a lack of comfort with or knowledge of the language required in the social situation. The child's silence must not be better accounted for by other disorders (e.g., communication disorder, pervasive developmental disorder, schizophrenia), and this disorder is typically presented before age 5 years; however, it may not be identified until the child enters school. Finally, the child's failure to speak must interfere with his or her educational or occupational functioning or with his or her social communication [1]. In the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* the term Selective Mutism replaces the former term, elective mutism. This change in terminology better reflects the non-oppositional nature of the disorder.

Description

Selective Mutism (SM) was first identified as aphasia voluntaria by Kussmaul in 1877 as being a condition where individuals who had the ability to speak would not speak in certain situations or to certain individuals. Children with selective mutism consistently fail to speak in certain social situations where speaking is expected, such as in school or with peers. However, these children do demonstrate the ability to speak in other situations. Often, a child with selective mutism will speak at home but not in a school or community setting. The child may communicate in nonverbal ways such as with gestures of the body, hands or head or by pushing and pulling. In some cases the child may make short mono-syllabic utterances or use an altered voice. Children with selective mutism are often shy, socially withdrawn and afraid of embarrassment.

Selective mutism has historically been characterized as a rare disorder with prevalence rates of less than 1% [1]. However, according to a study conducted by Kopp and Gillberg [13], the prevalence rate may be much higher. Moreover, selective mutism appears to be more prevalent in girls in clinically-referred samples [14]. In clinical settings, children with selective mutism are usually also diagnosed with an anxiety disorder, often social phobia.

Etiology of SM. The cause of selective mutism is unknown; however, recent work in the literature indicates that selective mutism may be a variant of an anxiety disorder, specifically social phobia [3], and may represent the severe end of the spectrum of social anxiety and speech inhibition [4]. Often there is a close relative or parent who has a history of exhibiting significant shyness, anxiety disorders and/or SM [17]. Other possible theories proposed as explanations for the cause of SM suggest that it is the result of traumatic experiences such as abuse, divorce, death, a life threatening experience and moving frequently [15].

Assessment of SM. When assessing for SM it is important that a comprehensive evaluation is conducted to rule out any other disorders. A comprehensive assessment should include a physical examination and medical history, and a developmental history of language, motor, cognitive, and social milestones. Psychological assessment of the child's current social and emotional functioning is necessary along with assessment of the child's cognitive and academic skills. In order to aid in treatment planning, a functional behavioral assessment should be completed to determine in what settings and to whom the child speaks so that intervention may target those settings and individuals [9].

Relevance to Childhood Development

Given that one of the diagnostic criteria of selective mutism is impairment in educational functioning and/or social communication, children with this disorder typically present with academic and social/emotional

difficulties such as delayed word attack and oral reading skills, limited opportunities for social interaction, and less involvement in school activities. Moreover, the ability of teachers and other school professionals (e.g., school psychologists) to assess academic and intellectual functioning may be impaired due to the child's reluctance to speak when queried. Because a child's mute behavior becomes more entrenched without intervention as time passes, and because of the possible negative impact of selective mutism on a child's educational and social functioning, early intervention is most beneficial [10]. Chronic anxiety symptoms can develop into adult social anxiety or social phobia, and people who were afflicted with selective mutism as children may continue to experience discomfort in social situations and difficulty conversing with others.

Although selective mutism is classified as a Disorder Usually First Diagnosed in Infancy, Childhood, or Adolescence, some researchers suggest it would be better categorized as an anxiety disorder. This conceptualization informs current treatments. Treatments include psychotherapy, cognitive-behavioral therapy and/or medication. It is important to identify and treat any specific speech or language related problems. Medications used to treat social phobia have been used successfully to treat children with selective mutism. Research indicates that selective serotonin reuptake inhibitors (SSRIs) may be the most effective type of medication in cases of selective mutism that are resistant to behavioral and psychosocial treatments; SSRIs include fluvoxamine (Luvox), sertraline (Zoloft), and fluoxetine (Prozac). Interventions that focus primarily on family functioning have shown some effectiveness, but current treatment trends that call for integrating families into treatment implementation are gaining popularity. Behavioral techniques incorporating the child and the environment into the assessment and intervention process are the most frequently used methods and are quite effective. Systematic desensitization is one type of behavioral intervention that has been applied to selective mutism. Behavioral interventions that include the use of reinforcement, token procedures, self modeling, self monitoring, prompting, stimulus fading, and response initiation procedures have proven to be successful in treatment [15]. The most effective treatments include an in-depth analysis of the child and the environment in order to design treatment plans that are tailored to the client. These treatments focus on altering the interpersonal and environmental factors that are contributing to symptoms of selective mutism. Multidimensional approaches address behavior and family systems and may incorporate medication if acceptable to the family.

Self Identity: Sexual Abuse of Adolescents

Maria-Eva Tsola, Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Synonyms

Child rape; Sexual assault; Sexual exploitation; Sexual maltreatment; Sexual molestation; Sexual victimization

Definition

Child sexual abuse is sexual contact with a child that occurs as a result of force or in a relationship where it is exploitative and unequal because of an age difference or caretaking responsibility. Sexual abuse appears to disrupt the progression of self-identity formation; these disturbances may include identity diffusion, fragmentation of self, and distortions in body image.

Description

A wide variety of behaviors are encapsulated in the definition of child sexual abuse, including rape, molestation, prostitution, or incest with children and the creation of pornography. In addition to certain sexual behaviors, child sexual abuse has a number of characteristics. These include lack of consent, ambivalence, exploitation, secrecy, force, and intent [1]. Prevalence studies reveal that females are the most frequent victims of child sexual abuse, but males are likely to be abused at earlier ages, for shorter durations, and the perpetrator is more often a stranger or nonrelative. Sexual abuse can occur at any point from infancy through adolescence [1, 2]. For all children, poverty has been found to be an important risk factor. For girls, other factors that increase the risk of victimization include: the presence of a stepfather; a sexually punitive mother; living separately from the mother; emotional distance from the mother; and having two or fewer childhood friends [1, 2].

Relevance to Childhood Development

Depending on their developmental stage, children may be particularly susceptible to the adverse effects of sexual abuse due to their dependency on adults for care and protection, their limited ability to influence the events and environment in which they live, and their cognitive and emotional developmental level [3]. A number of interactive factors probably make a significant contribution to the development of negative self-representations in sexually abused children. The age at which the first abusive incident took place, the duration and severity of abuse, the relationship of the perpetrator to the child, and the use of force by the perpetrator, collectively influence the severity of psychological symptoms that present during and following sexual abuse [1, 3–6].

The literature concerning the psychological consequences of sexual abuse for the period of childhood and adolescence indicates a broad range of adverse effects including affect dysregulation, disruptive and aggressive behaviors, precocious sexualized behaviors, insecure and atypical attachment patterns, sexual identity confusion, impaired peer relationships, conversion disorders and academic underachievement [4–10]. Progression of the psychological effects of child and adolescent sexual abuse is associated with particular psychiatric disorders. Adult psychiatric outcomes that are frequently reported and associated with sexual abuse include borderline personality disorder, eating disorders, obsessive-compulsive disorder, substance use disorders, anxiety, depression, posttraumatic stress disorder, phobias, sexual disorders, multiple personality disorder, panic disorder, and somatization disorder. Suicidal ideation and attempted suicide are also very common among victims of childhood sexual abuse [1–6, 8, 10, 11].

A number of core psychopathological features appear to be shared by the different psychiatric disorders to which victims of abuse appear to be most susceptible to. Disturbances in sense of self, are involved in the majority of these disorders ranging from the identity diffusion of borderline personality disorder to the fragmentation of self fundamental to multiple personality disorder. Profound distortions in body image can occur in the eating, dissociative, and somatoform disorders. All of these disorders show evidence of high rates of self-injurious behavior including self mutilation, suicide attempts, and risk taking which constitute a sign of

fundamental problems with self-esteem, internal conflicts, and estrangement from self [2, 9]. Sexual abuse therefore appears to disrupt the progression of self-identity formation.

