Library of Congress Cataloging-in-Publication Data

Health information systems : concepts, methodologies, tools and applications / Joel Rodrigues, editor.
p. ; cm.
Includes bibliographical references and index.
Summary: “This reference set provides a complete understanding of the development of applications and concepts in clinical, patient, and hospital information systems”--Provided by publisher. ISBN 978-1-60566-988-5 (hardcover)
1. Medical informatics. 2. Information storage and retrieval systems--Medical care. I. Rodrigues, Joel, 1972-
[DNLM: 1. Information Systems. 2. Electronic Health Records. 3. Medical Informatics--methods. W 26.55.I4 H43407 2010]
R858.H357 2010
610.285--dc22
2009052763

British Cataloguing in Publication Data
A Cataloguing in Publication record for this book is available from the British Library.

Additional Research Collections found in the "Contemporary Research in Information Science and Technology" Book Series

Data Mining and Warehousing: Concepts, Methodologies, Tools, and Applications
John Wang, Montclair University, USA • 6-volume set • ISBN 978-1-60566-056-1

Electronic Business: Concepts, Methodologies, Tools, and Applications
In Lee, Western Illinois University • 4-volume set • ISBN 978-1-59904-943-4

Electronic Commerce: Concepts, Methodologies, Tools, and Applications
S. Ann Becker, Florida Institute of Technology, USA • 4-volume set • ISBN 978-1-59904-943-4

Electronic Government: Concepts, Methodologies, Tools, and Applications
Ari-Veikko Anttiroiko, University of Tampere, Finland • 6-volume set • ISBN 978-1-59904-947-2

Knowledge Management: Concepts, Methodologies, Tools, and Applications
Murray E. Jennex, San Diego State University, USA • 6-volume set • ISBN 978-1-59904-933-5

Information Communication Technologies: Concepts, Methodologies, Tools, and Applications
Craig Van Slyke, University of Central Florida, USA • 6-volume set • ISBN 978-1-59904-949-6

Intelligent Information Technologies: Concepts, Methodologies, Tools, and Applications
Vijayan Sugumaran, Oakland University, USA • 4-volume set • ISBN 978-1-59904-941-0

Information Security and Ethics: Concepts, Methodologies, Tools, and Applications
Hamid Nemati, The University of North Carolina at Greensboro, USA • 6-volume set • ISBN 978-1-59904-937-3

Medical Informatics: Concepts, Methodologies, Tools, and Applications
Joseph Tan, Wayne State University, USA • 4-volume set • ISBN 978-1-60566-050-9

Mobile Computing: Concepts, Methodologies, Tools, and Applications
David Taniar, Monash University, Australia • 6-volume set • ISBN 978-1-60566-054-7

Multimedia Technologies: Concepts, Methodologies, Tools, and Applications
Syed Mahbubur Rahman, Minnesota State University, Mankato, USA • 3-volume set • ISBN 978-1-60566-054-7

Virtual Technologies: Concepts, Methodologies, Tools, and Applications
Jerzy Kisielnicki, Warsaw University, Poland • 3-volume set • ISBN 978-1-59904-955-7

Contents

Volume I

Section I. Fundamental Concepts and Theories

This section serves as the foundation for this exhaustive reference tool by addressing crucial theories essential to the understanding of health information systems. Chapters found within these pages provide an excellent framework in which to position health information systems within the field of information science and technology. Individual contributions provide overviews of the future of e-health, telemedicine barriers, electronic health records, and data protection. Within this introductory section, the reader can learn and choose from a compendium of expert research on the elemental theories underscoring health information systems research

Section II. Development and Design Methodologies

This section provides in-depth coverage of conceptual architectures, frameworks and methodologies related to the design and implementation of health information systems. Throughout these contributions, research fundamentals in the discipline are presented and discussed. From broad examinations to specific discussions on particular frameworks and infrastructures, the research found within this section spans the discipline while also offering detailed, specific discussions. Basic designs, as well as abstract developments, are explained within these chapters, and frameworks for designing successful e-health systems, pervasive healthcare applications, and ICTs for human services are provided.

Volume II

Section III. Tools and Technologies

This section presents extensive coverage of the technology that informs and impacts health information systems. These chapters provide an in-depth analysis of the use and development of innumerable devices and tools, while also providing insight into new and upcoming technologies, theories, and instruments that will soon be commonplace. Within these rigorously researched chapters, readers are presented with examples of the tools that facilitate and support the emergence and advancement of health information systems. In addition, the successful implementation and resulting impact of these various tools and technologies are discussed within this collection of chapters.

Section IV. Utilization and Application

This section introduces and discusses the utilization and application of health information systems. These particular selections highlight, among other topics, challenges in electronic medical record system adoption, wireless technology adoption in healthcare, and current practices in healthcare systems. Contributions included in this section provide excellent coverage of today's online environment and insight into how health information systems impact the fabric of our present-day global village.

Volume III

Section V. Organizational and Social Implications

This section includes a wide range of research pertaining to the social and organizational impact of health information systems around the world. Chapters included in this section analyze preparing healthcare organizations for IT adoption, demographic difference in telehealth outcomes, physician characteristics and electronic medical records, and patient perspectives and roles in creating health records and recording health data. The inquiries and methods presented in this section offer insight into the implications of health information systems at both a personal and organizational level, while also emphasizing potential areas of study within the discipline.

Section VI. Managerial Impact

This section presents contemporary coverage of the managerial implications of health information systems. Particular contributions address the implantation of an enterprise system in a healthcare network and applications of a case management software system in non-profit organization. The managerial research provided in this section allows executives, practitioners, and researchers to gain a better sense of how health information systems can inform their practices and behavior.

Volume IV

Section VII. Critical Issues

This section addresses conceptual and theoretical issues related to the field of health information systems, which include issues related to privacy, security, and quality. Within these chapters, the reader is presented with analysis of the most current and relevant conceptual inquires within this growing field of study. Particular chapters address the impact of privacy legislation on patient care, quality assurance approaches to healthcare, and improving the quality of healthcare research data sets. Overall, contributions within this section ask unique, often theoretical questions related to the study of health information systems and, more often than not, conclude that solutions are both numerous and contradictory.

Section VIII. Emerging Trends

This section highlights research potential within the field of health information systems while exploring uncharted areas of study for the advancement of the discipline. Chapters within this section highlight new trends in the creation of personal health records, healthcare education, and coding and messaging systems for health informatics. These contributions, which conclude this exhaustive, multi-volume set, provide emerging trends and suggestions for future research within this rapidly expanding discipline.

Preface

Health information systems play a vital role in improving the quality and efficiency of healthcare by ensuring access to and delivery of essential information. Developing secure, efficient information systems for the healthcare industry that address the needs of patients and clinicians in an increasingly complex environment is often a difficult task.

With the constant changes in the landscape of health information systems, it is a challenge for researchers, practitioners, clinicians, and experts to take in the volume of innovative advances and up-to-the-moment research in this diverse field. Medical Information Science Reference is pleased to offer a four-volume reference collection on this rapidly growing discipline, in order to empower students, researchers, academicians, and practitioners with a wide-ranging understanding of the most critical areas within this field of study. This collection provides the most comprehensive, in-depth, and recent coverage of all issues related to the development of cutting-edge health information systems, as well as a single reference source on all conceptual, methodological, technical and managerial issues, and the opportunities, future challenges and emerging trends related to the development, application, and implications of health information systems.

This collection entitled, **"Health Information Systems: Concepts, Methodologies, Tools, and Applications"** is organized in eight (8) distinct sections, providing the most wide-ranging coverage of topics such as: 1) Fundamental Concepts and Theories; 2) Development and Design Methodologies; 3) Tools and Technologies; 4) Utilization and Application; 5) Organizational and Social Implications; 6) Managerial Impact; 7) Critical Issues; and 8) Emerging Trends. The following provides a summary of what is covered in each section of this multi-volume reference collection:

Section 1, ***Fundamental Concepts and Theories***, serves as a foundation for this extensive reference tool by addressing crucial theories essential to the understanding of health information systems. Chapters such as "Inventing the Future of E-Health" by José Aurelio Medina-Garrido and María José Crisóstomo-Acevedo and "Multi-Dimensional Criteria for the Evaluation of E-Health Services" by Alalwany Hamid and Alshawi Sarmad define essential concepts in e-health, such as electronic health records and telemedicine, and provide frameworks for their evaluation. "Quality of Health Information on the Internet," by Kleopatra Alamantariotou and "Improving Data Quality in Health Care" by Karolyn Kerr and Tony Norris provide overviews of quality assessment of health information online and offer suggestions for both patients and clinicians. Later selections, including "Overview and Analysis of Electronic Health Record Standards" by Spyros Kitsiou, Vicky Manthou, and Maro Vlachopoulou and "Process Level Benefits of an Electronic Medical Records System" by Abirami Radhakrishnan, Dessa David, and Jigish Zaveri highlight the challenges and opportunities presented by the use of electronic health records in practice . These and several other foundational chapters provide a wealth of expert research on the elemental concepts and ideas which surround information in healthcare.

Section 2, ***Development and Design Methodologies***, presents in-depth coverage of the conceptual design and architecture of a number of health systems, including e-health services, mobile healthcare, and pervasive healthcare applications. "Patient-Centered E-Health Design," by Alejandro Mauro and Fernán González Bernaldo de Quirós begins this section with an overview of tools and techniques needed for the design of efficient patient-centered e-health services. "Planning Successful Telemedicine and E-Health Systems" by Michael Mackert, Pamela Whitten, and Emily Krol highlights key points to consider when planning for the implementation of new telemedicine or e-health systems. Similarly, "Shared Healthcare in a Regional E-Health Network" by Kari Harno and "Tele-Practice Technology: A Model for Healthcare Delivery to Underserved Populations" by Thomas W. Miller, Robert D. Morgan, and Jennifer A. Wood offer overviews of key considerations for healthcare delivery in regional contexts. With contributions from leading international researchers, this section offers copious developmental approaches and methodologies for the design and implementation of health information systems.

Section 3, ***Tools and Technologies***, presents extensive coverage of the various tools and technologies used in the development and implementation of health information systems. This comprehensive section opens with the chapter "Capturing Data in Healthcare Using Patient-Centered Mobile Technology," by Sarah Pajak, Lorraine H. De Souza, Justin Gore, and Christopher G. Williams, which describes how patient perspectives can be used to inform the development of new user-centered technology in healthcare. Mobile technology in healthcare is further explored in selections such as "Managing Mobile Healthcare Knowledge: Physicians' Perceptions on Knowledge Creation and Reuse" by Teppo Räisänen, Harri Oinas-Kukkonen, Katja Leiviskä , Matti Seppänen, and Markku Kallio, "Personal Health Records Systems Go Mobile: Defining Evaluation Components" by Phillip Olla and Joseph Tan, and "Adoption of Mobile Technology by Public Healthcare Doctors: A Developing Country Perspective" by Nesaar Banderker and Jean-Paul Van Belle. Later selections such as "Collaborative Virtual Environments and Multimedia Communication Technologies in Healthcare" by Maria Andréia F. Rodrigues and Raimir Holanda Filho explain how technology can be used for training and learning in healthcare environments. In all, this section provides coverage of a variety of tools and technologies that inform and enhance modern healthcare environments.

Section 4, ***Utilization and Application***, describes how health information systems have been utilized and offers insight on important lessons for their continued use and evolution. Including chapters such as "Best Practices for Implementing Electronic Health Records and Information Systems" by Beste Kucukyazici, Karim Keshavjee, John Bosomworth, John Copen, and James Lai and "Electronic Medical Records: TAM, UTAUT, and Culture" by Ken Trimmer, Leigh W. Cellucci, Carla Wiggins, and William Woodhouse, this section investigates the numerous methodologies that have been proposed and enacted as electronic health records have grown in popularity. As this section continues, a number of case studies in health information research are presented in selections such as "Providing Telemental Health Services after Disasters: A Case Based on the Post-Tsunami Experience" by Shashi Bhushan Gogia, "Planning and Control and the Use of Information Technology in Mental Healthcare Organizations" by I.J. Baars and G.G. Van Merode, and "Assessing Physician and Nurse Satisfaction with an Ambulatory Care EMR: One Facility's Approach" by Karen A. Wager, James S. Zoller, David E. Soper, James B. Smith, John L. Waller, and Frank C. Clark. Contributions found in this section provide comprehensive coverage of the practicality and current use of health IT.

Section 5, ***Organizational and Social Implications***, includes chapters discussing the importance of addressing organizational and social impact in the evaluation and design of any health information system. Chapters such as "Preparing Healthcare Organizations for New IT Systems Adoption: A Readiness Framework" by Robert Breas and Matthew Waritay Guah and "Managing ICT in Healthcare Organization: Culture, Challenges, and Issues of Technology Adoption and Implementation" by Nasriah Zakaria, Shafiz Affendi Mohd Yusof, and Norhayati Zakaria address specific issues and trends in organizational IT adoption among patients, clinicians, and IT professionals. This section continues with investigations of community health and public healthcare in chapters such as "Understanding Computerised Information Systems Usage in Community Health" by Farideh Yaghmaei and "Managing E-Procurement in Public Healthcare: A Knowledge Management Perspective" by Tommaso Federici and Andrea Resca, concluding with discussions on topics such as patient roles in recording health data and data systems for disaster preparedness. Overall, these chapters present a detailed investigation of the complex relationship between individuals, organizations and health records and technologies.

Section 6, ***Managerial Impact***, presents focused coverage of health information systems as they relate to improvements and considerations in the workplace. "A Process Architecture Approach to Manage Health Process Reforms" by Christine Stephenson and Wasana Bandara highlights the importance of adopting a business process modeling approach to facilitate healthcare reform in the private and public sectors. "Investing Trust Relationships in a Healthcare Network" by Stefanie Kethers, Günter Gans, Dominik Schmitz, and David Sier presents a case study that explores the managerial implications of trust relationships between two separate wards in a hospital. In all, the chapters in this section offer specific perspectives on how managerial perspectives and developments in healthcare methodologies inform each other to create more meaningful user experiences.

Section 7, ***Critical Issues***, addresses vital issues related to health information systems, which include patient privacy, healthcare ethics, and information quality and reliability. Chapters such as "Security-Aware Service Specification for Healthcare Information Systems" by Khaled M. Khan discuss the importance of developing security-aware healthcare software services and the current challenges associated with doing so. Later selections, such as "Privacy Management of Patient-Centered E-Health" by Olli P. Järvinen discuss informational privacy from a patient perspective, providing a framework that addresses key patient concerns and distinctions between different e-health interests. This section continues by asking unique questions about demographic inconsistencies in healthcare environments, models for e-health service evaluation, and trends in healthcare data quality.

The concluding section of this authoritative reference tool, ***Emerging Trends***, highlights areas for future research within the field of health information systems, while exploring new avenues for the advancement of the discipline. Beginning this section is "Toward a Better Understanding of the Assimilation of Telehealth Systems" by Joachim Jean-Jules and Alain O. Villeneuve. This selection proposes a conceptual model of the determinants relevant for the assimilation of telehealth systems in healthcare organizations. Trends in the usability of health information systems are presented in "Emerging Approaches to Evaluating the Usability of Health Information Systems" by Andre W. Kushniruk, Elizabeth M. Borycki, Shige Kuwata, and Francis Ho with the aim of improving the adoption of health information systems in both hospitals and other healthcare organizations. These and several other emerging trends and suggestions for future research can be found within the final section of this exhaustive multi-volume set.

Although the primary organization of the contents in this multi-volume work is based on its eight sections, offering a progression of coverage of the important concepts, methodologies, technologies, applications, social issues, and emerging trends, the reader can also identify specific contents by utilizing the extensive indexing system listed at the end of each volume. Furthermore to ensure that the scholar, researcher and educator have access to the entire contents of this multi volume set as well as additional coverage that could not be included in the print version of this publication, the publisher will provide unlimited multi-user electronic access to the online aggregated database of this collection for the life of the edition, free of charge when a library purchases a print copy. This aggregated database provides far more contents than what can be included in the print version in addition to continual updates. This unlimited access, coupled with the continuous updates to the database ensures that the most current research is accessible to knowledge seekers.

As a comprehensive collection of research on the latest findings related to technologies and healthcare delivery, *Health Information Systems: Concepts, Methodologies, Tools, and Applications*, provides researchers, administrators and all audiences with a complete understanding of the development of applications and concepts in Clinical, Patient and Hospital Information Systems. Given the growing needs of populations around the world for care and delivery of services, as well as disease control, quality diagnostics and secure records, *Health Information Systems: Concepts, Methodologies, Tools, and Applications*, addresses the demand for a resource that encompasses the most pertinent research in health information systems, healthcare technologies and telemedicine.

Health Information Systems:
Concepts, Methodologies, Tools and Applications

ABSTRACT

Healthcare systems are an information intensive industry in which reliable and timely information is a critical resource for the planning and monitoring of service provision. Health Information Systems can be a powerful tool to make healthcare delivery more effective and far more efficient. This chapter focuses on major current studies in the health information systems, discusses organizational, social, and managerial implications as well as critical issues, and presents emerging trends for future research efforts.

INTRODUCTION

From the early 1960s through the 1970s, a new epoch of computing in healthcare emerged. A large group of hospitals in the United States and some hospitals in Europe concurred on the necessity to advance a patient information management system prototype. These hospitals heavily invested money, time, and effort to move toward computerization. And seeing the sudden surge of interest among the hospitals and the potential market opportunities, some commercial companies also joined in an effort to support patient information systems. Nonetheless, many of the early projects did not thrive: the complexity of the information requirements of a patient management system was gravely underestimated.

Historical developments of these various systems play a paramount role in the health informatics and more specific hospital information system movements. These eventually led to the successful design and implementation of major computerized health record systems and databases such as COSTAR (Computer Stored Ambulatory Record System), RMRS (Regenstrief Medical record System), TMR (The Medical Record), HELP (Health Evaluation through Logical Processing) system, and POMR/PROMIS (the Problem-oriented Medical record/ Information system). COSTAR, a patient record system developed at Massachusetts General Hospital in the 1960s, was later extended to record patient data relating to different types of ailments and is used even today in several teaching hospitals and research universities across the globe. RMRS was a physician-designed integrated inpatient and outpatient information system implemented in 1972, and TMR is an evolving medical record system that was developed in the mid-1970s at Duke University Medical Center. Together with the success of the Technicon system, the efficiencies of these automated record systems soon provided considerable motivation for the integration of computing into health care systems (Tan, 2005).

As soon as health administrators and practitioners began to realize the efficiency and data processing power of computers, which increased when minicomputers were introduced during the late 1970s and early 1980s, computerization began to be seen as a magic bullet for controlling and managing the large and increasing volumes of medical and other administrative data processed on a daily basis. Health administrative data encompass health administrative and patient financial data and inventories of drugs and medical equipment, as well as routine transactional data including the management of patient billing, insurance co-payments, accounts receivable and payable and general ledgers. Medical data range from demographics of patients to clinical and health services data to epidemiological and health population statistics. By the early 1980s, computer miniaturization and cost reduction combined with increases in processing power resulted in a dramatic move away from massive health data processing using mainframe or minicomputers to new and more efficient forms of health management information systems, office automation, and networking technologies.

Nowadays, it is hard to imagine healthcare without Information and Communication Technology (ICT). The healthcare industry now relies on data and information for every facet of its delivery. Huge amounts of data are generated and because this occurs in a mostly unstructured paper environment, its use is restricted in supporting healthcare. ICT has capacity to transform the health industry and the way it manages its data, information and knowledge and to revolutionize the way in which clinicians work. The needs of clinicians should drive innovations that affect then and they must be vigilant overseers of any change to their practice bought about by technology.

The use of health information technology has been promoted as having tremendous promise in improving the efficiency, cost-effectiveness, quality, and safety of medical care delivery in the healthcare system. The realization of these benefits is especially important in the context of reports that show five years of consecutive annual double-digit increases in healthcare costs and increases in the numbers of adverse health events. At the same time, reports have suggested that still investments in healthcare industries are wasted on inefficient processes. Legislators and organizational leaders at the federal and state levels have emphasized the need for healthcare to follow the example of many non-healthcare industries, in which implementation of computer information technology has been critical in increasing the accessibility of mission-critical information, automating labor-intensive and inefficient processes, and minimizing human error.

Even though significant literature on health information systems is already accessible, many new ideas and applications are persistently emerging and provide potential opportunities and challenges for further research. The purposes of this introductory chapter are: (1) to review the literature on health information systems using a suitable classification and longitudinal studies to understand previous studies and future research trends, and (2) to present a framework of health information systems research which consists of concepts, methodologies, tools, applications, critical issues, and emerging trends. Our chapter is both descriptive and prescriptive, and intends to stimulate further interest in this area. It will provide a reference source for anyone interested in health information systems research and practices.

Analyzing HIS Research Trends

To provide in-depth knowledge of the health information systems, we have analyzed articles in journals and chapters of periodicals and books with extensive use of Google Scholar, ScienceDirect, IEEE Explore, and ACM Portal. Keyword searches were conducted by using mainly search strings such as "health information system", health AND "information system", and "ehealth information system". In addition, recent publications included in this volume and select journal publications were referenced to augment the literature.

This paper consists of ten sections. (1) introduction, (2) fundamental concepts and theories in health information systems, (3) health information systems development and design methodologies, (4) health information systems tools and technologies, (5) utilizations and application of health information systems, (6) organizational and social implications of health information systems, (7) managerial impact of health information systems, (8) critical issues in health information systems, (9) emerging trends in health information systems, and (10) a conclusion.

FUNDAMENTAL CONCEPTS AND THEORIES IN HEALTH INFORMATION SYSTEMS

In this section, we define Health Information System (HIS), and provide concepts and theories related to HIS. Then we classify HIS according to its use.

Defining Health Information System (HIS)

A health information system collects data as a part of the patient care process. This data can be used across a number of systems of many different purposes and as with all patient data, it must be subject to confidentiality and security safeguards. Patient data must integrate with data from other facilities and it must meet the needs of various professional groups. Health information systems generally comprise several different applications that support the needs of the organizations.

Some of the concepts and terminologies related to HIS are as follows.

- **Health/Medical Informatics and Telemetics.** Health informatics (Conrick, 2006) is the field that concerns itself with the cognitive, information processing, and communication tasks of medical practice, education, and research including the information science and technology to support those tasks. It deals with the resources, devices, and methods required to optimize acquisition, storage, and retrieval. Health informatics tools include computers as well as clinical guidelines, formal medical terminologies, and information and communication systems. More broadly speaking, its emphasis is on clinical and biomedical applications with the added possibility of the integrating these clinical components either among themselves or to more administrative-type health information system. In this regard, the field of health informatics and telematics has evolved very rapidly over the past several years.
- **Health information technology (HIT).** Health information technology (HIT) is the application of information processing involving both computer hardware and software that deals with the storage, retrieval, sharing, and use of health care information, data, and knowledge for communication and decision making (Goldschmidt, 2005).

- **Electronic medical record (EMR), Electronic health record (EHR), Electronic patient record (EPR).** Electronic medical record (EMR) is a medical record in digital format, whereas electronic health record (EHR) refers to an individual patient's medical record in digital format. EHR systems co-ordinate the storage and retrieval of individual records with the aid of computers, which are usually accessed on a computer, often over a network. One of the important trends is the move towards a universal electronic patient record (EPR). EPR is defined as electronically stored health information about one individual uniquely identified by an identifier. Essentially, EPR technology entails capturing, storing, retrieving, transmitting, and manipulating patient-specific, healthcare-related data singly and comprehensively, including clinical, administrative, and biographical data (Protti et al., 2009).

Theories Applied to HIS

There are several theories such as general systems theory, chaos theory, and activity system theory that can be applied to healthcare systems.

General systems theory (GST) (Bertalanffy, 1968) begins with the observation that what we see, hear, and interact with may be rationalized as a hierarchical network of systems and subsystems. In this regard, systems, which must have a purpose, can be whole and be part of other systems (subsystems) at the same time. Systems can also be characterized as being open or closed.

Open complex systems are characterized by input-process-output triads and feedback loops. GST easily describes the flow of appropriate and relevant information about sick patients (input), who are placed into the different subsystems of the acute health care system to be treated and cared for (process) until they are ready, perhaps, to be transferred to another subsystem such as a group home (intermediate output) before being discharged as healthy individuals who can continue to contribute to their work organizational systems (final output). Continual monitoring of the health status of these patients becomes the feedback loop in the system. These loops ensure the reliability and quality of health services provided, including those before and after the patients are discharged. A common example of an information system that controls this acute patient care process in a hospital setting is the admission-discharge-transfer (ADT) system.

In earlier works (Tan, 2001), the principles of GST concerning the behaviors of organizational systems and subsystems were used to think about the design of different classes of clinical and administrative health management information systems required to run hospitals and health provider organizations.

Previous work has demonstrated that systems that are interactively complex and coupled are prone to failure. Tan et al. (Tan et al., 2005) have analyzed how the parts of networks connect and interact to produce outcomes, and according to their research factors and challenges have been identified to consider when designing future-oriented healthcare networks. Their work discusses a chaos theory view of healthcare systems, which divides the causes of chaos into internal and external origins. Each origin is further subdivided into a human or individual level, an organizational level and a system level, and stages ranging from static to chaos. When either etiology, internal or external, surpasses the static stage, the potential for error increases.

Ideally, a health information framework should support and facilitate interventions to shift and maintain the complexity towards the static stage. In addition, it is very important that healthcare information systems are created with checks and balances to prevent system-induced chaos. Conceptually, a global health information system should provide efficient access to patient information, comprehensive surveillance, expert systems to facilitate decision-making and computational power. Information networks can be used to manage the complexity of healthcare. The adaptive system theory identifies the following concepts that should be incorporated when deploying emerging information and communication networks: acceptance of uncertainty; unpredictable healthcare systems; improved performance by feedback loops; flexible standardization; quick response time with backup redundancy at the edge of chaos; need of intelligent and effective leadership in the chaos stage (Tan et al., 2005).

The complex and dynamic components and relationships must be included in the architecture of healthcare information system in order to support the complete information needs in the healthcare activities. For this purpose, Activity System Theory (ATS) can be applied by integrating system thinking and social psychology, which uses recursive model of human activity system. A project IMIS (Integrated Mobile Information System for Diabetic Healthcare) (Bai, 2004) shows the practical application of the activity system theory for constructing healthcare information system. It was concluded that the activity system model could provide the service system designers with a comprehensive and integrated framework for designing healthcare information system.

Classification of HIS

Classification of health information systems can be done in various ways, which is shown in Table 1.

HEALTH INFORMATION SYSTEMS DEVELOPMENT AND DESIGN METHODOLOGIES

This section presents health care standardizations, frameworks for HIS development and design methodologies.

Healthcare Standardizations

Hospitals and other healthcare provider organizations typically have many different computer systems used for everything from billing records to patient tracking. Regarding the electronic health record, there have been various international efforts related to standardization, including CENTC251 in Europe (CEN-TC, 2009), HL7 in USA (HL7, 2009), the Healthcare task force of the Object Management Group (OMG, 2009), and OpenEHR (OpenEHR, 2009).

HL7 specifies a number of flexible standards, guidelines, and methodologies by which various healthcare systems can communicate with each other. Such guidelines or data standards are a set of rules that allow information to be shared and processed in a uniform and consistent manner. These data standards are meant to allow healthcare organizations to easily share clinical information. Theoretically, this ability to exchange information should help to minimize the tendency for medical care to be geographically isolated and highly variable. HL7 develops conceptual standards (i.e. HL7 RIM), document standards (i.e. HL7 CDA), application standards (i.e. HL7 CCOW) and messaging standards (i.e. HL7 v2.x and v3.0). Messaging standards are particularly important because they define how information is packaged and communicated from one party to another. Such standards set the language, structure and data types required for seamless integration from one system to another. HL7 encompasses the complete life cycle of a standards specification including the development, adoption, market recognition, utilization, and adherence (Blazona & Koncar, 2007).

Table 1. Classification of health information systems (Yusof et al., 2008)

Information Systems	**Descriptions**	**Characteristics**
Patient centered information systems	They are the electronic version of patients' information. Different terms are used to refer to these systems including EPR, EMR and computer based patient record (CPR)	• Manage comprehensive patient care information such as medical records, appointment scheduling, theatre management and ward reporting
Clinical information systems (CIS)	Represent separate systems in specialized service of clinical departments. Examples of CIS include patient monitoring systems and anesthesia documentation system	• Perform specific tasks including collection of specific data for patient care, research, management, planning and maintenance of national data repositories • Specific tasks operate in departments such as internal medicine, cardiology, neurology, obstetrics, surgery and psychiatry • CIS are used for administrative support, patient data collection, decision support, picture archiving, image analysis, monitoring, reporting, assessment and research
Radiology information systems	Support the acquisition and analysis of radiological images as well as administrative functions of radiology department. Example: picture archiving and communication systems.	• May be stand alone or integrated in hospital information systems
Laboratory information systems	Perform data validation, administration, electronic transmission and computer storage These systems often must interface with instruments and other information systems such hospital IS. A LIS is a highly configurable application, which is customized to facilitate a wide variety of laboratory workflow models. Deciding on an LIS vendor is a major undertaking for all labs. Vendor selection typically takes months of research and planning.	• In high demand when a large number of tests generate large data. Samples are analyzed fully automatically, and the results are computer generated • Support clinician to analyze trends to assess treatment effects
Pharmacy information systems	Maintain medication information	• Include functions such as keeping patients' medication records, checking prescriptions, and providing drug prescriptions and administration to physicians and nurses.
Hospital information systems	Consist of integrated hospital information processing systems. Examples: computerized physician order entry (CPOE), patient care information systems, nursing (bedside) documentation systems, nursing IS, general practitioner IS	• Support healthcare activities at the operational, tactical and strategic levels • Encompass patient management, administration, facilities management and medical applications • Contain database systems, data communication facilities and terminal or workstations
Telemedicine	It is supported by electronic processes and communication	• Facilitates exchange between primary care physicians and specialists as well as patients from disperse locations • Allows physicians to practice medicine at a distance

Frameworks for HIS Applications

Many of the information technology (IT) frameworks were developed before the advent of HIS. As HIS grew rapidly and gained strategic importance, the existing IT infrastructure became inadequate in supporting the complex capabilities of HIS applications.

The major architectural approaches in Table 2 describe architectural development processes that are broadly used in the software engineering and healthcare domains.

Table 2. Architectural approaches (Lopez & Blobel, 2009)

Architectural approaches	Related approaches	Domain	
		Software engineering	**Health informatics**
Architectural frameworks	Enterprise architectures	Zachman; FEAF; DODAF; RM-ODP; TOGAF; IEEE 1471-2000	Generic Component Model
Architectural models	Reference architecture; architecture styles	Object-oriented architectures; component-based architectures; MDA; SOA; business process models	ISO EN 13606-1; OpenEHR; HL7 RIM; CDA; GCM specialization
Description languages Middleware architectures Architecture development process	Modeling languages Component architectures; service architectures Analysis/design methods and models	UML; ACME ADL; OCL, Web services; CORBA; J2EE; COM; .NET RUP; SAAM; ATAM; ADD; TOGAF ADM; SEI CMMI; SPEM	OpenEHR, ADL OMG HDTF, CEN 12967 HL7 HDF; HL74SOA; CEN EN 12967-1

Design Methodologies for HIS Development

Traditional IT development approaches such as systems development life-cycle (SDLC) methods and functional team IT organization were outdated long before the advent of the digital economy. In response to the drawbacks of the traditional IT development approaches, various alternative systems development methods such as rapid application development (RAD) and object-oriented systems development were introduced in 1990s.

Due to its relative popularity, there are a large number of evaluation studies on clinical decision support systems (CDSS). Kaplan (Kaplan, 2001) reviewed studies focusing on the evaluation of CDSS, with the main emphasis upon changes in clinical performance and systems that could improve patient care. Kaplan's study includes many evaluations of CDSSs using designs based on laboratory experiments or Randomized Controlled Clinical Trials (RCTs).

Delpierre et al. (Delpierre et al., 2004) reviewed studies of computer-based patient record systems (CBPRS). The objective of their review was to carry out a systematic survey of studies analyzing the impact of CBPRS on medical practice, quality of care, and user and patient satisfaction.

Tan with Sheps (Tan & Sheps, 1998) use the term health decision support systems (HDSS) and, more specifically, clinical decision support systems and expert systems (CDSS/ES) to characterize many HIS applications. A group health decision support system (gHDSS) combines analytic modeling, network communications, and decision technology to support group decision-making processes such as group strategic thinking, problem formulation, and generation of goal-seeking solutions. This technology has the potential to increase the efficiency, effectiveness, and productivity of group interactions through asynchronous board meetings, on-line forums, or special group meetings in which board members and executives can network and share information with one another without being completely constrained by separation in time and geographical distance.

Intelligent decision support systems (IDSS) are basically DSS that have an intelligent component, which either replaces or enhances the model subsystem. In past years, some proposals for intelligent and agent-based decision support systems (e.g. Kebair & Serin, 2006; Liu et al., 2006; Sokolova, 2009) have been described. New approaches of researching IDSS appear following the rapid progress of agent systems and network technology.

A strategy to reduce medication error is to implement Electronic Prescribing Decision Support Systems (EPDS) (Ayres et al., 2006). In a clinical business context, EPDS should be a core function of a point of care clinical system but software vendors tend to develop it as either a standalone system or an additional module to a point-of-care clinical system.

Starting with the requirements for semantic interoperability derived from paradigm changes for health systems and their supporting health information systems, the need of an architectural approach for analyzing, designing, implementing, and maintaining advanced, sustainable, semantically interoperable HIS has been shown.

The weakest aspect in the evaluated architectural approaches for HIS development was the lack of a formal architecture development methodology covering the complete architecture lifecycle, and a clearly defined development process describing tasks, work products, roles, workflows, etc. The Rational Unified Process (RUP) (Kruchten, 2003) was found to be the most comprehensive source of methods and processes for system development, including architecture development. This development process constitutes the better approach to complete the HIS-DF, providing details on how to deliver a sound architecture description. HIS-DF tasks, responsible persons, products, guidance, phases, and workflows are described specializing (tailoring) the RUP process. RUP facilitates the flexibility, scalability and reusability of the methodology by describing method components and providing guidance and tooling for creating reusable Method Content (RUP Plug-ins) and documenting the methodology through exportable Web pages and XMI files.

Semantic interoperability is a basic challenge to be met for new generations of distributed, communicating and cooperating health information systems enabling shared care and e-health. Analysis, design, implementation and maintenance of such systems and intrinsic architectures have to follow a unified development methodology. The Generic Component Model (GCM) (Lopez & Blobel, 2009) is used as a framework for modeling any system to evaluate and harmonize state of the art architecture development approaches and standards for health information systems as well as to derive a coherent architecture development framework for sustainable, semantically interoperable HIS and their components. The proposed methodology is based on the Rational Unified Process (RUP), taking advantage of its flexibility to be configured for integrating other architectural approaches such as Service-Oriented Architecture (SOA), Model-Driven Architecture (MDA), ISO 10746, and HL7 Development Framework (HDF).

HEALTH INFORMATION SYSTEMS TOOLS AND TECHNOLOGIES

This section presents coverage of various tools and technologies and their use in creating and managing HIS. This section discusses Web technology standards, GIS technologies, artificial intelligence techniques, imaging technologies, agent technologies, data warehousing architectures, and data mining techniques.

Web Technology Standards

If the data exchange process simply provides static health information from health information systems and legacy databases, then the information dissemination process is straightforward. In this case, the Internet and the typical HTML (Hypertext Markup Language) offer a convenient platform through which the information can be predesigned, validated, and captured or presented as a user-friendly multimedia document. To improve the data's timeliness, validity, and integrity, the preferred data collection method is automated and direct data input at the source—for example, using predesigned documents stored in organizational intranets or extranets, then warehousing the completed documents either centrally or via on-line distributed network technology. Data direct entry requires that the acquired data be converted into easily readable and appealing user-oriented information.

To fulfill the need for dynamic and interactive Web interfaces, the World Wide Web Consortium (W3C) introduces a standard known as Extensible Markup Language (XML) (W3C, 2009), which is simple, extendible text format derived from SGML. A number of variations of XML have been developed. With XML, data or even documents can be simultaneously transformed into useful, meaningful, and interactive information in a format that is readily retrievable, comparable and transactional, where data can be used for exchanging dialogues and executing monetary payments. The data transfer and data distribution functions (that is, data retrieval and transmission activities) become integrated with those of presentation, exchange, and use. XML technology also allows the creation of multimedia and intelligent graphical Web interfaces and thus has the ability to compact large amounts of information conveniently. The information can be further packaged to support individual users by filtering out information that may not be needed for a particular application or for a particular data exchange transaction.

GIS Technologies

A geographical information system (GIS) is a powerful tool for collecting, recording, storing, manipulating, and displaying spatial data sets. A GIS uses spatial data such as digitized maps and can represent a combination of text, graphics, icons, and symbols on two-dimensional and three-dimensional maps. GIS technology might be used for digital mapping of a certain epidemic—for instance, HIV infection among a subpopulation across various counties in a province or state. This knowledge can then be used to effectively target interventions for specific population groups.

The development of Web-based GIS applications in medical fields has led to the collection and dissemination of information on several infectious diseases at national and international levels. Web-based GIS applications are used in several international surveillance networks.

Both GIS-related technologies and public health surveillance are concerned with the spatial and temporal dimensions of public health problems (Boulos, 2004). As part of an e-public health information system or application, GIS-related technologies can support direct or indirect (data extracted from available secondary sources) data input and verification from either a desktop computer or a Web-based browser that interfaces with a data storage system, which may be a data warehouse or a suite of databases. At least four data categories may warrant inclusion in a GIS-related application for use in bio-defense preparedness.

Artificial Intelligent Techniques

In the ICT domain, one of the most promising and interesting domains seemed to be Artificial Intelligence (AI). At the clinical level, applications utilizing AI, neural network (NN), and fuzzy logic techniques are being developed to provide clinical decision support to physicians (Coiera, 2003). It deals primarily with information used in medical decision making. The primary objective in this category of IT is to assist physicians and other medical experts in diagnosis and treatment.

Artificial intelligence (AI), combined with ontology, is becoming a powerful tool in mining data for patterns of significance within large bodies of data. As more knowledge from research is placed directly into machine-readable formats, opportunities will expand for “automated learning” in which AI systems generate hypotheses and, where possible, test them against appropriate data. These systems will be usable by consumers/patients in their own language, and by 2015, these systems will be culturally and ethnically sensitive in how they operate, present information and support health behavior and decision-making (HIS2015, 2006).

Imaging Technologies

For the storage of medical information, Picture Archiving and Communication System (PACS) have been developed to address some of the accessibility issues and e-networking requirements for the exchange of medical imaging data. Essentially, PACS are systems for storage of massive digital images, which are in accordance to DICOM (Digital imaging and communication in Medicine) standard (Blazona & Koncar, 2007). These systems also support simultaneous access to digital imaging data from various connected terminals, systems, and networks. Imaging technologies have urged healthcare facilities to implement PACS to enhance patient care and improve workflow.

With PACS and medical imaging technology maturing, the importance of organizational maturity and effective deployment of PACS in the hospital enterprise are becoming significant. Van de Weterring and Batendur illustrated relevant aspects of maturity and evolvability of PACS. From the results of a meta-analytic review on PACS maturity and evolvability, they proposed a model – the PACS maturity model (PMM) – that describes five levels of PACS maturity and the corresponding process focus (van de Wetering & Batenbur, 2009).

Agent Technologies

Agent Technology is an emerging and promising research area in software technology, which increasingly contributes to the development of value-added information systems for large healthcare organizations (Nguyen et al., 2009). Fonseca et al. (Fonseca et al., 2005) presented an inherently distributed Multi-Agent Medical Information System (MAMIS), which was designed with the goal of proving a solution for patient information search on a community of autonomous healthcare units and provide ubiquitous information access to physicians and healthcare professionals in a variety of situations.

The use of agent-based intelligent decision support systems (IDSS) to support decision making is important within HIS because they allow doctors and nurses to quickly gather information and process it in various ways in order to assist with making diagnosis and treatment decisions (Foster et al., 2005). Cohen and Hudson present an agent-based IDSS which is used for diagnosis and involves three levels. The lowest level is called agents, which contains multiple kinds of agents including user interface agents, data mining agents and problem solver agents. The second level is communicators which act as translators between the task-managers and the agents to ensure that every agent gets the information in their desired format. The top level is task-managers, which break the task up into sub problems that are assigned to agents (Cohen & Hudson, 2002).

Coffin et al. (Coffin et al., 2004) describes a reminder system. It uses intelligent agents to monitor circumstances that require notifying healthcare professionals about events. These events can include giving shots, vaccinations, surgeries, follow-up checks and other important events.

Favela et al. extended a handheld-based mobile hospital information system with ubiquitous computing technology and described how public displays are integrated with handheld and the services offered by these devices. Public displays become aware of the presence of physicians and nurses in their vicinity and adapt to provide users with personalized, relevant information. An agent-based architecture allows the integration of proactive components that offer information relevant to the case at hand, either from medical guidelines or previous similar cases (Favela et al., 2004).

Data Warehousing Architecture

Data warehousing architecture which is basically a conceptualization of how the data warehouse (DW) is built, consists of the following interconnected layers: operational database layer, data access layer, metadata layer, informational access layer. Data warehousing architecture for integrated information management simply provides an integrated source of aggregated, organized, and formatted data. The data in a DW are designed to support management decision-making and strategic planning. Accordingly, these data may sometimes be categorized in various forms, and most likely have already been aggregated and filtered after coming from legacy systems. Furthermore, DW can be combined with an executive information systems (EIS), an ES, an HDSS, group HDSS, or a GIS not only to increase data analytic and processing power but also to develop new and complex forms of e-health technologies. One of the most prominent uses of DW in e-healthcare is the automated collection of massive amounts of linked data from diverse sources for use in data mining techniques.

Sahama and Croll presented data warehouse architectures, which are practicable solutions to tackle data integration issues, and could be adopted by small to large clinical data warehouse applications (Sahama & Croll, 2007).

Data Mining Techniques

Data mining techniques explore data for hidden trends and patterns. Data mining tools include artificial neural networks, case-based (analogical) reasoning, statistical methods, genetic algorithms, and explanation-based reasoning. A number of studies have employed data mining to survey healthcare data (Kaur & Wasan, 2006; Obenshain, 2004; Silver et al., 2001).

Kaur and Wasan highlighted the use of classification based data mining techniques such as rule based, decision tree and Artificial Neural Network to massive volumes of healthcare data. In particular, they considered a case study using classification techniques on a medical data set of diabetic patients (Kaur & Wasan, 2006).

Data mining can provide the means to analyze relevant information in public health surveillance. Obsenshain presented the application of data mining of healthcare data in automated surveillance systems and explored the usefulness of data mining for research related to infection control and hospital epidemiology, especially where the data volume exceeds capabilities of traditional statistical techniques (Obenshain, 2004).

The authors focused on an analysis, which was performed by a team of physicians and IT researchers, using a commercially available on-line analytical processing (OLAP) tool in conjunction with proprietary data mining techniques (Silver et al, 2001).

The opportunity for a health maintenance organization (HMO) to explore and discover best practices by comparing and contrasting physician practice patterns for different treatment protocols corresponding to groups with specific case mixes is one benefit of applying DW and data mining technologies. The unraveling of the human genome to provide treatments for various challenging ailments is another noble example of DW and data mining technology applications.

UTILIZATION AND APPLICATION OF HEALTH INFORMATION SYSTEMS

This section investigates the use and implementation of health informatics in a variety of contexts. This section discusses health information exchanges, health knowledge management, e-health systems, e-public health systems, and m-health systems.

Health Information Exchanges (HIEs)

Health Information Exchange (HIE) (Overhage et al., 2005) is defined as the mobilization of healthcare information electronically across organizations within a region or community. HIE provides the capability to electronically move clinical information among disparate healthcare information systems while maintaining the meaning of the information being exchanged. Healthcare communities worldwide continue to adopt new approaches to better serve an increasingly complex patient population. Improved patient safety, streamlined provider workflow, more rapid and distributed access to medical information, and better clinical audits all place strains on healthcare infrastructures, which were originally designed for a single-entity approach (Jha et al., 2008).

With the maturation of EHRs and HIEs to address these business challenges, the focus most recently has shifted to patient-centered or "consumer-driven" healthcare, requiring a new level of integration between healthcare services and IT systems. As a result, clinical and business transformation of healthcare infrastructures has become central to business and political agendas, aiming to involve consumers, physicians, payers, and employers as never before.

Health institutions, governments, and coalitions worldwide are teaming to deliver fundamental transformation of healthcare IT and information services through three interrelated objectives. The impact of this effort is being felt across the entire healthcare continuum: a) clinicians are integrating their independent record and technology assets to create agile, patient-centered electronic health records, realizing new levels of patient safety and information exchange through organizational, regional, and national ways of working; b) HIEs are bringing together distributed enterprises and investing in standards for data sharing, integration, and information presentation across care settings; c) clinical transformation and interoperability of health information technologies on a national level is rapidly advancing health information exchange and driving public health initiatives, such as public health disease surveillance programs.

Health Knowledge Management

Knowledge management (KM) is a management paradigm that includes concerted, coordinated and deliberate efforts to manage the organizational knowledge through processes for identifying and leveraging it to enhance the organizations ability to compete. KM is purported to increase innovativeness and responsiveness. Liao classified such knowledge management technologies and applications into six categories: knowledge-based systems (KBS), data mining (DM), information and communication technology (ICT), artificial intelligence (AI) / expert systems (ES), database technology (DT), and modeling (Liao, 2003).

Quality care of patients requires evaluating large amounts of data at the right time and place and in the correct context. With the advent of electronic health records, data warehouses now provide information at the point-of-care and facilitate a continuous learning environment in which lessons learned could provide updates to clinical, administrative, and financial processes. Given the advancement of the information and communication tools and techniques of today's knowledge economy, utilizing these resources is imperative for effective healthcare. Thus KM techniques are now essential for quality healthcare management such that the healthcare industry is increasingly becoming a knowledge-based community. In this regard, knowledge based systems are assuming an increasingly important role in healthcare and medicine for assisting clinical staff in making decisions under uncertainty (e.g., diagnosis decisions, therapy and test selection, and drug prescribing).

Hsia et al. proposed a conceptual framework that integrates nursing process, KM activities, and enabling information technology (IT) for designing such a nursing knowledge management system. The framework indicates the critical knowledge management activities in nursing process and the enabling IT based on the task/technology fit theory. This framework would immensely help healthcare organizations to identify their IT needs and to plan for the KM activities and technical infrastructure of the nursing knowledge management system (Hsia et al., 2006).

To illustrate a feasible health knowledge management process that helps gather useful technology information and reduce many knowledge misunderstandings, Cheng et al. depicted the design of asynchronously sharing mechanism to facilitate the knowledge transfer, in which health knowledge management process can be used to publish and retrieve documents dynamically. It effectively creates an acceptable discussion environment and lessens the traditional meeting burden among development engineers (Cheng et al., 2008).

E-Health Systems

E-health is basically healthcare practice which is supported by electronic processes and communication. E-health can encompass a range of services that are at the edge of medicine/healthcare and information technology such as EMR, telemedicine, consumer health informatics, health knowledge management, virtual healthcare teams, m-health, e-healthgrids, healthcare information systems.

In general, e-health domains and applications can be divided into two primary clusters based on two key dimensions of systems integration characteristics. On one hand, systems that are characterized by a high degree of internal integration include applications such as the following: virtual patient records (VPR), document management (DM), geographical information systems (GIS), group health decision support systems (group HDSS), executive information systems (EIS), data warehouses (DW), and data mining. On the other hand, systems that are characterized by a high degree of external integration include the following: telecommunications, wireless and digital networks, community health information networks (CHIN), The Internet, Intranets and extranets, health informatics, and telemedicine or e-medicine (Raghupathi & Tan, 2002).

E-Public Health Systems

An e-public health information system must support the public health mandate of improving the health status of the community and the population at large. The information system must measure the health of the population against potential determinants of health. Community health assessment, for example, requires the collection, analysis, interpretation, and communication of key health statistics, data, and information (Araujo et al., 2009).

Emerging e-public health technologies include geographical information systems (GIS), data warehousing, and data mining methodology. These e-technologies, which have matured over the years, are now being applied to e-public health information systems.

M-Health Systems

Hospital environments inherently involve mobility due to the constant movement of medical professionals, support personnel and critical medical equipment. Given this intrinsic level of mobility, combined with the tremendous need for timely and accurate patient information and hospital efficiency, various wireless technologies are being adopted. Thus m-health can be defined as mobile communications network technologies for healthcare (Istepanian et al., 2006). This concept represents the evolution of "traditional" e-health systems from desktop platforms and wired connections to the use of more compact devices and wireless connections in e-health systems. The emerging development of m-health systems in the last decade was made possible due to the recent advances in wireless and network technologies, use of mobile technologies and devices such as cell phones and handheld devices, PDA. Although m-health can generally be considered to be an extension of electronic health, it has a number of unique characteristics and business models, as it embraces both emerging and enabling technologies (Varshney, 2006; Wu et al., 2007).

Kyriacou et al. reviewed wireless technologies and emerging wireless video systems used for m-health systems and also provided an overview of recently published wireless emergency healthcare systems, which clearly demonstrate the benefits and the need for their wider deployment. It is expected that m-health e-emergency systems will significantly affect the delivery of healthcare (Kyriacou et al., 2007).

Thus, the main wireless technologies that are used in m-health systems are GSM, 3G (W-CDMA, CDMA2000, TD-CDMA), satellite, and wireless LAN (WLAN). Emerging wireless technologies such as WiMax, Home/Personal/Body Area Networks, ad-hoc and sensor networks are also extensively used. Wireless PANs are defined with IEEE standard 802.15. The most relevant enabling technologies for m-health systems are Bluetooth and ZigBee.

For example, a variety of wireless technologies such as mobile computing and wireless networks have been applied to school-based health centers (Jen, 2009) and wireless healthcare using PDAs and handheld devices (Fontelo & Chismas, 2005).

ORGANIZATIONAL AND SOCIAL IMPLICATIONS OF HEALTH INFORMATION SYSTEMS

This section discusses community-based health systems, virtual communities, globalization, health level seven, health metric network, public health surveillance, human computer interaction, and health disparities.

Health informatics is an evolving field that considers health information technology at multiple levels of abstraction and complexity ranging from analysis of the impact of health information systems at the individual, organizational and regional level. Table 3 presents a conceptual framework for considering the interaction between humans and health information technologies (Kushniruk & Borycki, 2008).

Community-Based Health Systems

A community health information network (CHIN) may be conceived as a network that links health care stakeholders throughout a community or region. Such an integrated collection of telecommunication and networking capabilities can facilitate communication with patients as well as the exchange of clinical and financial information among multiple providers, employers, and related healthcare entities within a targeted geographical area. Central to a CHIN's success is the practical implementation of a computerized patient record system at the community or regional level. CHIN technology has become an important interactive research and communication tool, aiding both medical professionals and health consumers in search of health-related information and knowledge. Some example of community-based health systems can be given in Chiu et al., 2008 and Puri et al., 2009.

Table 3. Conceptual framework for considering the interaction between humans and HITs

Level 4	Healthcare system level (broader healthcare environment – eg national and international strategies and contexts)
Level 3	Organizational aspects of health information systems (social and organizational level)
Level 2	Users interacting with information system to carry out work task (level of workflow)
Level 1	Users interacting directly with IS (human-computer interaction)

Virtual Communities

Virtual communities serve as on-line support groups for both e-patients and e-caregivers. Numerous e-health companies are also promoting the concept of virtual communities as part of e-disease management programs. These communities provide consumers with general information, information about medical research on particular diseases, and information on available products and services specific to these diseases, as well as psychological support from affected patients facing the same condition (Forducey et al., 2005). Virtual patient records (VPR) are an integrated health database processing engine that links the accurate and rapid collection of various patient-related information and knowledge elements to generate an aggregated, well-classified, and organized set of administrative and clinical information and knowledge that e-health providers can retrieve, exchange, and disseminate as needed for e-clinical decision making, e-control, analysis, e-diagnosis, e-treatment planning and evaluation, and many other e-health-related cognitive activities. VPR enable the integration and sharing of healthcare information within large and heterogeneous organizations.

Globalization

Globalization refers to viewing the world as a single community for propagating the promotion of health and wellbeing through evolving virtual network and the sharing of e-health information and services. Globalization of e-healthcare will require effective use of individual, group, community, organizational, and societal resources. With the implementation of global call centers and Internet-enabled transactional services, e-health purchasers and providers can significantly streamline many administrative and financial processes, promoting global exchange of data for scheduling, shipping, billing, ordering, and purchasing healthcare products and services. Globalization of e-health services also has the potential to provide high-quality services to many underserved urban, rural, and remote areas (Haux, 2006).

Health Level Seven (HL7)

Health Level Seven (HL7) is an international community of healthcare subject matter experts and information scientists collaborating to create standards for the exchange, management and integration of electronic healthcare information, which is an all-volunteer, not-for-profit organization involved in development of international healthcare standards. HL7 and its members provide a framework (and related standards) for the exchange, integration, sharing and retrieval of electronic health information, which support clinical practice and the management, delivery, and evaluation of health services, are the most commonly used in the world. HL7 promotes the use of such standards within and among healthcare organizations to increase the effectiveness and efficiency of healthcare delivery for the benefit of all (HL7, 2009).

Health Metric Network

The Health Metrics Network (HMN) (WHO-HMN, 2009) is a global partnership that facilitates better health information at country, regional and global levels. HMN aims to increase the availability and use of timely and accurate health information by catalyzing the joint funding and development of core country health information systems. HMN has a single strategic goal—increasing the availability and use of timely and accurate health information by catalyzing the joint funding and development of core country health information systems. In pursuit of this goal, HMN lays out a vision and identifies strategies for health information system (HIS) development and strengthening, supporting countries in implementing such strategies, and generating new knowledge and global public goods through research, technical innovation, and sharing lessons learned.

Human Computer Interaction

The study of human computer interaction (HCI) is concerned with human, social, organizational and technical aspects of the interaction between human and machines. It is a broad area of study that deals with a broad range of phenomena, including the design evaluation and social implications of computer systems. There are a wide range of aspects of HISs that are related to cognitive that human information processing. The user interface to HISs can be defined as the component of the overall man-machine system responsible for communication with the user of the system. Thus HCI can be considered to be largely cognitive in that it involves processing of information by humans in close conjunction with computer systems. Therefore, the application of ideas, theories, and methods emerging from the field of cognitive psychology are highly relevant to the design and implementations of more effective HISs from the perspective of human users, for whom systems are designed to support and serve (Jacko & Sears, 2003).

Public Health Surveillance

Surveillance methods that can detect disease at an earlier stage are an important research direction for public health surveillance. These methods are referred to as syndromic surveillance because they have the goal of recognition of outbreaks based on the symptoms and signs of infection and even its effects on human behavior prior to first contact with the health care system. The Real-time Outbreak and Disease Surveillance system (RODS) is a computerized public health surveillance system for early detection of disease outbreaks, including those caused by bioterrorism. RODS processes clinical encounter data from participating hospitals and sales data of over-the-counter (OTC) healthcare products from participating stores and pharmacies (Tsui et al., 2003).

The role of public health surveillance is to collect, analyze, and interpret data about biological agents, diseases, risk factors, and other health events and to provide timely dissemination of collected information to decision makers.

Health Disparities

People have long recognized that some individuals are healthier than others and that some live longer than others do, and that often these differences are closely associated with social characteristics such as race, ethnicity, gender, location, and socio-economic status (Brach & Fraser, 2000).

Health disparities or healthcare inequalities refer to gaps in the quality of health and healthcare across racial, ethnic, and socioeconomic groups. There are several reasons for disparities in access to healthcare, which are as follows: lack of insurance coverage, lack of a regular source of care, lack of financial resources, legal barriers, the healthcare financing system, scarcity of providers, linguistic barriers, health literacy, lack of diversity in the healthcare workforce, and elderly age.

MANAGERIAL IMPACT OF HEALTH INFORMATION SYSTEMS

This section discusses contemporary coverage of managerial application and implications of HIS. The core concepts are such as health systems governance, interoperability, and healthcare strategy and evaluation.

Health Systems Governance

Governance is thought to be a key determinant of economic growth, social advancement and overall development. Assessment of governance as the gateway for promoting good governance of the health system is a key consideration that underpins this effort. Governance influences all other health system functions, thereby leading to improved performance of the health system and ultimately to better health outcomes.

Health systems governance is currently a critical concern in many countries because of increasing demand to demonstrate results and accountability in the health sector, at a time when increasing resources are being put into health systems where institutional contexts are changing rapidly.

Ten principles were proposed for the analytical framework for assessing governance of the health system. They are: strategic vision, participation and consensus orientation, rule of law, transparency, responsiveness, equity and inclusiveness, effectiveness and efficiency, accountability, intelligence and information and ethics (Siddiqi et al., 2009).

Interoperability

Interoperability means the ability to communicate and exchange data accurately, effectively, securely, and consistently with different information technology systems, software applications, and networks in various settings, and exchange data so the clinical or operational purpose and meaning of the data are preserved and unaltered. In the healthcare sector, interoperability is the ability of different information technology systems and software applications to communicate, to exchange medical data accurately, effectively, and consistently, and to use the information related to the patient that has been exchanged. Interoperability can also refer to legal interoperability (i.e., the regulatory issues of cross-border EMR implementations) (Bailey et al., 2008).

A study (Pirnejad et al., 2008) shows that in many studies heterogeneity of information systems and standards are referred as main impediments to building interoperable communication networks, however, social and organizational factors are also paramount. Lack of attention to how the technological artifact will affect and be affected by the organization in which it becomes embedded lies at the core of many technological failures.

Berler et al. illustrated that the integration of information systems represents one of the most urgent priorities of a Regional Healthcare Authority (RHA) in order to meet its clinical, organizational and managerial needs. Current practice shows that the most promising approach to achieve a Regional Healthcare

Information System (RHIS) is to use a HL7 message-based communication system implemented by an asynchronous common communication infrastructure between healthcare sites (Berler et al., 2004).

Strategies and Evaluations of Healthcare Systems

One of the critical aspects of healthcare systems is planning healthcare business strategies, healthcare technology management and diffusion, healthcare system implementation and evaluation, and envisioning and monitoring the impacts of health information technology. The planning aspect involves building a strategic vision to align the goals of senior management with the changing needs of the healthcare marketplace. Planning e-health strategies is crucial because it involves identifying e-consumer needs and business requirements, materializing telemarketing and virtual network management concepts, planning e-data warehouse mining and e-technology strategies, and championing sound methodologies for growing new and complex e-health applications. A major trend in planning e-health strategies is shifting responsibilities and power from traditional health providers and health system analysts to e-consumers, the people who ultimately determine the survival, use, and growth of the e-health business ventures (Tan, 2005).

It is important not only to focus on the impacts of healthcare systems on individuals, groups, communities, and societies, but also to realize how the implementation of healthcare system may ultimately affect the larger context of our healthcare delivery system both nationally and globally. Thus healthcare system implementation and evaluation that includes responsibility for overseeing the integration of health information technologies, the incorporation of transactional activities into the healthcare system, the incorporation of security and privacy mechanisms to ensure user acceptance and satisfaction, and the training and education of users migrating from legacy systems to the healthcare system needs to emphasized (Ammenwerth et al., 2004; Bradshaw & Urquhart, 2005).

CRITICAL ISSUES IN HEALTH INFORMATION SYSTEMS

This section discusses privacy and security issues as well as health ethical issues.

Privacy and Security Issues

Data security and confidentiality of health information are two of the most important concerns in the application of e-health technologies. Security access is a major concern as e-health technologies become available to a huge number of users spread across literally boundless geography. Appropriate firewall protection, data encryption, and password access can all be employed to manage security issues; however, computing viruses are getting more sophisticated as security technology increases.

The healthcare industry has also been facing pressing security challenges in the last few years. For one, EMR, among other systems, provides opportunities for care improvement as well as threats to the privacy of patients' information. Moreover, the Health Insurance Portability and Accountability Act (HIPAA) of 1996 outlines medical security and privacy rules and procedures to be applied by all healthcare providers in order to simplify and protect the administration of healthcare billing (Baumer et al., 2000; Mercuri, 2004). HIPAA aims at securing individuals' PHI (protected health information) and it only covers healthcare providers, health plans, and health care clearinghouses that transmit patient information in electronic form. However, other entities, such as secondary users (for example, researchers) who have access to such data, are not restrictedby HIPAA.

A number of technical protocols and methods have been proposed to resolve security issues. To enhance security, many e-health systems provide secure private channels over the Internet. The Secure Sockets Layer (SSL) protocol and Internet Protocol Security (IPSec) are the most widely used security protocols for PACS security (Dantu et al., 2007).

Privacy concerns are key barriers to the growth of health-based systems. Legislation to protect personal medical information was proposed and put in effect to help building a mutual confidence between various participants in the healthcare domain.

Access control is a preferred method for security management due to flexibility of assigning access privileges to roles rather than to individual users. Thus Wozak et al. showed that end-to-end security must be seen as a holistic security concept, which comprises the following three major parts: authentication and access control, transport security, as well as system security (Wozak et al., 2007).

Health Ethical Issues

Perhaps the most essential ingredient for vibrant e-health development is assurance for citizens and e-healthcare professionals that an e-healthcare system will in fact lead to improved health as opposed to fraud, medical misinformation, abuse of consumer data, marketing of products and services that are of little or questionable value, or e-care services that fail to satisfy their needs. Policies and mechanisms must be created to oversee the development and growth of e-health, including legislation against fraud and unethical practices and for protection of patient privacy and confidentiality of e-patient data (Harman, 2006).

Access to healthcare by low-income population can be hindered by legal barriers to public insurance programs. For example, in the United States federal law bars states from providing Medicaid coverage to immigrants who have been in the country fewer than five years.

EMERGING TRENDS IN HEALTH INFORMATION SYSTEMS

This section identifies seven emerging trends: Web services and semantic Web, Web 2.0, HealthGrid, Voice over IP, u-Health, Evidence-based Health Informatics, and e-health models and services.

Web Services and Semantic Web

Web services are software components or applications, which interact using open XML and Internet technologies. These technologies are used for expressing application logic and information, and for transporting information as messages (Wangler et al., 2003; Turner et al., 2004). Web services offer a platform-neutral interfacing and communication mechanism and have wide infrastructure support in terms of servers and development environments. They have significantly increased interest in Service-oriented architectures (SOAs) (Erl, 2005). The benefits of Web services include loose coupling, ease of integration and ease of accessibility.

In recent years, Web services technology has emerged as a set of standards for publishing, discovering, and composing independent services in an open network. Web services are also increasingly used in health information systems and electronic health records (Altmann et al., 2002; Bergmann et al., 2007; Wright & Sittig, 2008). Nevertheless, the application of SOAs and Web services is currently characterized by an abundance of alternative definitions, approaches and specifications.

Basically, two principle approaches can be applied to Web services (Alonso et al., 2004). The procedural approach focuses on bottom-up application integration. It is based on the architecture of the existing Remote Procedure Call (RPC) middleware, and the current Simple Object Access Protocol (SOAP), Web Service Definition Language (WSDL) and Universal Description, Discovery and Integration (UDDI) specifications. The document-oriented approach focuses on top-down business exchanges, and tries to describe in adequate detail the elements of this exchange, including the technology solutions. It is based on electronic commerce, documents and loosely coupled messaging, and includes specifications such as ebXML. The distinction between these two approaches is not merely related to the different messaging formats enabled by SOAP and WSDL, but rather to the entire design approach of the solutions. Indeed, technologies such as SOAP and WSDL can be used with both approaches (Mykkanen et al., 2007).

Furthermore, there are several overlapping Web services-related specifications available for features such as security, process description, transaction management and electronic contracts, which are required by interoperable complex systems and processes (Turner et al., 2004).

The semantic Web, which is an evolving extension of the World Wide Web, offers a united approach to knowledge management and information processing by using standards to represent machine-interpretable information. Thus semantic Web technology helps computers and people to work better together by giving the contents well-defined meanings. The semantic Web comprises the standards and tools of XML, XML Schema, Resource Description Framework (RDF), RDF Schema, and Web Ontology Language (OWL). The semantic Web has also drawn attention in the medical research communities (Cannoy & Iyer, 2007; Cheung & Stephens, 2009).

An important semantic Web application area is Web services. Semantic Web services aim to describe and implement Web services in order to make them more accessible to automated agents. Semantic web services can support a service description language that can be used to enable an intelligent agent to behave more like a human user in locating suitable Web services.

While the development of Web services and semantic Web has been impressive, numerous research opportunities exist. To realize these benefits, research and practitioner communities need to collaborate on standard and tool development to encourage the exploration and exploitation of semantic web technologies, and service-oriented application development to enhance inter-firm data sharing and collaboration. Ali and Kiefer presented an integrated approach of Web services and semantic Web into the field of medical devices and pervasive computing to build a new breed of medical devices, called Ambient Intelligent (AmI) medical devices. They illustrate the infrastructure, Semantic Medical Devices Space (SMDS), in which AmI medical devices can semantically interoperate not only with each other, but also with the legacy Hospital Information Systems (HISs) and Laboratory Information Systems (LISs) (Ali & Kiefer, 2006).

Web 2.0 Technologies

Web 2.0 refers to Web-oriented applications and services that use the Internet as a platform, with its unique features, relying on its strengths rather than trying to make the Internet suit a particular application. With its promise of a more powerful, engaging, and interactive user experience, Web 2.0 seems poised to revolutionize the way in which we interact with information resources. Web 2.0 is commonly associated with technologies such as weblogs (blogs), social bookmarking, wikis, podcasts, Really Simple Syndication (RSS) feeds (and other forms of many-to-many publishing), social software, and Web application programming interfaces (APIs) (Kristaly et al., 2008).

The collaborative concepts underpinning these Web 2.0 applications are very similar to the notion of Web-based, shareable and distributed electronic health/patient records. Patients and clinicians can securely and simultaneously access these records across multiple institutions and places, facilitating speedy information exchange, communication and collaboration among clinicians and between clinicians and patients to potentially improve clinical outcomes and cost reduction (Boulos & Wheeler, 2007)

Health 2.0 is term representing the possibilities between healthcare, e-health and Web 2.0. Health 2.0 refers to a number of related concepts including telemedicine, electronic medical records, and the use of the Internet by patients themselves such as through message boards, blogs, and other more advanced systems. A key concept is that patients themselves should have greater insight and control into information generated about them.

HealthGrid

A HealthGrid (HealthGrid, 2009) allows the gathering and sharing of many medical, health and clinical records/databanks maintained by disparate hospitals, health organizations, and drug companies. In other words, HealthGrid is an environment in which data of medical interest can be stored and made easily available to different actors in the healthcare system, physicians, allied professions, healthcare centers, administrators and, of course, patients and citizens in general. This large-scale sharing of medical records via network connections has the potential to bring us numerous benefits. It would enable real-time and remote access to large quantities of medical and clinical data regardless of the original healthcare setting in which they were acquired, and regardless of where and when the access is performed. This will, in turn, allow us to improve clinical decisions and diagnoses and to provide better patient care. HealthGrid aggregates longitudinal healthcare data, giving a more complete history of patients no matter where the care was provided and allowing real-time monitoring of trial results and research outcomes as well as early detection of disease and health problems. Applications in Healthgrids include areas such as microarray analysis, image analysis, in silico simulation, distributed database integration, and data mining, among others. HealthGrid is expected to reduce costs and improve healthcare efficiency (Breton et al., 2007). SHARE (Olive et al., 2009) was funded by the European Commission to define a research roadmap for a "HealthGrid for Europe," to be seen as the preferred infrastructure for biomedical and healthcare projects in the European Research Area.

Voice Over IP

Voice over Internet Protocol (VoIP) technologies have continued to evolve, including establishment of several important standards. The integration of different modes of communication is already happening and the increasing reliability of the network will foster the rate of adoption of VoIP. The driving forces for the individual and commercial adoption of the VoIP are the significant cost savings, portability, and functionality that can be realized by switching some or all of their voice services to VoIP. Chen et al showed the integration of mobile health information system with VoIP technology in a wireless hospital (Chen et al., 2008). However, there are risks associated with VoIP services, which may impact quality and security of the phone system for voice communications. If the VoIP user connects through an open wireless hotspot, there is also an increased risk of eavesdropping.

As VoIP technology and IP communication technology are still in an early stage, it would be interesting to investigate what factors are drivers and inhibitors for the adoption of these new technologies by firms and users, what value they create for health organizations, and how the technological features interact with users' characteristics.

Ubiquitous Computing and U-Health

Ubiquitous computing is a paradigm shift where technology becomes virtually invisible in our lives. The advancement of new technologies such as radio frequency identification (RFID) and sensor networks has initiated a trend towards ubiquitous computing, which is also called "anytime, anywhere" computing (Lyytinen et al., 2004). With the advent of the Internet and wireless technology, a worldwide communication system is available, enabling people to communicate at any time and anywhere and to exchange information online. Due to "anytime, anywhere" pervasive computing, organizational activities become more nomadic. The ubiquitous computing environment will make possible new forms of organizing, communicating, working and living. However, ubiquitous computing systems create new risks to security and privacy.

In general, u-healthcare can be divided into three sections depending on the transfer range of the patients' information: u-healthcare within medial institutions, between individuals and medical institutions, and among different medical institutions (Lee et al., 2009). Currently, newly built and large hospitals are trying to operate these hospital information systems by focusing on hospital information systems such as order communication systems (OCS), PACS, EMR, visual information system, and groupware.

In a ubiquitous computing environment, it is important that all applications and middleware should be executed on an embedded system. To organize the u-healthcare infrastructure, it is necessary to establish a context-aware framework appropriate for the wearable computer or small-sized portable personal computer in ubiquitous environment (Ko et al., 2007).

Evidence-Based Health Informatics

Evidence-based Health Informatics (EBHI) can be defined as the conscientious, explicit and judicious use of current best evidence when making decisions about the introduction and operation of IT in a given healthcare setting. Thus EBHI means integrating individual IT expertise with best available external evidence from systematic health informatics research. It has been argued that EBHI is an important step towards better healthcare IT.

Ammenwerth et al. discussed challenges found while conducting meta-analysis on computerized physician order entry (CPOE) and finally concluded that Evidence-Based Health Informatics is still in the beginning stage (Ammenwerth et al., 2009).

E-health Models and Services

E-health models and services can be various types such as Business-to-Consumer (B2C) and Business-to-Business (B2B) (Wen & Tan, 2005).

B2C models and services are among the most widely accepted and practiced service models currently proliferating the e-health marketplace. Examples include the following: virtual doctor visits, e-prescriptions, on-line medical suppliers, e-disease management, and health insurance services. B2B models and services include on-line medical suppliers, hospital and physician procurement, health insurance services, and automated services.

An emerging set of applications has been characterized by efforts to connecting e-consumers (consumer-to-consumer, or C2C) or e-providers (provider-to-provider, or P2P). The P2P model is a subset of the B2B models. Hybrids (for example, combinations of B2B and B2C; C2C and P2P; or B2C and C2C) and other models are used in the following applications and services: EMRs, connecting e-stakeholders, e-directories, medical digital libraries, on-line auctions, stakeholder health portals, and communities of e-health learners.

CONCLUSION

The aim of this chapter was to reflect on the past and current health information system (HIS) research trends and technological advancements and to identify emerging trends and research issues in HIS.

The foremost observations to be drawn from the previous studies include: (1) the realization of operational and strategic benefits was found to be contingent upon effective adaptation of health information system innovation, top management challenge, strategic planning rationale, and the extent of coordination; (2) the traditional ICT development methodologies and infrastructure became deficient in supporting the complex capabilities of emerging healthcare applications; (3) privacy and security issues as well as ethical issues are critical for the success of health information systems; (4) m-health has enormous potential to become a dominant form of market mechanism; (5) virtual communities and globalization have potential to become prominent e-health business models structured around user interests and needs. These observations should be taken into account in the design of future research in emerging trends in e-health systems.

About the Editor

Joel J. P. C. Rodrigues is a Professor at the Department of Informatics of the University of Beira Interior, Covilhã, Portugal, and researcher at the Institute of Telecommunications (IT), Portugal. He received a PhD degree in Informatics Engineering and a MSc degree from the University of Beira Interior, Portugal, and a 5-year B.S. degree (licentiate) in Informatics Engineering from University of Coimbra, Portugal. His main research interests include e-health, vehicular delay tolerant networks, sensor networks, body sensor networks, high-speed networks, e-Learning technologies, information and knowledge management, mobile and ubiquitous computing, and supervising several PhD and Master of Science candidates in these areas. He participated in several PhD and MSc juries. He has authored or co-authored over 80 papers in refereed international journals and conferences, book chapters, a book and a patent. He is the leader of NetGNA Research Group from IT (http://netgna.it.ubi.pt) and the founder and leader of the IEEE ComSoc CSIM Special Interest Group on Modeling and Simulation Tools (http://mst.it.ubi.pt). He is the Secretary of the IEEE ComSoc Technical Committee on Communications Software and the Secretary of the IEEE ComSoc Technical Sub-Committee on eHealth. He is member of many IARIA Workgroups and ComSoc Technical Committees related with his research areas and regularly participates on their meetings. Joel is the Editor-in-Chief of the *International Journal of E-Health and Medical Communications* (from IGI Global), and he has served as a guest editor for a number of journals including the *Journal of Communications* and the *Journal of Communications Software and Systems*. He is Co-chair of the Communications Software, Services and Multimedia Applications Symposium (CSSMA) at IEEE Globecom 2010, Organizer and General Chair of the IEEE ICC 2009 Workshop on Medical Applications Networking (http://man.it.ubi.pt/), Chair of the Symposium on Ad-Hoc and Sensor Networks of the SoftCom Conference, Workshop Program Chair of the 2009 International Workshop on Wireless Multimedia Computing and Security Services (WIMUCS 2009), Workshop Program Chair of the 2009 International Workshop on Network Assurance and Security Services in Ubiquitous Environments (NASSUE-2009), TPC Chair of IARIA International Conference on Communication Theory, Reliability, and Quality of Service (CTRQ 2008, CTRQ 2009), and chaired other conferences committees in the recent past years. He is and was member of many international program committees (IEEE ICC, IEEE Globecom, IEEE WCNC, IEEE CCNC, IEEE ISCC, IEEE ICCCN, ICTTA, SoftCOM, CTRQ, ICN, ICNS, ACHI, CONTENT, PATTERNS, ECUMN, ICSNC, CENTRIC, MMEDIA, SENSORCOMM, IPC, IWT, SSDU, CNSR, NGI, WLN, IPC, NGMAST, etc.) and several editorial review boards (*IEEE Communications Magazine*, *Journal of Communications Software and Systems*, *International Journal of Communications Systems*, *International Journal of Business Data Communications and Networking*, *IARIA International Journal On Advances in Life Sciences*, *IARIA International Journal On Advances in Internet Technology*, *IARIA International Journal On Advances in Telecommunications*, etc.). He chaired many technical sessions and gave tutorials at major international conferences. He is a licensed Professional Engineer and he is member of the ACM SIGCOMM, a member of the Internet Society, and a Senior Member IEEE Computer Society, IEEE Communications Society and IEEE Education Society, and an IARIA Fellow.

Section I

Fundamental Concepts and Theories

This section serves as the foundation for this exhaustive reference tool by addressing crucial theories essential to the understanding of health information systems. Chapters found within these pages provide an excellent framework in which to position health information systems within the field of information science and technology. Individual contributions provide overviews of the future of e-health, telemedicine barriers, electronic health records, and data protection. Within this introductory section, the reader can learn and choose from a compendium of expert research on the elemental theories underscoring health information systems research

Chapter 1.1

Inventing the Future of E-Health

José Aurelio Medina-Garrido
University of Cadiz, Spain

María José Crisóstomo-Acevedo
Jerez Hospital, Spain

INTRODUCTION

E-health involves the use of information and communications technologies to improve health in general and the healthcare system in particular (Alvarez, 2002; Chau & Hu, 2004; Roger & Pendharkar, 2000).

Healthcare, one of the largest industries in the world, suffers from some inefficiencies and inequities in both service provision and quality. Some of these problems are due to the poor management of the information flows (Kirsch, 2002). In this respect, there are business opportunities for e-health. But to understand what the future holds for e-health, we need to find a precise definition of the concept and identify the possible sources of business.

This article is structured as follows. The second section, the background, defines the concept of e-health. The third section outlines some of the business opportunities in the area of e-health based on the communications platform that is the Internet, and discusses some practical guidelines for e-health businesses to create value. The fourth section discusses the low level of adoption of e-health at present, as well as the future trends, in which e-health will presumably grow. e-health is also expected to be used to reduce the disparities in the population in access to healthcare, and for the treatment of the chronically ill. The fifth section is dedicated to the final conclusions.