The pubertal period contains multiple developmental tasks. Adolescents must establish a new and positive sense of self; choose an adult role; develop the capacity for intimacy and achieve mature sexual expression; establish strong intimate interpersonal relationships particularly with peers; initiate the process of developing autonomy, and crystallize their personal value systems [13]. Even though sexual abuse significantly compromises the adolescent's ability to accomplish each of these important tasks, the most commonly reported adult outcome of childhood sexual abuse is a severe disturbance in the individual's sense of self [5, 6, 9]. Several studies indicate that the intrinsic helplessness and powerlessness associated with child sexual abuse may result in a diminishment of the child's developing sense of his or her competencies, locus of control, and efficacy, and in severe difficulty defining and integrating different aspects of the self [1, 12, 13]. The effects of this inability to acquire a coherent sense of self appear to be long-term.

Data on the relationship of abuser to victim indicate that predominantly in the case of abuse by a family member, the victim's sense of trust is violated [1]. Close relatives, who would, under normal circumstances, serve as objects for identification and introjection come to be viewed by the abused child as punitive, rejecting, dangerous, and deceitful. In addition, children may integrate elements of their abuse into basic beliefs that subsequently function as a universal model of self, others, and the world [4, 6–8]. The individual may have conflicting thoughts and feelings about the self. Self-identification as a "victim" may result in low self-esteem and create a pattern of self-destructive behavior [6]. These core relational schemas seem to hinder the individual's later ability to create and maintain meaningful interpersonal attachments [4, 8, 9]. Relational disturbance generally comprises conflictual or chaotic relationships, problems with forming intimate adult relationships, and behaviors that are likely to disrupt close relations with others [8].

Self Management

LaShawn Jackson[1], Sally Meyer[2], Teri Berchtold[2], Brett R. Nelson[2]
[1]Fontana, CA, USA
[2]California State University, San Bernardino, CA, USA

Synonyms

Self-monitoring; Self-regulation

Definition

Self-management is an intervention technique used to help students manage the accuracy and amount of work completed in a given time frame using a checklist or form [9]. This technique is also helpful in establishing increased levels of autonomy for career, personal, and extra-curricular activities [4].

Description

In many classrooms, behaviors such as inattention or disruption may prevent students from actively engaging in academic activities or on-task behaviors [2]. The amount

of time a student spends actively thinking about or working on academic content [2] is determined by various internal and external factors such as Traumatic Brain Injury (TBI), Post Traumatic Stress Disorder (PTSD), Emotional Disturbance (ED), poor executive functioning, depression, temperament, adjustment issues, etc.

Students who have trouble focusing, are off-task, or engage in problem behavior can improve their academic achievement using self-management [9]. Individuals with disorders (e.g., ADHD or Autism) requiring behavior modification can benefit from self-monitoring as well [4].

Some of the steps of a self-management intervention include: (1) Identify the purpose or benefits of the student discontinuing their off-task/problem behavior; (2) ask the student to help with the self-management plan along with ideas for rewards or incentives (the rewards need to be powerful and occur frequently to sustain self-management behaviors); (3) create a user friendly self-management form that does not require much work for anyone involved (see Figs. 1 and 2); (4) demonstrate, model, or train how the self-management form or recording device will be used; (5) provide a small amount of time (e.g., 5–15 min) to check for understanding in relation to the self-management form and plan; (6) examine progress with the student and slowly lessen involvement with a goal of having the student function without an outside reinforcement system.

Relevance to Childhood Development

One major objective in education is to cultivate self-sufficiency and autonomy for childhood, adolescence, and life. Self-management has extensive utility for children and adolescents with or without disorders and can be modified to help multiple types of learners. Research also suggests that self-monitoring is a useful practice that assists in developing proper social skills. This technique can help decrease or extinguish behaviors that lead to negative labels (e.g., lazy, trouble maker, etc.), which lead to self-fulfilling prophecies manifested in the classroom. Furthermore, self-monitoring can build an increased sense of control over one's actions.

Research studies show that self-management techniques can improve academic achievement, improve on-task behavior, and decrease problem behavior. Additionally, self-management requires the student to review their own behavior and determine if they are succeeding or are in need of improvement [10].

Self-Actualization

Laura Barney
University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Self-fulfillment

Definition

Self-actualization is the tendency to actualize and the desire for self-fulfillment. This includes the desire to reach full potential and become what one is capable of becoming.

Description

The term self-actualization was first introduced into the psychology field by Kurt Goldstein, an organismic theorist, but was popularized and expanded on by Abraham Maslow who included the concept in his well-known developmental theory: Maslow's Hierarchy of Needs.

Maslow's Hierarchy of Needs consists of five tiers often depicted in pyramid form with the most basic needs at the bottom. The hierarchy begins with the Physiological needs, which include food, water, breathing, sex, and sleep. The second tier includes needs related to Safety and security such as physical health, resources such as money, nurturance, and shelter. The third tier represents the need for Love and Belonging by family, friends, and intimate partners. Esteem makes up the fourth tier and includes self-esteem, confidence, need for achievement and recognition, and respect for self and others. The fifth and final tier is the need for Self-actualization, the realization of one's full potential and the desire to reach that potential. In addition to the five levels of the hierarchy, Maslow discussed the importance of cognitive and aesthetic needs in facilitating the journey towards self-actualization.

This hierarchical system was established to capture the dynamic, interrelated events and behaviors that make up the developmental process. Maslow proposed this prepotency hierarchy where human behavior is dominated by the lower, more basic needs. Achievement of or interest in a higher need usually requires the fulfillment of a lesser need. For example, if one is hungry or lonely their energy and cognitive resources will be spent meeting those needs and not attempting to conceptualize and understand their full potential as an individual.

Characteristics of self-actualization include living in the present moment, being spontaneous and creative, trusting oneself and one's decisions without fear of regret, and being open to all possibilities. Achieving these characteristics requires that an individual has sufficiently met all other needs in the hierarchy.

Successful matriculation through the previous four tiers does not always result in self-actualization. Self-actualization is a process that can only begin when all other needs are met; this process may never be completed during a lifetime.

Relevance to Childhood Development

Maslow's Hierarchy of Needs, including self-actualization, can be incorporated into many of the other well-known theories of human development in that most theories include the attainment or development of certain behavioral and emotional characteristics. Maslow's hierarchy, like many of the developmental stage theories, is a progression; a child must accomplish goal A before goal B can be addressed.

During infancy and early childhood, individuals rely on others for fulfillment of their basic needs including food, water, safety, love, and eventually esteem. Many environmental factors can influence whether or not children's needs are met including socioeconomic status, parental/guardian resources, and quality of education. It isn't until adolescence or early adulthood that individuals move toward becoming solely responsible for fulfillment of their needs. An individual's ability to fulfill their own needs in adulthood often depends on how successfully their caregivers fulfilled their needs as a child. If, and only if, all environmental factors provide for a healthy development will an individual have the potential to reach the level of self-actualization in adulthood.

Self-Annihilation

►Suicide

Self-Care

Bernadette Hassan Solórzano, Brenda L. Verastigi
Our Lady of the Lake University Community Counseling Service, San Antonio, TX, USA

Synonyms

Adaptive behavior; Resiliency; Self-treatment; Stress management; Stress reduction

Definition

Self-care includes the decision and actions used with the intention of enhancing a healthy lifestyle. Among helping professionals it is a tool to avoid compassion fatigue and professional burnout [1, 3, 4].

Description

Self-care is essential to prevent burnout, stress, and compassion fatigue particularly among members of the helping professions. Exercising, meditation, Tai Chi, reading, listening to music, and eating balanced meals are examples of self-care. Any form of self-care is more effective when an individual is able to maintain a healthy perspective [2, 5]. When a mental health professional's psychological and/or physical health affects their work, their ability to help their clients begins to be compromised thus creating a possible ethical problem.

Therapists, crisis responders, medical professionals, police and firefighters, animal shelter workers, and veterinarians are but a few examples of people who experience loss and trauma that results in serial grieving. Critical Incident Briefing was implemented to facilitate some immediate release of emotions for these individuals. This response became increasingly important after the Oklahoma City bombing when a year later the suicide rate among the emergency responders was much larger than expected. In 2001 during the aftermath of the terrorist attacks, critical incident debriefers were on site to assist professionals during their breaks. Health care professionals spend many years studying to prepare themselves to be well trained. Self-care should be equally emphasized and not seen as self-indulgence.

Self-Care Behaviors

►Activities of Daily Living

Self-Care Development

Norma S. Guerra, Allegra Montemayor
University of Texas, San Antonio, TX, USA

Synonyms

A personal skill of caring for oneself; Thoughtful attendance to oneself

Definition

Self-care development involves the progressive expansion of skills related to caring for oneself that are refined by experience, direct instruction and maturity. Self-care includes the ability to improve, restore and maintain one's own personal health and psychological wellness [2].

Description

Self-care involves any activity of caring for personal needs. These needs may be addressed physically such as eating or exercising to maintain a healthy body or psychologically

such as moving away from potentially dangerous situations or emotions. Self-care strategy development has also been linked to self-sufficiency and self-management. Developmental milestones in evaluating normal child growth often consider personal self-management and care for self.

Self-care developmental techniques involve identifying explicit and implicit patterns of need and developing appropriate and socially acceptable strategies to respond and contribute to productive and functional personal growth and development. As the child grows and learns to meet personal needs, self-care can be observed in self-initiated behaviors. For example, the child moves from "falling asleep" to sleeping for rest for energy to play or to learn. Self-care might also be observed in verbal communications. With increasing skill and accomplishment, self-managed and self-determined goals related to self care are accomplished. As cognitive capacity and socialization develops so too does self-care. Self-care development is facilitated by creating an environment conducive to learning: teaching the child to listen to self, to identify internal and external needs, and to manage personal care will assist with development [3].

Self-Care Techniques

Developmentally, self-care techniques will change with maturity, skill and experience. For example, an infant cries as a technique for self care. By school age, telling the teacher about a bully may offer a more appropriate strategy and by adolescence, using self-reflective questions to identify triggers that create stressors may provide a foundation from which future self-care techniques develop.

Self-care techniques involve the development of self-managed, activity processing resources implemented in response to needs and desires. Building strong support systems and developing internal resources are important to maintaining a healthy lifestyle.

Relevance to Childhood Development

Self-care in children is an important part of individual development. It can be related to sense of identity, self confidence, independence and impacts social relationships both within and outside the family. Some self-care activities include: grooming, personal hygiene, physical activity, eating properly, and maintaining safety. These factors are beneficial to development; they involve the child in self-regulating a better quality of life. The family plays a critical role in the development of these self-care strategies. Family members teach children self-care through direct instruction and modeling and the child often learns these skills through trial and error and gradual approximations. Poor self-care choices often lead to greater behavioral problems that may impact daily lives and school. Poor self-care strategies can affect health as well as relationships with families or peers [1].

Importance of Parent–Teacher Relationships

Early childhood programs that promote communication between parents, children and teachers can help to build a strong working relationship in support of self-care. This communication can help early childhood professionals to better understand the parent's perception and to help them as they developmentally teach self-care techniques to their children.

Self-Choice

►Autonomy

Self-Concept

Darshon Anderson
Oklahoma State University, Stillwater, OK, USA

Synonyms

Self; Self-esteem; Self-image; Self-representation; Sense of oneself; Sense of self

Definition

An organized set of perceptions, cognitions, or evaluations that one holds about their abilities and characteristics.

Description

Social interactions, experiences, and the interpretation of those interactions and experiences that an individual has with their environment mold the self-concept. The perceptions that an individual holds about themselves and/or

abilities are influenced especially by reinforcements from those close around them such as parents, friends, other significant role models, and the attributions that individual gives for their own behaviors [1, 2]. Two distinct aspects of the self-concept that are interrelated in experiences include self-esteem and identity [3]. Self-esteem seeks out opportunities to enhance the evaluations one holds about themselves whereas identity gives structure (to the self-concept) and stabilizes the self in social systems. The self-concept is seen as multifaceted and hierarchical because the perception an individual holds about themselves encompasses various areas of life including social life (e.g., family, friends, religion) academic (e.g., school) and nonacademic activities (e.g., work, hobbies) [2]. In many scientific references, self-concept has been linked to individual achievement and correlations between it and other constructs examined [4]. Research suggests that it is possible for an individual to hold a positive self-concept in one area of life and a negative self-concept in another separate area. The evaluation an individual holds about themselves is not static and may change over time and across situations. Most changes to an individual's previous evaluation of themselves result from taking on new roles and/or life transitions [5]. Research has found that evaluations generally become more favorable over the lifespan, evaluations are represented by a moving baseline that is determined by situational factors, and that environmental stability plays a key factor in evaluation stability [5]. Research has also described the self-concept as the "working" or "assessable" self-concept due to its continually active state and the shifting amount of assessable self-knowledge available to the individual at a certain point in time [6]. The "working" self-concept lends support to the changing nature of the individual's self-evaluations across time and situations.

Relevance to Childhood Development

Self-concept begins to develop in children after becoming aware of themselves as distinct physical entities. Once the child recognizes their distinctness as a representation of the self, evaluations of the self are able to follow and can be seen in children as early as 18 months of age [7]. Behaviors that indicate a child has developed a concept of themselves include using self-referential terms (e.g., using their name or pronouns), use of evaluative words (e.g., dirty, bad, good), and references to competencies (such as saying "I can't" do something). During middle to late childhood (e.g., early elementary school years), self-concept is greatly shaped by self-perceived academic competence, social acceptance, and sports competence [8]. It is important during this time that children have positive feedback from parents, friends, and significant role models so they will not rely too heavily on their own self-perceived competency for evaluations, which could result in a lower self-concept. Research suggests children in middle to late childhood seek to maintain a positive self-image by utilizing overestimation, selective social comparison, and strategic association with others [8]. As the child continues to grow, life transitions and new roles taken will continue to shape and influence their self-perceived competencies and self-evaluations.

Synonyms

Autonomy; Psychological freedom; Volition

Definition

Self-determination theory focuses on the extent to which individuals' behavior is self-determined versus controlled. When acting in a self-determined fashion, people experience a sense of freedom, choice, and volition during their activity engagement.

Description

Key studies on self-determination have been conducted by Edward Deci and Richard Ryan [1, 4, 5]. Within the self-determination theory, it is argued that the satisfaction of the basic psychological needs for competence, autonomy, and relatedness will energize individuals' autonomous engagement in an activity. Within self-determination theory, the concept of autonomy is contrasted with heteronomy and is differentiated from the concepts of independence versus dependence:

Autonomy versus heteronomy: When being self-determined one is acting in an autonomous or volitional way because the activity spontaneously emanates from one's emerging interests or is congruent with one's abiding values. Acting in a self-determined fashion means that one endorses one's action at the highest level of reflection such that one fully stands behind one's activity. The opposite of autonomy or self-determination is heteronomy, that is, feeling controlled to partake in the activity, either because external forces or intra-individual demands are pushing one to engage in the activity [5, 6].

Independence versus dependence: Self-determination or autonomy needs to be differentiated from the concept of independence. Independence refers to being self-reliant and making decisions without the interference of others. Independence is contrasted with dependency which implies relying on others for advice or help. One can act independently or remain dependent on others for both autonomous (self-determined) or heteronomous (non-self-determined) reasons. Thus, people may volitionally choose to act independently (i.e., autonomous independence) or people may feel pressured to act independently, for instance, out of rebellion against controlling authorities (i.e., heteronomous independence). Conversely, people may volitionally turn to others for advice (i.e., autonomous dependence) or people may feel pressured to rely on others (i.e., heteronomous dependence) [7, 8].

Relevance to Childhood Development

From the perspective of separation-individuation theory, development towards independence implies that adolescents increasingly take responsibility for themselves without strongly depending or relying on their parents. This development would be particularly salient during adolescence and would contribute to maturity and psychosocial adjustment primarily during adolescence. In contrast, autonomy or volitional functioning as defined in self-determination theory is thought to be essential to optimal human development across the lifespan. Research has shown the importance of interpersonal support of autonomy for individuals' adjustment from early childhood to late adulthood [2].