DOI: 10.4018/978-1-60566-026-4.ch355

BACKGROUND

The term *e-health* is relatively recent and refers to healthcare practice that is supported by electronic processes and communications. The term has many definitions, depending on the functions, stakeholders, context, or the theoretical framework referred to. It includes a wide range of medical informatics applications, both specific (for example, decision support systems, citizen health information) and general (for example, management systems, healthcare services provision, etc.). But the increased importance of the communication function in e-health, and the use of electronic networks (particularly the Internet), differentiate e-health from traditional medical informatics (Pagliari, 2005).

Thus, e-health goes beyond healthcare informatics and incorporates the most advanced information technologies to medicine and healthcare. Among the most significant applications of the technologies to healthcare are the following:

- **Electronic medical records,** which allow different healthcare professionals to share information about a particular patient.
- *Telemedicine*, which uses information and communications technology (ICT) to enable physician-patient contact at a distance.
- **Evidence-based medicine,** in which a system updates information about the most appropriate treatments for each patient, thereby enhancing physicians' treatment possibilities.
- **Citizen-oriented information,** through which citizens are provided with information about health topics.
- **Specialist-oriented information,** whereby a system distributes information to specialists about medical journal articles, practices and protocols in the area of health, new medical advances, epidemiological alerts, etc.
- **Virtual healthcare teams**, made up of healthcare professionals sharing information about patients electronically to improve their knowledge and decision-making.
- **Health e-commerce,** which involves providing value-added electronic services to both professionals and citizens, and economically exploiting some or all of the services. In this respect, e-health is supported by the Internet and related technologies and combines medical informatics, public health, and business. This type of e-health does not exclude the previous ones. To the contrary, it includes them or complements them. The following section discusses the concept of Health e-commerce, indicating what types there are, what they consist of, and how they obtain their revenues.

Some authors go further than the concepts explained in this section and predict a change of mentality and culture among both citizens and practitioners. One author goes so far as to argue that e-health "..characterizes not only a technical development, but also a state-of-mind, a way of thinking, an attitude, and a commitment for networked, global thinking, to improve healthcare locally, regionally, and worldwide by using information and communication technology" (Eysenbach, 2001).

BUSINESS OPPORTUNITIES BASED ON E-HEALTH

As we mentioned above, the inadequate management that a large part of the healthcare sector makes of its information flows (Kirsch, 2002) and processes, as well as the new advantages offered by present-day ICT, mean that e-health opens up significant business opportunities.

One of the most notable business opportunities offered by e-health is e-commerce. The most important forms that *e-commerce* can adopt on the Internet include (Parente, 2000): portals, connectivity sites, business-to-business applications, and business-to-consumer applications.

Portals dedicated to health tend to provide all types of information, guidance, and medical advice to consumers and professionals. Portals generally represent starting points for consumers, offering them various online activities as well as diverse information. Their general objective is to be the first place that customers go to when they are looking for something on the Internet. For this, they need to establish a brand that attracts visits and creates loyal customers. Their main sources of income come from the advertising they contain and occasionally from users' subscriptions.

Table 1. Examples of business models in e-health (Source: Adapted from Parente (2000))

Portal	Connectivity	B2B	B2C
Medscape drkoop.com OnHealth HealthGrades.com	Healtheon/WebMD TriZetto XCare.net Claimsnet.com	Neoforma.com Medical Manager Allscripts eBenx	drugstore.com PlanetRx HealthExtras

Sites dedicated to facilitating connectivity in the healthcare sector have the objective of linking and integrating the various information systems seamlessly. The income of this business model comes from the company's external users, who pay fees to obtain information. Health e-commerce connectivity initiatives involve accessing electronic medical records on the Internet, evaluating the quality of providers according to their clinical results, and using quality information in the selection of physicians. For example, some hospitals provide their patients with directories of their physicians on the Internet, which are searchable by zip code and clinical specialty (Coile, 2000). Because these sites obtain their revenues from the fees generated by each information transaction, their objective is to maximize the number of transactions. These companies obtain transaction fees from health plan providers, physicians, hospitals, clinical laboratories, pharmacies, consumers, and companies offering financial, marketing, or delivery services in the healthcare sector.

Business-to-business (B2B) e-commerce involves selling products and services to other firms on the Internet. The income from this business model comes from the sale of the product or service itself. *B2B Health e-commerce* includes businesses dedicated to selling refurbished medical equipment or pharmaceutical refills on the Internet. Indeed, pharmaceutical refills are a large market with a high turnover, and are ideally suited to be traded on the Internet at competitive prices offering next-day home delivery (Coile, 2000). Apart from the products sold in this way, some companies are now beginning to offer services such as online management consultancy.

Business-to-consumer (B2C) e-commerce sells products and services directly to the consumer via the Internet. As in the previous model, the income comes from the sales themselves. The B2C business model in the healthcare area allows consumers to acquire products and services such as health insurance, prescription drug refills, over-the-counter drugs, medical supplies for the chronically ill, vitamins, homeopathic medicines, and home fitness equipment (Coile, 2000).

Table 1 shows examples of some of the most important firms in the e-health sector. The firms are classified under the business model that most closely matches their main activities or sources of income. But the limits are often hazy, and the firms can often be classified in more than one category.

After the bursting of the Internet bubble it became clear that an e-business, such as one based on e-health, should in the first place be a business venture, and not just a technological one. e-health firms are businesses, and so they must seek to create value. In this respect, some authors offer *practical guidelines to e-businesses* about how to generate value (Earle and Keen, 2000; Shapiro and Varian, 1999), and these are also valid for the particular case of e-health:

- Cultivate stable relationships with customers. Building a critical mass of loyal customers allows firms to avoid customer acquisition costs for each transaction. The idea is to build solid relationships with strong ties. For this reason, some firms offer some services for free on their Web sites.

- Build a powerful brand. The concept of brand is redefined on the Internet. It is a relationship brand. Customers cannot see the product or service until they pay for it. Thus, e-health firms need to have a good reputation. This reputation, which takes substantial time and money to build, can be quickly acquired working together or allying with another firm that already has a good reputation.•
- Improve the logistics. This is important for e-health firms that distribute physical products such as medical equipment or drugs. Logistics capabilities are critical for the generation of value. But some firms have opted to focus on those core activities they know how to do well, in order not to spread efforts or resources too thinly, and have allied with top logistics firms that can undertake this function.
- Harmonize the channels in the name of the customer. Customers choose the communication channel that offers them most advantages. Firms need to provide the option that best helps to build and maintain the relationship, and that choice is for the customer to make, not the firm. In this respect, customers need to be offered a number of communications channels (Web forms, e-mail, telephone, fax, post, cell phone SMS, personal digital assistants (PDAs), a combination of physical and virtual branches, etc.).
- Become an intermediary that provides value, or use one that does. Business on the Internet is dominated by nerve centers such as portals with powerful brands and other intermediaries that bring the supply and the demand together. These will control the interaction between providers and customers, and will advise customers about the Web sites they should visit when looking for a particular product or service. Only the intermediaries that offer consumers or firms value will survive and prosper. Intermediaries that do not provide value must use one that does if they wish to be profitable.
- Analyze how much the firm invests in producing and selling information. Information is expensive to produce, but extremely cheap to copy. In this respect, trading data electronically allows firms to distribute information enjoying economies of scale, which means they can cut unit costs and consequently the price of their product or service.
- When firms compete in commodity markets they need to create economies of scale that cut costs (and prices), be flexible to adapt to any change and quick, both to enter a market and exploit the business opportunity and to exit when this is no longer profitable.

FUTURE TRENDS

E-health tools show plenty of potential, but they are relatively undeveloped and have not yet been adopted to a great extent (Wilson, 2005). Some authors have predicted that some of the new technologies applicable to e-health will be adopted very quickly and massively (for example, telemedicine or PDAs), but there remain problems in this respect. Occasionally, the main *source of income of the business model* has seen undermining. This has been the case, for example, of the supply of information to the consumer, as they are not used to paying for this. On the other hand, some technologies do not have a large enough potential market to grow very quickly, for example, applications for supply-chain management (SCM) or procurement. Consequently, firms do not find them so attractive to invest in (Kirsch, 2002).

Electronic medical records are also expected to take off in the future. No paperless hospitals can be found just yet, but some authors predict that some hospitals will be completely paperless in the not-too-distant future (Coile, 2000). If these predictions prove right, extreme care will be needed to protect patients' privacy and interests.

A proper implementation of *e-health will require political commitment*, an adequate legal framework, and R&D and Innovation (Wilson, 2005). The political commitment should be reflected in the development of electronic health cards and health information networks and online health services. The legal framework must offer adequate coverage in terms of data protection, digital signatures, e-commerce regulations, and the professional qualifications required to use telemedical applications. The R&D and Innovation needs to promote the development of new technological tools and help to spread best practices in this new field.

Another potential future trend for *e-health is to apply information and communications technologies to reduce the disparities in the population* in access to the healthcare system (Ahern, Kreslake, & Phalen, 2006; Cashen, Dykes, & Gerber, 2004; Gibbons, 2005). Demographic and socio-economic factors are arguably behind these disparities, such as: ethnic origin (whites vs. minorities), geographic (urban vs. rural) (Galea & Vlahov, 2005), gender (masculine vs. feminine) (Mcgrath & Puzan, 2004; Quinn & Overbaugh, 2005), income level (poor vs. non-poor) (Federico & Liu, 2003), and age (elderly vs. non-elderly) (Pyle & Stoller, 2003).

In the future, *e-health is also expected to increasingly facilitate the treatment and monitoring of patients with chronic illnesses* (Ahern, Kreslake & Phalen, 2006). This will reduce the constant and inconvenient traveling to and from medical centers that these patients are subjected to, not to mention the healthcare system's work overload in this respect.

CONCLUSION

E-health will lead to a behavior change in the area of healthcare, through which the use of information technologies, the Internet and communications technologies enable improved and more effective healthcare (Eng, 2002).

One of the main areas of interest in e-health is to improve health communications by using technologies. In this respect, both healthcare organizations and public healthcare agencies are increasingly using the Internet in their communications and to transfer information.

These efforts are generating various socio-economic phenomena, in particular e-health as a business opportunity – the chance to create an e-business. Four models familiar from traditional e-businesses have also been adopted by e-health businesses: portals, connectivity sites, business-to-business applications, and business-to-consumer applications.

Although more attention is commonly paid to technological questions, we must also remember that an e-business is first of all a business. E-health businesses, as businesses, need to create value for their customers. In this respect, they are advised to cultivate stable relationships with their customers, build a powerful brand, consider the logistics carefully, offer a number of channels to their customers, be an intermediary that provides value, seek economies of scale when they produce and sell information, and be quick and flexible and create economies of scale when they compete in commodity markets.

At present, e-health activities are defusing only gradually, and have been slow to be accepted. But a greater development is forecast for the future; in particular, we will conceivably see phenomena such as paperless hospitals and a more complete coverage of the population's healthcare needs (education about health, treatment of chronically ill patients, and reduction in the disparities in access to healthcare).

KEY TERMS AND DEFINITIONS

Business-to-Business (B2B) E-Commerce: Economic transactions between firms using information systems and technologies.

Business-to-Consumer (B2C) E-Commerce: Commercial transactions and activities between firms and the end-consumer using information systems and technologies.

Commodities: Raw materials, unfinished products, or products sold loose, or any other product characterized by being undifferentiated. Such products cannot be differentiated from other products in function of the producer that manufactures them or the supplier that sells them.

E-Health: The provision of any healthcare service that is supported by electronic processes and communications.

Electronic Medical Records: Computer-based patient medical records. Patient medical records are a systematic documentation of a patient's medical history and care.

Evidence-Based Medicine: Medical practice involving the sharing, updating and consultation of a system containing information about the most appropriate treatments for each patient. This helps to improve the treatments chosen by the physicians who use this system.

Health E-Commerce: E-business based on the economic exploitation of health-related information and services.

Health Plan: An individual or group plan that provides, or pays the cost of, medical care.

Over-the-Counter (OTC) Medicine: A medicine that can be bought without a doctor's prescription, such as some analgesics.

Telemedicine: The use of information and communications technologies to exchange information between practitioners, or to deliver medical services to a patient remotely.

Virtual Healthcare Teams: Teams made up of healthcare professionals that share information about patients electronically in order to improve their knowledge and decision-making.

Chapter 1.2

Multi-Dimensional Criteria for the Evaluation of E-Health Services

Alalwany Hamid
Brunel University, UK

Alshawi Sarmad
Brunel University, UK

ABSTRACT

E-health is an emerging field in the intersection of information systems, healthcare and business, referring mainly to healthcare services delivered and enhanced through the use of information and communication technologies (ICT). An important area of research is the evaluation of e-health services. A holistic e-health evaluation framework should address the aspects that are hampering healthcare services from embracing the full potential of ICT towards successful e-health initiatives. In order to build a holistic evaluation framework for e-health services, this article suggests framework characteristics for the appropriate evaluation for e-health services. The article argues that e-health services evaluation framework should be criteria based. The criteria have to be multi-dimensional that grounded in, or derived from, one or more specific perspectives or theories. The proposed evaluation criteria in this article can serve as part of an e-health evaluation framework, improve our understanding of the role of information systems in health care, and develop our ability to deliver high quality services. [Article copies are available for purchase from InfoSci-on-Demand.com]

BACKGROUND

E-health is a very broad term encompassing various activities in an evolving field. This is reflected in the broad and various definitions of the term. An example of these definitions is the one that has been adopted by the World Health Organization. According to the Organisation, E-health can be defined as ‘being the leveraging of the information and communication technology (ICT) to connect provider and patients and governments;

to educate and inform healthcare professionals, managers and consumers; to stimulate innovation in care delivery and health system management; and, to improve our healthcare system' (Hans Oh et al., 2005).

The variety of e-health applications is considerable, ranging from a self-help guide about treating common health problems at home to a virtual clinic which allows diagnostic consultations between patients and practitioners at separate sites. In light of the dynamic and evolving meaning of e-health concept and the wide range of applications that the term e-health has covered, the questions are what the term e-health means and what is the e-health application that should be considered. In this paper although we employ e-health as a broad term, the scope will be limited to the service delivery aspect by electronic means of information, advice, and consultation.

E-health, which are basically enabled and driven by the use of information and communication technologies in healthcare, have the potential to change the healthcare industry worldwide in terms of their infrastructures, and the costs and quality of services (Wickramasinghe & Misra, 2004; Wickramasinghe & Goldberg, 2004). Despite the potential that e-health may bring to the healthcare sector, the sector is the slowest in moving to the form of e-health among other government services. Skinner (2003) argues that the slow progress is related to the fact that healthcare does not have the standards in place that other sectors do. Holliday and Tam (2004) have a broader explanation; they see that slow progress is more related to institutional, cultural and financial factors.

An important area of research is that of the evaluation of e-health services. It could contribute to important knowledge that can be used to support the value of existing e-health projects, and to increase the quality and efficiency of future e-health initiatives. Despite its importance, the evaluation of e-health services as many researchers agree, is both an under developed and under managed area in theory and practice (Brender, 2006; Friedman & Wyatt, 2000).

This study forms a part of a research that aims to develop, and assess a holistic evaluation framework for e-health services. Towards this aim, the objectives of this paper are; addressing the challenges in developing such a framework, suggesting framework characteristics for the appropriate evaluation for e-health services, and proposing a multi dimensional criteria for e-health evaluation. The proposed multi-dimensional criteria can serve as part of e-health evaluation framework, and also to provide useful and necessary tools to allow the development of successful e-health initiatives by assisting the healthcare organisation to identify and thus address areas that require further attention. The selection process of the proposed criteria will take into account the challenges faced at the intersection of the three areas, healthcare services, information systems, and evaluation methodologies.

THE RESEARCH APPROACH

According to Lowery & Evans (2004) and Myers & Avison (2002) that selecting an appropriate research approach is about setting a research strategy considering the underlying characteristics or assumptions about what constitutes valid research. Such strategy should guide the researcher through the research process by embodying a particular style and employing different research methods.

The process of selecting and deploying appropriate research approach for this study, is an important and critical issue, and should only be decided on after considering a number of factors including;

- The research question and its context (how to identify the key factors for the evaluation of e-health services?)

- The multi-dimensional aspects of e-health, as it has different roots and complex relationships associated with using information communications technologies, management as well as health regulations, and governments policies.
- The large number of stakeholders involve in e-health evaluation, each with their own particular needs, values and objectives.

As this study forms a part of a research project which will progress through a number of phases, the research will be based on a sequential multi-method approach (Creswell, 2003). Adopting the sequential multi-method approach paves the way to the use of the appropriate method for each research phase and creates the opportunity for multiple analyses about the same collected data.

This study represents one phase of the research project, and will be based partially on two lines of studies relating to the behaviour of users of new products or services. These studies are: diffusion of innovations (Rogers, 1995) and technology acceptance (Davis, 1989). The aim of using both studies is to build theoretical framework that aids in the selection process of the multi dimensional criteria. Broad examining and critical analysis of the existing evaluations initiatives specifically those who were based on e-health services case studies was also used to overcome the limitation of the theoretical framework.

In the next phase of the research project the authors will carry out an empirical validation and examination of the proposed evaluation criteria, the validation will be performed through case study methodology (Yin, 2003). This process is very important; it will address potential improvements, and verify the adaptability of the proposed criteria to various e-health contexts.

E-HEALTH EVALUATION CHALLENGES

The research in the area of e-health evaluation is a complicated and difficult subject (Brender, 2006; Friedman & Wyatt, 2000). The complexity and difficulty lies in the challenges encountered at the intersection of three research fields, each well-known for its complexity; healthcare services, information systems, and evaluation methodologies.

Healthcare services are characterized by having many stakeholders which are working in different disciplines and pursuing different goals (Alvarez, 2003; Connell & Young, 2007; Ray, 2007). Healthcare services are also dictated by complex regulations, especially those that apply to directly manage patients' information. The medical knowledge itself and methods of healthcare delivery are changing rapidly and require a high degree of formalized working practices (Friedman & Wyatt, 2000). The regulations of healthcare services particularly in developed countries is complex in its diversity and wide ranging in its scope, ruling the relation with patients, health professionals, the public, taxpayers, employers, educators, regulators, and many others across the country. The medical knowledge is an enormous and dynamic field, Mcconaghy (2006) states that the medical knowledge doubles approximately every five years. Moreover the main aspects of this knowledge require an interactive environment to be transferred or practiced.

Information systems and its evaluation as many researcher (Serafeimidis & Smithson, 2000; Jones & Hughes, 2001) assent is another complicated and difficult research field. Symons and Walsham (1988) argue that the complexity is due to the multiple perspectives involved, and the difficulties of quantifying benefits. Willcocks (1992) has a similar view but he also believes that the complexity of information systems evaluation is changing and becoming more and more complex nowadays. This is because the nature of information systems investments is changing both in terms of technological capability and the benefits they can deliver, as well as in terms of diffusion in most aspects of society. The evaluation of information systems in public sector has proved to be even more complex as an accurate evaluation requires conducting the evaluation process in more challenging context. To overcome the complexity and difficulty of information systems evaluation in public sector, it is necessary to address and consider a number of evaluation challenges in the development of the required evaluation framework. The first of these challenges is the investigation of various perspectives (Jansen, 2005), which may not only require addressing and meeting the general needs of a target group such as citizens, but also requires including the specific needs of the specific target groups of citizens that are using a particular service. The second challenge in evaluating information systems in public sector is in identifying and quantifying benefits. Beynon-Davies, (2005) states that it is difficult to determine the precise benefits associated with information systems in public sector. An explanation to this lies in the different goals and objective of the information systems investments in public sectors, the benefits gained by these initiatives will be different as well, and the assessment of these benefits also vary according to the different perspectives of the stakeholders for the value of these benefits. The third challenge in evaluating information systems in public sector is the fact that in order for the evaluation to be proper, it should consider the social and technical context of use. This is a result of the opinion that information systems research is as much a social science as an information systems science (Mingers & Stowell, 1997).

The establishment of an evaluation methodology is the last complex and difficult research field. The field is suffering from the limited experience of using methods, the unfamiliarity with evaluation techniques and the difficulty in interpreting results (Ballantine et al., 1999; Farbey et al., 1999; Powell, 1999). The limited experience of using methods in e-health evaluation is related to a certain extent to the gap between the theory and practice. Eng (2002) argues that this gap is a result of the tension between e-health research efforts in academic institutions and commercial organizations. He believes that the academic sector succeeds in developing scientifically rigorous evaluation methodologies, but these methodologies are not designed to answer real-world concerns. On the other hand, when commercial organizations conduct evaluations of e-health applications, they usually adopt methodologies with limited applicability to other situations. In adopting such methodologies, they maintain obtaining quick and practical answers because of market pressures.

Table 1 summarizes the challenges encountered at the intersection of healthcare services, information systems, and evaluation methodologies.

DEVELOPING AN EVALUATION FRAMEWORK FOR E-HEALTH SERVICES

The evaluation in the area of e-health services as many researchers argue, is dominated by economic and organizational aspects, has no standard framework for evaluating the effects and outputs of implementation and use, and the area in general is both under developed and under managed in theory and practice (Brender, 2006; Eng, 2001; Friedman & Wyatt 2000; Rahimi & Vimarlund, 2007). Nevertheless, there is a wide range of information system evaluation frameworks, some of them were proposed and used in a healthcare context.

Existing evaluation frameworks that have been proposed or used in e-health context are suffering from many limitations. These limitations include, that they are either designed to focus particularly on the supply side of the healthcare

Table 1. The challenges encountered at the intersection of healthcare services, information systems, and evaluation methodologies

The Research Field	The challenges Encountered	References
Healthcare Services	• Healthcare services are characterized by having many stakeholders which are working in different disciplines and pursuing different goals. • Healthcare services are dictated by complex regulations. • The medical knowledge is an enormous and dynamic field. • The main aspects of medical knowledge require an interactive environment to be transferred or practiced.	Alvarez (2003) Connell and Young (2007) Ray (2007) Friedman and Wyatt (2000) Mcconaghy (2006)
Information Systems	• The multiple perspectives involved. • The difficulties of quantifying benefits. • The nature of information systems investments is changing both in terms of technological capability and the benefits they can deliver, as well as in terms of diffusion in most aspects of society. • Consider the social and technical context of use.	Walsham (1993) Beynon-Davies (2005) Jansen (2005) Willcocks (1992) Mingers, and Stowell (1997)
Evaluation Methodologies	• The limited experience of using methods. • The unfamiliarity with evaluation techniques. • The difficulty in interpreting results.	Ballantine et al. (1999) Eng (2002) Farbey et al. (1999) Powell (1999)

services (organizational perspective) or they are designed to target a specific user or a specific application of an e-health initiative. Moreover, the healthcare dimension is either ignored or not fully considered in the design and the implementation of these evaluation frameworks.

Though the development of a comprehensive evaluation framework for e-health services is beyond the remit of this study, it is vital to examine the current evaluation frameworks in order to choose the appropriate evaluation approach and select the suitable framework that can accommodate the proposed criteria. We have selected for our analysis a number of evaluation approaches that we believe are more suitable for the evaluation in the healthcare context.

One of these approaches is focused mainly on the evaluation criteria, which can be called criteria-based evaluation approach. What is typical for this approach is that the information systems interface and the interaction between users and the systems work as a basis for the evaluation together with a set of predefined criteria. The chosen criteria rule the evaluation process and its results (Cronholm & Goldkuhl, 2003). In the same direction and based on what drives the evaluation, Cronholm and Goldkuhl (2003) identified another two approaches named goal-based and goal-free evaluations. The goal-based evaluations use goals from the organisational context to assess the information system. Goal-free evaluation is based on gathering data about a broad range of actual effects of the system and evaluating the importance of these effects in meeting demonstrated needs (Patton, 1990). Among the three previous approaches, the criteria based one is the most appropriate for e-health services evaluations. The appropriateness stems from the fact that e-health applications are principally complex in nature, hence they require an approach that can be derived from a multitude of perspectives and theories such as TAM or DOI.

Another group of evaluation approaches were introduced to address one or more of the perspectives of the system stakeholders. Freeman (1984) was among the first, who introduced the stakeholders' concept. Since then, several researchers have adopted the stakeholders approach in their research of information systems evaluation. However, there is only limited literature that recognizes healthcare stakeholders and their changing role in the evaluation of e-health services.

Moreover, even in the limited literature available on healthcare stakeholders, the description and identification of these stakeholders seems to be generally ignored (Mantzana & Themistocleous, 2006).

One of the popular and general approaches in categorizing e-health stakeholders is dividing them between supply side stakeholders (organizational perspective) and demand side stakeholders (users' perspective). According to Löfstedt (2007) most research in the area of e-government, and also in the development of e-services in public sector is dominated by supply side factors and there where none or a few efforts that focused on the demand side. Gustafson and Wyatt, 2004, acknowledged the dominant of supply side factors in the field of e-health as well. They stated that despite the fact that users are the most important stakeholder in the e-health evaluation, assessing e-health from users' perspective and addressing the key factors that influence the users' acceptance to the new adopted technologies is still lacking behind.

For practical reasons this study will focus on the demand side stakeholders. We believe that the acceptance and satisfaction of e-health services are dependent primarily on users' motivation to adopt and utilize these services, user utilization being important for the success of e-health services.

The stakeholder's evaluation approach is part of the school which suggested five levels of evaluation approaches for healthcare information systems, which are macro, sector, firm, application, and stakeholder. This suggests that different criteria would inevitably apply to each of these approaches (Connell & Young, 2007).

There is also another group of evaluation studies which is defined by the basis on which the evaluation is performed. In this direction Grover et al. (1996) categorize three approaches: Comparative, normative and improvement. In the comparative approach, the evaluation is based on comparing a particular system with other similar systems. The normative approach compares the system against a theoretical ideal system or, in essence, against best practice. The improvement approach is intended to assess how much the system has improved over time. In this study we intend to use only the comparative and normative approaches because the main aim is toward proposing evaluation criteria for proposed implementations rather than historical ones.

Furthermore, another group of evaluation studies classified evaluations based on when the assessment is performed (Brender, 2006; Cronholm & Goldkuhl, 2003; Grover et al., 1996). According to these studies the evaluation can be carried out during the analysis and planning phase, or during the development and the adaptation phases, or after the development has completed and the system is in use. An example of this kind of evaluation is process evaluation approach which is intended to evaluate the efficient use of resources, and is normally performed during the analysis and planning phase. There is also the response evaluation approach which assesses the users reaction to the system, and is usually performed during the final stage of implementation, or while the system is in use. The equity implementation model presented by Lauer et al. (2000) is an example of the response evaluation approach. The model was based on the equity theory (Adams, 1965), a well-established theory in the social sciences and was adopted in e-health assessments to examine and understand user reaction to the implementation of a system. Lauer et al. (2000) stated that the focus of this approach is on the effect of the changes that such a system brings about on the system users.

The last example in this group is the impact evaluation approach, which is intended to assess the overall social and technical impact of the system on users and organisations, and is normally performed while the system is in use. According to Grover et al. (1996), because the impact evaluation is the most comprehensive, it is the most difficult approach to undertake. The impact evaluation approach can be quite beneficial in evaluating e-health services because it would comprehensively recognize users and organisations needs, by measuring the acceptability as well as the risks and benefits of e-health services (Gustafson & Wyatt, 2004). In this study, the focus will be on the criteria that influence the user's reaction to the e-health services and the social, economical and technical effects of these services.

To conclude, we suggest that the appropriate evaluation framework for e-health services which can accommodate the proposed evaluation criteria would have the following characteristics:

- The framework has to be sufficiently generic to be applicable to a wide range of applications but also sufficiently detailed to provide effective guidance
- The framework has to support the evaluator in making precise and effective choices at various stages of the evaluation process
- The framework is criteria-based. The criteria can be grounded in, and derived from, one or more specific perspectives or theories
- The framework only considers one stakeholder or a group of stallholders with a common perspective in an evaluation process. For example, as in the case of this study, the framework may consider the demand side perspective and specifically the criteria that influence the user's reaction to e-health services, and the impact of these services on the users
- The framework combines both comparative and normative approaches toward proposing evaluation criteria for e-health services.

USERS' BEHAVIOUR TOWARDS NEW PRODUCTS OR SERVICES

There are many studies on the behaviour of consumers of new products and services, these studies were adopted in research to predict user's acceptance of innovations including e-health services. Towards aiding the selection process of the multi-dimensional evaluation criteria, this study will make use of two lines of these studies

The first one is Diffusion of Innovations Theory (DOI). DOI is one of the popular theories which were introduced by Rogers (1995) to explain how a new idea or innovation propagates in a social system. The theory is based on 50 years of research, and was adopted by many researchers in different research fields including the e-government research. For example, the theory was used by Carter and Belanger (2004) to assess the citizen adoption of e-government initiatives. Since being introduced, the diffusion of innovations theory was adopted in different ways in many studies including the use of the important part of the theory and the well-known S-shaped curve of adoption and the categorization of adopters.

In applying diffusion theory to e-health services evaluation, the most relevant points to recognize are the innovation perceived attributes identified by Rogers' study and their applicability to e-health services: Rogers (1995) describes the characteristics of an innovation in terms of its perceived attributes, and these attributes are responsible in controlling the rates of diffusion of the innovation. Rogers (1995) identified three primary perceived attributes, which are relative advantage, compatibility, and complexity. He added two other innovation attributes, which are trialability and observability.

From the five factors of DOI theory, we will only include in this study the primary ones, which are relative advantage, compatibility, and complexity. We believe that the other two, trialability and observability, are not pertinent for e-health services. Rogers (1995) considers trialability and observability as less important than the other three. Tornatzky and Klein (1982) have the same view, and they conclude that relative advantage, compatibility, and complexity are the most relevant factors to adoption research.

The second line of studies relating to the behaviour of users to new products or services is Technology Acceptance Model (TAM) (Davis, 1989). TAM is widely used to study user acceptance of technology. It was designed to examine the mediating role of perceived ease of use and perceived usefulness in their relation between systems characteristics as external variables and the probability of system use as an indicator of system success. However, as noted by several researchers (Hufnagel & Conca, 1994; Melone, 1990; Paul et al., 2003), TAM suffers from the absence of significant factors, including considering both human and social change processes and their affects on the adoption and utilization of new information systems. Paul et al. (2003) added that although technology acceptance model is useful, using TAM specifically in empirical research may give inconsistent results.

The technological acceptance model was used in the evaluation of e-services in the public sector by many research studies (Al-adawi et al., 2005; Carter & Belanger, 2004). The model was also applied to healthcare by Lapointe et al. (2002). In applying technology acceptance model to e-health services evaluation in this study, we will consider the mediating role of both perceived ease of use and perceived usefulness.

PROPOSED MULTI-DIMENSIONAL CRITERIA

E-government services evaluation and e-health services evaluation in particular are unable to reveal the full value of e-government projects without considering the perspectives of all the e-government services stakeholders and the e-government value measures presented by evaluation criteria consisted of all the key issues perceived by each of the stakeholders.

As mentioned earlier healthcare services are known to be a complex domain. This is related to the fact that healthcare is a safety critical area, dictated by a complex regulations. These regulations should be carefully considered in the selection process of the evaluation criteria, and in the description of the criteria used for a specific e-health service.

Hence, the proposed criteria are derived from two sources. The first source is two lines of studies relating to the behaviour of users of new products or services. The second source is a broad examination of the existing evaluations initiatives specifically those who were based on e-health services case studies. The first source represented by DOI and TAM which are popular and widely used theories, but still have their own merits and limitations. One of the main limitations of both theories is that they are not conclusive models and they suffer from the absence of significant factors. To adapt both theories for e-health context and overcome their limitations, critical analysis of e-health services case studies were used.

Considering the technical dimension, the economic dimension, and the social dimension in selecting and grouping the proposed evaluation criteria for this study, the criteria will be grouped in three sets of criteria, which are usability, direct costs and benefits, and trust. This classification should serve the deployment of the evaluation framework.

The Usability Criteria

The first set of evaluation criteria is the usability criteria. Usability in the proposed criteria may represent perceived ease of use and perceived usefulness as depicted by Davis (1989) technology acceptance model (TAM), or complexity as defined by Rogers (1995) diffusion of innovation.

Davis (1989) defines perceived usefulness as "the degree to which a person believes that using a particular system would enhance his or her job performance". He also defines perceived ease of use as "the degree to which a person believes that using a particular system would be free of effort". Rogers (1995) defines complexity as the "degree to which an innovation is perceived as difficult to understand and use"

We believe that perceived ease of use is predicted to influence perceived usefulness, since the easier a system is to use, the more useful it can be. We also believe that complexity and perceived ease of use are measures for the same issue. Therefore we are considering the three issues belonging to the same set and they will be represented by the usability criteria.

Usability has different interpretations and meanings depending on the context of use. Bevan and Macleod (1993) define usability as the quality of interaction within a particular context. Another description of usability which considers user's perspective is proposed by Nielson (1993), according to him, usability relates to how well users can use the functionality of a system or service in terms of what it can do. Researchers have provided broad dimensions and introduced long lists of aspects by which the usability can be assessed. These include accessibility (Steinfeld & Danford, 1999), functionality (Melander-Wikman et al., 2005; Nielson, 1993; Steinfeld & Danford, 1999), compatibility (Bevan et al., 2007; Chau & Hu 2001), user' satisfaction, easy to learn and use (Melander-Wikman et al., 2005; Nielson, 1993), and user interface (Melander-Wikman et al., 2005).

Accessibility is an important subset of usability. According to Terry, Ma, and Zaphiris (2003), accessibility means an effective and efficient user interface which is inclusive of more people in more situations and can achieve user satisfaction. Those people are different in their accessibily requirments and needs. A high percentage of them particularly those who suffer from disabilities or cronic illness are more likely in need than others for accessible and effective e-health services. Mont (2007) reported that an estimated 20 percent of American and Australian populations and 12.2 percent of British population have disabilities. Another research by Lenhart et al. (2003), shows a high percentage of about 38 percent of Americans with disabilities are using the Internet. The same research also shows that users with disabilities are more likely than the general population to use e-health services and have access to these services only from home.

Accessibility requirements for e-health services should generally accommodate all people, but particularly remove or reduce all the barriers that can hamper disabled people from fully benefiting from e-health services. One of the efforts for determining accessibility is the guidelines developed by the "Web Accessibility Initiative", a working group of the World Wide Web Consortium (Caldwell et al., 2007)

Despite the importance of accessibly in the evaluation of e-services in public sector and e-health services in particular, studies show that governments either ignored or did not pay enough attention to the accessibility importance. According to the Global e-government Survey conducted by World Market Research Centre and Brown University (2001), only 2% of government websites worldwide have some form of disability access and only 7% of the e-government websites were accessible. Another study by West (2000) show that only 15 percent of American government websites offer some form of disability access, such as TTY (Text Telephone) or TDD (Telephone Device for the Deaf) or are approved by disability organizations. The study also revealed that only 4 percent of American government websites offer foreign language translation features on their websites. Another example for ignoring accessibly in healthcare services is a cross-sectional study by Zeng and Parmento (2004). The study was aiming to evaluate the accessibility of consumer health information of 108 Web sites, and reported that no Web site met all the accessibly criteria in their assessing framework.

Compatibility is another important criterion to be included in the usability criteria. According to Rogers (1995), compatibility is measured by the degree to which an innovation is perceived as being consistent with the existing values, past experiences, and needs of potential users. Chau and Hu (2001) argued that compatibility is positively affecting user's attitude toward accepting new technologies in healthcare environments. They based their argument on the assumption that users would be more likely to consider technology useful if they perceived it to be compatible with their existing practices. In addition, users would consider technology easy to use if they did not need to change their practices significantly in an environment that can not cope with radical change.

Functionality is a broad criterion of the usability criteria which supposes to cover the user's requirements from a system to perform specific tasks in a specific situation; this includes accuracy, validity, robustly, speed and availability (Melander-Wikman et al., 2005).

User satisfaction is generally regarded as one of the most important measures of system or service success and should be included in the proposed usability criteria. The user satisfaction criterion can be measured by various dimensions including utility, reliability, efficiency, customization and flexibility (Horan et al., 2006).

Table 2 summarizes the proposed usability criteria, list of measuring aspects by which the criteria can be assessed and suggestions for measuring descriptions. The aim of proposing the measuring descriptions is to provide general guide for assessing these aspects. The applicability of the descriptions for specific context is out of the scope of this study.

The Direct Costs and Benefits Criteria

The second set contains the direct costs and benefits criteria. The criteria in this set are primarily based on Rogers's relative advantage. According to Rogers (1995), relative advantage is "the degree to which an innovation is seen as being superior to its predecessor". It is essentially a cost–benefit analysis of how useful a given innovation when compared with what is already available. Relative advantage represents mostly the economic return involved in the adoption of an innovation, but could also include the immediacy of reward, social prestige, or savings in time and effort (Rogers, 1995). The direct costs and benefits criteria have traditionally dominated the traditional information system evaluation process, and they were criticized by many authors (Farbey et al., 1995; Serafeimidis & Smithson, 2000) for their limited relevance to the role of information systems. This limitation is in their definition of stakeholders, targeting only direct tangible costs and benefits and being only based on accounting and financial instruments. On the other hand, many authors (Eng, 2002; Glasgow, 2007; Gustafson & Wyatt, 2004; Smaglik et al., 1998) argue that direct costs and benefits are important and should be

Table 2. The usability criteria and suggestions for measuring descriptions

Evaluation Criteria	Measuring Aspects	Suggestions for Measuring Descriptions
Easy to learn and use	Easy to learn	Measured by the time needed to learn to work with a service.
	Easy to use	Assessed by the simplicity of the service and how easy it is to understand and comprehend its functions
Accessibility	Content Accessibility	Measured by the degree of compliance with the Web Content Accessibility Guidelines
	User interface	Judged by the available options of user interfaces (e.g. Graphical interface, Multi-screen interface, Attentive User Interface).
	Disability access & translation	Is the system offering some form of disability access and foreign language translation features?
Compatibility	Compatibility	Assessed by how quickly and easily the e-service can fit into the whole healthcare system.
Functionality	Accuracy	Measured by the degree to which information provided by the service is free of errors.
	Validity	Measured by the clarity and regularity of information updating.
	Robustly	Judged by the technical functionality of the service.
	Speed	Judged by the system response time; web page load time; download time.
	Availability	Assessed by the availability of the service 24hrs/7days per week and the existing of alternative choices.
User satisfaction	Utility	Assessed by the completeness and usefulness of the service content (Loiacono et al., 2002)
	Reliability	Judged by the appropriately of the service functions in terms of the technology as well as the accuracy of the content (Zeithaml et al. 2000).
	Efficiency	Judged by the time spent to complete the information task, quality of the information found, appropriateness of information found, and satisfaction with the outcome (Wang et al., 2005).
	Customization	Measured by the degree of service tailrarity to meet the needs of individual user (Burgess, 2004).
	Flexibility	Assessed by whether a system or a service provides choice of ways to state a need and delivers dynamic information (Zeithaml et al. 2000).

considered in evaluating e-health services. Despite the above mentioned opinions regarding the limitations of using the economic issues in the evaluation; we tend to support the opinion of including them as part of the evaluation criteria because healthcare services have a high economic impact on governments and users comparing to any other services (Bower, 2005; Friedman & Wyatt, 2000; Gustafson et al., 2001).

One of the efforts in assessing the direct financial cost and benefits of e-health is the e-health impact project which was commissioned by the European Commission (DG Information Society and Media) (Stroetmann et al., 2006). The main aim of the project was to evaluate the economic and productivity impact of e-health services. The research project developed a generic economic assessment and evaluation framework for e-health applications, and was mainly focused on citizens' perspective in assessing ten e-health application cases. The ten cases were selected from across the European Union for their proven, sustainable e-health application. The result of the assessment, which was carried over a period of 15 years, indicates a positive, sustainable economic impact of these e-health services.

Table 3 summarizes the proposed direct costs and benefits criteria and suggestions for measuring descriptions for e-health services evaluation. Adopting the proposed evaluation criteria and their descriptions for a specific e-health service should take into account the relevancy of each of the evaluation criterion to the prevailing situation. This mainly depends on the maturity of the e-health initiative, and could lead to partial use of the evaluation criteria.

The Trust Criteria

The third set of the proposed evaluation criteria is the trust criteria. Trust has been acknowledged as a crucial property of information systems that provide e-services in a variety of contexts, because failing to address the trust aspects correctly may have a profound impact on the e-services (Fruhling & Lee, 2004; Presti et al., 2006). The aspects of trust must be tackled properly during the development and use of e-services. Trust can be defined as "the willingness of a party to be vulnerable to the actions of another party based on the expectation that the other will perform a particular action important to the trustor, irrespective of the ability to monitor or control that other party" (Mayer et al., 1995). Trust in e-health services is associated with data security and privacy of personal health data (Rodrigues, 2003). Given the sensitive nature of healthcare information, trust requires maintaining security in handling of patients' information, protecting their privacy, and assuring them that their personal information will be treated confidentially. Without this assurance, it will be difficult to promote the use of e-health services.

Enhancing trust involves enhancing security measures. This requires a large variety of measures and principles. Slaymaker et al. (2004) identified several aspects for security to be considered in any e-health project. These aspects include: user authentication, encrypted data movement, data integrity, security breach detection, physical security, audit trails, client and server authentication, and availability.

Trust in e-health services is also associated with the privacy of personal health data. According to Davis et al. (1999) "Privacy is the state of being free from intrusion, and in the context of health care, it concerns the responsibility of a care provider to protect a patient from any disclosure (i.e., discovery by others), even unintentional, of

Table 3. The direct costs and benefits criteria and suggestions for measuring descriptions

Evaluation Criteria	Measuring Aspects	Suggestions for Measuring Descriptions
Costs	Money Saving	How much money the citizens are saving by using the e-health service.
	Time Saving	How much time the citizens are saving by using the e-health service.
Benefits	Effort Saving	Measured by the degree of convenience in using a particular e-health service.
	Quality	Assessed by the added value to the Citizens information and knowledge about their conditions, diagnoses, treatment options and healthcare facilities, as well as the appropriate timing of the service
	Access	Judged by access level comparing to the same quality of services through alternative channel.

personal health data by providing security to the patient and the patient's records".

Moor (1997), stated that the main consideration in developing policies for protecting privacy is to make sure that the right people, and only the right people, have access to relevant information at the right time. Moor (1997) also proposed a controlled and restricted access technique for managing privacy. The technique is based on setting up zones of privacy and provides the opportunity for different people to be authorized for different levels of access to different kind of information at different times.

In practice, studies show that governments and health organizations have different levels of consideration for trust, security and privacy in their initiatives. An example is the study of Jarvinen (2005) which concludes that governments and health organizations have low levels of consideration for privacy. The study which covers 39 American health organizations reveals numerous examples of practices that make the customer vulnerable can be found in the analysed healthcare privacy policies. These practices include the absence of an adequate privacy notice, not give the users reasonable control over their information and the use of technical and confusing language in the privacy policies that make it difficult for the user to fully understand them. Another study by West (2000) also confirms similar finding. The study shows that there is very low consideration to the security and privacy in the American e-government websites. The study reveals that only 7 percent of American government websites have a privacy policy, and another 5 percent show some form of security policy. On the other hand, there are positive examples for the consideration of security and privacy such as the privacy provisions in Canada or quality seals for e-government services which was introduced in Austria (Aichholzer, 2003).

Table 4 summarizes the proposed trust criteria and suggestions for measuring the aspects of the criteria. Although the table provides clear and useful set of criteria, the criteria are general

Table 4. The trust criteria and suggestions for measuring descriptions

Evaluation Criteria	Measuring Aspects	Suggestions for Measuring Descriptions
Security	User authentication	Measured by how strong the user authentication is and if its key capabilities are sufficient for e-Health services
	Encrypted data movement	Assessed by the suitability of the technology used to protect the transfer of data.
	Data integrity	Determined by if the information is complete, whole, valid and digitally signed when required
	Security breach detection	Judged by the ability of the system to monitor and look for suspicious activity on the network.
	Physical security	Assessed by how secure is the area that holding the database equipments and if it is located in an area with limited and controlled access.
	Audit trails	Judged by the ability of the system to record the modification of data, to keep the most up to date version of data and to retrieve old versions of data.
Privacy	Responsibility	Measured by the degree of protection supplied by the healthcare organization for patient information from any disclosure.
	Access Control	Assessed by the degree of control on different level of access to different kind of information at different time.
	Confidentiality	Measured by the degree of compliance with the UK Data Protection Act (1998)

and it may be necessary to modify them to suite specific e-health initiative. The aim of proposing the measuring descriptions is to provide general guide for assessing the criteria aspects. The applicability of the description for specific context is out of the scope of this study.

CONCLUSION

This paper argues that the first requisite towards developing a holistic evaluation framework for e-health services is to deal effectively with the complexities, and overcoming the barriers through a multi stage strategy. The e-health services evaluation complexities are correlated mainly to the multi-disciplinary nature of the field and the challenges at the intersection of three areas, each well-known for its complexity, healthcare services, information systems, and evaluation methodologies. The paper starts with a summarization for these challenges.

Working towards building a holistic evaluation framework through a multi stage strategy, the paper suggests framework characteristics for the appropriate evaluation for e-health services. The paper argues that e-health services evaluation framework should be criteria based, while the criteria have to be multi-dimensional that grounded in, and derived from, one or more specific perspectives or theories, and cannot be entirely framed within the bounds of a single theory or perspective. Understanding the multi-disciplinary nature of e-health services evaluation and the challenges that it faces is the first requisite towards dealing effectively with the complexities, and overcoming the barriers of e-health services evaluation.

The paper provides a set of clear and useful e-health evaluation criteria that can be used as part of e-health evaluation framework, and to address areas that require further attention in the development of future e-health initiatives.

The proposed criteria were mainly derived from two sources. The first source was two lines of studies relating to the behaviour of users of new products or services. The second source was a broad examining of the existing evaluations initiatives, specifically those who were based on e-health services case studies. Hence, general evaluation criteria were proposed that cover the technical, economic and social dimensions. The proposed evaluation criteria can also be adapted to a specific e-health service by analysing the criteria that apply in that situation.

The limitation of this paper lies in the absence of empirical validation and examination of the proposed evaluation criteria that has not yet been applied in the fieldwork. Hence, the proposed factors require an empirical validation which will be performed by the authors in the next stage of this research using multiple case study strategy and will form the basis for further research.

Chapter 1.3

Health Technology Assessment: Development and Future

Lise Lund Håheim
Norwegian Knowledge Centre for the Health Services, Norway

Berit Mørland
Norwegian Knowledge Centre for the Health Services, Norway

ABSTRACT

Scientific publications in medical fields are rapidly increasing and are overwhelming in numbers. This poses a challenge to health authorities, and health professionals who need knowledge to make informed decisions in finding the best evidence for treatment and practice in the health provision to the public. They need an accessible system that handle the information flow using a systematic approach. This applies to developing and industrialized countries alike. The rapid development of health technologies with the introduction of new drugs, devices, and complex treatment modalities to achieve better health outcomes increases the need for evaluation of the treatment effect. This chapter illustrates how the health service handles the information flow utilizing information technology, and the great benefit that is gained by this methodology.

DOI: 10.4018/978-1-60566-356-2.ch046

THEORETICAL FRAMEWORK AND METHODOLOGY OF HEALTH TECHNOLOGY ASSESSMENT

The development of evidence based medicine (EBM) has been one important way of a systematic thinking in medicine (NHS Centre for Reviews and Dissemination, 2001; Egger, Smith, & Altman, 2001; Chalmers & Altman, 1995). But in fact the systematic way of identifying and assessing documentation started in the mid seventies with the establishment of the Health Program of the Office of Technology Assessment (OTA) under the Congress in USA (Banta & Luce, 1993).

EBM has been following several paths. The proceeding of the field of health technology assessment (HTA) is one of them (NHS Centre for Reviews and Dissemination, 2001). It has been defined as a process that systematically assesses the medical, social, ethical, and economic implications of the development, diffusion, and use of health technology.[1] In HTA two approaches are combined by making and using systematic reviews of published literature, and appraising relevant issues linked to the task at hand providing a national/local context. Health economic issues related to these technologies are important in setting priorities in health care. Ethical discussions are important to raise the awareness of moral dilemmas as well as patients' views, rights and other implications in the healthcare decision making. Technologies using groundbreaking biotechnology in particular may pose legal problems. The organization of the service may need to be discussed. Patient safety and patient rights are relevant to take into consideration. The aim of HTA is to inform and provide decision makers at all levels of the healthcare system in broad terms about the current best knowledge of health technologies to assist them in making the best informed decisions on which health technologies will provide the highest quality health service and treatments of the best value for money (prioritization).

HTA is a multidisciplinary field of policy analysis. It combines the systematic review of published scientific literature of particular health issues with appraisals that put the health technology in question in a broader context. In this work there is an extensive use of information technology in the search for scientific literature indexed in databases on scientific literature (NHS Centre for Reviews and Dissemination, 2001; Møreland, 2003a; Health Technology Assessment; Lund Håheim & Mørland, 2003). The identified studies are evaluated for relevance of population, intervention, outcome and study design, before being included in the evidence base of the relevant subject. The overall grade of evidence is then evaluated. There are a great number of databases that are searched for specified literature. It is done in a defined and specific manner and the search strategy is published so that it may be repeated by others or at a later date. HTA is done in a transparent way by publishing all the information on how the work was done. The report is indexed to databases as systematic reviews. External review teams are frequently used in this work (Mørland, 2003a; Health Technology Assessment). The teams are most often multidisciplinary having members of the medical professions, epidemiologist, health economist, statistician, and user/patient representatives, or others as needed. The range of disciplines is founded in the need to make sure the literature assessment is relevant and of highest quality. The members of the teams gain knowledge of the methods used in making systematic reviews, and can therefore bring this knowledge back into their own work place. As they are often chosen on a background of being "opinion leaders" in their field, they are important in the challenging work of implementing the results and increase the impact by having the full knowledge of how the work was undertaken. This individual knowledge assists in the transfusion of knowledge of health technology assessments through the health service.

HTA has developed steadily over the years to be a world wide effort to improve the decision making in the health services by presenting best evidence, but the work stops short of making political decisions or making guidelines. Its products are the applied use of research results and it is founded on research into best ways of performing assessments, and increasingly meeting the challenge of finding most efficient ways to disseminate and implement results. HTA relies heavily on information technology (IT) in all parts of the work. In assessing research the work relies entirely on information technology as it is used both in searching and collecting relevant studies/literature, during the assessment process, until the final report is made and it is disseminated. Different tools have been developed that are being used to streamline the work process by using standard forms and checklists, and data programs for grading the evidence level of the studies included and reporting results. For making the quantitative syntheses of effect estimates the statistical method of meta-analysis has been developed. Without the development of IT, and its efficient use in searching and sorting huge amount of literature, the EBM and HTA would not have been possible. Information technology is the basic tool which the work is based on and the use is continually being validated through research efforts on its own methodology.

HISTORIC DEVELOPMENT AND INTERNATIONAL COLLABORATION

HTA seeking scientific evidence on the best outcomes of medical interventions is a field that, as mentioned above, has developed over the last 35 years to become a useful tool for the health services (Banta & Luce, 1993; Jonsson, 2002). There has always been a need to assess the effects of health technologies. Observational methods, opinions, beliefs, and expert statements have been broadly used, but do not give the best evidence in terms of assessing the best clinical effect of e.g. a specific treatment. Then randomized controlled trials are considered to be the best study design, secondly are the controlled study designs. The studies are ranked according to study design and internal and external validity. The study results are then synthesized and graded. The increased production of scientific studies called for a systematic review of the results they provided, in order to make the best available scientific assessments of effect of interventions. HTA was first formally established as a working method in the mid-seventies with the establishment of the Health Program of the Office of Technology Assessment (OTA), USA. Many basic structures developed at OTA are still relevant. A concurrent development happened in Europe with the establishment of similar organizations. The first European workshop on evaluation of medical technology was held in 1979. Health economists from Switzerland, Sweden, UK, and WHO/Europe organized a conference titled Economic Evaluation in Health Care Technologies. During the first half of the 1980s the HTA activities were gaining momentum in Europe. The first agency was established in Sweden in 1987 and soon other agencies followed. One of the first studies made by the Swedish agency was successful in both documenting scientific evidence for best clinical practice in the use of preoperational laboratory routines, and showing the important economic gain by following this practice. The HTA work became more formalized with time in Europe and also the Canadians and Australians were very active. In 1991 the Cochrane Centre was established and in 1993 the Cochrane Collaboration (www.cochrane.org). Consensus conferences also played an important part in some countries in the development of HTA.

International collaboration is very much appreciated and is an integral work in HTA. The exchange of knowledge was the basis for the initiative of a scientific journal called International Journal of Technology Assessment in Health Care first published in 1985. This year there also was a meeting at the WHO in Copenhagen where the International Society of Technology Assessment in Health Care (ISTAHC) was established. It was reorganized in 2002 into Health Technology Assessment international (HTAi).

The health authorities and policy makers saw the use of establishing HTA centres that could relate health technology assessments to their national specific situation on the macro and meso level rather more than on micro clinical level. They were interested in the quality of the health care provided, equity in treatment across groups, equal access for necessary treatment, and involving more than medical professionals. It has also become increasingly important to include cost-effectiveness analysis. The need for international collaboration has resulted in the establishment of INAHTA (International Network of Agencies for Health Technology Assessment, started in 1993) (http://www.inahta.org/) (Hailey & Menon, 1999). INAHTA, a non-profit organization, has now grown to 46 member agencies from 26 countries including North and Latin America, Europe, Asia, Australia, and New Zealand. All members are non-profit making organizations producing HTA and are linked to regional or national governments. Many organizations throughout the world assess healthcare technology. There is an evident need to cooperate and share information from different cultures. INAHTA serves this purpose. The Secretariat is located at SBU in Sweden.

The EU has for a long time seen HTA as an important tool to improve health care. Several research programs were introduced in the 1990s. Such programs were the EUR-ASSESS (1994-97), HTA-Europe (1997-98) and ECHTA/ECAHI (2000) (Jonsson, Banta, Henshall, & Sampietro-Colom, 2002) that where established in order to stimulate coordinated efforts for collaboration between agencies. The work is now being taken further in the 3-year EU-project for a sustainable network of HTA-agencies called European Network for Health Technology Assessment (EUnetHTA) (2006-9). EUnetHTA will be described in more detail and is expected to form the basic network of the future organization of HTA in Europe (http://www.eunethta.net). EUnetHTA will be supporting the policy makers in making informed decisions on health care, but also decision makers on all levels and the clinical level (micro level). It aims to become the focal point for HTA by establishing a communication and clearinghouse facility making a common direct contact between users, providers, and stakeholders of HTA. A major aim of developing this network is to reduce duplication of HTA reports through the development of methods and material that ease the translation of the products into national/regional conditions. The products are core HTA information, adaptation tools, efforts for monitoring new technologies, and information on how to establish an HTA-agency. New technologies will be registered on a regular basis and a newsletter on early warning of new technology will be provided. It will be a comprehensive system of information on all levels of HTA production and use for the best of the community at large.

THE NORWEGIAN HTA EXPERIENCE

Norway has since 1997 had a national centre for HTA (Mørland, 2003a; Health Technology Assessment). The Norwegian Centre for Health Technology Assessment (SMM) was from the start the first and only HTA agency in Norway and has continued being this. The organization consisted of the main agency (10-12 scientists), its steering committee and a consulting panel of 60 experts representing a range of health institutions, universities, hospitals, central health administration, and professional and patient organizations. SMM was housed purposely outside the central health administration. Review teams led by SMM using international principles of HTA in their work formed the major working method (NHS Centre for Reviews and Dissemination, 2001; Health Technology Assessment). In this way knowledge dissemination of HTA as a working method and of the results of the subject under study was achieved. One may say that SMM was perhaps more pointing at the clinical /micro decision-level, than most other HTA agencies. The reports were published and presented at dedicated seminars and national/international conferences. The web-page was soon established and a newsletter published regularly all using a publication profile that was made early on making the products easily recognizable

Examples of work are the report on Hip replacement prostheses that revealed that more than 50 different types were in use in Norway and that a third of these lacked sufficient scientific evidence on clinical results (Nordsletten, Havelin, Indrekvam, Aamodt, Utvåg, & Hviding, 2002). Another report that made an impact on changes in the service was that on the use of PCI. A meta-analysis of 17 studies showed PCI to reduce mortality, re-infarction, and stroke (Wiseth, Gundersen, Halvorsen, Nordrehaug, Steigen, & Myhre, 2002). But some questions were also raised by the health policy (macro) level, i.e. the documented clinical outcomes from using PET as a diagnostic procedure, and the possible future need for PET in Norway (Mørland, 2003b).

In sum, this multilevel way of organizing and disseminating the work ensured a rapid spread of knowledge of HTA in Norway. What started as a three year trial project proved a sustainable working method.

SMM was reorganized in 2004 with two other related organizations into the Norwegian Knowledge Centre for the Health Services (NOKC) (http://www.kunnskapssenteret.no/). NOKC summarizes and disseminates evidence concerning the effect of treatments, methods, and interventions in the health services, in addition to monitoring health service quality. The aim is to support good decision making in order to provide patients in Norway with the best possible care. The centre serves as the Norwegian HTA agency, and hosts branches of the Cochrane Collaboration and the Campbell Collaboration. One department is dedicated to patient satisfaction surveys, patient safety, quality measurements and quality registers. An internet library with links to publications and databases of literature has been established. The Centre is organized under The Directorate for Health and Social Affairs, but is scientifically and professionally independent. The Centre has no authority to develop health policy or responsibility to implement policies.

RESEARCH IN HTA

HTAi (and formerly ISTAHC) conferences and the Journal of Technology Assessment in Health Care (JTAHC) are major focal points for presentation and publication of research on health technology assessment methods and results. The aspects cover a broad range.

The research areas can be illustrated by the main themes that have been chosen for the HTAi conferences the last years: The History of HTA, Krakow, Poland, 2004; HTA and Clinical practice (Hospitals), Rome, Italy 2005; HTA and Health Policy, Adelaide, Australia, 2006; HTA for Evidence-based Public Health, Barcelona, Spain, 2007; and HTA in Context, Montreal, Canada, 2008.

In the conference held in Barcelona 2007 the range of research areas were impressive. Themes of the panel sessions are presented in Table 1.

HTA as a methodology is the focus of research and development. In the following will be given two research examples from SMM and NOKC that illustrates the way the two subjects are 1) Review Teams Experience and 2) Implementation of Reports.

Review Teams Experience

The review teams at SMM worked after the principles of consensus group work, but in a more systematic way, independently evaluating the identified literature after preset criteria (Christofides et al., 2006). In order to follow up their experience with the work, every participant received a survey after completion of a report. It was of importance to evaluate the use of review teams as a working method and to what degree the experts should be involved in the literature assessments. The composition of the review teams reflected an interdisciplinary approach. SMM should work in close cooperation with the clinical services, research centres and health authorities and select members from these areas. The participants were chosen among opinion leaders in their field. Team members were chosen from different areas of medicine, and health care. As the HTA reports also handle appraisal issues like health economics, ethics, law, and health service organization, additional expertise from these fields was sought if needed and these persons joined the team as needed.

Methods

At the completion of the HTA-report the review team members were given a questionnaire on their

Table 1. Overview of research themes presented at the HTAi conference in Barcelona, Spain, 2007.

Methods for knowledge transfer: What is the impact of Knowledge networks in Public Health and HTA?
HTA, Industry and Health Systems: Are we ready to set up an agenda for effective cooperation?
Patients and Citizens: involving patients and the public in the development of health guidance.
Evaluation of interventions: Evidence or ignorance – Air pollution, Health and Policy.
Evaluation of breast cancer: screening and treatment.
Assessing Telemedicine
Patients: information and involvement.
Evaluation of Mental Health intervention.
Evaluating economic consequences of Human Papilloma Virus: screening and vaccination
HTA for clinical practice.
Ethics and socio-cultural aspects in HTA.
HTA for quality and reimbursements policy decisions
Methods for HTA: Qualitative
Evaluating interventions for substance misuse
Assessment of viral diseases prophylaxis and prevention
Teaching HTA: What knowledge and skills should students of HTA acquire?
HTA, industry and Health Systems: Understanding systems for post-regulatory assessment and decisions on health technologies
Assessing oftalmological interventions
Evaluating interventions for vulnerable groups
Economic Analysis of Public Health Interventions
Evaluation of foetal abnormalities and infant interventions
HTA in context
Evaluating complementary medicine
Evaluation of interventions: from population screening to individual treatment: where is the gap?
Assessing interventions for obesity
Evaluation of colorectal cancer: screening and treatment
Pandemic Flu: Managing the inevitable

experience. The working period lasted from 4 to 33 months. The questionnaires were sent to all 112 participants in the 17 review teams for the period of January 1998 to June 2003. Responses to the questionnaire were given by 58 participants (51.8%). The number of team members ranged from 4 to 14 persons. The questionnaire was concentrating on the theme/mandate of the assessments, the composition of the review team, the organization of the work, the working method, and the interest of participating in the update of the report.

Results

The results showed that a total of 83% thought the theme was well argued for doing an HTA, and 62% thought the mandate for the assessments was sufficiently clear. About 80% were positive to the composition of the review team. In all 22% expressed that the work method was too extensive and 43% wanted more tuition. General comments were that the working method gave added competence in assessing medical literature, relevant professional training and tutoring in a working method that ensured the legitimacy of their work. Participating in a review team gave credit points in the further education in medicine. The review team participants were satisfied with most aspects of the work. Suggestions for improvements in the working process were given. Delays occurred especially as people did not deliver their share of work due to heavy work load. Seventy-six percent were satisfied with the scientific leader at SMM. One person thought it had been a waste of time, but 83 percent were interested in making an update of the report at a later date.

Conclusion

We concluded that nothing in the results indicated the need to discontinue the work process with review teams in doing HTAs, but decided to increase the tutoring of participants.

Implementation of Reports

Making HTA reports is a time consuming effort on behalf of many persons. As most HTA agencies do not have the concrete mandate and responsibility to implement the results themselves as a matter of principle, it is of strong interest to observe if they are disseminated and implemented.

We present results whether the work and the specific conclusions obtained, have had an impact on the problem areas of the health services which they addressed. The reports were published by SMM from 1998-2003 (Lund Håheim & Mørland) and by NOKC from 2004 to 2007.

Methods

All the reports are made in accordance with the HTA principles for systematic reviews. The systematic reviews of the literature were within effects of treatment, prevention, diagnosis, screening, or other. Health technology assessments are expected to include an appraisal of related factors important to the evaluation of the results. The appraisal can be within health economics, ethics, Norwegian practice, organisation, or law. Five HTA-reports were on health economics alone.

We assembled information about our reports regarding who commissioned the reports, field of subject, and the type of appraisal included. Several reports concern more than one medical field, but in this presentation (After Table 2, See Table 3) is chosen the main field. Codes for different conclusions were based on the synthesis of the results. Known lines of impact were recorded. From reviewing the reports it was apparent that results indicated areas where insufficient evidence was available and in the conclusions were often pointed out areas for further actions. We grouped these in three:

1. The reports could conclude with suggestion on the medical practice or technology as such, being discontinued, i.e. stopped being used, change in current practice, no change in current practice, introduced as new method or further survey required before a certain conclusion could be drawn.
2. Secondly, the report could call for other concrete actions, i.e. establishing or extending existing registry, or establishing or changing guidelines.
3. Thirdly, new data or more research was asked for, i.e. on the current use, on studies of higher evidence level, or that the new method was introduced within the framework of a scientific study.

The impact of the conclusions was grouped in nine as affecting national procedures, national guidelines, distribution of duties, clinical guidelines, national drug use, advice of no change, advice not considered. It was also recorded whether there was given advice of no change, advice not followed or that no information was available.

Table 2. Overview of commissioners of HTA-reports by the year of completion of the reports

Year	**Ministry of Health**	**Hospital-service**	**Directorate of Health and Social Affaires**	**SMM / NOKC**	**Others**	**Total**

Results

HTA Reports from SMM

Of the 31 reports included were 18 commissioned from external sources and 13 from SMM itself by the Board of Governors (steering group) or by the panel of advisors (mostly clinical experts) (Table 2). The implementation of the results was not found to be significantly different if the commissioner was external or internal. External sources were primarily the Ministry of Health. During the period others such as the Directorate for Health and Social Affairs and the National Advisory Council on Priorities in the Health service needed SMMs services. Other commissioners could be the Norwegian Board of Health, Norwegian Medi-

Table 4. Appraisal issues included

	Number*	Number
Norwegian practice	24	4
Health economics	21	8
Medical ethics	13	9
Organisational issues	17	7
Legal implications	6	2

* Numbers may be more than one for each report

cal Control Authority, Regional hospital services, clinicians or the public.

SMM made no preferences as to which medical field would be of interest (Table 3). Six reports have been on prevention, four on diagnostics, two on screening, and the majority of 19 on effects of treatment. A wide range of subjects have been covered, including dental interventions (wisdom tooth extractions). The subjects have often been comparisons of different modes of treatment, e.g. in the report on ovarian cancer treatment where cytostatica and radiation therapy were compared. Another example is the report on palliative cancer surgery which covered treatment of symptoms and function within five surgical specialities.

One or more appraisal themes have been included for each report (Table 4). Twenty-four reports presented information on relevant Norwegian practice such as rate of PSA-tests for prostate cancer evaluation, and distribution among hospitals of specific kinds of surgery. Health economic analyses were included in 21 reports ranging from information on DRG, presenting simulation analyses and QALY-calculations in cost-utility analyses. SMM established a separate small unit for health economics to cover cost-effectiveness analysis. A discussion around ethical considerations was included in 13 reports. SMM had employed a specialist in medical ethics. Organisational issues were of interest for 17 reports such as ventilation and cleaning routines of operating theatres including a survey of current practice in major Norwegian hospitals (Segadal et al., 2001; Segadal et al., 2003). Legal implications were few and discussed in 6 reports only. One example was Gene therapy – status and potential in clinical medicine, where a short overview of how international regulations differ from Norwegian ones (Smeland et al., 2000). Comments and recommendations from the group of experts were presented for a simpler yet adequate legal process for study protocols and safety regulations on gene therapy in Norway.

Recommendations in the report included suggestions and need for further actions if seen necessary from the level of evidence available (Table 5).

The impact of the conclusions of the reports has in some instances been multiple (Table 6). Twelve of the 31 reports made, influenced national policy decisions such as the establishment of PET technology in Norway (Mørland, 2003b). Two national guidelines were altered. Distribution of duties was changed as a result of the reports such as treatment with PCI in myocardial infarctions (Wiseth, Gundersen, Halvorsen, Norderhaug, Steigen, & Myhre, 2002). Clinical guidelines were changed due to four reports. In three reports there was advised no change in practice and of 7 we had no info. One health economic report did not alter the introduction of a new kind of prescription (on physical activity), although the economic consequence did not support it.

HTA Reports from NOKC

NOKC increased the number of completed HTA--reports using external reviewers from 8 in 2004 to 21 in 2007 totalling 60 over a four year period as a result of increasing number of staff and the consolidation of the new organisation (Table 2). Systematic reviews on organizational issues in the health service are excluded. The commissions have to a large extent changed from SMM to NOKC and many are now channelled through The Directorate for Health. An increasing number is coming from the regional hospital boards and this is encouraged. Few reports are initiated from other sources. A separate health economic analysis are becoming more important as part of the evidence base for policy decisions. As an example NOKC have made a separate health economic analysis in addition to three HTA-reports, on new technologies or drugs, and as evidence for a policy decisions on a possible start of a HPV-vaccination program in Norway (Neilson & Freiesleben, 2007).

Discussion

The reason behind the commissioning of these reports are multiple and varied. The aims have been to clarify areas of diverse opinions within the health service, establish the best knowledge available on certain issues in a world of a rapidly increasing flow of published medical articles, or make an overview and establish status of complex fields of treatment.

The relevance of the assessments is important for the implementation. The choice of themes was considered carefully. Points of consideration were that the process must not take too long time in order for the report not to be outdated. In some fields the development is fast and a revision of a report is necessary within a few years.

Implementation is also dependant on the professionals, the health authorities or the public finding the reports relevant to answer problem areas that were in need of clarification. The subject of the reports ought to address areas that are in due course for a change and for which it is possible to give a direction for change. When the problem concerns a lot of patients, there is a dispute among health professionals, treatment is costly, resources are scarce, introduction of new technology or facing out old none effective treatment, a systematic review of effect of treatment is called for. This is part of the foundation for getting acceptance for its results among health service employees, central administration and politicians. We have experienced that impact is greater among policy makers at the macro and meso levels rather than the micro level i.e. clinical level. They are also the main commissioners of HTA reports. More effort is needed to make an impact at the clinical level. This experience appears to be shared by the NHS HTA programme in UK. The impact of NHS HTA program in UK was assessed after 10 years (1993-2003) (Hanney, Buxton, Green, Coulson, & Raftery, 2007). They were interested in identifying which factors which were associated with HTA research that made an impact on health care policy and clinical practice. Four approaches were done. First a systematic literature review was made of research programs on impact. Secondly, the work of the National Coordinating Centre for Health Technology Assessment (NCCHTA) was reviewed, lead researchers were surveyed, and 16 detailed case studies were undertaken. They conclude that the HTA program had considerable impact in terms of knowledge generation and perceived impact on policy and to some extent practice. They believe that the programs objective and relevance to NHS and policy customers may partly explain the high impact. The strict scientific methodology and peer review may also be a contributing factor. They suggest health research impact studies in an ongoing manner to be valuable.

One aim of our study was also to look into the consequence of the change in different organizational structures of SMM and NOKC after the reorganization. Combining information from Tables 4, 5, and 6, we see there are differences in including the appraisal issues in the reports. NOKC often get the tasks from commissioners using the assessments and implement them into guidelines. They will, as a consequence, often do the appraisal themselves.

SMM as well as NOKC have, however, put an increasing emphasis on health economic issues as this perspective concerns the importance of the best use of resources in the health service. There is after all a limited amount of economic resources and they ought to be spent in a manner to the best of all. An evaluation of new and established treatment modalities is important in order to achieve the best level of quality in the health service without excessive spending of money on non efficient treatment.

The acceptance and implementation of the results of these HTA-reports into new policies, new guidelines or change in clinical practice are dependent on the receivers of the reports finding them useful. It was not observed a difference in implementation with time. The publication strategy has most likely been adequate throughout this period in order to reach the most relevant persons and groups that are interested in the subject and were in a position to make the necessary alterations. The reports have had a certain news interest when they have been first published and they exerted their impact most likely within the first six month after publication.

Conclusion

The reports have had an impact on the use of medical technologies on national and professional level. The implementation of the results was not found to be dependent on the commissioner being external or internal during the SMM period. The commissioning changed to Directorate of Health and Social Affairs from The Department of Health. The number of appraisal themes and reports including these dropped when NOKC was established. This can be seen as a result of large expectations to the newly formed unit that had to deliver faster to the authorities. SMM also generated ideas for these reports which were often channelled from the hospital area or direct contact with other commissioners. The degree of implementation of the results of the report did not appear to change during the period.

EUROPEAN DEVELOPMENT OF A SUSTAINABLE NETWORK ON HTA

The European Commission (EC) and the Council of Ministers in 2004 recognized the need for establishing a sustainable and effective European network of HTA (Christofides et al., 2006). It is an open network connecting agencies with each other and developing necessary tools and a common information technology communication platform to facilitate cross-border collaboration aimed to inform policy decisions on the use of health technologies at the national or regional level. The expressed aim was to improve the coordination among the HTA organizations further, reduce duplication of work, save time, and resources. In short, the three year project was launched in 2006 called European Network for Health Technology Assessment (EUnetHTA) co-funded by an EU grant which will prepare for establishing a permanent network as from 2009 (http://www.eunethta.net/). The aims of the network are to reduce duplication of work by HTA institutions, for instance by establishing a system for producing and sharing core HTA information, support the establishing of new HTA organizations and other important activities. The project is structured around the eight work packages (WP) that were established to develop the different tasks and functions needed for the future network and for coordinating the project. It has a steering committee, an executive committee, and a secretariat. A total of 63 HTA institutions and organisations are working with evidence based medicine from Europe or overseas have joined EUnetHTA. They are preparing to share scientific evidence and methodological frameworks.

European agencies taking an active part and receive funding are termed associated partners (AP). Other partners are termed collaborative partners (CP). The partners have chosen which work packages they want to take part in. There were no limitations as to the number of partners in any work package. Each WP has one or two lead partners. The eight WPs have distinct tasks. WP 1 is the executive committee (EC) where the eight work package leaders are main members. The lead partner DACEHTA, Denmark, holds the Secretariat and has the administrative responsibility for the project. WP2 has two strands. One strand develops the web-communication and all aspects related to developing the extra- and intranet for the EUnetHTA. The other strand develops a clearinghouse functionality which is a central

information hub in the network of agencies and that will facilitate knowledge transfer and sharing within EUnetHTA. WP3 concerns the continuing internal evaluation of the project which was a prerequisite from the EU. The evaluation collects information through yearly Participant surveys and five monthly WP-leader interviews. The other five WPs each develop essential deliverables making common grounds for the work in HTA agencies in Europe and increase the interchange of knowledge for producing HTA reports. WP4 has developed the HTA core model which is a tool for comprehensive analysis of the elements to be included in an HTA-report that can be adapted to different countries. Core HTA information has been developed and is being piloted on one medical device and one diagnostic technology. WP5 makes the adaptation tool kit to assist HTA agencies to adapt HTA reports from other countries or settings than their own. WP 6 works on the information process towards health authorities and stakeholders by producing a textbook and organizing a stakeholder forum on the EUnetHTA extranet and arranging a stakeholder meeting. WP7 develops the program for searching for new technologies and for making a newsletter on these technologies. WP8 is producing a handbook on the development of an HTA agency and curriculum proposal for training in HTA work to assist in the establishment of new HTA agencies. These WPs have varying numbers of AP and CP members. Altogether there are 27 countries, 24 EU-members and 3 EEA members, and a number of organizations now collaborate in EUnetHTA.

EUnetHTA holds a vision of contributing to the generation of HTA reports to inform policy and health care decision makers in Member States in order to bring about high quality, safe, accessible and efficient health care for citizens across Europe. HTA agencies hold the value of transparency in their work processes and the sharing of information. Their products shall be based on best scientific evidence in a common methodological work process. The collaboration so far has been successful and the project is heading for a transition period towards the established network. (See Table 7)

CONCLUDING REMARKS

Health technology assessments are being in demand by the health authorities, health decision makers, health workers, and the public. Best scientific evidence as basis for decision making is important. The additional evaluation of the consequences for the health service regarding health economics, ethical, legal, professional, and organisational aspects strengthens the foundation for decisions to be taken in our common search for the best use of health resources. The use of information technology management in this work is essential and totally integrated in this work. It is information technology that allows for most importantly the retrieval of the scientific information by literature searches in relevant databases, assembling the information into reports, and communication between collaborating partners.

Chapter 1.4

Researching Health Service Information Systems Development

Said Shahtahmasebi
The Good Life Research Centre Trust, New Zealand

ABSTRACT

Information is considered the currency within health systems. Numerous reorganisations and restructuring, coupled with many buzz words (e.g. evidence-based practice) and the various advancements in ICT (information and communication technology) are apparently designed to improve the utilisation of this currency. However, what constitutes information appears to vary between health professionals. For some, only the data derived from RCTs (randomized control trials) is considered evidence, for others it is the conclusions drawn from focus groups, whilst for others, finding information goes well beyond subjectivity and experimental design and comes from understanding human behaviour and other processes. Although advancements in ICT have greatly improved access to information (currency), the data often disguised as information appears only as small change. Restructuring and reorganizing have been used to inflate the value of this currency (information) leading to the replacement of information departments by the Public Health Intelligence Units or Observatories. However, a change in behaviour is difficult to bring about and manage, while it is easier to change the tools with which the tasks are carried out. It is all too easy to fall into the trap of reproducing what has been produced before by information departments only under a different guise, as well as using different configurations, software or updated hardware and ICT (e.g. the Internet). These units hardly concern themselves with exploring the underlying message of the data. A quick trawl of the web pages of these entities can be testimony to this fact. The process so far has been, in effect, one of test-tubing health outcomes and then extracting the data from the test tubes. Although we have been eager to embrace technological advancements and change, we have failed to monitor the impact and consequences of change on our behaviour and thus on health outcomes. This chapter will delve into the current availability of information for public health policy purposes and will argue its ineffectiveness as information/evidence in the context of human behaviour and social processes. Behaviour and processes are by nature dynamic. Specifically, the feedback effect, a feature of dynamic process, can have a profound attenuating effect on data that

DOI: 10.4018/978-1-60566-356-2.ch037

was once important, thereby affecting not only the shelf life of a policy but also its intended outcomes. Examples from published reports by public health intelligence units/observatories in New Zealand and the UK, plus references to teenage smoking and suicide, will be used to illustrate these concepts and issues. A conceptual but pragmatic model of data collection based on current health care data management systems will be argued as a way forward for translating data into information and tangible evidence with a view to informing the process of public health policy formation. This chapter discusses a holistic approach to identifying data needed as evidence to inform the process of policy formation/decision making as a conceptual model.