Within self-determination theory, an autonomous versus controlled functioning is said to result from being exposed to an autonomy-supportive versus controlling environment. The provision of choice by parents and teachers represents one key ingredient of an autonomy-supportive environment that will promote autonomous functioning. In line with this, several studies have convincingly demonstrated that choice provision does increase one's interest and subsequent persistence at the activity at hand. However, children cannot be provided with unlimited freedom to fully choose their own course of action as parents, teachers and other socializing agents will introduce various norms, rules and regulations over which children have little or no choice. Although choice is constrained in these situations, children can still volitionally stick to these rules or freely adopt the norms that are transmitted to them. The volitional acceptance of these norms and rules will be facilitated when parents and teachers at home or in classroom settings succeed in presenting rules and instructions in an informal fashion rather than in a controlling manner [3]. This will be the case when the presented rules and instructions are sufficiently explained (rationale provision) and when socializing agents empathically solicit children's opinion when these rules and norms are introduced. When teachers and parents are controlling, however, they tend to use controlling reward systems or severe punishments; they will rely on evaluative systems, make use of strict deadlines and will use controlling language ('should'; 'expect') as to ensure compliance. However, such controlling environments do yield a substantial cost as indexed by reduced

interest in the activity at hand, lowered creativity and decreased well-being. Thus, from the self-determination perspective, it is fundamental to create an autonomy-supportive (i.e., volition promoting) environment if one is to facilitate children's well-being and growth.

Self-Efficacy

Definition

Self-efficacy refers to the beliefs that individuals have about their capabilities to complete a particular task successfully.

Description

Bandura, acknowledged as one of the principal initiators of self-efficacy theory, suggested that one's perceived self-efficacy has a powerful influence over one's choice of an activity, the kind of effort one expends, and how much one is able to maintain that effort in the face of difficulty. Consequently, self-efficacy beliefs have been proposed to influence children's motivation.

Schunk suggested that there are four leading sources for how children develop their self-efficacy level for a given achievement. These four sources are: past performance accomplishments, vicarious experiences, forms of persuasion, and physiological indexes. Schunk explained that learners who have had positive past experiences with a learning task tend to develop higher self-efficacy levels than those with negative experiences. As learners observe successful performances of peers, they also develop high self-efficacy levels. Learners who have been convinced by an authoritative figure that they are capable tend to see themselves as capable too, thus developing high self-efficacy. Lastly, learners who tend to have low anxiety symptoms when performing a task, as would be indicated by changes in heart rate, will likely interpret the situation as one for which they have high self-efficacy.

In general, success raises efficacy and failure lowers it. Lowered efficacy can affect children's motivation negatively, although once a child develops a strong sense of efficacy, one or two occasions of failure will not have much effect. Self-efficacy is not a personality trait or part of one's character, and there is no such thing as a "self-efficacious" person. Rather, self-efficacy is an appraisal that one makes and a belief that one has about his or her competence to succeed at a particular task, similar to one's confidence level, although confidence is more global. Self-efficacy is situation specific, a context-specific assessment of competence to perform a *specific task*.

Relevance to Childhood Development

Children tend to behave in ways that are consistent with their perceptions about themselves. Those who have positive beliefs about themselves tend to put in more effort, persist in the task, use effective strategies, and are therefore more successful in school. Young children often develop self-efficacy based on their own improvement over time while older children tend to evaluate themselves based on how they compare to their peers.

Self-Esteem

Kristopher I. Bradley
Oklahoma State University, Stillwater, OK, USA

Synonyms

Self-concept; Self-image; Self-worth

Definition

Self-esteem is defined as a person's evaluation of their own self-worth.

Description

Self-esteem is how positively or negatively a person views their worth. People who have a favorable global evaluation of themselves are said to have high self-esteem, while people who have an unfavorable global evaluation of themselves are said to have low self-esteem. High self-esteem has been shown to have a strong relationship with life satisfaction [1] and with happiness [2]. Studies have also demonstrated a correlation between self-esteem and other attitudes and behaviors, such as school performance, but it is important to note these correlations are not always strong and that these correlations do not mean causality. While it is possible a person with high self-esteem will get good grades, it is also possible that a person will get good grades and then view themselves more positively and thereby increase their self-esteem [3].

One of the most common methods of measuring self-esteem is a self-report measure called the Rosenberg Self-Esteem Scale [4]. The scale consists of ten questions with the choices of Strongly Agree, Agree, Disagree, and Strongly Disagree. As with other self-report measures, it is impossible to know for certain if the respondent truly believes in their replies or if their replies are an attempt to appear socially desirable. Also, one of the issues with using a self-report measure for self-esteem is that the answers rely on the respondent's perception and not necessarily on reality. For example, people with high self-esteem may claim to be more attractive and intelligent than the average person, but their peer ratings of their attractiveness and their IQ scores might not differ from the average person [5]. People with high self-esteem also claim to be more popular and socially adept, but when judged by their peers, they again appear to be average [3].

While there are benefits to high self-esteem, such as happiness and life satisfaction, there are also potential drawbacks such as aggression and prejudice. Low-self esteem was once theorized to be the cause of violent and aggressive behavior, but recent theories postulate the opposite. When people with overinflated judgments of their self-worth are threatened, they are more likely to become aggressive [6]. Evidence has also shown people are more likely to become more prejudiced when their self-esteem is threatened. Individuals who had an experimental threat to self-esteem were able to restore their self-esteem by derogating out-group members [7].

While self-esteem can be related to self-concept and self-efficacy, they are not exactly the same. Self-concept is defined as our knowledge of who we are and can include our physical characteristics, our psychological states, and our considerations of how other people may judge us. Self-efficacy is defined as the belief in one's ability to carry out specific actions that produce desired outcomes in a particular domain [8].

Self-Evaluation in Academic Settings

Timothy J. Cleary
University of Wisconsin-Milwaukee, Milwaukee, WI, USA

Synonyms

Self-reflection; Self-regulation; Strategic thinking

Definition

Self-evaluation is a key regulatory process through which an individual compares self-generated or externally-provided performance information to personal standards or goals [1, 2].

Description

Self-Evaluation Within a Self-Regulation Framework

Several theoretical models of self-regulated and strategic learning have been developed over the past few decades to enumerate the basic mechanisms and processes through which students exert control over their learning, skill development, and pursuit of personal academic goals [3]. From a social-cognitive perspective, self-regulated functioning involves self-generated thoughts, feelings, and behaviors that are planned and cyclically adapted based on performance feedback in order to attain self-set goals. Zimmerman proposed one such cyclical model that depicts self-regulation in terms of three sequential phases: forethought (i.e., processes that precede efforts to learn or perform; goal setting and strategic planning), performance control (i.e., processes occurring during learning efforts; self-monitoring and self-control), and self-reflection (i.e., processes occurring after learning or performance; self-judgments and self-reactions) [1]. These phases are hypothesized to be interdependent so that changes in forethought processes will induce changes during the performance phase which will, in turn, influence self-reflection processes. A self-regulatory cycle is completed when self-evaluation processes influence forethought beliefs and behaviors during future learning efforts.

The act of self-reflection is a multi-faceted decision-making component of the cyclical loop whereby individuals engage in various types of self-judgments (i.e., self-evaluation, causal attributions) and evaluative reactions (i.e., satisfaction, adaptive inferences). Each of these reflective processes have been shown to be significant predictors of student achievement and motivational beliefs [4–6]. For example, individuals who attribute success and or failure to controllable factors, such as strategy use and effort, and who exhibit positive adaptive inferences, such as modifying strategies following failure, will typically demonstrate enhanced levels of achievement and more positive perceptions of efficacy, task interest, and satisfaction [4, 6]. In other words, when individuals engage in self-reflection phase processes and focus on their use of strategies or other personal processes, students are more likely to sustain high levels of motivation and strategic planning.

However, before students immerse themselves into attribution and adaptive inference reflections, they must first self-evaluate how their current academic performance compares to a personal or objective standard. Ultimately, identifying a performance outcome as successful or unsuccessful sets the stage for further self-reflective thought and action. The goal of this brief entry is to illustrate the process of self-evaluation, with particular emphasis placed on the nature and type of evaluative standards used to judge performance outcomes. Research has shown that the type of standards one uses to evaluate a performance has important achievement, regulatory, and motivation implications [4, 5]. Examples of applied self-regulation intervention programs that emphasize self-evaluation will also be presented.