INTRODUCTION

The central issue in information technology (IT) and its management is information itself, for without it, decision making and policy formation would have had to follow a different process. However, with the advancement in technology and the development of social, health and political models, we may have spent more resources on the relationship between technology and access to information than on how information and technology may be utilised to inform the process of decision making more effectively and efficiently.

In the health service sector, IT management has been focused on using the technology to manage health data primarily to develop information systems that cater for the storage of data without hindering access to it. Within the health service, this line of approach may be limiting by unwittingly reinforcing the assumption that the development of an information system is specific to the task under study. Therefore, by allowing market forces to dictate to the management of the health service sector, there will naturally be competing models of IT management which in turn will lead to different IT models operating different sections of the same organisation, for example, variation in IT models between and within GPs, hospitals, and private health service providers.

In recent decades we have witnessed rapid advancements in technology which may have contributed to improvements in ICT (information and communication technology) such as faster communication and data transfer devices, smaller but faster storage devices with large storage space e.g. hard disks, and database software. However, to some extent the advancement in ICT may have encouraged a move to develop models to improve inter-agency access to data. Certainly, using the latest database package and appropriate hardware, technology data from various sources can be uploaded, stored and retrieved centrally.

Although IT management involves adopting models that utilise various tools including hardware and software to improve the collection, storage and access/retrieval of data, too much emphasis on the technology and access to data may have helped to shift the focus away from the actual data itself. The health service sector generates huge volumes of data, including morbidity and mortality outcomes. However, social and lifestyle information is often collected separately as part of projects with specific aims and objectives. In the UK, hospital records were expanded to include the routine collection of data on social class. In the early 1990s attempts to utilise these pieces of information with other health outcomes proved ineffective as social class had only been collected for a handful of patients' records.

Indeed, in order to include socio-economic data in the analysis of health outcomes, the Analysis Unit in the former Yorkshire Regional Health Authority (UK) using a multi-method approach, utilised a mix of databases from various sources (Bensley et al 1994, also see Shahtahmasebi 1997, 1999, 2001). The process of preparing, analysing and presenting the information involved extracting health and census data from various sources into a readable format and preparing and matching census based socio-economic data with health records for use with statistical, graphics and mapping packages. The project design appeared fairly routine because theoretically all the necessary data was available and the only main issue was to match different data from various sources. Dealing with different types of data from different sources is not always straightforward. By using today's technology, parts of the project may be considered routine as most statistical packages, in addition to statistical analysis, are capable of sophisticated graphics and mapping analysis.

There are two questions that immediately come to mind: fourteen years on, can we expect to see census based socio-economic data along with health outcome data from various sources in one database? And why, in the era of advanced ICT, do we have to rely on creative methodologies to generate proxy data for socio-economic and lifestyle using routinely collected data?

BACKGROUND

Like any other business, the health sector relies heavily on information for its operations; from a government's fund allocation to the distribution of resources, to health care service development and interventional programmes. Morbidity and mortality statistics have been used for these purposes. Given that geographical regions may vary in health care needs, clearly more information about each region than just the numbers in each health outcome are necessary. And if health care planning and resource allocation were to be proportional to the size of the population, then a population-based comparison of health care needs between geographical regions based on mortality and morbidity statistics is also essential.

Population-based standardisation also enables comparison of prevalent trends of given health outcomes between predefined areas within and between regions. Data items such as age, sex, post code, diagnosis, and mortality cause have been routinely collected and are available through patients' records.

However, as health care systems have became more and more complex, in order to respond to all the ill-health needs of its population, a few began to equate resources with rising demand and inequalities in health. The fable of the physician on the river bank may describe the problem more clearly, retold by (McKinlay 1975), though attributed by him to Irving Zola:

> *"You know", he said, "sometimes it feels like this. There I am standing by the shore of a swiftly flowing river and I hear the cry of a drowning man. So I jump into the river, put my arms around him, pull him to the shore and apply artificial respiration. Just when he begins to breathe, there is another cry for help. So I jump into the river, reach him, pull him to shore, apply artificial respiration, and then just as he begins to breathe, another cry for help. So back in the river again, reaching, pulling, applying, breathing and then another yell. Again and again, without end, goes the sequence. You know, I am so busy jumping in, pulling them to shore, applying artificial respiration, that I have no time to see who the hell is upstream pushing them all in."*

Thunhurst (1982) argued that we have spent too long measuring the flow of the river, the size of the fishing nets and the rate at which people are brought to shore. Health statisticians and health professionals need to refocus, Thunhurst argues, to investigate the largely unmapped terrain upstream, particularly in solving the problem of differential class experiences of health.

In an earlier paper, Shahtahmasebi (2006) argued that despite the attempts to research and map upstream, the health services still rely heavily on downstream research, thus building up information systems consisting of data collected after the event i.e. an occurrence of ill-health which necessitated a consultation with a health service professional.

The principle of collecting information on morbidity and mortality as and when they present themselves in order to cater for the health needs of the population will lead to, or has inevitably led to, a reactionary health care system. Assuming that there are no other constraints such as budgetary resources or otherwise, the system would be as good as the fable of the physician on the river bank. In other words, the health care system would be reacting to cries of help from people in need of being saved.

There is no doubt that mortality and morbidity data are essential to help with the planning and distribution of resources to deliver health care. However, without interrogating these data and asking the question "why", the health care system remains ignorant of disease development and in particular how the health care system could have been more effective in preventing an outcome.

Today's health care systems are far too big and complex, and governments around the world spend huge sums of money maintaining a health care system. In the short term, maintaining is often all that can be done. Due to the dynamics of public health, the feedback effect (i.e. the more demand, the more need for maintenance) will lead to a costly future maintenance of the same system as health care systems will continue to be stretched. Thus the fable of the physician on the river bank comes to life. This feedback effect gives rise to additional complexities which will then confound the feedback effect. The need to react to the ever increasing downstream events means that health care systems appear to drain more resources and thus there is a great urgency to maintain at least the current level of care services making it more difficult to justify spending sufficient resources to investigate upstream events. Research and Development (R&D) funding and evidence-based decision making is often restricted to RCTs of specific treatments or to bring about a change in providing care (i.e. method of delivery of care). The urge to continue to react to ill-health is also fuelled by incompatible upstream research, often considered academic and thus separate from the everyday operation and decision making of the health care system.

The problem with relying on separate study design type research to investigate upstream is an inherent inability to generalise the results and relate them back to the population. This inconclusiveness fuels further the urgency to rely on "available" information to plan and maintain a reactive health care system. For example, within the suicide literature, despite the large volume of work, criticisms have been aired that our knowledge of suicide is based on scant scientific evidence (De Leo 2002, Institute of Medicine 2002,Cutcliffe 2003). The study design and the quality of data have been cited as being responsible for the ambiguities in the evidence. One of the consequences of accepting this relationship to explain suicide is to concentrate on building a case that would associate the suicide case with mental illness. And given the public mindset, it would be only too easy to suggest a link to mental illness after the event. For example, in suicide research Beautrais (1994, 2001, 1996) claims that depression and mental illness are the cause of suicide, Khan et al (2000) claim that antidepressants do not reduce suicide and may increase the risk of suicide while Hall et al (2003) claim that antidepressants reduce suicide rates. The latter study compared the first point in the time series with the last point which happened to be lower than the first point and did not make much of the upward trend of suicide rates in between. Suicide data, in particular those based on psychological autopsy type investigations such as Beautrais (1994, 2001, 1996), are often plagued with a high degree of bias and the confounding and compounding of random effects with the structural error such as error-in-variables. Given the current public mindset, helped by the medical model and the media, namely that depression causes suicide, the collection of data on suicide cases after the event from friends and relatives will be highly biased towards mental ill-health as in the Canterbury Suicide Project (Beautrais

1994, 2001, 1996). These studies have failed to address the methodological issues related to design, data collection and analysis thus resulting in misleading conclusions. *Uncritical* use of this type of information as evidence to inform practice will lead to a disparity in service development and delivery. While some practitioners will adapt, only a few may exercise caution. For example, the NZ Medical Journal claims depression is a common, serious and significant illness and links it to suicide and recommends medication [http://www.nzma.org.nz/journal/117-1206/1200/]. It is not surprising to hear that young people have been prescribed antidepressants including preschool children. But more alarming is the prescribing of antidepressants to some children under a year old [http://www.nzherald.co.nz/section/1/story.cfm?c_id=1&objectid=10462684]. It seems arguable, therefore that, if discovered early enough, suicide is commonly treated as depression regardless of the circumstances (also see Shahtahmasebi 2008).

It is this ambiguity in the literature, possibly due to poor study design, inappropriate methodology and inadequate statistical and analytical methods (e.g. see Shahtahmasebi 2006, 2007a), that encourages an elective approach to decision-making where decisions are made subjectively and the evidence to support them is sought after policy implementation (also see Short 1997). There is also ample anecdotal evidence to suggest that such an elective modeling approach encourages policies that artificially tackle an outcome i.e. in effect manipulating outcome(s) rather than attending to the associated parameters.

We must not confuse the advancements in technology with the progress made in understanding health and public health care delivery. All the progress we have made in keeping patients alive longer through past medical and technological research has been uni-directional with only one aim; to intervene. Even the current resources allocated to genetic research have only one aim, namely to intervene. Although on the one hand we appear to be making advances at a faster and faster pace, on the other hand, it feels as though that we have given up; that we are unable to improve ourselves further by understanding health so we attempt to intervene physically by changing our biological code in the hope of affecting change.

THE CONCEPT AND METHODOLOGY BEHIND THIS CHAPTER

If information is indeed the main currency in health service development and delivery, it is only reasonable to study the flow of information and its quality, relevance and appropriateness. In particular, given the resources dedicated to the utilisation of IT within the health industry to improve access to information for the main reason of practicing "evidence based" decision making. To do this, I have adopted a pragmatic approach of briefly exploring how easily a task carried out in the early 1990s could be carried out today. It is assumed that the reader is familiar with the technological progress both in hardware and software, as well as the culture within the health service, in particular towards internet technology and emails since 1990.

In this context, this chapter is a discussion paper on the relationship between technological advancements and evidence-based practice which has led to the creation of "intelligence" units and public health "observatories". In other words, how the technological advancement has been utilised within the health sector to improve information and thus access to data.

A pragmatic approach was adopted to explore the internet for public health data. It soon became clear that new entities purporting as "intelligence" units and "observatories" have become the middle men of 'data' in the health sector. To get some idea as to what "intelligence" refer to, an internet search and scan of selected web pages was carried out. Subsequently, a conceptual model that may help understand the nature of information that may be required as evidence is also discussed.

An important point of this chapter is to ask "how is the advancement in technology being utilized, and whether the utilisation of technology has shifted focus away from the value of data as information?"

The reader may be feeling, quite rightly, bewildered, firstly, that all the progress we have made may appear to be still "downstream" and secondly, how this lack of progress may be related to information and ICT. Let us consider two aspects of information, the flow of information and "information" itself.

FLOW OF INFORMATION

As mentioned in the introduction, the 1994 Public Health Directorate's Annual Report (Bensley et al 1994) was an attempt to explore morbidity and mortality data in the light of social circumstances and geographical area of residence. To achieve this, project data from mortality data sets, hospital records, census, population, digital road maps and geographical boundaries and other additional data had to be extracted from different databases. Furthermore, in addition to the census based deprivation scores, as proxy for social class and lifestyle, individuals were associated with the profile of their area of residence. The idea was that since postcodes were consistently collected for most patients, this data item could be used to link the various data.

In theory, and indeed on paper, the methodology appears easy enough. However, in 1994 it was not merely a case of pressing a few buttons and creating a database of your choice. Each set of data items was received from a different source. One can imagine the number of information departments, officers and data analysts that were necessary to liaise with in order to obtain the data, not to mention the man-hours spent purely on data administration and recovery and the cost of purchasing data. To perform the various tasks involved in the analysis and presentation, a number of software packages were used from the humble spreadsheet to statistical, graphics and mapping packages. Obviously, these computer packages could not directly communicate with each other and the results from one package, e.g. the statistical analysis, output had to be in ASCII and then imported into a spreadsheet to be read by another, e.g. the mapping package.

Although meeting the challenges of utilising different datasets can be exciting and satisfying, the question was raised yet again: why are health data from the same organization in different sources some of which are incompatible with each other? Indeed, this was raised in the meeting of the steering group on the 'Health of the Nation's targets on Mental Health' and was adopted as one of the main guidelines on data collection (Yorkshire Regional Health Authority, May 1993 pp12). The guideline prescribed that the health service commissioners develop a *unified* database by 1994 with particular reference to suicide.

It is fairly obvious that health services operate with a number of professions from medical personnel to managers and PAMs (professions allied to medicine). Although information is important in health care delivery, yet, medical training conditions students in all disciplines about a more important item: a doctor's/consultant's time. In their training, medical students are taught to be concise and brief in their presentation of a patient's case, whereas they should be taught a *critical* assessment of all the information about a patient's case. In training the students to observe facts, the system inadvertently conditions the dynamics of disease development out of the training. Thus, it may lead to a pattern of care that treats the symptoms as opposed to the cause. For example consider the treatment of suicide as mentioned above.

The application of IT within the health industry to improve access to information began with replacing the paper trail. However, while the design and implementation of IT systems were broadly based on the paper trail, computerised systems made access easier and quicker. This means that only some aspects of IT (storage, faster access and retrieval) have been taken advantage of as the same information is simply transferred from paper to disk whether it is a GP service, hospital/Trust, district or area health authority and so on. From an epidemiological view point, this transition may have sped up and overcome some of the obstacles of the past to produce aggregate measures of health outcomes. For example, relevant information departments may have set up databases containing mortality or morbidity (hospital records) and appropriate population files on the main server available to be queried through the organisation's network. There is still no sign or a hint of a unified database.

Even without a unified database, given that most existing records and data in the health sector are available electronically, IT has had a large impact on access time. It all sounds very good, in particular when compared with the experiences of a decade ago in trying to utilise different health outcomes data. Nevertheless, it appears that these achievements have been really a remold of the past into a different medium i.e. faster access to the same data. In other words, the technology has been under-utilised to improve the communication and flow of information between the various sections of the health industry e.g. giving clinicians access to patients' health and health related records, and vice versa.

INFORMATION

Whether or not the flow of information is reasonably satisfactory, our main concern must be the nature and type of information. Currently, routine health/demographic/epidemiological data collection appears to be resource management oriented. It is absolutely essential to investigate trends in mortality and morbidity by cause, age and sex, just as it is also necessary to understand the underlying and causal relationships between the various processes and health outcomes. Therefore, collecting upstream data or information becomes a critical part of the health care service development and delivery. As will be discussed in the next section, this is more easily said than done.

One major aspect is deciding what constitutes appropriate information, while another is what constitutes the appropriate dissemination of information. A common perception of the medical profession is that it operates with knowledge and trust. Therefore, why should the public not listen to, and act on, their advice? For the most part, the flow of information is considered separately and in isolation in developing health care services. What we often choose to ignore is that there are other agents who wish to get the public's attention. With the advancement in information technology, competition has become intense to reach not only more people but those who were previously difficult to reach. Thus what was once an information superhighway has become part of an elaborate industry that includes a whole collection of competing media to provide public access to information e.g. the Internet, television and the entertainment industry, radio, newspapers, popular and tabloid magazines, multi-media, voluntary and government agencies. Therefore there are competing forces seeking more of our attention. For example, the effects, if any, of antismoking campaigns may be counteracted by the covert pro-smoking campaigns through the media and the entertainment industry e.g. see (Gilpin et al. 2007; Shelley et al 2007; Ibrahim & Glantz 2007; Healton et al 2006; Peters et al 2006). Yet, through the information industry, the expectation that "the cure" is only around the corner has become the public norm. The public have become well aware of the advancements in medical science. The idea of the fountain of youth or the magic pill may well relate to man's wish to fulfill his heart's desire without worrying about responsibility and the consequences. In particular, this leads to the presumption that it may not be long before cancers, heart disease and respiratory and other health problems can be treated, thus, making smoking (or other risky behaviour) safe. In the meantime, transplantation has become quite routine and therefore is a viable option. Although superficially "the public's right to information" may be used to disseminate information, the consequences could be adverse, from the expectation of a magic pill, to the Hawthorn effect, to apathy, to the ineffectiveness of science and confusion in setting health care goals. Once again the BBC provides the examples: "Children could get 'diet pills': Children as young as 12 could be given anti-obesity drugs to help them shed excess weight (http://news.bbc.co.uk/go/em/-/1/hi/health/4130992.stm)"; "Many 'imagine' food intolerance: Millions of people in the UK have self-diagnosed a food intolerance and may be cutting out essential foods as a result, a survey suggests (http://news.bbc.co.uk/go/em/-1/hi/health/7000291.stm)"; "Media 'sensationalising science': 'Irresponsible' science reporting undermines public confidence in science and government, a report says (http://news.bbc.co.uk/go/em/-/1/hi/sci/tech/4771154.stm)"; "Sun warnings confuse the majority: Many people are confused by weather warnings designed to help them reduce their risk of developing skin cancer, research shows (http://news.bbc.co.uk/go/em/-/1/hi/health/4566627.stm). There are many other agencies and products using a whole array of information technology to attract the public's attention. The hasty reporting of research results and the media's slant and trivialization of claims and counter claims to the public's amusement could have eroded public sensitivity to the critical receptiveness of information. We do not know how this increased insensitivity affects behaviour. For example, consider the development of organ transplant from its early days to it becoming routine practice. Yet in order for some to live another group must die. And what do we know of the effects of calls by officials such as "everyone should become donors" (BBC 2007) on public expectations and behaviour?

Due to the dynamics of human behaviour, it may not matter how much morbidity and mortality data is made available in a clinical database, for at the end of the day clinicians have to treat the same symptoms over and over again. Individuals are queuing to lie on the operating table. All that clinicians may infer from these activities is a probabilistic association between certain individual characteristics with aspects of ill-health or a disease cross-sectionally or retrospectively. Even threats of refusing care to individuals who knowingly engage in risky behaviour such as smoking has been ineffective.

Thus, temporal dependencies may be understood through exposure, feedback, individual and social behaviour (see Shahtahmasebi 2007a).

DYNAMICS OF INFORMATION SYSTEMS

Information relates to its source and is only good if the dynamics of the source are taken into account. For example, despite advanced statistical techniques and an understanding of the seasonality and cyclic effects, trend analysis will provide some idea of change in the population proportions but we still have to rely on specific epidemiological or other health related studies to gain insight into the disease development process. However, our gained insight is continuously subjected to question due to the conflicting outcomes as discussed earlier (also see Shahtahmasebi 2008). It is not surprising that we may ask the question "how much of our knowledge is actually real insight?" It is therefore of great concern that health and social policies have been developed on our perception of knowledge, without attention to the feedback effect, researchers, policy makers and policies are now part of the problem and not the solution (Shahtahmasebi 2006, 2007a, 2008).

Although, health outcomes are collected at the point of delivery of care, be it a GP consultation or clinical, these are related to the source; individuals whose pattern of behaviour is influenced by processes such as their own characteristic, their social environment and external processes such as the environment. Thus, making human behaviour a dynamic process.

Indeed, the creation of Public Health Intelligence Units (PHIU) and Public Health Observatories (PHO) may be used as a testimony to the recognition of the importance of the above issue. Accordingly, an understanding of the dynamics of the health process is essential if service development to be based on evidence. Furthermore, in recent years, most health sector vacancies in the field of statistics, information, epidemiology or similar jobs appear to promote an understanding between data/information and policy development and can be summarized as follows:

The work is interesting and varied, involving providing statistical advice and analysis for the purpose of developing policies and strategies in support of ... responsible for large-scale data collection and maintain our own and other large datasets, which we use to produce and develop management information, performance indicators and other publications ...

However, it can be noticed from the second part of the above job description that the slant soon changes to a management "culture" of information such as an emphasis on performance indicators and management information which contradicts the first part of developing policies and strategies. To develop policies, information must be able to inform the process of policy development.

The PHIU and PHO boast a multi-disciplinary group of epidemiologists, statisticians, geographers and social scientists to provide intelligence/information which informs health care service planning. For example, the East Midland PHO (UK) is described as one of the nine observatories funded by the Department of Health to strengthen the availability and use of health information at local level (http://www.empho.org.uk/). Similarly, the PHIU in New Zealand boasts a multidisciplinary team of experts in their own fields that make up the PHIU and provide links to a volume of reports and resources such as viewing data in map format.

The question arises as to whether or not these fundamental changes in health information provision to improve health care, have made any difference. Although, evaluation must be an integral part of every policy, every change in organisation or every new strategy and no doubt those authorities responsible for the setting up of the current information systems will have been assessing outcomes, it is not too difficult to get an idea of what the "intelligence" in the PHIU might stand for.

A Google search on "public health intelligence" (using quotes to limit the results to the string rather than each word) resulted in 43,300 hits. A similar search for "public health observatory" resulted in 97,500 hits. Clearly, the majority of the items found are not directly relevant and may merely be related documents. However, a number of key phrases may be observed from those listed on the first few pages and relevant to the PHIU such as to improve access to health data, availability of data, to provide knowledge and information, to improve health, to inform and shape health. All these units appear as initiatives of the health departments of relevant governments.

Obviously it is a huge task, and well beyond the scope of this chapter, to scrutinise each and every single PHIU. From personal experience in the UK, most regional units such as PHIU and PHO perform and produce similar tasks, albeit within their own regions. The slight variation between them may be due to the locality and make up of the staff. For the purpose of illustration some web-links from the first page of the google search results were explored further. The exploration of these websites was based on IT, i.e. applications of (information) technology, and advancement in information. The former refers to access to data, while the latter refers to the nature and quality of information.

There is no doubt that health services information administrators have embraced the technology to make data more accessible to health care organisations and the public. The PHIU's pages visited offer some sort of resources kit for either viewing data or creating tables on chosen parameters such as age, sex, cause and area. Also available for online access are annual reports and other interim bulletins and one-off study results. Perhaps the most advanced feature offered by most is the choice of how data may be viewed. For example, data may be viewed graphically e.g. as a regional map, time series plot, or in tabulated format.

However, for data to be processed, prepared and presented in such a way that can be accessed, queried, tabulised, and graphed on the internet, access to its original source must also be made easy. This will make the work of information/public health specialist much easier. In some of the most recent (UK or NZ) annual reports, it was reported that several different health and social databases had been accessed to produce the reports. So the technology part of IT has, at least, in parts, helped to achieve the philosophical aim of improving access to data by other clients.

A closer examination, however, indicates that these improvements in accessing data have not had a great deal of influence on the information component of IT. Most of the data available is of the aggregate form of proportions, rates and ratios of diseases for each sex and age group. The fact that this type of data can now be graphed and presented in more styles and formats has little bearing on access to information. In essence we are still mapping the current flow and still do not have the means of gaining insight about the flow upstream. Some websites such as the New Zealand's PHI claim that the undertaking and ongoing projects to probabilistically link health records such as hospitals with records from other health care providers. Although record linkage may be carried out with some success using software technology (e.g. see Stott et al. (1994)), record linkage on its own has a limited application and is often utilised alongside other forms of data systems such as surveys or cancer registry e.g. see Tait & Hulse (2005), McGuire et al. (2007), Myint et al. (2006, 2007 & 2008), Hockley et al. (2008). Record linkage may not be as effective as a unified database. The point is that most of the reports produced by the PHIU and PHO on their web pages express public health as a process and there is much talk about other social and economic processes, yet, there is very little evidence of public health being treated as such in their published reports through the data made available.

The current emphasis and guidelines by the Department of Health (UK) on neighbourhood does very little to engage participation by the public at local level and is analogous to the reinvention of the wheel. For example, the annual report posted on the Doncaster PHIU for 2008 provides a method of identifying neighbourhoods as the building blocks for community action. A much more superior work for this purpose has already been published (Openshaw 1983) and applied successfully within the UK National Health Service (e.g. see Thunhurst 1985, Bensley et al 1994). It is very interesting that after some hard work and the use of limited resources to reinvent the wheel, the report recommended the development of an education package of the neighbourhood taxonomy to educate health networks, practitioners (nurses, GPs etc), the academia and that a rollout of successful interventions be targeted, initially within clusters to capitalize on the knowledge of similar environments. This indicates the authors typically prejudging the outcome. Yet again nothing new in this process which is essentially a top-down approach where decisions are made before giving the public a chance to participate. Any public participation has frequently taken the form of a survey. Problematic issues arising from surveys and the consequences of using incomplete information to inform policy formation has been raised and discussed elsewhere (Shahtahmasebi 2008, 2007a&b, 2005a, 2003a).

On the other hand, whilst data can now be easily accessed, the interpretation is often limited to visually observable features. This point is quite clear from studying some of the reports. The documents provided by the New Zealand PHI on their webpage report annual morbidity and mortality statistics. These statistics are often presented graphically with a short description of what the graphs show, see Shahtahmasebi (2008). While some PHIU appear to suggest innovative or new data, most are based on different presentations e.g. using GIS and mapping to present morbidity or mortality data or the neighbourhood building blocks proposed by Doncaster PHIU. All equate to re-inventions of the wheel.

The main point is that despite the application of advanced technology, very little improvement has been made in the availability of new data connecting public health to the dynamics of upstream. Because we are preoccupied with indices and aggregate indicators of health outcomes, we are *still* measuring the current and flow of the river, which does not provide insight into what may be going on upstream.

Both PHIU and PHO claim to improve access to health information as their first goal. It seems, however, that in addition to the duplication, there is yet more work to be done in terms of fully utilising the "T" of IT as both PHO and PHIU appear to be involved in some sort of facilitating role in terms of data collection, collation, processing before it is reported and made available online.

A HOLISTIC APPROACH

Health care services collect individual data at the point of care delivery. Similarly, social care services collect individual data at the point of delivery. Despite the intelligence in the PHIU it is still difficult to get simple data for simple epidemiological feasibility studies. For example, although rates and ratios for suicide and hospitalization due to self-harm are readily available (NZHIS 2001) and have been used to highlight differences in rates between males and females (Shahtahmasebi 2008), from such data it is not possible to answer fairly simple but important questions of proportions and duration, such as:

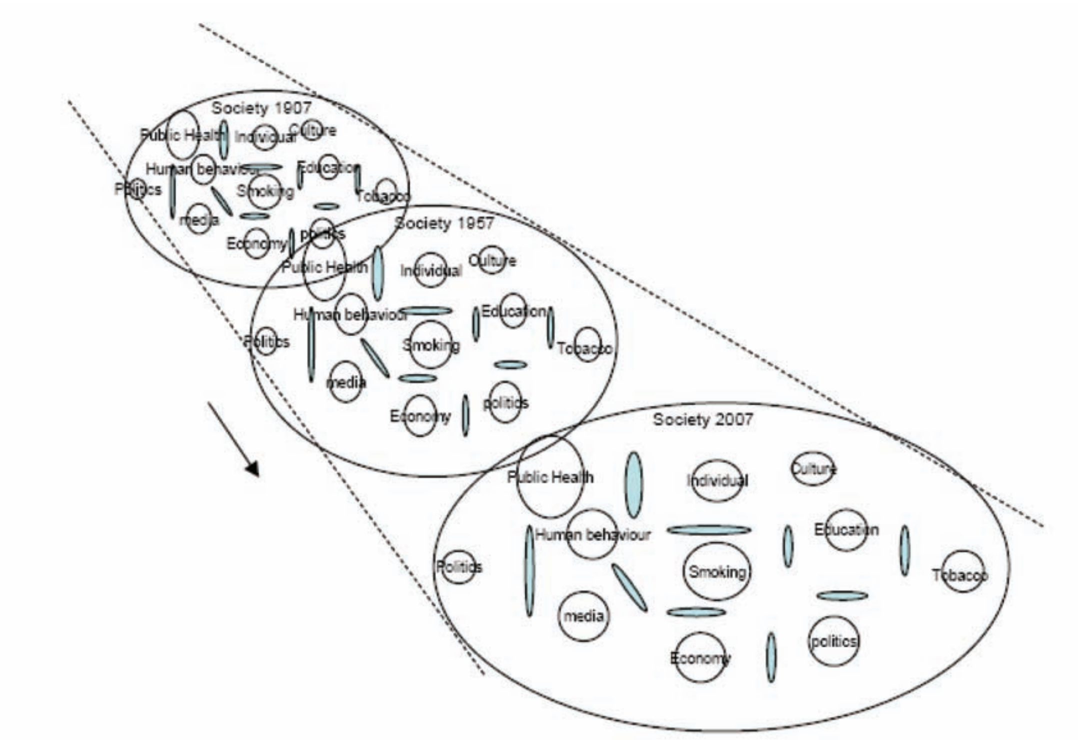
- What proportion of hospitalisations due to self-harm were new cases?
- What proportion were repeat attempters?
- What proportion received psychiatric care and for how long?
- What proportion received any medical care in the community and for how long?
- What proportion completed suicide?
- What proportion have not re-attempted?

And so on. To do so, the above had to be included as part of a major proposal (Shahtahmasebi et al 2001, Shahtahmasebi & Bagshaw 2003b).

These new entities impress upon the public the virtues of evidence-based decisions to improve public health. While they also refer to health and social as processes, it is not clear whether by processes it is meant the administrative aspect of health/social care policy development, or the health/social outcomes, or both. Regardless of what is meant by process, currently accessible data does not lend itself to the understanding of any process. Processes are by nature dynamic.

Most of the above issues were discussed in an earlier paper (Shahtahmasebi 2006) and summarised in Figure 1. The circular line around the process "society" is merely convenience to distinguish time periods and does not indicate that it is a closed process. The solid ellipses symbolize filters, interfaces and unobserved effects which may be process outcomes in their own right. These processes may, for instance, be the outcome of implemented policies that were either withdrawn or were based on incomplete information. The transparent circles symbolize social processes that are directly responsible for social changes and may influence the outcome of interest (in this case smoking) directly or indirectly. It can

Figure 1. An example of a conceptual model of smoking (Shahtahmasebi 2006).



be visualized that this influence will be through relationships and interactions with other processes and unobserved filters/interfaces over time. For example, broadcasting images of smokers, under the banner of art and entertainment or in visual antismoking campaigns, taking a deep puff and then exhaling with an expression of profound satisfaction may be more effective than the old images of cool and confident hero. Most televised anti-smoking advertising in New Zealand show the act of smoking during a televised anti-smoking campaign i.e an anti-smoking message may begin with a smoker lighting up a cigarette and taking a deep puff. The anti-smoking message may be the effect of smoke on internal organs in which case the camera follows and tracks the path of smoke all the way into the lungs and blood stream; or if the message is passive smoking, the smoker is shown to exhale the smoke into the environment and onto other people e.g. in the car or in the house over children etc. What more or better publicity could an industrious cigarette manufacturer wish for?

The main issue here is that, in terms of information, we may have improved access to numbers, rates and ratios of morbidity, mortality and possibly other events such as administration of a treatment e.g. type of medication, surgery, but we do not have any ideas or information on the competing forces in society (as shown in the diagram) on our health-related behaviour. As an example, consider smoking behaviour and suicide. Smoking is considered a major cause of morbidity and mortality yet, despite the restriction placed on the sale (including advertising) of tobacco, taxation regime and smoking in public places, people continue to smoke. It seems that the single message of "smoking kills" on its own is not sufficient, which may be due to advancements in medical technology e.g. the hope that the cure for heart disease and cancers in particular lung cancer are not too far away. Other competing forces may include the tobacco industry and the media's portrayal of smoking and constantly exposing the public to smoking under "art", "entertainment" and public interest or news worthiness (for a discussion of such issues see Shahtahmasebi 2007a). Similarly, as mentioned above, despite the improvements in access to health information in some cases, information on suicide does not go beyond numbers, rates and ratios which makes health care planning a hit and, perhaps more frequently, a miss. Any "hits" may be the temporary feedback effect coinciding with the effects of other competing forces. To illustrate, consider the suicide report issued by Doncaster PHIU on their web page (Doncaster PHIU 2003). Once again the same data (i.e. rates and ratios by sex, age and groups) are presented graphically and a description of the graphs (highs and lows) is given. This report, however, takes an extra step of looking into the claim that a pain killer (co-proxamol) had been a common method of committing suicide and therefore in 1998 attempts were made by the Doncaster Health Authority to reduce access to this drug. The report then presents a graph of superimposing the rate of prescriptions of co-proxomal on the number of suicides using co-proxomal and makes a tantalizing projection that such a policy may have had a significant effect on reducing suicide (Doncaster PHIU 2003, page 8). The report does not appear to take into account the fact that in 1995, 1996 and 1997, when the prescription of co-proxomal was at its highest, there were the same number of suicides as in 1999 and 2001 after the reduction in prescribing co-proxomal. By the same token, such a policy of removing access to a method of suicide may have an effect on suicides using that method but there is evidence to suggest that suicide victims do switch to more violent methods to ensure successful completion (e.g see Shahtahmasebi 2005a&b). It can, therefore, be argued that research and health care development must treat suicide as a process of decision-making which is not too dissimilar from a decision to smoke with the same set of competing forces influencing the decision- making process. In Figure 1 smoking may be replaced by suicide.

If the intention of health/social care services is purely to cater for the population needs they are serving and if there are no resource limitations, trends of outcomes of interests may be used to forecast needs and resource allocation. However, neither health and social outcomes nor resources are static. Clinical successes may be counteracted by the increasing trends previously unnoticed in other outcomes or changes in social outcomes. For example, as a result of clinical successes in making organ transplantation fairly routine, social expectations may have changed accordingly; the public are expected to automatically become donors. On the other hand, those in need of a transplant may be praying for a donor which is ironic as it means someone else must die for a transplant organ to become available.

The feedback effect, a feature of a dynamic process from successes in advancement in technology, has placed the emphasis onto not only maintaining but also increasing the pace of progress e.g. designer organs for transplantation using cloning technology. Thus we have not been able to concentrate on exploring upstream to gain insight into why and how we are in the current position.

Clearly, it is not possible for one service provider to design and collect information on a massive scale as conceptualised in Figure 1. Certainly, I am not proposing that health services around the world to develop complex IT systems. Furthermore, I suggest that adopting a new phrase or a change in title should not be a revolution in name alone! I am proposing that the authorities go beyond their buzzwords invented every now and then to gloss over the reinvention of the wheel such as case-mix, "intelligence" units, observatories, neighbourhood and so on and so forth. In other words, we need to understand that we need information *not* only to calculate budgets and costing of services for intervention, but to develop the sustainable and effective services we need to gain an insight into disease development. We need information from other processes. Theoretically, given the advancement in ICT, this is neither impossible nor difficult to achieve.

In the UK the NHS routinely collects information in various formats e.g. from qualitative and textual reports such as health visitors' records to minimum data sets and hospital records. From these records it should be possible to gain factual and objective information on the population from birth to death. Apart from the quantitative hospital records and mortality data, almost no other NHS records have been utilised (see Shahtahmasebi 1997b). It is plausible that until recently there may have been technical issues with utilising such records. However, the technology is now available, such as powerful palmtops with cell phone technology and networking capability. But it must be first recognized and acknowledged that appropriate information is necessary for any sustainable policy development.

One of the features of the conceptualisation in Figure 1 is an understanding that data from various processes is essential. It can then be conceptualised that in order for the model to work data must be allowed to flow between processes. This means depoliticising and sharing of data. Most countries now have IT systems for the monitoring of health, social, education and economic outcomes. A unified database may take the form of a *virtual* warehouse, perhaps acting as a buffer or filter, providing access to *more* data collected at various stages of life.

Assuming that the technology can be utilised to accommodate privacy and confidentiality requirements, there are two immediate benefits for clinical practice and research. The virtual warehousing can be used to generate aggregate and anonymous multi-level population based data for research, be it a pilot or feasibility study, to explore and assess a broad issue or to test developed hypotheses using appropriate modelling methodologies.

The second advantage is that individuals can be given an access key (such as their own National Insurance Number) to access all information held on them. This facility can be extended to provide further information in the form of responding to online voluntary update forms. Perhaps the greatest gain will be in the clinical and practice where the health care professionals are able to access primary care records (GPs, public health nurses, health visitors, etc) as well as hospitals, and socio-economic and education parameters. However, access to all records may not be appropriate for every health/social consultation, and access to all information may only be provided by the individual who may offer their access key to the health professional. On the other hand, an ability to have an objective life events history complemented by the patient's own recounting will be an important tool in predicting and preventing or modifying health-related behaviour, in particular suicide and self-harm, obesity and smoking.

CONCLUSION

Although it is apparent that routinely collected data such as mortality and hospital records may be readily accessible, it is more difficult to access primary care data such as GPs and nursing and social care records. Nevertheless, data is routinely collected by the various care organisations and their internal departments but the various data or information systems do not communicate with each other in terms of the flow and sharing of data. Whether the blocking issues are political so that each department is viewed as a separate entity to perform a certain task, or incompatible technologies, or a combination of processes, it is, nevertheless, possible using the current information technology to create a multidimensional flow of information. An important implication may be access to additional data/information from publicly funded projects (e.g. medical and health research councils, government departments, research and development). These projects may be linked to the virtual warehouse in a multi-way flow of information, to some extent, to fill the current and future gaps in data and research. The concept of a holistic approach to inform the process of policy formation is the subject of a proposal currently being developed by the author. Therefore, it is difficult to prejudge the outcomes in terms of strength and weaknesses. However, the idea of a holistic approach is to create a flexible policy that can respond to the short-term needs and is sustainable to respond to future needs. The limitation or weaknesses associated with such an ideal 'framework' are the complexities associated with human behaviour (e.g Politics, conflict and politics e.g see Irestig and Timpka 2007), methodology (e.g see Pilemalm and Timpka 2007) and costs. On the other hand, assessments of a flexible policy, at least theoretically, lead to the projection that sustainable policies may be more economical over time as the need for short-term expenditure will be greatly reduced.

The intention of this chapter is to highlight the shift away from evidence given the current emphasis on "evidence" for decision making. It is a good feeling to know that one can find data at a few click of the mouse through fast access to the internet. However, very few question the limitation of the data that can easily be accessed as evidence. On the other hand there are a number of specialty longitudinal databases such as the longitudinal census and FACS (the Department of Work and Pension's Families and Children Study). As discussed in this chapter, analytical methodologies are equally as important as the research methodology to translate data into information (e.g see Emerson et al 2008). Although, the creation of longitudinal databases is a step in the right direction, given the technological advances to date, a unified database is still well out of sight.

KEY TERMS AND DEFINITIONS

Evidence-Based Practice: Critical evaluation of research results to inform policy development.

Health Information Systems: Any formal utilisation of ICT, IT, databases and Public Health.

Information and Communication Technology (ICT): Any means of storing, retrieving and transferring/communicating information.

Information Technology (IT): Any means of storing and retrieving data/information.

Public Health: Formal study and prevention of diseases.

Smoking: The act of smoking tobacco.

Suicide: Terminating one's own life.

Unified Database: Multi-dimensional multi-layered multi-disciplinary database.

This work was previously published in Handbook of Research on Information Technology Management and Clinical Data Administration in Healthcare, edited by A. Dwivedi, pp. 598-615, copyright 2009 by Medical Information Science Reference (an imprint of IGI Global).

Chapter 1.5

Monitoring and Controlling of Healthcare Information Systems (HIS)

Stefan M. Graeber
Saarland University, Germany

Ansgar Kutscha
Diakonie Hospital Schwaebisch Hall gGmbH, Germany

BACKGROUND

Information management (IM) at a health care institution encompasses the management of information, the management of application systems, and the management of information and communication technology whether computer supported or not, that is, IM provides function, performance, and quality of HIS. Management means, as well, the responsible persons and organizational units as the tasks of planning, directing, and monitoring HIS. IM has to be done systematically to enable an orderly processing of information coherent with the goals of the health care institution.

While planning and directing are supported comprehensively by basic methods of strategic planning and project management (Brigl, Ammenwerth, Dujat et al., 2005; Haux, Winter, Ammenwerth, & Brigl, 2004; Winter, Ammenwerth, Bott et al., 2001), the monitoring is neglected sometimes and thus insufficiently supported (Ammenwerth, Ehlers, Hirsch, & Gratl, 2007). As nevertheless a continuous and careful monitoring is a very important task in interaction with all other management tasks, we will define the relevant terms and describe the most significant concepts and methods.

Monitoring

Generally, *monitoring* of HIS means the continuous observation of whether the directives and objectives defined in the strategic information management plan will be reached, and whether the HIS is able to fulfill the required tasks. Therefore, the IM must be able at any time to assess the state of the HIS using quality criteria which can be derived from the objectives. Its results affect directing and planning again by feedback mechanisms.

The tasks of monitoring may be linked to the strategic level (auditing HIS quality as defined by means of strategic information management plan's directives and goals as well as quality of the strategic management process itself), the tactical level (check whether the initiated projects are running as planned and whether they will produce the expected results), and the operational level

DOI: 10.4018/978-1-59904-889-5.ch116

(verifying the proper working and effectiveness of all HIS components) (Haux et al., 2004, p. 182-184).

Nowadays the management tasks providing an excellent service for all users of HIS are embraced by the term *IT service management* (ITSM). There are several frameworks describing an architecture for installing and maintaining ITSM. The most known framework is the *IT infrastructure library* (ITIL) (www.itil.org). It is a set of best practices enabling organizations to deliver their services more efficiently and thus at last to reach for a maximum of customer (patient) satisfaction. ITIL may be regarded as a guideline for monitoring of HIS.

IT Controlling

Management decisions require information or data. In this context, the part of IM delivering information needed as basis for management decisions is called *IT controlling*. For this purpose, IT controlling applies different approaches and methods, for example, the continuous measuring and interpretation of indicators and characteristic values explaining the current state of HIS, or the realization of evaluation studies. Thus, among other IT controlling, comprises following tasks (the terms reference model, indicator, and evaluation project are outlined below):

- Defining and operationalizing objectives (in cooperation with partners of IM)
- Defining models, selection and application of reference models
- Defining indicators and appropriate values
- Planning, initiating, and continuous measurement of indicators
- Planning and performance of evaluation projects
- Reporting results
- Analyzing results (which may influence all preceding steps by feedback-mechanism) (in cooperation with partners of IM)
- Preparing decisions (in cooperation with partners of IM)

Depending on tasks and questions, different methods of information acquisition are applied. Sometimes one performs ad-hoc-studies (field studies) to find hypotheses, to get some insight in the features of performance measuring, or to detect problems and deficiencies (screening). An example of screening is a survey performed to discover the problems with a new nursing documentation system two weeks after installation. More important are the continuous data collection via indicators and occasional deeper investigations (evaluation).

Indicators and Characteristic Values

Indicators are variables whose values (characteristics values) represent an aspect of HIS. To discern good and bad quality of information processing and to assess the achievement of goals, one has to compare the current value of indicator with one or more predefined reference values. With standardized indicators comparisons between different HIS become possible. Relevant aspects may be all components of HIS, for example, strategy, projects, quality, processes, functionality, or parts of IT infrastructure. The indicators can be qualitative (e.g., user satisfaction), quantitative non-monetary (e.g., failure time), or quantitative monetary (e.g., cost). They should be specified as follows:

- Comprehensive description, including its purpose and correlation with the objectives
- Data source, measurement procedure, and algorithms (when indicators are derived from others)
- Characteristic values and reference values (limits), for example, corresponding to quality goals
- Time interval for measurement (e.g., daily, weekly)

- Time of availability
- Responsible organizational unit and person(s)
- Procedure to check adequateness, completeness, and correctness of results afterwards (evaluation of indicators)

To describe complex aspects of HIS, several indicators have to be considered. The combination of logically associated indicators is called an *indicator system*. The Balanced Scorecard (see next paragraph) is an example for an indicator system.

Balanced Scorecard

A suitable tool for management and controlling is the *Balanced Scorecard* (BSC) (Kaplan & Norton, 1992, 2000). At first developed for strategic management of an organization, the BSC can be applied for purposes of monitoring too. It provides feedback around both the internal business processes and external outcomes in order to continuously improve strategic performance and results. When fully deployed, the balanced scorecard transforms strategic planning into the "nerve center" of an enterprise. Using BSC the manager may establish a "balanced" situation between the traditional financial measures and other success factors of an organization. The BSC combines the continuous measurement of performance with a reviewing and refinement strategy as well an ongoing evaluation process.

The basic terms are so-called *perspectives*, for example, potentials (learning and growth), internal processes, customers, and financial perspective. Depending on the view, the term customer can vary: customers from the view of health care organization are mostly patients, customers from the view of IM are users of IT applications. For each perspective, strategic objectives, indicators, and measures to achieve these objectives must be defined.

Models and Reference Models

A *model* is a simplified representation of a section of the real world (subject area). Models are developed for understanding, analysis, or improvement of subject area. Depending on purposes of modeling the relevant aspects of subject area are selected and built in only. Models become an important tool for the IM, because they help overwhelm the complexity of HIS.

A metamodel can be considered as a toolbox for building models. With general metamodels like ARIS (www.ids-scheer.com/international/english/products/53961), one can describe processes independent of the business field. The three-layer graph-based metamodel (3LGM²) is a specialized tool for static HIS modeling. The domain layer consists of functions and entity types. The logical tool layer focuses on application components, and the physical tool layer describes physical data processing components. Additionally several inter-layer-relationships are defined (Winter, Brigl, & Wendt, 2003). The 3LGM² allows building of models of HIS presenting their current state with adequate levels of granularity. So one can find out, for example, which functions are supported by which application systems, or the kind and scope of communication processes between different applications. In this manner, deficiencies may be detected, too, for example, gaps in information transfer. Additionally the 3LGM² allows to integrate indicator systems and to compute indicators along the relations between the model objects (Kutscha, Brigl, & Winter, 2006).

A *reference model* is a template for a well-defined class of models, that is, from a reference model concrete models are derived by modification, restraints, or additions (Haux et al., 2004, p. 73). Furthermore one can check by comparison, whether concrete models have the same features as the reference model, for example, completeness of functions. Therefore the use of a reference model can deliver relevant indicators. Depending on subject area, there are reference models for organizations, information systems, software, or procedures.

Reference models support the quality assessment better than models. They function like standards, that is, if the quality of reference model is proved, the quality of a concrete model may be made evident by comparison using quality indicators. The reference model itself should be evaluated also to provide that the model is a sufficient map of reality.

For the monitoring of HIS, one needs reference models for information systems to find out whether the business processes are supported by efficient tools, or the necessary information flows are established (Winter et al., 1999). But also reference models for procedures are useful (see examples provided).

Evaluation

Evaluation is the act of measuring or exploring properties of a health care information system (in planning, development, implementation, or operation), the result of which informs a decision to be made concerning that system in a specific context (Ammenwerth, Brender, Nykanen, Prokosch, Rigby, & Talmon, 2004). With the information acquired by evaluation, one can learn something, answer relevant questions, or make decisions. In this manner the screening mentioned above can be regarded as a "simple" evaluation. Evaluation of health care systems is a main topic of research in medical informatics (Brender, 2006; Friedman & Wyatt, 1997). Therefore, here some methodical principles are outlined only.

There is a wide spectrum of evaluation methods. It reaches from simple surveys to exactly planned longitudinal investigations. Some studies are performed like clinical trials. It means that one should try to apply principles of Good Clinical Practice (http://www.ich.org/LOB/media/MEDIA482.pdf). But often some techniques are not applicable (e.g., randomizing or blinding). Nevertheless reliable studies can be performed, if some recommendations are taken into account (Ammenwerth, Graeber, Herrmann, Buerkle, & Koenig, 2003). All decisions and steps should be documented in a detailed study protocol. An adequate study design and appropriate methods to answer the study questions have to be selected. The combination of quantitative and qualitative methods may be helpful. Wherever possible, validated evaluation instruments should be used. Often a multi-methodic and/or multidisciplinary approach is necessary (Ammenwerth et al., 2003).

Evaluation studies can be formative or summative. Formative evaluation strives to improve the HIS component under evaluation by providing the developers (and implementers) with feedback. Summative evaluation tries to demonstrate the outcome of a "mature" HIS component in routine (Friedman & Wyatt, 1997, p. 304).

Organization of IM

Organizational structures for IM differ considerably among health care institutions. In general, each institution should have an adequate organization for strategic, tactical, and operational IM, depending on its size, internal structure, and needs. Reference models for the organization of IM in hospitals are given in Haux et al. (2004, p. 187ff).

The relation between IM and IT controlling may be formed very differently. Between the two "poles" (IT controlling totally embedded without own directives vs. IT controlling as specific organizational unit beside IM) several structures are possible.

Next to organization the performance of IM plays an important role. For example, the performance level of IM can be assessed by the Capability Maturity Model (www.sei.cmu.edu/cmmi/). The IM should have a high maturity level, that is, it should function as *business enabler* for the hospital.

Table 1. Perspectives and corresponding objectives for a BSC (examples)

Perspective	Objectives
Potentials Employees Infrastructure Organization *Information management* …	*Efficient support of processes by IT* Establishing interdisciplinary functional units …
Processes Medicine Research Teaching Administration …	Establishing structured and transparent workflows for patient care (e.g., clinical pathways) Better and faster implementation of current medical evidence …
Customers Patients and relatives Cooperating practitioners Cooperating hospitals Students Consultants …	Increasing the integration of in- and out-patient care Enhancement of user satisfaction …

EXAMPLES

Table 1 shows perspectives (without financial perspective) and corresponding objectives from a BSC established at a German university hospital. The main perspectives of BSC were modified slightly. A part of the indicator tree for the subperspective *information management* and the appropriate objective *efficient support of processes by IT* is presented in Table 2. The indicator tree defines the indicators and their dependencies, which have to be measured for a perspective. Overall this BSC contains 11 composite performance indicators reflecting particular strategic objectives. These measures are expressed in terms of actual performance as percentage of expected performance. For further examples of BSC application, see Kaplan and Norton (2000).

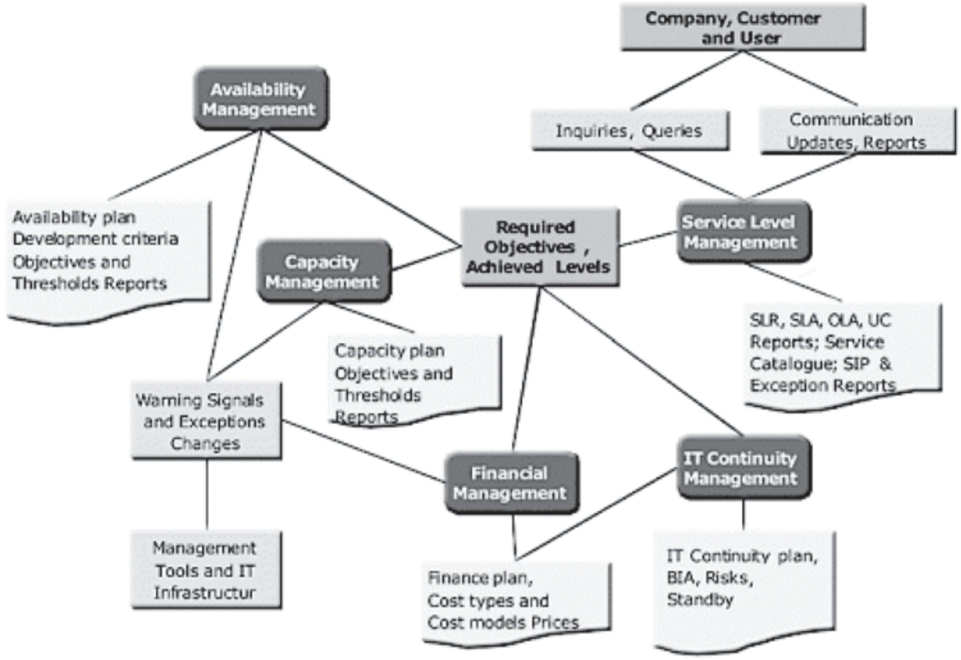
Ammenwerth et al. (2007) developed a so-called HIS-monitor to describe the strengths and weaknesses of information processing at hospitals. This monitor is a matrix whose rows represent several quality indicators while the columns define the necessary processes and subprocesses of patient care. The matrix is filled out during standardized interviews with hospital staff. Thus, one can reveal the processes that are not sufficiently supported by IT.

Table 2. Part of the indicator tree

Function level Availability of application infrastructure Failure time Applications Basic services Hardware Network Reaction time/problem-solving time Number of problems Number of problems solved within one day Completeness of medical record Ratio of digital images Ratio of released documents User satisfaction Functionality Availability Support …
Dissemination level …
…

ITIL is an example for a reference model for procedures. It defines the necessary management tasks at tactical level (service delivery, Figure 1) and operational level (service support, Figure 2).

Figure 1. Tasks and objects of service delivery (from Ammenwerth et al., 2007)



The advantage of ITIL for the alignment of IT with business objectives is reported (Kashanchi & Toland, 2006).

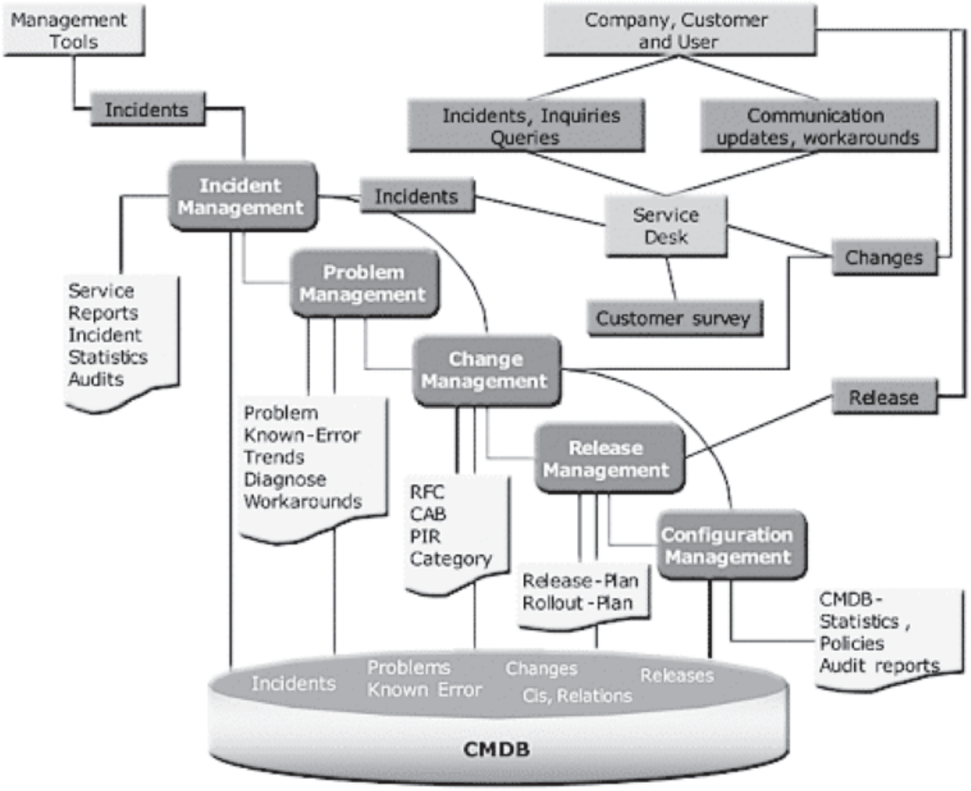
An example of a reference model for a hospital information system is the requirements index for information processing in hospitals (Ammenwerth, Buchauer, & Haux, 2002). German experts established the index in a consensus-based, top-down, and cyclic manner. Each functional requirement was derived from information processing functions and subfunctions of a hospital. It contains 233 functional requirements and 102 function-independent requirements. The functional requirements are structured according to the primary care process from admission to discharge, handling of patient records, work organization and resource planning, hospital management, research, and education. For example, with the index, one can find out the ratio of implemented functions.

Only three examples of evaluation studies are mentioned here, two of those were conducted and published by the first author. A method for the selection of software for a subsystem of HIS is described in Graeber (2001). An investigation of user satisfaction with clinical workstations was published in Graeber (1997). Machan, Ammenwerth, and Schabetsberger (2006) published the rather comprehensive and understandable description of an evaluation project to assess the electronic transmission of medical findings. Evaluation projects of the last 20 years can be found in the Web-based inventory of evaluation studies in medical informatics (evaldb.umit.at). The database can be searched with keywords. Many entries may be used as patterns for successful evaluation studies in fields of HIS.

Problems and Challenges

Often an insufficient organization of IM is the main obstacle for an effective HIS monitoring. This problem includes the lack of highly qualified staff for ambitious management tasks. Sometimes the objectives of IM are not adequate defined or they

Figure 2. Tasks and objects of service support (from Ammenwerth et al., 2007)



are not consequently derived from the enterprise goals (Brigl et al., 2005). Also a general deficiency of awareness of the importance of monitoring and controlling as well as insufficient consideration of the needs of customers and users can inhibit the establishment of an IM resp. ITSM structure at health care institutions.

A further problem is the development from *hospital* information system to *health care* information system. A modern HIS encompasses many different health care organizations and institutions with different IT infrastructures. This complexity makes a comprehensive and effective IM very difficult.

Although the successful use of BSC in health care sector is described (Stewart & Bestor, 2000; Protti, 2002), its application for HIS monitoring yields some new aspects. Especially the following success factors have to be considered:

- The method must be strongly supported by the enterprise management
- The application of BSC requires a lean management. Otherwise a schism may occur between the management and the need to get detailed understanding of work processes and motivation from staff (Brender, 2006, p. 86)
- An early and continuous communication with employees about the purpose and results of BSC is needed
- All involved people must have an open mind for definition of perspectives, objec-

tives, indicators, and measures as well for the interpretation of results
- One should prefer less but significant indicators
- IT-support of BSC is not compulsory, but helpful. One should strive for the integration of BSC in a data warehouse system
- The BSC has to be evaluated periodically

Although the effort for the development of BSC can be considerable, its use for monitoring is very functional. It helps to translate the vision of a health care institution and to gain consensus, to communicate the objectives, to link goals with strategy, to allocate resources, and to provide feedback and ensure learning. It is an efficient way to link day-to-day operating activities to the strategic objectives.

A suitable model of HIS is an important prerequisite for an efficient IM. With the 3LGM² not only technical and semantic aspects but also computer-based and paper-based information processing are integrated in the model. Deficiencies in the current state of HIS can be detected and hence the quality of information processing can be assessed. Such a model can be the basis of the strategic information management plan (Brigl et al., 2005) as well as of economic analyzes (Kutscha et al., 2006). A disadvantage of 3LGM² is the static view. For modeling of dynamic aspects a business process metamodel (e.g., ARIS at www.ids-scheer.com/international/english/products/53961) has to be used.

Contrarily to other branches, reference models for the information management in health care are seldom. A cause may be that most models are too specific and not suited as reference. These restrictions concern the BSC too. Therefore the development of valid reference models for HIS is a major challenge.

Rapid changes in technology (e.g., telehealth) and increasing complexity of HIS cause also new conditions for evaluation projects, for example.

- Studies must be carried out in different types and size sites, with different HIS components and different groups of users
- People, organizational, social, and ethical issues must be taken into account
- Evaluation aspects must be incorporated into all phases of a project
- Importance and effect of formative evaluations are increasing

Problems and challenges of evaluation projects in medical informatics are discussed detailed in Kaplan and Shaw (2004).

KEY TERMS AND DEFINITIONS

Balanced Scorecard: The balanced scorecard (BSC) is a *management* tool that enables organizations to clarify their vision and strategy and translate them into action. Using BSC, the manager may establish a "balanced" situation between the traditional financial measures and other success factors of an organization. The BSC combines the continuous measurement of performance with a reviewing and refinement strategy as well an ongoing evaluation process. The basic terms are so-called perspectives, for example, potentials (learning and growth), internal processes, customers, and financial perspective. For each perspective, strategic objectives, indicators, and measures to achieve these objectives must be defined.

Evaluation: Evaluation is the act of measuring or exploring properties of HIS (in planning, development, implementation, or operation), the result of which informs a decision to be made concerning that system in a specific context. Contrarily to continuous data collection, evaluation studies are carried out to answer special questions, usually in form of a project with a clear time limit. When possible, for such studies the same criteria and methods as for clinical trials should be applied.

Indicators and Characteristic Values: Indicators are variables whose values (characteristics values) represent an aspect of HIS. To discern good and bad quality of information processing and to assess the achievement of goals, one has to compare the current value of indicator with one or more predefined reference values.

IT Controlling: In this context, the term controlling (or more precisely IT controlling) is restricted to the tasks of information acquisition and data collection as basis for decisions of IM. For this purpose IT controlling applies different approaches and methods, for example, the continuous measuring and interpretation of indicators and characteristic values explaining the current state of HIS, or the realization of evaluation studies.

IT Service Management: Beside the internal business processes, the focus of monitoring should be the external outcome, as well. To provide an excellent service for all users of HIS and at last to reach a maximum of customer (patient) satisfaction, nowadays the appropriate management tasks are embraced by the term IT service management (ITSM). There are several frameworks describing an architecture for installing and maintaining ITSM. The most known framework is the IT infrastructure library (ITIL), which defines the necessary management processes at tactical level (service delivery) and operational level (service support).

Monitoring: Monitoring of HIS means the observation as to whether the directives and objectives defined in the strategic information management plan will be achieved, and whether the HIS is able to fulfill the required tasks. Therefore the IM must be able at any time to assess the state of the HIS using quality criteria which can be derived from the objectives. The tasks of monitoring may be linked to strategic level (monitoring of the achievement of strategic information management plan), tactical level (monitoring of projects), and operational level (operational monitoring, that is, verifying proper working and effectiveness of all HIS components).

Reference Model: A reference model presents a kind of model patterns for a certain class of aspects. It can be used to derive a specific model or for purpose of comparison. Comparing a specific model of HIS (or subsystem) with a reference model congruencies and differences may be stated and used for planning and direction of HIS.

Chapter 1.6

IT Benefits in Healthcare Performance and Safety

Stephen Bolsin
Melbourne University, and The Geelong Hospital, Australia

Mark Colson
The Geelong Hospital, Australia

ABSTRACT

There is no doubt that carefully designed IT solutions enhance the capture of performance and critical incident reporting data in clinical environments. This chapter will examine the effectiveness of recent initiatives in this area and the value of the information that can be generated. While outlining the proposed savings to healthcare systems that can be anticipated by improved performance monitoring and incident reporting, the authors will also explore the additional value that the IT solutions can offer to clinicians in terms of improved learning experiences and ethical behaviour. Extensions of these applications will be discussed, with the necessary prerequisites (e.g. ease of data entry, single data entry/multiple data use, speed of data collection, rapid and accessible feedback of results, etc.) that underpin these advances. The potential barriers (e.g. technophobia, fear of performance monitoring, poor ethical standards) to successful uptake and implementation in healthcare are also considered.

INTRODUCTION

The earliest work on accurately monitoring the success and failure of healthcare systems is attributed to Florence Nightingale and Lord Moynighan in the UK and Ernest Codman in the US. The pioneering of the professional role of nurses by Florence Nightingale in the 19th Century is well known, but her extension of healthcare analysis into the audit of hospitals is less well publicised. She worked with the British Home Secretary Lord Moynighan in producing these early audits, which, in the absence of computing power, were time consuming and extraordinary for their time (Chambler & Emery, 1997; Nuttall, 1983). Later, in the early 20th Century, a New England physician, Ernest Avery Codman, attempted a similar analysis by defining the "outputs" of a hospital and attempting to relate these to different practices. Again all of Codman's analyses were undertaken without the assistance of computers and represent a large number of calculations that can currently be undertaken by modern computers in fractions of a second. However his work was uniformly unpopular with his colleagues and he was ostracised by the local medical community

(Codman, 1914; Kaska & Weinstein, 1998). The importance of these early pioneers of audit and performance monitoring was that they assumed that individual and system performance could be measured and then optimized (Spiegelhalter, 1999). The tacit assumption that ensured their lasting unpopularity with the medical profession was that healthcare performance was not already perfect; or that system or individual error was occurring in the hospitals and health systems that they examined. Largely due to the work of these pioneers and the application of sophisticated computing programs and devices we now know much more about the frequency and cost of these adverse events in healthcare.

Errors in medicine are expensive, not only in terms of human life and the suffering they impose on patients, relatives and carers but also the financial burden that they impose on healthcare systems in the developed world (Kohn, Corrigan, & Donaldson, 1999; Lesar, Lomaestro, & Pohl, 1997; Michel, Quenon, de Sarasqueta, & Scemama, 2004; Vincent, Neale, & Woloshynowych, 2001; Wilson et al., 1995; Woods, 2000). Information about these episodes in complex healthcare delivery has only become widely available through the use of large computing and IT systems designed to collect clinical information. The most recent estimates indicate that this cost was $17-29 billion, in the US alone, in 2000 and may have contributed to between 48,000-98,000 deaths in the same period (Fenn, 2002; Kohn et al., 1999). Despite this human and financial cost, rates of adverse events do not appear to be falling, certainly in Australia and the US there is little evidence that adverse event rates are decreasing (Ehsani, Jackson, & Duckett, 2006; Wilson & Van Der Weyden, 2005).

Studies of adverse events have defined generic failings that have contributed to these identified errors (Thomas et al., 2000; Thomas et al., 2000; Wilson, Harrison, Gibberd, & Hamilton, 1999). Incident reporting in clinical medicine improves patient safety by reducing future errors. This occurs as incident reports lead to the identification of underlying generic and systemic errors and measures are put in place to prevent their recurrence (Barach & Small, 2000; Bolsin, Faunce, & Colson, 2005; Kraman & Hamm, 1999; Wolff, 1996; Wolff, Bourke, Campbell, & Leembruggen, 2001).

PERFORMANCE MONITORING

Monitoring the Performance of Healthcare Systems

The feedback of performance data to medical practitioners in healthcare has been demonstrated to improve the quality of measurable patient outcomes in several situations. Mark Chassin, as Head of Public Health in New York State, developed a comprehensive, compulsory IT-based programme for the collection and dissemination of risk-adjusted outcomes from cardiac surgery to all cardiac surgeons and hospitals undertaking cardiac surgery in New York State (Chassin, Hannan, & De Buono, 1996; Hannan, Kumar, Racz, Siu, & Chassin, 1994). Remarkably the use of the IT-enabled data collection and outcome feedback programme led to a 40% reduction in risk-adjusted mortality over a 3-year period (Hannan, Kilburn, Racz, Shields, & Chassin, 1994). Another voluntary cardiac surgery programme set up with similar goals also in the Northeast of the USA, and also employing sophisticated computing programs and enormous computing power, achieved almost identical results (O'Connor et al., 1996). This confirmed the value of measuring outcomes from complex interventions, adjusting for the patient's risk in the intervention and feeding back risk-adjusted outcomes in a sustained and systematic fashion. The importance of this work relates, in part, to the uniformity of the findings in a complex speciality of medicine (cardiac surgery), and the use of risk-adjustment to validate the process of data collection and feedback to the clinicians. However the timing of the studies also shows that the profession has known about this method of achieving quality improvement for patients for well over 10 years but made little progress to concrete implementation across many specialities.

An early concern about this type of database collection related to the anonymity of the data collected and whether the highly sensitive performance data could be accessed by anyone other than those professionals closely involved in the data collection (Green & Wintfeld, 1995). In fact these concerns proved completely unfounded. Publicity about the data collection led a North American television programme, *Newsday*, to attempt to obtain access to the information contained in the database. The television journalists mounted a legal case, in the New York courts, to obtain disclosure of the performance data. The data that they requested to be disclosed was not only of individual cardiac surgeons, or cardiologists but also of each particular hospital contributing to the data collection. Mark Chassin and the New York State Health Department vigorously defended the challenge to the secrecy of the database claiming clinicians would shun the data collection in the future if the detailed information about individual and institutional risk-adjusted performance was revealed. This persuasive argument carried some weight with the Judge, who saw the need for privacy for the profession and the survival of the database. He was able to relate the database survival to future good that the data collection and feedback would contribute to patient outcomes in the State of New York. The counter argument put forward by the journalist's legal representatives was that the information that the Department of Health had collected was so important to future patients who might be considering, or at risk of, cardiac surgery, or cardiac procedures, that the information should be made public.

This argument carried more weight with the judge and he ordered the release of all the information in the database. The response of the journalists and the press was not to publish only the risk-adjusted outcome data from the database but to publish the crude mortality rates for named individual surgeons and physicians as well as the crude mortality rates for named hospitals. Apart from the uproar within the profession in the US and across the world there was remarkably little response from the clinicians who contributed to the database. The hard work of Mark Chassin and the New York Health Department ensured that the data collection survived and has continued.

The importance of this sequence of events is that it demonstrated that anonymity and institutional clinical privacy in data collections is not a prerequisite for their success or for the clinicians contributing data to trust such data collections. This is an important conclusion and can be applied to all databases of this nature. The outcome of the court case in New York was to demonstrate that future performance monitoring projects involving sophisticated, IT systems and computer calculations as part of database analysis do not need to be set up as privileged data collections. The computer reliant, electronic performance monitoring data collections and analyses of the future do not need to be set up as secret, private or legally privileged. However when they are set up they can expect to significantly reduce morbidity and mortality rates in that medical speciality and geographical region.

Work in San Francisco also demonstrated that the feedback of outcome data in other specialities such as urological surgery also improved patient outcomes (Shortell, Bennet, & Byck, 1998). A similar data collection for cardiac surgery has been set up in the State of Victoria, Australia with regular, risk-adjusted mortality and morbidity results which are fed back to voluntarily participating cardiac surgeons (Reid et al., 2004). These data collections require a considerable amount of data input and in the case of the Victorian State programme a dedicated data input clerk is employed at each centre. However there is no reason to propose that these programmes, designed with such data entry requirements, need to be sustained with such a costly workforce. There is ample evidence that using well-designed data entry screens individual practitioners can and will correctly and continuously enter performance data into hand held computing devices (Bent, Creati, Bolsin, Colson, & Patrick, 2002; Bolsin, Faunce, & Colson, 2005).

The value of the crude or risk-adjusted outcome data from such data collections has recently been given much more emphasis by two Australian bioethicists. Stephen Clarke and Justin Oakley have proposed, in the American journal *Philosophy & Medicine*, that clinicians who do not know their own crude or risk-adjusted outcome data cannot gain *full* or *proper* informed consent from their patients (Clarke & Oakley, 2004). This ethical assertion has potential wide-reaching ramifications for clinicians and healthcare organisations. If it is not possible to obtain true informed consent from patients without a clinician knowing their mortality and complication rates it is necessary for clinicians, on their own or in specialist groups, to try to collect the necessary performance information. This assertion, if either the profession, or the healthcare industry, or most importantly the public, accepts it, has enormous implications for information technology and the future of performance monitoring data collection in health care. The logical consequence of requiring doctors and their healthcare organisations to provide prospective patients with their performance data is enormous (Bolsin, Faunce, & Oakley, 2005; Bolsin, Patrick, Colson, Creati, & Freestone, 2005; Bolsin et al., 2005). There will be an urgent requirement for detailed, reliable data collections utilising large amounts of computing power and also requiring the development of sophisticated computer programs to link doctors in particular, but health care professionals in general, to detailed data collections, housed in possibly remote databases and linked to mobile computing devices (Bolsin et al., 2005). Such devices, similar to the recently released iPhone, will be the data entry point for clinical information to be entered into the database and then disseminated with appropriate flags and restrictions (e.g. privacy, confidentiality, end-user status, security) to be used in a series of computer analyses to produce performance and outcome measures irrespective of site, location, professional speciality or grade (Bolsin et al., 2005a; Bolsin et al., 2005b; Bolsin & Freestone, 2007). This exciting vision of optimised patient care in a modern health service is not as remote as it may sound with foundational work already achieved in the Geelong Hospital in Australia and successful "proof of concept" studies published (Bent et al., 2002; Bolsin & Colson, 2003; Bolsin et al., 2005; Bolsin & Colson, 2000; Bolsin & Colson, 2003; Bolsin & Day, 1998; Bolsin et al., 2005; Bolsin & Freestone, 2007).

IT improvements, since this pioneering work was undertaken more than 10 years ago in North America, have made the processes of data entry, data collection, data collation and data analysis much quicker and easier (Bent et al., 2002; Bolsin et al., 2005; Bolsin & Freestone, 2007). There is no reason why these advances should not be incorporated into current health care programmes in order to accommodate the principles of quality improvement and quality assurance in modern healthcare systems (Garg et al., 2005).

The major challenge for IT specialists employed in the healthcare arena is to design data entry and access screens for the busy clinician, that accommodate their requirements for personal access, ease and speed of data entry. Another important consideration surrounds the addition of value or "value adding" that such portable computing devices can achieve through providing laboratory or imaging results, educational links or decision support applications (Bolsin et al., 2005a; Bolsin et al., 2005b; Bolsin & Freestone, 2007). The easily achievable goal must be simple, rapid, reliable data entry at each point of care by multiple health care professionals using mobile computing platforms; each professional obtaining extra value from the data input by simultaneously accessing their own performance data (individually analysed with personalised feedback), and the units outcome data, risk-adjusted by accepted specialist risk-adjustment algorithms. The evidence clearly demonstrates that the design, adoption and widespread use of such performance monitoring programs in clinical care would significantly reduce the occurrence of complications and death in routine and highly specialised healthcare interventions (Hannan, Kilburn et al., 1994; O'Connor et al., 1996; Reid et al., 2004; Shortell et al., 1998). Furthermore the savings attributable to such improved practice would more than pay for the introduction of the IT system proposed and would also lead to year on year savings to the health care providers involved (Bolsin, Solly, & Patrick, 2003).

Although it would appear on the face of it to be an axiom of modern healthcare, as well as a common sense conclusion, the evidence that compliance with the guidelines of Specialist Colleges or Societies in Medicine improves outcomes has been relatively hard to find. The demonstration of the value of adhering to accepted clinical guidelines from specialist societies has only recently been published (Peterson et al., 2006). In a landmark article in the New England Journal of Medicine Peterson and co-workers analysed data from a clinical trial designed to examine outcomes from patients presenting with acute myocardial infarction and acute coronary syndromes. The study examined data collected for a large multicentre, randomized, controlled trial and therefore represented the highest quality of data available in clinical medicine (Barton, 2000; Benson & Hartz, 2000; Concato, Shah, & Horwitz, 2000). Furthermore the study was able to breakdown the contributing centres into 4 groups, or quartiles, with differing compliance with the AHA & ACC guidelines for the management of Acute Coronary Syndromes (ACS) and Non-ST Elevation Myocardial Infarction (Non-STEMI). These conditions are known to the layperson as cardiac ischaemia and acute myocardial infarction or angina and heart attack respectively.

They showed that not all centres, collecting data for a multicentre trial, had the same level of adherence to specialist society guidelines (Peterson et al., 2006). Failure to comply with Specialist Guidelines in this analysis was not blindly interpreted on a simple "Yes" or "No" basis but involved examination of documentation for reasons for failure to comply. For example if a patient had a history of asthma, (when β-blockers can be contraindicated) and therefore was not prescribed β-blockers, the centre was deemed to have complied with the Guidelines. The study did not examine cutting edge or 'time critical' components of the American Heart Association (AHA) & American College of Cardiologists (ACC) guidelines, but concentrated on nine relatively simple actions in the guidelines. For example "Did the patient receive aspirin, a β-blocker, heparin or an intravenous glycoprotein IIb/IIIa inhibitor in the first 24 hours after diagnosis?". Or "Did the patient receive aspirin, a β-blocker, clopidogrel, an ACE inhibitor and a statin prior to discharge?". The detailed analysis of the large computer database of institutional performance and outcome, demonstrated that those centres that had greater compliance with American Heart Association and American College of Cardiologists (AHA & ACC) Guidelines had a lower mortality than those centres that had much lower compliance with the guidelines (Peterson et al., 2006).

When the mortality for each group of centres was examined there was a statistically significant and graded *increase* in mortality associated with the *decrease* in compliance with the AHA & ACC guidelines. The quantative expression of this effect was that there was a 10% reduction in mortality, for each condition (ACS or Non-STEMI) for every 10% increase in process compliance. Given that the maximum compliance of any centre was 90% and the worst compliance was <40% there is obviously significant room for improvement and reduction in mortality.