Nature of Self-Evaluative Standards

In order to self-evaluate performance and skill development, students need to employ a standard or benchmark as a point of comparison. These standards take many forms and can vary across source, type, and level of difficulty.

Sources of evaluative standards. Evaluative standards can be generated by external sources, such as parents, teachers, and curriculum developers, or by an individual student. In terms of external sources, parents who pressure their children to attain a minimum grade of B in all classes or a teacher who sets a standard of 90% homework completion for receiving bonus points are typical examples of how external standards might be imposed on students. Another external source, which tends to be more objectively and systematically-derived, involves curriculum benchmarks and/or basic academic skill levels. For example, researchers have established early literacy benchmarks for students in kindergarten that are typically used to determine the intensity and level of intervention services that students need to improve their reading skills [7].

All forms of externally-initiated standards are important in self-regulation models because they provide a benchmark against which students can judge the effectiveness or acceptability of their test grades or other performance indicators.

From an autonomy-supporting or self-regulatory perspective, however, one must be cognizant that external standards may or may not be used by students when evaluating their school-based performance if they do not accept these standards as relevant or important to their academic success. Motivation researchers have shown that when students are afforded the opportunity to develop their own goals or self-standards they will often become more interested and engaged in academic activities [8]. As a practical example, a 14-year old aspiring writer will not automatically use readily available external evaluative criteria, such as English course grade, as the basis for judging her writing skills if she does not believe or accept this grade to reflect her writing potential. In contrast, she may place greater emphasis and value on her normative performance (i.e., a top-three placement) in creative writing competitions. In this situation, the student will probably not become overly concerned about a grade of B in her English class, yet will experience significant emotional and motivation turmoil if she does not perform well in the writing competitions. In short, although evaluative standards can be self-generated or provided through external sources, they will be used most frequently and have the greatest impact on student behavior and motivation when they are personally meaningful or relevant to that student.

Types of self-evaluative criteria. Students can use different *types* of evaluative criteria to judge their competency and skills. Three common types of evaluative standards include: (a) mastery, (b) previous performance, and (c) normative [1]. These different criteria are important to consider because they can play an influential role on the conclusions and interpretations one generates about performance and personal competency. Mastery criteria typically involve using markers or benchmarks that represent core sets of skills ranging from novice to expert. Schools often use mastery criteria in their curriculum materials as well as part of the Individual Education Program (IEP) utilized within Special Education circles. This type of criterion is important because it focuses students' attention on key indices of skill development or progress towards an important academic outcome. The second type of criteria, called prior performance or self-criteria, is a standard that is used to directly assess growth by comparing prior outcomes of an individual to his or her current performance outcomes. Both mastery and self-criteria are emphasized in applied self-regulation intervention programs because they naturally direct students' attention and reflective thoughts on their own behaviors and outcomes, a necessary condition for nurturing the development of self-directed or regulated learners [9].

Normative comparisons are a third type of criteria that are commonly observed in school environments, particularly in settings which emphasize, either directly or indirectly, public displays of student performance. In short, students employing this type of standard evaluate their skills and performance relative to their peer group. Social comparisons can yield impressive motivational benefits for students, particularly for those who are high achievers, because they imply that students are more competent or capable than others. Unfortunately, when students struggle in school *and* rely on normative comparisons to judge their capabilities, there is a high probability that their sense of efficacy and competence and resulting motivation will be adversely affected [1]. Of greatest importance, however, is that reliance on normative standards shifts students' attention from personal progress and growth to factors that are largely unpredictable and out of their control. When academically at-risk students begin to focus much of their energy and attention on how their peers perform they can often lose sight of or fail to recognize actual progress that they are making; such as when a student improves her math test grades from a 69% to a 79% yet focuses only on the class average score 88%. If this student does not learn to monitor and evaluate progress based on self-criteria, she will probably not see the ten-point improvement in a positive fashion and may begin to exhibit adverse negative emotional and regulatory reactions, such as feelings of anxiety and incompetence.

Level of difficulty. The difficulty level of the standards that students use to judge their performance outcomes can also play an important role in cultivating adaptive or dysfunctional self-evaluations. Suppose a seventh-grade student, Natasha, earned science test grades between 65% and 72% over a 2 month period. In the hopes of increasing her performance, Natasha decided to establish a difficult and challenging goal of 95% for her science tests. On her next two tests she received scores of 77% and 79%, respectively. One of her classmates, Tony, earned identical science test grades but developed a more modest yet challenging science test grade standard of 83%. Despite exhibiting identical science test scores, it is highly probable that Natasha and Tony will evaluate their performances in qualitatively distinctive ways. For example, because Natasha's test performance fell far below her self-standard or goal she is at-risk for developing feelings of

dissatisfaction, anxiety, and low self-efficacy. In contrast, Tony is much more likely to interpret his grades of 77% and 79% as successes because he is increasingly getting closer to his standard of success. Similar to normative comparisons, when students develop and/or use personal standards that are overly difficult or challenging, they will have much greater difficulty recognizing personal progress, even when adequate or some growth is being made [8]. Setting short-term and moderately challenging standards is important from a regulatory viewpoint because such standards provide students with multiple opportunities to evaluate and reflect on their personal mastery of key academic skills or tasks.

Application of Academic Self-Evaluation Interventions Across Grade Levels

Over the past couple of decades, the number of school-based self-regulation intervention programs has steadily increased [10–14]. Regardless of the variations in the theoretical foundations or developmental focus, these programs place primary importance on teaching students to self-evaluate using mastery- or self-criteria. As indicated previously, the use of these types of standards or self-evaluative criteria promotes adaptive self-regulation because students are continuously prompted to focus on their own behaviors and performances rather than on external or uncontrollable factors.

Butler's Strategic Content Learning (SCL) program has been successfully applied in middle school, high school, and college settings. A basic assumption of this approach is that students are *active interpreters* of task demands, their own knowledge and skills, and their development of these skills in relation to self-generated goals and standards [11, 12]. The SCL adheres to a largely constructivist paradigm whereby tutors are primarily responsible for facilitating or helping students generate their own strategies for solving academic-related activities.

Another school-based intervention, called the Self-Regulation Empowerment Program (SREP), evolved from social-cognitive foundations and has been implemented with secondary school youth. This intervention involves teaching students to engage in the three-phase cycle of self-regulation, but places particular importance on teaching students how to adaptively reflect on personal progress [10, 15]. In one study, ninth-grade students who were failing or near failing in biology participated in approximately 22 sessions of SREP over a period of 2.5 months [15]. A key part of this program was the use of a Self-Regulation Graph as the primary vehicle to link all three cyclical phases. In this graphing procedure, students were taught to plot test grade standards or goals, to self-record their strategies, and then to plot their actual test grades. The use of this graph enabled students to use self-criteria (i.e., difference between their test grade standards and actual test grades) to evaluate the adequacy of their math test scores and to also link these self-evaluative judgments to their use of specific learning strategies.

Emphasizing self-evaluation and other self-regulation principles in school-based settings is not only appropriate in middle school, high school, and college settings but also in the primary grades [13, 14]. Graham, Harris and colleagues have conducted extensive research on the effectiveness of the Self-Regulated Strategy Development (SRSD) program for over 20 years [13]. Much of this research has focused on children in the primary grades with writing skill deficits. As part of this program, students are taught strategies to improve their writing performance but are also instructed to self-record and graph writing outcomes and then to compare these scores to a goal or set criterion. An interesting component of SRSD instruction is that students are not only taught to evaluate their behaviors and performance from a summative perspective, but also are often instructed to evaluate their engagement and execution of the writing process. This focus on self-evaluation is particularly useful in promoting adaptive regulatory behaviors because it directs students' attention on the essential processes that are needed to successfully perform an academic task. Research has shown that when novices or inexperienced learners focus on outcomes before they master the requisite strategies or skills for a task, they will often not attain a high level of performance and may actually demonstrate lower motivational levels [6].