We know many of the components of optimal care that are currently not being delivered are routine items in an ideal clinical pathway (Forkner, 1996; Hindle & Yazbeck, 2005; Spur, Flammini, & Goulart, 1996). The clinical pathway is an ideal composite amalgam of items of care delivered by many different health care professionals and includes multi-professional features such as drug delivery, coordination of care (e.g. arranging appointments prior to hospital discharge), communication (e.g. discharge summary) and checking (e.g. Laboratory or imaging results) (Choong, Langford, Dowsey, & Santamaria, 2000; Forkner, 1996; Swanson, Yellend, & Day, 2000). We know that often in complex care situations important steps are missed because of "human error" but we also know that the memory of an appropriately programmed computer can supplement and improve on the fallibility of human behaviour (Garg et al., 2005; Kohn et al., 1999; Wilson et al., 1995; Wilson & Van Der Weyden, 2005) (See incident Reporting below). Consequently if the mobile computing platform can be designed to provide this extra connectivity between different members of the health care team such as doctors, nurses, pharmacists, primary care physicians, community nurses, dietitians, etc, it is possible to create a connected network of health care workers informed about each patient's clinical pathway, knowledgeable about relevant immediate, medium and long-term future care plans and goals and connected to all relevant secure information sources, with automated reminders on critical components of care about the patients for whom they have been, are and will be caring (Bolsin et al., 2005; Bolsin & Freestone, 2007; Garg et al., 2005).

The value that computing and Information Technology are contributing to the ability to analyse outcomes from complex medical processes is currently enormous but widely underutilized (Garg et al., 2005). IT-based analyses similar to the one quoted are capable of identifying patterns of practice and assigning causes of both good and bad performance, linked to patient outcomes. This incredibly constructive and valuable application of computing, power, Information Technology and programming must be applied to all aspects of health system activity. Even if healthcare managers or clinicians are reluctant to improve process compliance surely their patients would be urging optimal compliance at almost any cost.

Individual Performance Monitoring

The errors identified in the Quality in Australian Healthcare study have been attributed to different generic causes (Wilson et al., 1999).

These include:

- 35% complication/failure of technical performance
- 15.8% decision action failure
- 11.8% failure to arrange procedure/investigation/consultation
- 10.9% lack of care/attention

Many of the errors in the first category (complication/failure of technical performance) could be reduced by the adoption of simple IT solutions that are currently available (Bent et al., 2002; Bolsin, 2000; Bolsin & Colson, 2003a; Bolsin et al., 2005; Bolsin & Colson, 2003b; Freestone, Bolsin, Colson, Patrick, & Creati, 2006; Garg et al., 2005). Work in the Geelong hospital, Victoria, Australia demonstrated that accredited anaesthetic trainees provided with a simple and 'easy to use' program on a portable, handheld computing device would log their success or failure (i.e. performance) of practical clinical procedures for subsequent analysis and monitoring (Bent et al., 2002).

One of the important components of the data analysis and feedback was the employment of a relatively 'simple to comprehend' technique for the analysis and display of performance data. The technique used was the 'Cumulative Summation' analysis or Cusum (Page, 1954). This industrial statistical methodology had been developed in the 2^{nd} World War, but had been transferred to the surgical arena by MRC Research Statistician, David Spiegelhalter, in a seminal paper examining outcomes from paediatric cardiac surgery (de Leval, Francois, Bull, Brawn, & Spiegelhalter, 1994). We decided, in Geelong, to employ this sensitive analysis of the performance data logged by the anaesthetic trainees because it provided reliable early warning of a performance deviation from normal. The measurable change in performance could be in a deleterious direction that required remedial management, as patients and healthcare managers would want, to successfully ensure the quality of the healthcare delivered in their organization. However the analysis is also able to statistically identify meritorious performance indicating that skills had been acquired, competence achieved and training in this area could be completed (Bolsin, 2000; Bolsin & Colson, 2000; Bolsin et al., 2003). This ability of the analysis to routinely identify the acquisition and maintenance of competence is an important requirement in healthcare delivery.

Assessment of competence has been one of the major challenges encountered by healthcare regulators in recent years (GMC, 2006; Irvine, 2004, 2006a; Irvine, 2006b; Irvine, 2004). Lack of competence led to many of the publicized medical scandals in several countries (Kennedy, 2001; Sibbald, 1998; Van Der Weyden, 2005). The manifest inability of healthcare professionals and regulators to agree measures of competence has been surprising despite recommendations in journals of healthcare quality (Bolsin, 2000; Bolsin & Colson, 2003a; Bolsin et al., 2005; Bolsin & Colson, 2000; Bolsin & Colson, 2003b; Bolsin et al., 2005; Bolsin et al., 2003). The Cusum test provides a simple and effective method for making this assessment and is explained in more detail below. While some clinicians are already using the Cusum analysis to assess competence in training and routine practice the test is by no means routinely applied (Lim, Soraya, Ding, & Morad, 2002). While I do not consider that the Cusum test is a final goal in the measurement of competence and assessment of practical tasks in healthcare I believe that it is a good starting point for the objective assessments that healthcare professionals, regulators and patients will require.

The 'Cusum' Statistical Test

Cusum (an invented word derived from Cumulative Summation) is a statistical method first described during World War 2, when it was used to ensure the quality of bullets in a production line (Page, 1954). Cusum extends the concept of plotting cumulative failure using boundary lines, such that instead of reaching an endpoint (crossing a boundary line) after which the process must be re-started, the process is continuous, and can continue indefinitely. The beauty of Cusum is that to create a Cusum plot, one need only define four parameters. These are:

1. The acceptable failure rate
2. The unacceptable failure rate
3. Alpha – or the risk of making a type 1 statistical error.
4. Beta – or the risk of making a type 2 statistical error.

In the biological literature, by convention, alpha and beta are normally set at 0.05 and 0.20. However, when performing Cusum analysis, setting both alpha and beta to 0.10 dramatically simplifies the graphical representation such that acceptable and unacceptable boundary lines are superimposed. This enables the plot to be quickly interpreted since a plot spanning two boundary lines in the positive direction confirms unacceptable performance, while a plot spanning two lines in the negative direction confirms acceptable performance. (See Figures 1 and 2)

At a higher level, the greatest power of Cusum analysis is that performance data can be analysed in a rigorously scientific fashion, which is therefore detached from the often emotive

Figure 1. A cumulative failure graph showing acceptable performance (Bolsin 2000; Bolsin and Colson 2000)

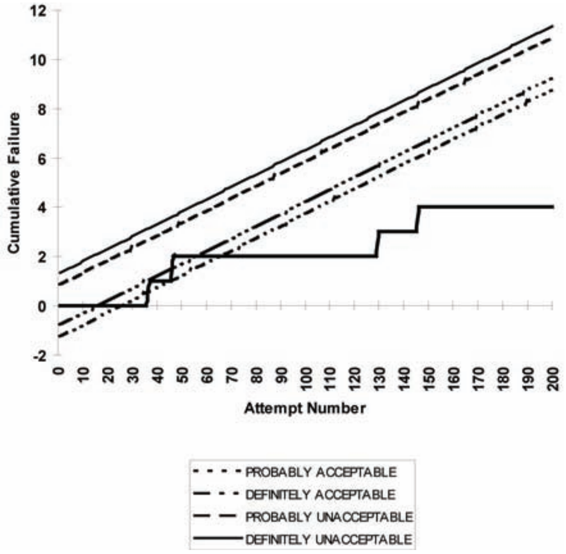

Figure 2. A Cusum graph showing the same data as used in Figure 1 and showing acceptable performance and acquisition of competence (Bolsin 2000; Bolsin and Colson 2000)

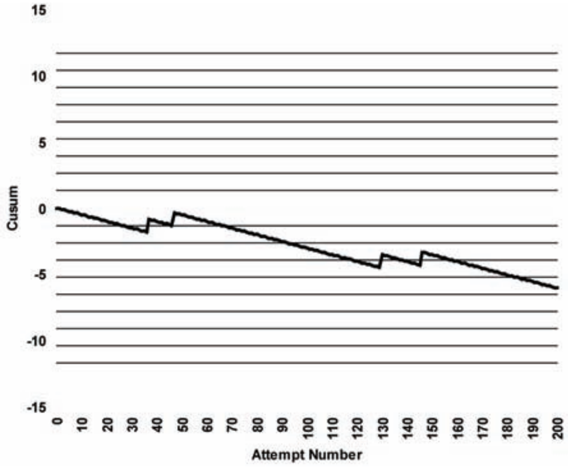


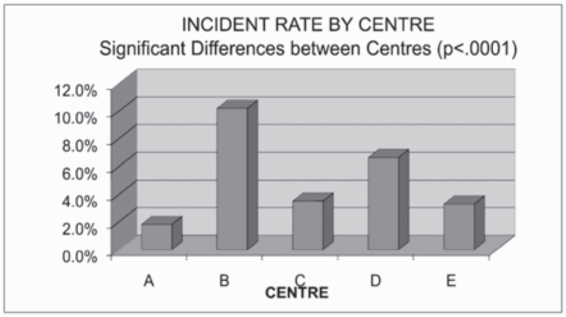
nature of the findings. Without Cusum, a group of doctors would often have great difficulty analyzing raw performance data and reaching a conclusion of unacceptable performance. With Cusum, they don't actually need to agree with any such conclusion, but simply with the four Cusum parameters. The Cusum process itself does the rest!

These records also proved invaluable in demonstrating competence when complications attributable to the procedures logged were encountered (Bolsin et al., 2003; Lim, Soraya, Ding, & Morad, 2002). It must be emphasised that the most important factors contributing to the reliable collection of this data were the ease and speed of data entry by the individuals performing the procedure at the point of care (Bent, personal communication). The financial savings, attributable to the collection of such performance records in the single specialty of anaesthetics, and relating to anaesthetic trainees alone, have been calculated (Bolsin et al., 2003). These have shown that the collection of the performance data alone justifies the expenditure on the devices and data collection system without consideration of their added contribution to incident reporting, improved ethical behaviour and educational and learning capacity (Bolsin et al., 2005a; Bolsin et al., 2005b; Bolsin et al., 2005c). Subsequent programs were developed for specialist practice in Obstetrics and Gyneacology but have not been taken up widely by the profession. The reasons may include lack of support from the Specialist Associations and Royal Colleges; fear of formal performance monitoring in the aftermath of several well-publicised medical scandals including the Manitoba paediatric cardiac surgery scandal in North America (Sibbald, 1998), the Bristol Royal Infirmary paediatric cardiac surgery scandal in the UK (Kennedy, 2001) and the Bundaberg surgery scandal in Australia (Van Der Weyden, 2005); a poor business model that made individual subscription to the program too expensive for individuals; an Institutional (Hospital level) lack of desire to support clinical performance monitoring; an Organizational (State level) lack of vision to perceive the widespread benefits of clinical performance monitoring; a professional fear of technology, particularly Information Technology (IT) in clinical settings (Bolsin et al., 2005b; Bolsin et al., 2005c).

In the context of individual performance monitoring it is well worth noting that the application of complex risk-adjustment is not necessary to detect abnormally bad patterns of medical care. In the infamous case of Dr Harold Shipman, a UK GP, who is thought to have murdered over 200 of his patients, routine analysis of crude data from his practice would have detected a statistically significant elevation of the mortality rate in his practice. The problem would have been flagged by the comparison of crude mortality rates from Dr Shipman's practice and comparing them with the average from other practices in the UK (Spiegelhalter et al., 2003). The retrospective analysis undertaken by Treasure and Co-workers demonstrated that had a routine data collection with routine analysis of crude mortality data been in place it is likely that Dr Shipman's murderous behaviour could have been detected at a much earlier stage (after about 20 excess deaths) and that as more than 180 unnecessary deaths attributable to Dr Shipman's psychopathic behaviour could have been prevented (Spiegelhalter et al., 2003). In this case all that was required was an IT supported data collection that recorded the number of deaths in each General Practice in the UK. Such simple data could have prevented the greatest serial killer in the UK from murdering scores of patients under the innocent cover of his routine General Practice.

However, I believe that the quality assurance benefits of integrated performance monitoring should not be confined to medical professionals (Bolsin et al., 2005b; Bolsin & Colson, 2003; Bolsin et al., 2005c; Bolsin et al., 2003). The quality improvement and financial benefits of all health care professionals entering individual and unit performance data into personalized mobile computing devices to achieve standardized uniform data collections with educational and decision support are achievable now. Unfortunately the vision of the health care professions and associated bureaucracy has not kept pace with the evolution of both medical ethicists and computing and IT. Consequently the solutions presented by the use of novel new IT devices and user-friendly programs are not harnessed or engaged in the drive for sustainable improvements in quality of care and patient safety.

Figure 3. A bar chart of incident reporting rates from different hospitals (Bent, Creati et al. 2002; Freestone, Bolsin et al. 2006)



INCIDENT REPORTING

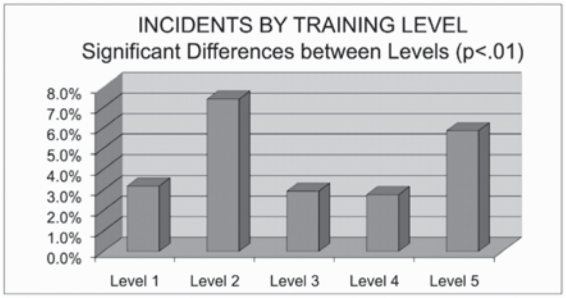
Considering again the causes of 'medical error' identified in the Quality in Australian Healthcare study there are 3 causes (highlighted below) that can be grouped together as 'system error' (Wilson et al., 1999). The key to reducing such errors in healthcare rely on the accurate detection of adverse events, detailed analysis of the causes and introduction of 'forcing functions' to prevent the causes from occurring again:

- 35% complication/failure of technical performance
- 15.8% decision action failure
- 11.8% failure to arrange procedure/investigation/consultation
- 10.9% lack of care/attention

Such work has been undertaken by Alan Woolf in a small hospital in Victoria, Australia where he has demonstrated a reduction in adverse events by such activity (Woolf, Bourke, Campbell, & Leembruggen, 2001). However Dr Woolf and his co-workers required review of the patient's case notes by clerical staff to identify adverse events before they were analysed by a medical group to implement safety strategies. This Limited Adverse Occurrence Screening (LAOS) is used because incident reporting rates in the hospital at that time were not high. In fact poor incident reporting has been a feature of all modern healthcare systems (White, 2004; Kohn, Corrigan, & Donaldson, 1999; Bolsin, 2005c). Work in the Geelong hospital has identified that the application of cutting edge IT solutions to incident reporting in clinical practice can favourably impact incident reporting rates achieving 99.5% (Bent et al., 2002; Freestone et al., 2006). Moreover the analysis of such incident reporting databases provides additional interesting information about the distribution and occurrence of critical incidents in the clinical setting. Unfortunately the preliminary analysis of the data from selected hospitals in Australia underscores the lack of information currently available in this area. For example is hospital A (Figure 3) safer than hospital B or vice versa? Hospital A with a high incident reporting rate may be the safest hospital with a high level of incident reporting attributable to an active safety culture. Conversely hospital A may be a hospital in which many errors occur because of a poor safety culture, lack of incident reporting, and poor safety record. Only analysis of accumulated data over several years showing declining standardised incident reporting rates would confirm improving patient safety.

Another recent debate in healthcare relates to the safety of hospitals at night. The IT data collection provided a robust solution. We were able to use the same data to demonstrate that incident reporting rates did not rise in the evenings or at night. This confirmed that the hospital was as safe,

Figure 4. A bar chart of incident reporting rates from grades of registrar trainee (Bent, Creati et al. 2002; Freestone, Bolsin et al. 2006)



for anaesthetic trainees, during the night and evening as it was during the day. This data was used to inform and reassure the Clinical Governance structures within the hospital. (See Figure 4.)

Incident Reporting, Ethical Behaviour and Cultural Change

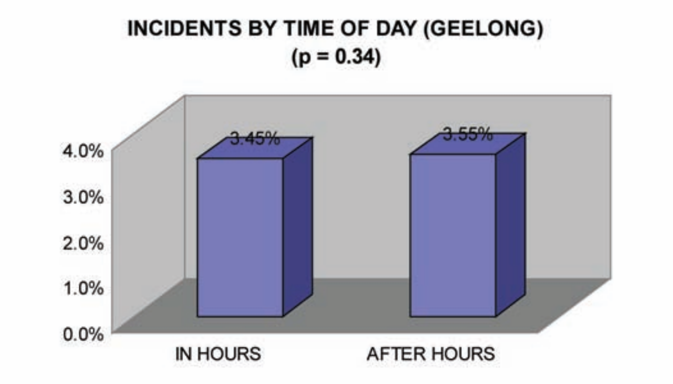
One of the most fascinating linkages demonstrated by the introduction of modern IT devices and programs in the field of patient safety has been that between IT adoption and improved ethical behaviour (Bent et al., 2002; Bolsin et al., 2005a; Bolsin et al., 2005b; Bolsin et al., 2005c; Freestone et al., 2006). The work undertaken at Geelong Hospital, Victoria, shows that incident reporting programs, employing mobile computing devices with programs designed to facilitate incident reporting in the clinical setting can achieve very high levels of incident reporting (Freestone et al., 2006). Contrasted with the reluctance of many clinical staff to report poor care or critical incidents in clinical medicine the 99.5% incident reporting rate identified in this study is an indication of improved ethical behaviour (Bolsin et al., 2005c; Evans et al., 2006; Firth-Cozens, 2002; Firth-Cozens, Firth, & Booth, 2003; Kingston, Evans, Smith, & Berry, 2004; White, 2004).

The important link between IT and medical ethics represents a conceptual advance in thinking in this complex area of medical behaviour. It also seems to demonstrate that all aspects of medical practice and thinking can be positively impacted by the adoption of well-designed IT programs. (See Figure 5)

PATIENT SAFETY

The evolution of personal computer technological has been almost exponential since IBM released the first Personal Computer in 1981. Hardware speed and capacity has increased roughly accordingly to Moore's Law, which states that the number of components on a computer chip doubles every 18 months or so. As computing hardware improved, the software has had to evolve to accommodate and exploit the dramatic increase in prevailing processor power and speed. For many years, the sole axis of computer evolution revolved around faster and more powerful desktop devices. More recently, pioneers such as Stanford University began networking multiple personal computers together to create a network. The benefits of networking were immediately apparent – initially they were limited to sharing of data and messaging. However, vastly more sophisticated applications began to emerge which ultimately resulted in the development of the World Wide Web or Internet, as we know it today. While the Internet initially utilized a hard-wired connection between all computers, this slowly gave way

Figure 5. A bar chart of incident reporting rates according to "Time of Day" in the Geelong Hospital (Bent, Creati et al. 2002; Freestone, Bolsin et al. 2006). ["In Hours": 8.00am-18.00pm; "Out of Hours": 18.00pm-08.00am]



to wireless connections. Simultaneously, ever smaller computing devices were being created. The marriage of the two technologies – wireless and truly portable small devices resulted in the highly functional Personal Digital Assistants or PDA's that are commonly used today.

Nowadays, we have available very powerful yet small PDA's utilizing long-range wireless networking connections. The combination of functions that can now be incorporated into a device the size of a mobile phone is now enormous and epitomised by the 'iPhone', which has access to the internet, e-mail, telephone network and all the commonly available computing programmes (Mac Corporation, 2008). The arrangement is ideally suited to a highly portable and personal error performance reporting system and yet sadly, the use of such applications is limited and patchy, owing to a dearth of suitable software systems. This is likely to change in the near future, and the responsibility for effecting this change must inevitably fall upon the medical profession and healthcare managers and bureaucrats. One of the intriguing explanations for the failure of healthcare managers, professionals and bureaucrats to take up these obviously beneficial advances in computing and IT in the healthcare arena has been proposed by Avril Henry, who describes some of the differences between the younger Generations X & Y and their older Baby Boomer and Veteran counterparts. Baby Boomers and Veterans are "technophobe" mistrusting or misunderstanding technical and electronic devices and lacking spontaneous innovation to learn in this area. By contrast the Generations X & Y are "technophile" and spontaneously search for and adopt innovations in the areas of computing and IT (Henry, 2006). Furthermore, as Avril Henry has pointed out, these surveys reveal that Generation X, and Generation Y want learning opportunities in the work environment and value such opportunities (Henry, 2006). The learning that these junior members of the workforce do value is internet and web-based education that can be easily provided by mobile computing platforms (Bolsin & Fraser, 2006; Bolsin et al., 2005c). An interesting comment in Ms Henry's analysis is that Gen X and Gen Y members of an organisation's workforce will value an employer that provides such learning opportunities and leave organisations that do not provide them (Henry, 2006). At times of workforce shortage in medical and nursing ranks linking learning to cutting edge technological devices in an improved ethical environment are highly likely to improve recruitment and retention in modern healthcare organisations.

Table 1.

Generation	Birth year	Characteristic Features (85% conform)
Veterans	1935-50	Technophobe; poor ethics; prefer classroom learning
Baby Boomers	1951-65	Technophobe; poor ethics; prefer classroom learning
Generation X	1966-80	Technophile; want ethical leaders; IT/internet learning
Generation Y	1981-95	Technophile; more ethical; prefer IT/internet learning

As Avril quite rightly puts it "These are the generations (X & Y) that the baby boomers and veterans hand the television remote to when they want something more than just a channel change". Unfortunately these technophobe generations, who hold the positions of influence and authority in healthcare are also holding back the exciting innovation and development, that must be adopted, to enable the professions, and more importantly the patients, to gain from the opportunities of improved health care that exist through IT and computing advances.

While many feel threatened by such a scenario, a more enlightened view would be that this narrative has much to offer the modern health care professional. Portability is crucial to the adoption of such solutions. Physicians have shown a reluctance to embrace IT solutions, which require queuing to use a fixed desktop PC. The device needs to be portable and personal not just for the convenience of the user, but also for the extra functionality that this mobility will confer. (See Table 1)

CONCLUSION

Current health care delivery can be improved in areas of individual performance, unit performance monitoring, incident reporting and adherence to approved clinical pathways (Bent et al., 2002; Bolsin, 2000; Bolsin & Colson, 2003; Bolsin et al., 2005b; Bolsin et al., 2005c; Bolsin & Freestone, 2007; Bolsin et al., 2003a; Freestone et al., 2006; Garg et al., 2005; Hannan, Kilburn et al., 1994; Peterson et al., 2006). The use of mobile computing platforms with imaginative and sophisticated programming has allowed and will allow many of these desirable objectives to be achieved relatively easily (Bent et al., 2002; Bolsin et al., 2005c; Bolsin & Freestone, 2007; Freestone et al., 2006). The unanticipated benefits of improved ethical behaviour derived from such well-programmed, mobile computing devices confirms the value of such interventions and the use of modern technology (Bolsin et al., 2005a; Bolsin et al., 2005c; Bolsin et al., 2005b). The technical ability and technophile characteristics of the next 2 generations of healthcare employees should encourage the extension of existing, and development of further, similar imaginative programs and devices. The linkage of these programmed devices to educational and learning opportunities via educational websites and programmes, which can improve recruitment and retention of junior staff, represents another exciting, but underdeveloped, facet of computing and information technology in the healthcare arena.

IT Adoption and Evaluation in Healthcare:

Evolutions and Insights in Theory, Methodology, and Practice

ABSTRACT

This article focuses on the evolution of theory, methodology, and practice regarding the role of adoption, implementation, diffusion, and evaluation factors, and the interaction of these factors at various levels, to healthcare system success. These topics continue to present challenges to organizations, the research community, and to society in general. The first place that new waves of thought are often aired is at conferences. This article explores the evolution taking place in this domain by looking back through the years over work presented at the longest standing conference track focused on adoption, implementation, diffusion, and evaluation factors in e-health and the interaction of these factors at various levels to healthcare system success. [Article copies are available for purchase from InfoSci-on-Demand.com]

INTRODUCTION

Although Information Technology (IT) is seen as an enabler of change for healthcare organizations both nationally and locally, adoption decisions are complex given a multitude of technologies, stakeholders, and potential levels of analysis. The research presented in this article conveys the complexity and breadth of issues explored by information systems researchers in addressing adoption, implementation, diffusion, and evaluation via a multidimensional review of articles accepted over the past six years at arguably the most noted minitrack conference focused on IT adoption, implementation, diffusion, and evaluation in healthcare information systems. This review shows that there are many disruptions in the innovations of healthcare information systems. Continuous learning, evaluation, and understanding in both practice and research can help to avoid these disruptions and help to smooth IT implementation in the future.

The following sections move back in time to grasp the evolution of e-health adoption and evaluation. We begin by introducing that background and the methods used to conduct this literature review. We then present an analysis of trends, and insight from this body of past work by exploring evolution in theory, methodology, and practice. We close by addressing the future of e-health diffusion and some major lines of thinking.

BACKGROUND AND LITERATURE REVIEW METHOD

The entry for “**academic conference**” on Wikipedia© notes, “together with academic or scientific journals, conferences provide an important channel for exchange of information between researchers.” For purposes of reviewing the evolution and developments in a new and emerging area of interest, such as e-health as explored by IT researchers, it is important to consider conference papers and their associated presentations. While we acknowledge the value and necessity of reviewing work published in refereed journals to understand the school of thought in a domain or sub-specialty, we focus this work on conference papers to emphasize three issues. First, conferences often serve as the first airings of studies and ideas that later make their way into journals. Given the extended turnaround times between first submission and publication in some journals, fresh directions in research may not make their way into press until years after having been presented at a conference. Thus, in work such as the current study, that seeks to look at the evolution of thought, method, and practice, tracing representation in conference proceedings may more closely follow the timeline of the completed studies and present a broader picture. Second, in an interdisciplinary field such as health information systems, the ultimate journal destination of work presented at conferences may scatter and fragment into various journal domains making it difficult to reconnect the threads of thought, method, and practice in the work going on in the domain. Thus, we hope to encourage researchers doing work in this domain to follow our example and visit the work from targeted conferences in their canvas of the literature, even if only to trace the destination of subsequent journal articles that might otherwise be missed in a multi-disciplinary field. Third, topically targeted conferences and tracks/minitracks at general conferences tend to attract “birds of a feather” and thus, promote multi-way dialog on presented research. This dialog may, in turn, influence the direction of colleagues working in the area of interest.

We focus our study on the Hawaii International Conference on System Sciences (HICSS) - IT Adoption, Implementation, Use and Evaluation in Healthcare minitrack within the Information Technology in Health Care (ITHC) track. HICSS is the oldest international system science conference, and the Health Care track is the oldest of the information system conference healthcare tracks. The IT Adoption, Implementation, Use and Evaluation in Healthcare minitrack has been one of the focal tracks in the ITHC. Per online search and review of the agendas and programs from major IT general conferences and targeted meetings since 2000, the IT Adoption, Implementation, Use and Evaluation[1] minitrack appears to be the longest running consistent track dedicated to this focused topic in the field of information systems. This minitrack started in 2002 and has been on-going to date. The average acceptance rate for papers in this track is approximately 50%. One or more of this article's authors participated in the presentations and ensuing discussions of all the papers reviewed as part of the current study. Thus, the authors of this article have not only individually or collectively read each paper, but have dialoged with authors and seen the various reactions and spontaneous thought generated by these works. Therefore, this review is a reflection and interpretation of not only what was written, but also of what was said and discussed among participants. We readily admit there are some limitations in exclusion with the approach chosen for this study. However, this novel lens of using the continuity of the forum from a long standing, respected conference forum for full papers dedicated to this targeted topic may yield insight into early trends that other methods may not. Specifically, we hope to garner insight through the advantage of longitudinal continuity, the screening process, and the ability to reflect on the papers along with the associated presentations and dialog.

Looking at this long-running track also provides the vantage for perceiving evolution in growth and interest in this topic. Between 2002 and 2009, 43 manuscripts have been published in what is in HICSS 42, the IT Adoption and Evaluation in Health Care (AEHC) minitrack within the ITHC Track at HICSS. Although the number of research publications within the minitrack equates to 5.6 per year, since 2005, which is the second official year for the current minitrack, the average between 2005 and 2009 has increased by 2 manuscripts to 7.6 accepted papers per year. More recent years have yielded up to nine papers suitable for presentation and publication, with growing audience attendance. Elaborated versions of the research presented in AEHC have been published in established journals as CAIS, MISQ and more specific healthcare IS journals as IJHIS, IJMI, IJHTM and others.

We summarize papers accepted into this track in Appendix A. To delve into the collection of papers, we begin by discussing their evolution and insights in thought and theory. We follow with a discussion of evolution and insights in methodology and then move to evolutions and insights in practice as evidenced by the research. It is our hope that this review will assist researchers interested in this area leverage past efforts in advancing theory, designing the methodology of their study, and providing relevance and connection to healthcare practice.

EVOLUTION AND INSIGHT IN THOUGHT AND THEORY ON LEVELS OF E-HEALTH IMPACT

In this section, we analyze the collection of studies from the perspectives of levels of interest. Table 1 summarizes the representation of papers in the collection at each level of e-health impact.

IT Adoption: Individual Level

Hu, Liu Sheng, and Tam (1999) and Lapointe, Lamothe, and Fortin (2002), with their application of the TAM model on telecare and level of analysis on clinical care, inspired us to create the research track. Both research teams have a totally different research approach but come to the same conclusions that usefulness or benefits are the main drivers for IT success in healthcare. Relevance can be used to explain usefulness (Schuring and Spil, 2002). Dhillon and Forducey

Table 1. Level of study

Level	Number	Per cent
Policy/Governmental	2	4.651%
Organizational	13	30.233%
Project	5	11.628%
Individual – Providers (Physicians, nurses, etc)	14	32.558%
Individual – Health Care Consumer	3	6.977%
Total	43	100.00%

(2006) draw our attention to the topic of adoption relevance in their telemedicine case study. The authors report that by involving all stakeholders in the project at various stages, without causing perturbation of the basic rehabilitation services delivery process, providers were able to increase their revenue and profitability; the patients realized savings by avoiding travel to a healthcare facility, saved valuable time, and in many cases, avoided serious medical complications resulting from delays in the delivery of services.

Topacan, Basoglu, and Daim (2009) bring together the emerging field of information services with e-health by explaining why telecare applications are adopted by healthcare professionals. Padmanabhan, Burstein, Churilov, Wassertheil, Hornblower, and Parker (2006), also acknowledge the individual level and point out the need for both objective and subjective measures in an evaluation of a handheld support triage prototype called iTriage*,* speaking to its impact on the quality of the triage decision making process.

The Unified Theory of Acceptance and Use of Technology (UTAUT) (Venkatesh, Morris, Davis, and Davis, 2003) was referenced in multiple papers including work by Trimmer, Wiggins, Beachboard, and Woodhouse (2008). In this study, “Electronic Medical Records Use – An Examination of Resident Physician Intentions,” physicians who were experienced with an EMR provided their perspectives on future use and adoption of EMRs. The UTAUT is also applied to e-health by Goh and Agarwal (2008) in “Taking Charge of Your Health: The Drivers of Enrolment and Continued Participation in Online Health Intervention Programs.” In this study, the authors analyzed responses from an online health portal to assess adoption and post-adoption of an online program. Their analysis provides a discussion of direct and interaction effects of a theoretical model. Schaper and Pervan (2007) show us a large quantitative UTAUT study in Australia with over 2000 responses which found that a positive attitude has significant influence on the use behavior.

Other authors go back to one of the sources of the UTAUT model and use the psychological models of Ajzen and Madden (1986) to describe the impact on the individual level. Ilie, Courtney, and Van Slyke (2007) use the Theory of Planned Behavior in a qualitative way. They end in saying that while the use of an Electronic Medical Record may be mandatory for the physician-residents in their study, if they had a choice, the majority of physicians would use the paper chart. A new dimension for technology adoption is discussed based on personality traits and the way in which they influence computer anxiety in a study by Brown, Deng, Poole, and Forducey, (2005). Computer anxiety, of course, is an inhibiting factor in the adoption of, in this case, telemedicine applications. Horan, Tulu, Hilton, and Burton

(2004) also root their work in UTAUT sources to develop a conceptual model for physician acceptance and test this socio-work structure via a survey. The model is a micro approach as it focuses on work-practice considerations of physicians, factors affecting physicians' acceptance and use of decision support system in the clinical setting and task-technology fit .

Relevance and perceived usefulness can be studied from a psychological point of view or from an individual cost/benefit point of view. LeRouge and Hevner (2005) propose *Use Quality* as a refined construct to the DeLone and McLean (2002) model in response to the underlying IT research assumption that there seems to be an appropriate manner and flow for system use. Within the telemedicine context, they define use quality as the practice of applying appropriate processes and protocols in the use of high-end telemedicine encounters to fulfill the desired purpose of patient care.

Bhattacherjee and Hikmet (2007) provide a dual-factor (perceived usefulness and perceived threat) model for assessing the implications of IT threats on an individual's IT usage. This empirical study supports their hypothesis that threats will negatively influence IT use. Cho, Mathiassen, and Gallivan (2008) focus on a telehealth innovation that enables physicians at a teaching hospital to access and diagnose strokes in rural environments. The perspectives of various stakeholders regarding the innovation and its adoption are presented in this longitudinal research. Another longitudinal study, also addressing issues at a teaching hospital, is presented by Ryan, Doster, Daily, and Heslin (2008). They discuss the eventual process improvements that came about after the implementation of a new information system for the hospital's preoperative services.

Finally, many individual adoption studies apply the Technology Acceptance Model (TAM) (Davis, 1989) model in its original form . Raitoharju (2005) derives from a general study that IT stress is a major inhibitor of acceptance in healthcare. The development of IT scores that assess IT capacities in healthcare is a critical step forward toward addressing important research questions involving the relationship between IT capacities and outcome measures. "IT Capacities Assessment Tool: A Survey of Hospitals in Canada" by Jaana, Pare', and Sicotte (2009) presents the development of an instrument for scoring IT capacities in Canadian hospitals. "The Importance of Being Useful and Fun: Factors Influencing Intention to Use a Mobile System Motivating for Physical Activity" by Svendsen, Søholt, Munch-Ellingsen, Gammon, and Schurmann (2009) studies the impact of a mobile phone based motivation system on modifying health behaviors, focusing on health interventions as "fun."

All of the studies in this section have one important thing in common. They focus on the individual level and they find that the value proposition is probably the most important dimension of successful adoption of e-health systems. The value proposition has many disguises, Rogers (1995) called it relative advantage, Davis (1989) called it perceived usefulness and Delone and Mclean (2002) called it net benefits. The individual level studies present a range of examples addressing the nature of value to individuals in the healthcare environment.

IT Adoption: Organization and Project Level

On an organization level, previous strategic choices, strategic priorities, size and location of the organization, information assurance, and many other factors may play a role. Maass and Eriksson (2006) highlight managerial challenges encountered during the adoption of a Picture Archiving and Communication System (PACS) at Turku University Central Hospital (TUCH). The results are based on a five-year survey consisting of statistical data, cost analysis, modeling, customer satisfaction inquiries, time and motion studies, observation and staff interviews.

On a project level, resources, and project management play a role. Kiura (2006) focuses on the need to explore the project level by reporting on a project establishment undertaking as proposed by the STEPS (Software Technology for Evolutionary Participatory System Design) Methodology. Project establishment in STEPS is aimed at getting an inner understanding of a project's environment. This article focuses on evolving a 'participatory culture' to assist in better understanding the project environment.

The contribution by Gagnon, Lamothe, Fortin, Cloutier, Godin, Gagné, and Reinharz, (2004) "The Impact of Organizational Characteristics on Telehealth Adoption by Hospitals," analyses adoption on organizational level. It is structured around hypotheses that are based on previous research and that are tested on the basis of research in 32 healthcare centres involved as telehealth services. The contribution by Maass and Suomi (2004), "Adoption-Related Aspects of an IS System in a Health Care Setting" focuses on adoption of a digital image (PACS) system. It particularly considers financial aspects of this implementation.

Reardon and Davidson (2007) discuss that there is not enough organizational vision to overcome physicians' hesitance to adopt Electronic Medical Records systems (EMR). Questions about interpretability, plausibility, and discontinuity of this innovation and organizational vision remain.

More evidence of the troublesome implementation problems on group and organizational level can be found in section 4 and in reviewing the papers listed in appendix A. Even if, as suggested in the previous section, the relevance of the e-health system is clear, the complex structure and culture of healthcare organization can disturb the successful introduction of IT systems.

IT Adoption: National Level

On a national system-level, reimbursement structures, regulations, inter-organizational concerns, and the existence of standards may have an explanatory role in the slow adoption and acceptance of healthcare IT. To this end, Sherlock and Chismar (2006) argue that the airlines' evolution of computerized reservation systems (CRSs) provide lessons learned to analyze problems and issues in the development of electronic health records. CRSs' turbulent evolution was driven by environmental, technological, and structural factors within the airline industry, which these authors assert is analogous to current trends in the healthcare industry and they predict that similar patterns of adoption will occur in electronic health records.

A second paper with a national focus is "A Telemedicine Transfer Model for Sub-Saharan Africa" (Kifle, Mbarika, Tsuma, Wilkerson, and Tan, 2008). Focusing on Information Communications Technology (ICT) and infrastructure, the authors report the analysis of survey data provided by physicians in twenty-one different African Nations. The results of their analysis provide policy makers in Sub-Saharan Africa with a perspective on ICT projects. In addition, research from Sood, Nwabueze, Mbarika, Prakash, Chatterjee, Ray, and Mishra (2008), "Electronic Medical Records: A Review Comparing the Challenges in Developed and Developing Countries," provides a perspective on barriers to adaptation and implementation between different countries. "The Effects of Culture of Adoption of Telemedicine in Medically Underserved Sub-Saharan Africa", by Meso, Mbarika, Kifle, Okoli, and Nwabueze (2009) reveals that ICT infrastructure and national health services facilitate improved telemedicine capabilities. However, in countries underserved by ICT and national health policies, telemedicine, while highly valued, remains scarce.

Burley, Scheepers, and Owen (2008), present a case study focusing on stakeholders, effectiveness, and efficiency issues regarding mobile systems in Australia. They present the advantages and the balance between the internal system requirements and external systems.

Although the international and national studies are not yet numerous enough to draw valid conclusions, it seems that telecare is being embraced by undeveloped countries as one of the answers to their knowledge and information management problems. To solve these problems, good theory and methodology, as demonstrated in the next section, will provide a solid basis for the learning process.

METHODOLOGICAL EVOLUTION AND INSIGHTS

We canvassed the papers to provide insight to future researchers regarding methodology in healthcare IT research. We address multiple methodological considerations below to highlight methodological considerations that may intrigue and perhaps, inspire readers of the current paper through what has been done, or perhaps, through what is absent.

Epistemological Perspectives

The collection of papers includes interpretivist, positivist, and interventionist studies demonstrating that health IT can be studied from multiple epistemological perspectives. In their study on resident physicians' intentions to use EMR, Trimmer, et al. (2008), illustrate that IT research in healthcare can be done using an interpretive paradigm. In contrast, that same year, Ryan, et al. (2008), demonstrated that a positivist method of case research may also be used, in their investigation of the impact of soft innovation within a hospital environment, from empowered and integrated individuals driven by integrated information.