Researchers examining the effectiveness of math-based self-regulation interventions in the primary grades have also supported the basic premise that self-evaluative standards based on self-criteria are effective in promoting adaptive regulation and achievement [14]. Fuchs and colleagues conducted a study with third-grade students to examine the contribution of self-evaluation and goal-setting to students' math problem-solving skills. In this study students were instructed to chart their daily scores on a math worksheet and then evaluate whether their scores beat prior performances. Similar to other intervention programs, the process of comparing one's own performance outcomes over time is important because it directs students' attention on their own behaviors and performance attainments, limiting the attention they devote to irrelevant or distracting factors that will not improve their performance.

In sum, the use of self-evaluative standards is a critical component of the cyclical model of self-regulation

because it helps to operationally define whether students' skills and performance outcomes are adaptive. However, the mere act of self-evaluating is not enough to promote adaptive self-regulatory thought and action. It is also important to help students select personally-meaningful or valuable evaluative standards that naturally direct their attention on the essential task components which they are expected to perform. It is when students focus on the adequacy of their own skills and regulatory strategies that they can most effectively initiate modifications and adaptations to optimize their successes.

Self-Fulfilling Prophecy

Anne Fierro Vanderlaan
Saybrook University, Meridian, ID, USA

Synonyms

Expectancy effect; Pygmalion effect

Definition

The self-fulfilling prophecy holds that what a person believes about him/herself (or what others believe about them) will influence their performance. The self-fulfilling prophecy can act positively or negatively, depending on whether expectations are positive or negative.

Description

In educational contexts, the self-fulfilling prophecy is often used to explain differences in performance among students, such that a high-performing student might be responding to high expectations from others (e.g., teachers, parents, classmates) while a low-performing student might be responding to low expectations. [2] illustrated the self-fulfilling prophecy through an experiment in which elementary school teachers treated students differently based on their initial positive expectations of those students, and over the course of the school year, students performed in ways that were consistent with teachers' positive expectations. Subsequent research suggests that the effect can be positive or negative depending on whether teachers' expectations are positive or negative. Thus, if teachers have positive expectations for a student, they are more likely to ask that student more difficult questions, smile and establish eye contact more often, and call on them more often in class, thereby gradually leading to better performance from the student. On the other hand, if a teacher has negative expectations for a student, the teacher is likely to

behave more critically or negatively, thereby creating a less rewarding environment for the student. In both situations, the student responds to cues from the teacher which leads to performance that is consistent with the teacher's expectations.

If parents and teachers understand how positive and negative expectations can change behavior, they can use this phenomenon to influence the child to behave in ways that are consistent with expectations. Expectations may be based on numerous characteristics, such as students' gender, ethnicity, socioeconomic status, language, appearance, and test scores.

Self-Injurious Behavior

Heather C. Trepal
The University of Texas at San Antonio, San Antonio, TX, USA

Synonyms

Cutting; Non-suicidal self-injury (NSSI); Self-harm; Self-inflicted violence; Self-mutilation

Definition

Self-injurious behavior (SIB) includes self-inflicted harm to the body, with or without tissue damage, without the intent to die.

Description

SIBs are usually employed to reduce anxiety and tension in the mind and body and to relieve emotional pain [4]. They may also be used to punish the self and to express anger and emotions that cannot be put into words. There is some evidence that those who employ SIB do so in an attempt to feel "real" and avoid dissociation or emotional detachment [3]. Cutting and burning are the most common forms but other behaviors, ranging from hair-pulling to bone-breaking may also be classified as forms of SIB. Self-hitting and head banging are usually associated with children with autism or developmental disabilities. Piercing and tattooing are not considered SIB since they are usually associated with bodily decoration. Variables contributing to the development and reliance on SIBs are complex and may include a host of life experiences such as abuse, neglect, loss, violence and the inability to recognize, express or handle emotions [5]. Although not sex specific, there is some evidence that females in their teens are at the greatest risk of developing and relying on these behaviors [2].

At present, SIB does not have a formal diagnostic category in the DSM-IV-TR [1]. SIBs have been diagnostically linked to Borderline Personality Disorder (BPD), but this assumption has been challenged by recent prevalence studies. It has also been theorized that endorphins, the natural painkillers in the body which are released when someone self-injures, may play a role in

the addictive or repetitive nature of self-injury. Many myths surround SIBs, with the most common being that those who self-harm want to commit suicide. The behaviors often mean just the opposite and through SIB adolescents are able to relieve emotions that might lead to suicide. Serious risks may result from SIB including infection and unintentional fatal harm. Therefore, it is important that children who self-injure receive a thorough risk assessment. Cognitive-behavioral therapy (CBT), Dialectical Behavior Therapy (DBT) and psychotropic medications have all shown promise in treating these behaviors.

Self-Judgment

Patricia Phaedonos[1], Xenia Anastassiou-Hadjicharalambous[2]

[1]Center for Therapy, Training and Research, Nicosia, Cyprus

[2]University of Nicosia, Nicosia, Cyprus

Definition

Self-judgment results from thoughts individuals have about themselves and the meanings attached to those thoughts. The thoughts, hence, produce related feelings such as anxiety, anger, and depression. Judgments (The process of forming an opinion, or reaching a conclusion based on the available material.) people make about themselves can become habituated as they are used to explain and validate unhelpful thoughts (e.g., If I am harsh on myself, other people will not be as harsh) and they might, accordingly, be intended to protect people against emotional pain, failure and rejection.

Description

Bandura (1993) introduced the notion of self-efficacy (An individual's sense of their abilities, of their capacity to deal with the particular sets of conditions that life puts before them.) [2]. He stated that individuals need other people to be with them, to listen to them and to pay attention to them. Furthermore, new challenges appear continuously as people grow older. As a result, people attempt to become more competent, engage in new behaviors and therefore make new judgments of their personal effectiveness. These judgments concerning personal effectiveness usually determine and influence how individuals might think, feel and behave. Moreover, people's judgments may affect their motivation and willingness when it comes to coping with challenging situations. On the one hand, the more able people perceive they are, the more likely they are to persist with a challenge. On the other hand, the less able people think they are, the less likely they are to cope with a difficulty.

Self-judgments compose one's self-esteem (The degree to which one values oneself.) after evaluating how one acts during times of perceived importance. One's understanding of a situation might distort healthy self-attitudes. That might happen because people commonly are much more judgmental and critical when it comes to themselves, whereas they are usually more understanding when it comes to other people, sometimes even strangers [4].

Neff (2003) discusses the notion of self-compassion (An emotionally positive self-attitude that should protect against the negative consequences of self-judgment.). It is argued that if people accept that failure is a part of human experience, they will subsequently become less self-judgmental. In addition, as one becomes less judgmental of oneself, then there is no need to compare to other people to enhance their self-esteem and they can therefore be less judgmental concerning other people [5].

Self-compassion requires self-forgiveness. It does not necessarily mean that failures must not be credited, nevertheless it means that individuals are not too harsh on themselves when they perceive a failure. A person that has self-compassion is not threatened during a failure, but challenges oneself and tries to improve. That is, a person feels safe to allow oneself to discover unhelpful thoughts, feelings and behaviors. People do not keep away or hold back distressing feelings in order to feel self-compassion. Self-compassion protects people from negative self-judgment [6, 7].

According to Neff (2003) self-compassion consists of three elements. The first one is "self-kindness," which means that one is being kind and understanding of

oneself. The second element is "common humanity," which is identifying one's experiences as parts of the larger human experience and not personal ones. Accepting that failure and inadequacy are common, in respect to other people, reduces personal blame and negative self-judgment. The third element is "mindfulness" which implies that people should not identify with unhelpful thoughts, but hold them in balanced awareness and help oneself accept situations as they occur [5].

Thus, individuals can allow themselves to become less self-judgmental, and deal with their thoughts and feelings as they are, without having their self-esteem affected. In order to accept the experience for what it is, one must be aware of their unhelpful thoughts. If individuals dwell on emotions connected to failure or inadequacy, they are more likely to judge themselves negatively. Neff (2003) supports that the less self-judgmental one is, the more balanced self-awareness one gains [5].

Distress can be reduced when individuals move away from negative thoughts and permit themselves to be aware of their thoughts without being self-judgmental. People who are trained to use mindfulness can focus their attention to the present and become aware of how their thoughts can guide them to behave in a certain way. Individuals, therefore, allow themselves to become less judgmental of themselves, because their focus is detached from the assessments they make concerning rejection and failure [1, 3].

Self-Knowledge

►Self-Understanding

Self-Management

►Self-Regulation

Self-Monitoring

Synonyms

Self-management; Self-observation

Definition

As part of self-regulation, *self-monitoring* is the process of observing and recording one's own behavior.

Description

To achieve a goal, one must observe, evaluate, and record the process and be aware of how well one is doing. Self-monitoring is critical to determine whether one is making progress at a task. Self-monitoring has been documented to increase students' attention and the number of tasks they complete. Through self-monitoring, individuals can modify their behaviors so that inappropriate behaviors can be replaced with more appropriate ones. Typically, individuals who see that they are making progress towards their goals are more likely to sustain their efforts and can lead to a sense of accomplishment. Thus, self-monitoring can lead to increased motivation.

Researchers have offered a few suggestions for promoting self-monitoring:

1. Encourage children to create questions about the material they are learning, and then answering the questions they create
2. Demonstrate to children the process of evaluating their own performance
3. Delay feedback so that children can evaluate their own performance
4. Suggest specific criteria so that children can use them as a guide to evaluate their performance
5. Encourage independent learning over time

Relevance to Childhood Development

Young children often have difficulty monitoring their own behavior. However, as they mature cognitively and through guidance, children are more able to control and observe their actions. Children may not always be aware of how frequently or how well they do something. To help them focus on their behaviors, adults can ask them to observe and record their behaviors. Through this strategy, significant improvements in children's academic and social behaviors can be seen.

Self-Regulated Learning

Definition

Self-regulated learning is the process of taking responsibility for and having awareness and control over one's own learning.

Description

Self-regulated learning describes learning that is guided by *strategic actions* (planning, self-monitoring, control, and evaluation). In particular, self-regulated learners set goals, reflect on past experiences, use strategies, monitor their progress, and are aware of their strengths and weaknesses. As a result of these actions, self-regulated learners tend to do well academically.

Examples of self-regulated learning would be scheduling ahead and organizing effectively to achieve desired goals. Periodically checking to see if progress is being made towards the goal is an example of self-monitoring, a crucial step in self-regulated learning. If progress is not being made, self-regulated learners will modify their plan accordingly to reach their goal. Control includes the ability to direct one's attention to the goal at hand and not letting outside distractions interfere in the learning process. Lastly, evaluation is simply assessing the outcome of one's efforts so that improvements can be made for future tasks.

Relevance to Childhood Development

In order help students develop self-regulation, there are a couple of strategies suggested by researchers:

1. Scaffold students' learning process and then gradually allow students to take responsibility over their own learning.
2. Emphasize the relationship between taking responsibility and academic achievement.
3. Encourage students to set their own goals and then monitor and evaluate their progress.
4. Frequently allow students to monitor their comprehension and evaluate their own performance.

Children often begin the learning process from watching others (also known as vicarious learning). When children are given a task to accomplish with a set goal from a parent or a teacher, they learn strategies to complete the goal. Over time, they are able to set their own learning goals.

In relation to the development of self-regulated learning, as children learn initial strategies to accomplish small tasks and goals, for example, completing their homework

on time, they will eventually set higher goals for themselves later on, such as completing college.

As children grow, they become increasingly competent in evaluating their own performance. Young children often seek adults' approval as a means of evaluation on how well they have done. Older children (middle school students) show an increase in self-awareness and self-evaluations become more frequent and accurate.

Self-Regulation

Héfer Bembenutty
Queens College of the City University of New York, Flushing, NY, USA

Synonyms

Academic delay of gratification; Active learning; Autonomy; Delay of gratification; Impulse control; Self-control; Self-directed learning; Self-discipline; Self-evaluation in academic settings; Self-management

Definition

Self-regulation of learning refers to the process in which learners self-initiate thoughts, behaviors, and feelings in order to pursue valuable academic goals.

Concept of Self-Regulation

During the last 3 decades, self-regulation of learning has emerged as an important area of research helpful to explain academic success. The seminal work of Albert Bandura placed self-regulation of learning as a pivotal component of any major academic endeavor. For instance, self-regulation of learning has been studied in most major areas of human development and learning such as in school, college, and medical settings, sport and industrial organizational tasks, and in direct classroom instruction as well as on online instruction.

According to Bandura [1], individuals can influence and be in dominion of their environment in order to fulfill important goals. They can produce desired consequences and manage their behavior in a purposeful manner to secure objective attainment and realization. Likewise, Zimmerman [5] observed that students could engage in self-directive learning processes by using their social and cognitive resources in order to attain academic achievement. Zimmerman [5] proposed that learners have the capacity to engage in a cyclical self-regulated learning process in which they establish standards, set academic goals, regulate their beliefs and motivation, select learning strategies to be used, monitor their academic progress, and self-evaluate their progression toward goal completion. Further, Zimmerman [5] observed that in the face of obstacles, learners need to delay gratification [2].

Skilled self-regulated learners are those who generate extraordinary motivational beliefs in order to secure goal accomplishments. They are also those who when conflicts arise between pursuing important academic goals and alternative tempting options, learn how to remain task-focused despite immediate impulses to succumb to attractive temptations. On the other hand, less-skilled self-regulated learners are unable and often unwilling to generate appropriate self-efficacy beliefs, interest, task value, and outcome expectancies that could secure their successful attainment of predetermined academic goals. These differences between these two types of learners may be explained by learners' personal characteristics such as personal goals, vicarious experiences, history of reinforcement, and modeling, as well as environmental and social conditions that influence learning.

Self-regulated learners value learning and set suitable achievement goals. They plan and manage time effectively. They hold positive beliefs about their own abilities and use appropriate cognitive strategies such as critical thinking, organization, rehearsal, and elaboration. By contrast, less regulated learners do not see the value of learning and are often unwilling or unable to set goals. They act reactively and impulsively rather than reflectively and often fail to delay gratification. They focus on rote memorization rather than on deep and effective learning strategies.

Cyclical Phases of Self-Regulation

According to Zimmerman [5], self-regulation of learning involves three cyclical phases. Specifically, during the *forethought* phase, learners, as proactive agents, engage in self-generating goals, strategic planning, intrinsic interest on tasks, and sustain self-efficacy beliefs. Then, self-regulated learners proceed to self-monitor their goals, beliefs, and use of strategies by comparing their performance with appropriate standards, by seeking help when it is necessary, and by engaging in social and environmental control. During this *performance* phase, learners initiate actions by which they enact volitional control and use strategies such self-instruction, imagery, self-monitoring, and attention control. Finally, during the *self-reflective* phase, the process of self-regulation ends with learners' self-reflection of their level of satisfaction with task completion and self-evaluation of task completion. During this phase, learners initiate self-evaluation of their performance, examine their attributions and self-reactions, and adapt their performance according to their successes or failures.

Components of Self-Regulation

An important motivational factor associated with self-regulation and academic achievement is self-efficacy. *Self-efficacy* refers to the beliefs that individuals possess about their ability to perform an expected task [1, 5]. Students with high self-efficacy may decide to continue working on an important assignment when anxiety arises or when faced with tempting alternative activities. However, students with low self-efficacy beliefs may not only succumb to a temptation, they may let disruptive thoughts interfere with performance.

Effort regulation is another self-regulatory variable associated with achievement [4]. Effort regulation refers to students' intention to put forth resources, energy, and time to secure completion of important academic tasks [4]. In an academic setting, self-regulation of academic tasks is imperative because it could determine academic achievement and performance. It is well documented that deficiencies in self-regulation of learning, cognitive capacity, and poor study habits interfere with academic performance among learners [5].

Self-regulation has three components. First, self-regulated learners engage in *self-observation* by scanning, examining, and viewing their own behavior, feelings, emotions, and reactions. Second, effective learners engage in *self-judgment* by comparing their behavior and actions to established standards such as teachers' rubrics or consulting knowledgeable peers or adults. Third, skilled learners engage in *self-reflection* by responding effectively to the outcomes of their efforts. These appropriate responses range from engaging in self-praise and self-reward for successfully completing designated tasks to changing strategies that were not helpful in the attainment of specific goals.

Relevance to Childhood Development

Self-regulation during skills acquisition could explain individual differences among learners. In the classroom, some students exhibit adaptive self-regulatory strategies and motivational patterns while engaging in academic tasks, such as exerting appropriate effort for success, enjoying the challenge, using appropriate learning strategies, setting specific goals, and displaying high self-efficacy levels [3]. In contrast, other students cease trying, lose interest in the activity, are unable to set specific goals and strategies, and have low self-efficacy [3]. Students exhibiting low skills to self-regulate their behavior rarely achieve high levels of academic success.

Self-Regulation of Emotion

▶ Regulation of Emotion

Self-Reinforcement

Anthony R. Artino, Jr.
Uniformed Services University of the Health Sciences, Bethesda, Maryland, USA

Synonyms

Reinforcement; Self-consequating; Self-motivation; Self-reward

Definition

Self-reinforcement is a process whereby individuals control their own behavior by rewarding themselves when a certain standard of performance has been attained or surpassed.

Description

Self-reinforcement is a method of self-conditioning that acts to strengthen the association between certain stimuli and certain responses [8]. In the behavioral theory of operant conditioning, the most fundamental principle is that a response followed by a reinforcer is strengthened and is therefore more likely to occur again [7]. Reinforcement, then, is the act of following a response with a reinforcer and is one of the primary tools of operant conditioning.

Socially-mediated reinforcement (or direct reinforcement) involves the delivery of reinforcement from another person [3, 7]. In his description of social cognitive theory, Bandura [3] proposed two other forms of reinforcement: vicarious reinforcement and self-reinforcement. Vicarious reinforcement occurs when an observer witnesses another person being reinforced for a behavior, which results in the observer increasing his production of that behavior [2]. Self-reinforcement, on the other hand, occurs when an individual establishes a personal standard of conduct and then rewards himself based on successful attainment of that standard [3]. An example of this would be a student who decides she will treat herself to dessert if she can complete one more chapter in her textbook.

Self-reinforcement processes have played a prominent role in behavioral theories of self-regulation (sometimes referred to as self-control or self-management; [4, 5]). Self-regulation of behavior involves three key sub-processes: self-monitoring, self-instruction, and self-reinforcement [6]. Although scholars differ somewhat in their description of the self-reinforcement sub-process, they all agree that behavior can be acquired and maintained through the self-administration of reinforcers that are contingent on the performance of certain responses [4]. For example, Bandura [1] argued that self-reinforcement represents an essential facet of self-regulation in that individuals regulate their behavior by making self-rewards contingent on self-prescribed standards of performance. In Bandura's [1] view, self-reinforcement has three defining properties. First, individuals must have full control of reinforcers such that they are freely available. Second, reinforcers are self-administered contingent upon performing requisite behaviors, which necessarily entails the self-denial of awards until the conditional behavior has been accomplished. Finally, self-reinforcement requires the adoption of performance standards that determine the specific criteria for reinforcement [1].

Social cognitive theorists have described self-reinforcement (or so-called self-consequating) as one of the many strategies used by students to self-regulate their learning and motivation [8, 10]. In an attempt to address the dynamic, adaptive nature of self-regulation, contemporary social cognitive views go beyond previous behavioral theories by considering not only behavioral factors but also cognitive and affective components [6]. For example, Zimmerman and Martinez-Pons [10] found that elementary school students reported using various self-consequating strategies, such as giving themselves concrete rewards for finishing school work in the face of other more appealing activities. Moreover, Wolters [8] described empirical evidence that in addition to concrete rewards or pleasing behavioral activities, students may also make verbal statements to themselves as a more immediate way of self-consequating their motivation and behavior. For instance, while reading a textbook, a student might tell himself, "You read another chapter, great job! You are making outstanding progress now." Ultimately, using such self-praising or self-reinforcing statements has been found to be an effective means of increasing one's effort while completing academic tasks [8].

Relevance to Childhood Development

As an important component in self-regulation, self-reinforcement has been shown to be an effective strategy for controlling behavior, motivation, and learning. Furthermore, evidence from several theoretical perspectives indicates that learners who use self-reinforcement strategies also report more adaptive motivational beliefs, such as greater self-efficacy beliefs, the use of various cognitive and metacognitive learning strategies [9], and improved study habits and academic performance [5]. In sum, self-reinforcement is positively associated with a variety of favorable academic outcomes in children. Research has also revealed that self-reinforcement strategies can be learned and therefore can be taught by parents and teachers to support the growing independence of children. What is more, the reinforcement itself may be more important than the agent of reinforcement (self or others; [6]). In fact, research has shown that self-reinforcement can be as effective in modifying student behaviors as reinforcement administered by a teacher [5].

Self-reinforcement helps children become active agents of their personal and academic endeavors. It does so by giving them the personal belief that the outcomes of their efforts depend, in large part, on them, and that they decide

what consequences should follow their efforts and actions. Developmentally, self-reinforcement is initially supervised by parents and teachers at early stages of skill acquisition [6]. However, independence and free choice of self-rewards are internalized by children as they mature and acquire a stable level of self-regulation. Moreover, as children acquire the skills of self-reinforcement, teachers and parents continue to serve as social models for appropriate self-reinforcement behaviors. Eventually, children internalize the basic patterns of the models and begin to select, on their own, appropriate reinforcement consistent with the task at hand and their cognitive and social development. Although direct reinforcement administered by parents and teachers is important, the ultimate goal is for children to acquire the ability to engage in successful self-reinforcement of their own behavior, motivation, and learning.

Self-Talk

Changiz Mohiyeddini, Cecilia A. Essau
Roehampton University, London, UK

Synonyms

Egocentric speech; Inner speech; Internal dialogue; Internal monologue; Private speech; Verbal rehearsal and self-statements

Definition

Self-talk refers to a person's talk to oneself about oneself (e.g., [4, 29, 31, 33]). Self-talk includes all the intentional and automatic self-focused aloud or within one's own thoughts that run through an individual's mind [9]. The notion of automatic self-talk emphasizes that individuals are not always aware of doing so [35].

Description

Self-talk seems to be one of the most frequent cognitive activities in human life, in that almost every minute of our waking lives we talk to ourselves [24]. Hence, it is plausible, following the common notion in psychology that emotions and behavior can be generated through multiple cognitive processes, to assume that self-talk may provide a direct impetus for human emotion and behavior [10]. Yet on the other hand, it could be expected that the emotional states that are activated by self-talk may intensify the impact of self-talk and contribute additionally to influence behavior [23].

A growing body of empirical results has helped to expose the role of self-talk as an important strategy in reasoning [16], problem solving [8] or in planning (Morin, 1988). A burgeoning literature shows that self-talk is closely related to self-awareness [24], self-efficacy (e.g., [32]) and plays a crucial role in self-regulation [9, 21]. According to Depape et al. [8], self-talk seems to be a prerequisite of personal intelligence [12, 13] and of emotional intelligence [30] since it helps to integrate perspectives of others in one's own private speech and perspective. Segrist (1995) maintains that self-talk fosters both private self-consciousness and public self-consciousness because it facilitates acquiring information about the self. According to Morin [24], the frequency, duration and intensity of self-talk increases when conflicting perspectives within the self or between self and others occur.

It is crucial to differ between self-talk with positive (e.g., you can do it!) or negative (e.g., you are a loser) contents. Empirical results show that positive self-talk fosters creativity [3] and is associated with higher athletic performance [7, 22] whereas negative self-talk is related to poorer athletic performance (e.g., [17, 20]). These findings have stimulated interest in intervention programs fostering positive self-talk and reducing negative self-talk in athletes (e.g., [1, 34]). Reinforcement of athletes to use positive self-talk and avoid negative self-talk is perceived to be one of the most strongly advocated and frequently applied coaching strategies [15, 28].