Fruhling, Tyser, and de Vreede (2005), followed the interventionist perspective using the action research model to evaluate the use of extreme programming for developing and implementing a biosecurity healthcare application. "Action research has the dual intention of improving the practice and contributing to theory and knowledge" (Fruhling, et al., 2005, p. 5). This approach may have merit in healthcare IT studies where the research question is "how" oriented; a depth of understanding is needed of the complex environment, and aligns itself well with the general call for continuous learning in the healthcare environment.

Kiura (2006) also uses action research to gain an inner understanding of a project's

environment in the early stages of a systems development project for a hospital in a developing country. Kiura's intervention was to introduce participatory design concepts through Joint Application Design (Wood and Silver, 1995) and the Software Technology for Evolutionary Participatory System Design (STEPS) methodology..

Method Type

IT in healthcare research calls to qualitative, quantitative, design science, and conceptual studies as can be seen by the distribution of methods in Table 2.

We elaborate below on the details of Table 2 to provide further insight.

Quantitative Methods

Survey research was by far the most prevalent method used for collecting data in the healthcare IT studies presented in this HICSS minitrack. Many of the studies scrutinized technology acceptance and used previously validated items from the UTAUT (Venkatesh, et al., 2003) and related predecessor models to compose some or all of the survey questions.

Table 2. Distribution of methods of study

Method Type of Study	**Number**	**Percent**
Qualitative	14	32.56%
Quantitative	11	25.58%
Quantitative and Qualitative	7	16.28%
Design Research	5	11.63%
Conceptual Paper	6	13.95%
Total	**43**	**100.00%**

In most studies the survey instruments were distributed to survey participants in only one form. Kifle, et al (2008) remind us of the importance of checking for method bias in their study which used both a web and a paper based version of a survey instrument. This may be of particular concern in the healthcare environment where users may be more infrequent computer users and prefer to use paper-based methods for response.

Regression, partial least squares, basic statistics, and structural equation modeling were the most frequent statistical analyses performed. Factor analysis, Chi-Square tests, analysis of variance, and principal component analysis were each used in one study. A rather unique form of analysis was performed by Brown, et al., (2005) . They use the survey method to gather data on various traits proposed as exogenous determinants of computer anxiety for physical therapists using telemedicine systems. The traits were measured using LaForge's Interpersonal Checklist (ICL) (LaForge, 1977) and computer anxiety was measured using a scale inspired by Thatcher and Perrewe (2002). The research is distinguished in method from others in our pool of papers regarding the method of analysis. The researchers measured respondent trait position along the quadrants in the Interpersonal Circumplex Model and used multiple contrast tests to test the proposed hypotheses.

Qualitative and Mixed Designs

Many of the papers using qualitative methods indicate their choice was made due to the need to gain a rich understanding of the healthcare IT context and of the stakeholders in order to address the research question. Qualitative studies may be conducted in a number of ways including case studies, interviews, direct observations, and focus groups. The collection of papers in this review clearly demonstrates that healthcare IT can be researched using many qualitative methods.

Interviewing as a stand- alone method or as part of a case study, was the most frequently used method of collecting data. Qualitative data from interviewing is often analyzed by coding key words and phrases into themes and categories. However, Wiggins, Pumphrey, Beachboard, and Trimmer (2006) used a method of analyzing qualitative interview data that consisted primarily of the creation of a case narratives to develop an accurate and rich description of a phenomenon as seen through the eyes of the interviewees.

The majority of the qualitative studies used a case method and collected data from many sources to facilitate both understanding and breadth, as well as for triangulation. Qualitative methods of data collection represented, in addition to interviews, include workflow modeling, focus groups, review of archival data, direct observation, and usability testing. Though the general characterization of many of these studies is qualitative, data collection frequently included quantitative elements, such as survey data, quantitative analysis of operational data, and time and motion studies. The study by Shaper and Pervan (2007) serves as an interesting example of triangulation using qualitative and quantitative methods. Schaper and Pervan (2007) tested their proposed model quantitatively in a national survey sent to 6453 Australian occupational therapists to provide cross-sectional data on behavioral intention and acceptance of ICT and other issues surrounding utilization of ICT. Interviews, direct observation and other case study field methods were used to qualitatively support the proposed model and the national survey was used to qualitatively support the proposed model. Paré, Mirou, and Girouard (2008) chose to employ another form of mixed qualitative and quantitative design, namely a ranking-type Delphi survey . In this study, the opinions of a panel of experts (i.e., clinical information systems project managers) were elicited through iterative, controlled feedback to build an authoritative list of clinical information systems implementation risk factors and determine the relative importance of these risk factors. A three-phase process was used: phase 1: risk brainstorming; phase 2: the combined list was circulated to all panelists for corrections, additions, and, eventually, validation; and phase 3: ranking of the risk factors in order of priority to the project.

There is a range of how long one should spend in the field to perform a case study. Some studies report a time frame as short as three months. Others, such as Maass and Eriksson (2006), advocate a much longer time frame for an implementation study, perhaps extending into years. They argue that infrastructures grow and develop over a long period of time in healthcare contexts and an information infrastructure is built through extensions and improvements to what already exists – rather than from scratch. What is implemented has to be hooked into the existing infrastructure, which supports the extended longitudinal approach if the goal is to really understand not only the initial implementation and training, but also what happens as users gradually integrate the system in their work practices and learn the possibilities and the limitations of the system. Maass and Eriksson (2006) illustrate this through their case study which analyzes data consisting of statistical information, cost analysis, modeling, customer satisfaction inquiries, time and motion studies, observation and staff interviews.

Schaper and Pervan (2007) provide another example of a longitudinal case study that exemplifies using an extended time period for comparative data collection points. This seven-month longitudinal multi-method field study was designed to test a proposed ICT acceptance and use model and the associated individual and organizational impacts of use or non-use within a small non-profit, community-based healthcare organization. The questionnaire was administered at three points in time: one week post-training, three months post-implementation and seven months post- implementation.

Design Research

In reviewing Table 2, one might be surprised to see Design Research as a category in a healthcare IT literature review. To validate the propriety of this category, we reviewed seminal design research pieces (particularly focused on defining design research) such as those by March and Smith (1995) and Hevner, March, Park, and Ram (2004). We also consulted the Association of Information Systems, which provides a compendium of Design Research thought and references (http://www.isworld.org/Researchdesign/drisISworld.htm) and provides an appropriate summary for the purposes of the current paper. This compendium indicates:

Design research involves the analysis of the use and performance of designed artifacts to understand, explain and very frequently to improve on the behavior of aspects of Information Systems. Such artifacts include - but certainly are not limited *to - algorithms (e.g. for information retrieval), human/computer interfaces and system design methodologies or languages.* (Association of Information Systems, 2008)

The intent of including this category in this paper is not so much to debate the semantics of design research, but to properly identify and showcase a particular group of papers in our collection that stood out from the more classic methodological definitions. The primary purpose of the papers in our "design science" category is to leave the healthcare IT research community with an artifact for future work. Thus, we reviewed the methods of the papers included in this study for those with a primary focus of identifying a problem, providing a suggestion, and developing an artifact for addressing the problem for practitioners and/or researchers to use. Some authors extended this to include evaluation and results of using their artifact in practice, thereby addressing additional steps in the design research process.

To illustrate, the artifact in Fitch's (2004) work, the Ilities Application Method, has the intended purpose of aiding communication, closing the knowledge gap, correctly establishing system requirements, and putting a system into place that is fit for its purpose. The Ilities Application Method and its associated templates are stated to be tools for practice and research. In another design science study, Mantzana and Themistocleous (2006) design and evaluate (via case study) a methodological artifact designed to help (a) address the uncertainties related to the actors in a healthcare setting during adoption, (b) enhance existing adoption models, (c) facilitate healthcare organizations in making robust decisions and (d) provide guidance to increase adoption of innovations. Their study focused on identifying actors involved in the innovation process within healthcare organizations.

It is not surprising that many of the papers that we classify as design research relate to tools and algorithms used for assessment, as artifacts which are needed for evaluating pre-existing tools and processes may not work with emerging technologies. The first of these types of papers appeared in 2006. Randomized control trials (RCT) are often referred to as the gold standard of evaluation for interventions in the healthcare sector. However, RCT's may not always be possible or provide the complete picture when it comes to healthcare IT evaluation. As part of their contribution, Dhillon and Forducey (2006) develop and illustrate the execution and benefit of a methodology for evaluation that considers Access to Health Care, Quality of Care outcomes and satisfaction, and Cost of Care for evaluating telemedicine systems.

The collection of 2009 papers includes two design research papers related to evaluation artifacts. Jaana, Pare', and Sicotte (2009) introduce an IT assessment scoring tool that aims at capturing the level of IT sophistication in hospitals on eight IT dimensions related to the implementation of computerized processes and emerging technologies with the level of internal and external systems integration. The instrument was validated through a survey of hospitals in two provinces in Canada (Québec and Ontario). The study by Roberts, Ward, Brokel, Wakefield, Crandall, and Conlon (2009) assesses the methods researchers use to evaluate health information systems and scrutinizes the recommended metrics and algorithms in the context of a case study that describes the introduction of a technically and systematically complex implementation of a healthcare IT system. They advocate that the analytical approach used should integrate: "(1) key engineering-derived tools such as statistical process control run charts designed to allow a visual examination of fluctuations in process over time and to help identify if those fluctuations are due to random events or a systematic change; (2) a human factors approach that considers the effect of an innovation's implementation upon the human interactions within the system; (3) the capture of robust data that enables stronger analyses of system performance; and (4) appropriate quantitative statistical tools designed to analyze and interpret system models" (Roberts et. al, 2009, p. 2). The researchers report on the benefits of using their linear piecewise spline mixed effects algorithmic model with a jump that the knot to address these concerns.

Conceptual Work

The conceptual papers in this collection provide an in-depth discussion of topics on which the authors have taken a position and want to point out issues which may be often overlooked in research efforts and in practice. Regarding the overlooked or missed, Raitoharju (2005) indicates that IT stress is an issue in the healthcare sector and should be taken into account in evaluating adoption and acceptance. Sood, et al., (2008) illuminate the unique challenges faced by developing countries toward the development, progression and sustainability of electronic medical records. Sherlock and Chismar (2006) use a compare and contrast approach to highlight lessons from the airline reservation system that may be applied to the future of electronic health records, but not readily recognized. Khoumbati, Themistocleous, and Irani (2005) illustrate both the advantages and disadvantages of various integration technologies (e.g. web services, enterprise application integration) that healthcare organizations are exploring and implementing that may be missed by practice and research. McCleod and Clark (2007) put the spotlight on issues of incorrectly identifying the user of health information systems. Yusof, Paul, Lampros, and Stergioulas (2006) review health information system evaluation studies and take the position that the current models are deficient. They then present a research framework that extends the then current models of health information system evaluation.

Experimental Design

Padmanabhan, et al., (2006) conduct a 'two group post-test only' laboratory experiment to evaluate the extent to which a triage prototype used as a decision support tool, impacts the quality of the triage decision-making processes and outcomes. The twenty-nine participants in the experimental groups attempted ten test case scenarios in random groups of five using the triage system. The control group attempted the same randomized case scenarios using paper and pencil. The "effectiveness" of the decision making process (degree of problem understanding, perceived clarity of choice strategy, perceived clarity of the problem solving process, user satisfaction, user confidence and perceived usefulness) and the "efficiency" of the process (accuracy, consistency and actual implementation) were compared for each group via the post-test.

The papers for the 2009 conference indicated in increasing interest in experimental design. Roberts, et al., (2009) use a longitudinal experimental design and analysis to study the trends in adverse drug events (ADEs) and the potential detection of them through HIT implementation. Another 2009 paper introduces the first field experiment by Paré, Sicotte, Chekli, Jaana, and De Blois (2009). The research team used a pre-post research design to evaluate the effects associated with the deployment of a telehome care system.

Sources of Data

One of the issues in designing a healthcare information systems research study is deciding what data to collect from whom. There are multiple resources in this complex environment and deciding on the best sources of data may be challenging.

The system user is the desired source of data in many of the studies on adoption, diffusion, use, and evaluation. However, identifying the user or knowing from which user to solicit data may not be as obvious as it seems in a healthcare setting. Regarding user identification, recent work by McLeod and Clark (2007) highlights the vulnerabilities of making incorrect assumptions regarding who is the health technology user and the impact user misconception can have on the results of the research. They indicate that multiple past studies in adoption and diffusion have focused on the physician as the primary user of health information systems technologies. However, by grounding our definition of use and performing closer inspection, the actual primary user that should be the subject of study in many cases may be another medical professional, such as a nurse or even support staff. Similar misconceptions may occur in designing studies when assumptions are made that a patient is the user of a consumer health web site or other technology. On closer examination, the system under study may actually is used more often by a caregiver in the home.

Multiple studies have also underscored the importance of soliciting data from multiple stakeholders, as there may be a variety of perspectives and pockets of complementary system knowledge when it comes to healthcare IT. Fitch (2004) contributed "Information Systems in Healthcare: Mind the Gap." It considers the knowledge gap and communication ambiguities between healthcare professionals and information technology planners that can result in incorrect translation of user requirements into system requirements. LeRouge and Hevner's (2005) work highlights the importance of data collection from all direct participants for health technology process design and evaluation. This team illustrated that the perspectives of multiple participants (patient, provider, presenter/medical personnel in the room with the patient) were needed to landscape a comprehensive picture of key attributes to assess quality in telemedicine encounters. Though the groups identified often share common attributes, each participant group possesses unique attributes, given their perspective and role in the process.

The research studies in our collection vary in their treatment of the various types of medical professionals (e.g., physicians, nurses, technicians) as one subject pool or distinct subgroups. Wu, Wang, and Lin (2005) do not distinguish these user groups in assessing what determines medical professionals' acceptance of mobile healthcare systems. Mantzana and Themistocleous (2006) take the position that the factors affecting adoption may vary by stakeholder. This team illustrates a method that researchers and practice can use to identify and detail the complex network of stakeholders in a healthcare information system to illuminate different adopter categories and different perspectives on the role of an IT system in various parts of the healthcare delivery process.

Goh, and Agarwal's (2008) work reminds us that primary data collection from human stakeholders is not the only source of data for healthcare IT. Their study used data analysis based on de-identified archival data from a health-program provider company that hosts its programs on a popular online health portal site. This data source was provided as a snapshot from the company's database. The information that serves as the input for the analysis was drawn from the users' responses to health risk appraisal (HRA), users' activity logs, and users' enrollment and participation in the health intervention programs.

Having reviewed the various levels of study and the methodologies employed, we turn now to evolutions and insights regarding the actual applications and uses of healthcare IT investigated in our collection of papers.

EVOLUTIONS AND INSIGHT IN THE USE OF TECHNOLOGY IN HEALTH PRACTICE

Electronic Medical Record Systems

There are at least three different, yet very closely related applications in this area. An Electronic

Medical Record (EMR) is an active tool that provides access to decision support, resources, and alerts. Electronic Patient Records (EPR) goes one step further than EMR: it contains healthcare related information gathered across at least two health organizations. Finally, Electronic Health Records (EHR) is still broader in that it includes wellness information and information that is not routinely collected or kept by health facilities. These three terms, EMR, EPR, and EHR are often used interchangeably by health professionals to describe the same thing; however we would like to start this section with the acknowledgement that, at least technically, there is a slight ascending order among them.

We start with what might be an unusual parallel between the airline and healthcare industries. Sherlock and Chismar's 2006 work points out a somewhat surprising number of analogies and similarities between these two very large and complex industries and predicts that, just as the airlines' computerized reservations systems evolved into vertically integrated, interoperable systems, so with healthcare's EMRs. Until that day, however, researchers continue to investigate the adoption, acceptance, and implementation of EMR throughout the world.

Of concern to many, is the attitude of physicians in regard to EMR. A 2007 study by Ilie, et al., investigated factors that most contribute to physicians' attitudes about, and usage of, EMR. Using Theory of Planned Behavior and a case study approach, this research posited that physicians' EMR behavior would be primarily determined by their attitude and perceptions about EMR use. They found that a majority of the residents and attending physicians identified the complexities of using EMR as a major negative influence on their perceptions and that the EMR system that they were using was not compatible with the workflow of the physicians.

In a similar vein, Trimmer, et al., (2008) found that while overarching attitudes regarding the EMR were positive, a consistent concern voiced by residents was ease of use. Residents unanimously commented on the importance of the accuracy of patient documentation and the ability to easily locate data. Performance expectations related to either gender or age were not observed. In the next iteration of their inquiry, "Prior Experience and Physicians' Intentions to Adopt EMR," Wiggins, et al., (2009) investigate one specific mediating factor of the UTAUT theory: the impact of prior experience with EMR. This preliminary work demonstrates that at least among this group of residents and physicians, there is not necessarily a positive relationship between experience with EMR and a physicians' intent or desire to adopt it.

Finally, with private physician practices as the unit of investigation, Reardon and Davidson (2007) posed the question of how physicians perceive the organizing vision for EMR and found that stakeholders need to do a better job of communicating the plausibility of EMR and at presenting representations of the EMR before an independent physician practice will find the organizing vision as clear, consistent, rich, and as balanced as it needs to be to be approved for adoption.

Moving away from questions about physicians and their reasons for or against adopting and using EMR, MacKinnon and Wasserman (2009) ask "What are the critical success factors for EMR systems implementation?" and propose that an understanding of Enterprise Resource Planning (ERP) systems will contribute to the successful implementation of EMR systems. They yielded strong support for the proposition that treating EMR systems as a type of ERP was a success factor for implementation. Other insights include the necessity of choosing a CCHIT certified and a KLAS evaluated EMR system.

Demonstrating that EMR adoption and implementation is a concern worldwide, "Electronic Medical Records: A Review Comparing the Challenges in Developed and Developing Countries," by Sood, et al., (2008), indicates challenges faced in developing countries hinder the development and progression of EMR and the authors suggest that developing countries may need to build on current structures of healthcare data bases and with technologies which have already be shown to work and add only relevant and disease specific modules unique to each country's needs over time.

In concluding this discussion of EMR, it is vital to point out that EMR has been, and continues to be, touted as the answer to any number of problems plaguing the healthcare industry. The studies above are a strong indication that this area of research is rich, with much yet to be investigated. EMR is a worldwide topic that can be viewed and investigated through a narrow user/organization lens or through a wide-angle national/global lens. As one of the primary impetuses for the use of EMR is to enhance and enable access to, and communication of, health information among caregivers, patients, health organizations, regional systems, and perhaps nations, many questions remain and much work remains to be done.

Clinical Systems

We move now from EMR to the investigation of IT systems used to support specific activities in clinical settings. The findings in this area are somewhat mixed. For example, the 2005 work done by Padmanabhan, et al., described an evaluation methodology for assessing a mobile triage support system on a handheld PDA. The researchers found few opportunities for improving the level of patient care by triage nurses using the decision support technology. More recent research by Burley, et al., (2008) on a similar topic asked in what way do mobile systems deliver internal value in emergency healthcare organizations? Their work indicates that the introduction of mobile services can support ambulance services by providing more efficient and effective information. Yet the authors caution that there is a delicate balance between internal data capture requirements versus external requirements of readability of the final electronic patient care record.

Indeed there is a well-established mythology in healthcare that describes failures in the implementation, use, and adoption of clinical IT. In their 2008 paper, Paré, et al., investigate the typical risk factors associated with clinical information systems, electronic patient record systems, picture archiving and communication systems (PACS), and computerized physician order entry system projects. The researchers then go on to ask "What is the relative importance of these risk factors?" Hypothesizing that the success of any given clinical information system project lies in the ability to identify the risk factors in order to reduce them and thus to improve chances of success, this work finds that failure rates due to unidentified and unanticipated risk factors still prevent clinical information system projects from being beneficial. Managers need to recognize what typical project risks are and their impact of these risks on project success.

Perry (2007) considers the options for process-based systems as "assistants" to professional mental health staff, and considers the extent to which such systems can complement or manage types of tacit knowledge, such as 'know-how' or emotion. The central problems identified in this study are that mental health staff find that person-to person knowledge transfer is reassuring, and trustworthy, while electronic methods are seen as untrustworthy. These findings underscore the idea that there is no evidence that IT-mediated knowledge transfer conveys social reassurance.

Still, all is not doom and gloom. The 2009 research, "On The Economic Role of RIS/PACS in Healthcare: An Empirical Study" from Ayal and Seidmann presents a case study measuring process times and revenues, as well as survey results from staff and customers about perceived operational benefits of integrating RIS/ PACS into a health system. It was hypothesized that RIS/ PACS would improve billing, significantly reduce diagnostic exam times, and improve customers' level of satisfaction of the diagnostic imaging service. Patterns in the surveys were identified using the Principal Components Analysis (PCA) methodology. Results show that physicians were satisfied with their level of interaction with departmental personnel, though customers were indifferent with the quality of the services.

What becomes abundantly clear when considering the clinical applications of healthcare IT is that this is an emerging area that will continue to grow and evolve. Indeed, it is an area that is at the very crux of multidisciplinary research. The places where disciplines intersect, such as nursing and quality, or clinical laboratory and patient satisfaction, are fertile and important areas for future research.

Administrative Applications of Health Information Technology

One could easily argue that EMR and telemedicine applications are excellent examples of administrative uses of HIT as they are seen as avenues to increased efficiency, access, and quality. These applications have been discussed above. The use of information technology in healthcare began with business applications such as accounting and billing and potential administrative applications of HIT continue to be investigated. A case in point is Fruhling, et al., (2005) work that examines the development and implementation of a biosecurity healthcare application. This paper focuses on programming and software engineering, but still makes the point that as terrorism, infectious agents, dirty bombs, and other chemical threats become more likely, healthcare as the largest information business in the US, needs to turn to technology applications such as telehealth to develop and implement biosecurity applications for healthcare.

Another example of research that addresses the administrative uses of IT is Khoumbati, et al.'s 2005 paper on Enterprise Application Integration (EAI). The integration of healthcare information systems with EAI is described with respect to the way they can be integrated at both an internal hospital level and externally with other hospitals, primary healthcare providers and with other stakeholders. The author identified technical, cost, medical errors, decision support system, security, and confidentiality of patients' data as factors that motivate the adoption of EAI in healthcare organizations. The authors conclude that, from a business perspective, EAI reduces the overall integration cost due to the reduction in integration time and maintenance costs.

Telemedicine

A broad number of applications under the umbrella of telemedicine have been increasingly investigated over the years. Telemedicine is the use of telecommunications for the care of patients and can involve a number of various electronic delivery mechanisms. The overarching research questions about telemedicine investigate its acceptance and effectiveness. For example, Wu et al., (2005) studied mobile applications asking what determines health professionals' acceptance of mobile healthcare technology, they conclude that compatibility and self efficacy have significant influence on intentional behavior. Management support, as they had hypothesized, did not influence behavior in this study. Dhillon and Forducey's (2006) "Implementation and Evaluation of Information Technology in Telemedicine" reviewed effectiveness evaluation techniques of telemedicine systems. They report on the successful utilization of HIT in regard to access, quality, and cost in a rural telehealth system. LeRouge and Hevner (2005) indicate that the way technology is used may affect effectiveness in defining quality for medical video conferencing.

In 2008 three research teams investigated three very different and very specific applications of telehealth. Goh and Agarwal (2008) asked these research questions: 1) what factors affect an individual's initial enrollment in an online health intervention program, 2) what factors affect continued participation in the program, and 3) how do the drivers of initial participation differ from those of continued involvement? They found that individuals who are less satisfied with their life and their work are more likely to enroll in a program, social ties are not significant in predicting enrollment, and perception of individual risk of contracting the illness has a positive and significant effect on enrollment. In addition, they found a strong moderating effect of gender, which suggests that gender plays a central role in sustaining participation; site owners need to consider increasing their efforts in sustaining the participation for females more than for males.

Cho, et al.'s (2008) work investigated how a telehealth innovation evolved from its initial adoption by a small network of hub hospitals to wider diffusion into a larger population of rural organizations. Their study resulted in six specific recommendations for success: 1) Develop a long-term plan for post-pilot stages. 2) Position innovation as a win-win proposition. 3) Align with rural hospital processes. 4) Accommodate rural area technology infrastructure issues. 5) Consider institutional arrangements and legal issues and, 6) Build and manage the knowledge base from initial adoption.

Then, in a completely different vein, Kifle, et al., (2008) examined Information and Communication Technology Transfer (ICTT) as it applied to telemedicine in Sub-Saharan Africa. Positing that telemedicine capabilities are positively related to social outcomes of telemedicine, this research found that social outcomes of telemedicine are positively related to value outcomes of telemedicine. Specifically, policies that favor the development of ICTs in general are positively related to telemedicine capabilities, policies specifically tailored to ensure data security and standards are positively related to telemedicine capabilities and to the level of ICT infrastructure, policies specifically tailored to promote the application of ICTs in healthcare are positively related to the level of ICT infrastructure, and that more reliable and readily accessible ICT infrastructure is positively related to telemedicine capabilities.

The investigation of telehealth and factors that impact its acceptance is an overarching theme for the 2009 conference. Are there specific characteristics that are related one's willingness to accept and use telehealth applications? For example, does culture play a role in the adoption of new telemedicine technology? Meso, et al., (2009) find that, among underserved communities, culture significantly influences individuals' intentions to use new technology prior to the implementation of the technology. However, once the telemedicine technology is in place and individuals become more familiar with using it, culture no longer plays a significant role in usage behavior. In a similar line of inquiry, Topacan, et al., (2009) interviewed potential users of telemedicine and asked semi-structured, open-ended questions to study and analyze their perceptions of a prototype service developed for the study. These researchers found that characteristics of the potential users (such as age, education level), cost of services, security, time use, and social factors would influence the adoption of a health information service such as telemedicine among the study group participants.

Taking a slightly different approach, a 2009 study by Svendsen, et al., (2009) of mobile phone based, tailored motivational systems investigated whether they would help to combat growing health problems associated with a lack of physical exercise. Study questions were related to motivation, self-efficacy in regard to exercise, and TAM related issues. Behavioral intention and acceptance of the mobile system was driven by an individual's intrinsic motivation and by the perceived usefulness of the application. The researchers suggest that mobile phone based motivation systems will work best if presented to the public as fun and game-like, and only secondarily if offered as a health enhancing tools.

One study asked, "What are the impacts of the implementation of software aimed at optimizing clinical services delivered at patients' homes?" Paré, et al., (2008) concluded that the implementation of the telehome care software had positive effects on staff productivity and upon accessibility to care services. Specifically, the software allowed the allocation of an additional hour that was used on patient care. Nurses were able to increase the number of home visits as well as devote more time to patient care rather than on paperwork.

Overall, it appears that the use of telecommunications is increasing in healthcare. The important question remains, what is the overall impact of traditional telemedicine media and emerging devices such as mobile phones and hand-held instruments on quality, access and cost?

FUTURE OF E-HEALTH ADOPTION AND EVALUATION

This analysis roughly follows the diagonal of table 3 that highlights the results. For nearly more than two decades researchers on e-health have explicitly shown that value, benefits, perceived usefulness or relevance are the most important determinants for successfully implementing e-health systems in the clinical domain. For almost two decades, practice seems to ignore these scientific findings and continues to introduce standard software in a complex individual medical setting with many disappointments as a result. How can we break through this deadlock situation? Many researchers think that Business Process Management (BPM in table 3) will help to diffuse information systems in healthcare. We think that this will only be the case when e-health provides value driven from an individual perspective of the healthcare professional. Many e-health applications only deliver efficiency as net benefit (see Table 3) and often this efficiency is delivered on the wrong side of the organization. It is therefore important to identify the individual stakeholders (Table 3) and know who the end user is (in Telemedicine often the patient) and who will exert the effort to implement the system.

On the group and organizational level, the main challenge is to integrate the back office and front office (see Table 3) of healthcare. Instead of EMR, here we are talking about ERP (enterprise resource planning) in healthcare or about enterprise wide systems combined with information services in the front office. Enterprise Application Integration is already widely used in business, but healthcare is just in its first steps toward integration. Another challenge on the organizational level is to manage the clinical systems and avoid unanticipated risks (see Table 3). In the future, integration in general, by using standards and building interoperable architectures, will have to stabilize the turbulence in e-health implementations. Because Electronic Medical Records have a value beyond the individual end user, the organization must create vision on how to communicate this to the whole healthcare chain and back again to the end user. On even larger scale, an ICT infrastructure is needed to be able to bridge the digital divide.

Interorganizational systems and mass customization are buzzwords that have strong influence on the globalization of e-health. Telemedicine is

Table 3. Overview analysis

LEVEL/ APPLICATION	*EMR*	*Clinical systems*	*Administrative Applications*	*Telemedicine*
Individual	**(Net) Benefits**	Process/BPM	Efficiency	Stakeholder
Group/organizational	Organize vision	**Unanticipated Risk**	**Back/ Front Office**	ICT infrastructure
(Inter)national	Healthcare Databases	Knowledge	Standardization	**Big Leap Forward**

seen as a weapon to break down the digital divide in healthcare and promises a big leap forward (see Table 3). Global systems like Google Health © l seem to break open the market, but still the dangers at the individual professional level might inhibit the diffusion of these systems. In the end, these systems have to evolve into knowledge management systems that can leverage healthcare at the global level. On the international level, standardization and knowledge dissemination should go hand in hand to solve global healthcare problems.

CONCLUSION AND DISCUSSION

This comprehensive review of HICSS papers underscores our understanding that adoption decisions are complex given a multitude of technologies, stakeholders, and potential levels of analysis when technology is introduced into healthcare settings. The research reviewed spans different technologies such as telemedicine, telehomecare, enterprise wide systems including RIS/PACS and EMR, infrastructure, and capacity assessment. Research in this area addresses implementation, intention to adopt and use, culture, performance, interventions, and methodology. Individual, organizational, and (inter)national levels of analysis are represented.

Many studies focus on the individual level and concentrate on adoption rather than on implementation. Although perceived usefulness and performance expectancy in all quantitative studies are significantly related to e-health success and many qualitative studies report on value, benefits, and relevance to the professional, *the value proposition remains under-developed in healthcare.* Moreover, even if the value of e-health is evident, there is much difficulty in implementing these systems due to lack of participation and resources. The risks on the group, organizational and (inter) national level are high with many stakeholders with many different interests.

In recent years, the international level and specifically the digital divide, has become a theme in e-health evaluation. Transferring knowledge across the digital divide will be an important subject on the international calendar. Also international comparisons might strengthen national initiatives when cultural differences are considered.

Results show a multitude of methodologies varying from quantitative psychological studies to qualitative demographic case studies to design science. The span and divergence of research methods underscore the complexity of this context and the fact that a multitude of studies and methods are needed to gain understanding. Though the scope of each individual study is limited, the collection of studies call researchers to consider mixed methodologies. The presence of design science pieces demonstrates that tools, techniques, and frameworks acknowledge the need for a planned and organized method of approaching the challenges of, and many variables involved in, implementation and evaluation in practice.

In addition to the many messages discussed above, readers should interpret this communication as a welcoming call to the many opportunities that are available in e-health research. The wide range of research approaches and levels of analysis should be appealing to a broad set of researchers, as we work toward improving the adoption and evaluation of Information Technology and its eventual benefit to improved societal healthcare.

ACKNOWLEDGMENT

We would like to thank all authors and referees for contributing to our successful Hawaii International Conference on System Science minitrack and hope to work with you in the future.

APPENDIX A. TABLE OF PAPERS REVIEWED

Title of Paper	Author	Year	Dependent Variable	Research Method	Research Design	Data Source
The Dynamics of IT Adoption in a Major Change Process in Healthcare Delivery	Liette Lapointe, Lisa Lamothe, Jean-Paul Fortin	2002	Implementation	Qualitative	Multi case study - Mixed- Observation, Interviews, Documentation	Caregivers, promoters, consultants, patients, and hospital management
Does the Extended Technology Acceptance Model Apply to Physicians	William G. Chismar, Sonja Wiley-Patton	2003	Adoption	Quantitative and Qualitative	Survey	Pediatricians
The Impact of Organizational Characteristics on Tele-health Adoption by Hospitals	Marie-Pierre Gagnon, Lise Lamothe, Jean-Paul Fortin, Alain Cloutier, Gaston Godin, Camille Gagné, Daniel Reinharz	2004	Adoption, Implementation	Quantitative and Qualitative	Survey and semi-structured interviews	Directors of Professional Services
Use of Online Systems in Clinical Medical Assessments: An Analysis of Physician Acceptance of Online Disability Evaluation Systems	Thomas A. Horan, Bengisu Tulu, Brian Hilton, Jacqueline Burton	2004	Evaluation	Quantitative	Survey	Physicians
Adoption-related Aspects of an Information System in a Health Care Setting	Marianne C. Maass, Reima Suomi	2004	Implementation, Adoption and Evaluation	Quantitative	Mixed - cost analysis, workflow modeling, customer satisfaction survey,	Physicians and nurses
Information Systems in Healthcare: Mind the Gap	C.J. Fitch	2004	Implementation and Use	Design Science	N/A	N/A
It's More than Just Use: An Investigation of Telemedicine Use Quality	Cynthia LeRouge, Alan R. Hevner	2005	Telemedicine use quality	Qualitative	Multi-case study Qualitative methods (observation, focus group, and interviews) and Quantitative methods (survey)	Patients, physician, other medical providers (e.g., nurses), IT personnel, support staff
Experiences with Extreme Programming in Tele-health: Developing and Implementing a Biosecurity Health Care Application	Ann Fruhling, Kimberly Tyser, Gert-Jan de Vreede	2005	Implementation and Evaluation	Qualitative -	Action Research - Direct observation, interviews, usabiliity evaluation, review of documentation	System development team

APPENDIX A. CONTINUED

Title of Paper	Author	Year	Dependent Variable	Research Method	Research Design	Data Source
What Drives Mobile Health Care? An Empirical Evaluation of Technology Acceptance	Jen-Her Wu, Shu-Ching Wang, Li-Min Lin	2005	Use	Qualitative	Mixed - Survey and interview	Users - physicians, medical technicians, nurses
When acceptance is not enough – taking TAM-model into healthcare	Reetta Raitoharju	2005	Adoption, Evaluation	Conceptual Paper	N/A	N/A
Integration Technology Adoption in Healthcare Organisations: A Case for Enterprise Application Integration	Khalil Khoumbati, Marinos Themistocleous and Zahir Irani	2005	Adoption	Conceptual Paper	N/A	N/A
Towards a Sociability Theory of Computer Anxiety: An Interpersonal Circumplex Perspective	Houghton G. Brown, Liqiong Deng, Marshall Scott Poole. Pamela Forducey	2005	Evaluation	Quantitative	survey	Physical therapists
Towards a Framework for Health Information Systems Evaluation	Maryati Mohd. Yusof, Ray J. Paul, Lampros K. Stergioulas	2006	Evaluation, Implementation	Conceptual Paper	N/A	N/A
Challenges in the Adoption of Medical Information Systems	Marianne Maass, Owen Eriksson	2006	Adoption, Implementation	Quantitative and Qualitative	Longitutidinal Case study (consisting of statistical data, cost analysis, modeling, customer satisfaction inquirie time and motion studies) observation and staff interviews)	Management, Medical Staff
A Mobile Emergency Triage Decision Support System Evaluation	Neha Padmanabhan, Frada Burstein, Leonid Churilov, Jeff Wassertheil, Bernard Hornblower,Nyree Parker	2006	Evaluation	Experiment - Quantitative	Experiment	Nursing students
What Airline Reservation Systems Tell Us about the Future of EHRs	Sheila Sherlock, William G. Chismar	2006	Design and implementation	Conceptual Paper	N/A	N/A

APPENDIX A. CONTINUED

Title of Paper	Author	Year	Dependent Variable	Research Method	Research Design	Data Source
Implementation and Evaluation of Information Technology in Telemedicine	Harpal Dhillon,Pamela G. Forducey	2006	Evaluation and Implementation	Design Science	Verifying case study included review of reports generated from a telerehabilitation system; patient survey; provider satisfaction survey; hospital cost records	Patient, provider, system
Project Establishment in the Context of Participatory Design: Experience from a Hospital Information System Development Project in a Developing Country	Salesio Mbogo Kiura	2006	Implementation	Qualitative	Action research - using joint application design and STEPs	Hospital staff
Entrepreneurial Governance in a Rural Family Practice Residency Program	Carla Wiggins, Lela Pumphrey, John Beachboard and Kenneth Trimmer	2006	Adoption	Qualitative	Interviews and document analysis	Family practice residents
A Method for the Identification of Actors Involved in the Adoption of Innovations in Healthcare Organizations	Vasiliki Mantzana, Marinos Themistocleous	2006	Adoption	Design	Validating case study included interviews, documentation, observation	Hospital management, staff, and medical providers
Paper versus Electronic: Challenges Associated with Physicians' Usage of Electronic Medical Records	Virgiia Ilie, Jim Courtney, Craig Van Slyke	2007	Adoption	Qualitative	Case study - Semi strucured interviews and direct observation	Attending physicians and residents
Identifying the User in Healthcare Information Systems Research	Alexander J. McLeod Jr, Jan Guynes Clark	2007	Evaluation	Conceptual Paper	N/A	N/A
An investigation of factors affecting technology acceptance and use decisions by Australian allied health therapists	Louise K. Schaper, Graham P. Pervan	2007	Use, Adoption	Quantitative and Qualitative	National survey and logititudinal case study	Occupational therapists, hospital management, staff, and medical providers at a community based health care center

Chapter 1.8

Health Infonomics:
Intelligent Applications of Information Technology

Michael Mackert
The University of Texas at Austin, USA

Pamela Whitten
Michigan State University, USA

Bree Holtz
Michigan State University, USA

ABSTRACT

Researchers are currently challenged to document the economic aspects of information across an array of contexts. While some lessons can be applied generally, certain contexts present unique challenges for researchers interested in the acquisition, management, and use of information. Health is one such field currently undergoing a revolution driven by new applications of information-based technologies and services. This chapter provides background on health informatics and current issues as health informatics impacts the provision of health in doctors' offices, shifts the provision of healthcare services into patients' homes, and presents new opportunities to address public health concerns. An outline of a future research agenda in health informatics and a look at the prospect of health informatics applications provides the necessary foundation for focused work on the economic impact of this information-driven transformation in healthcare delivery.

DOI: 10.4018/978-1-60566-890-1.ch012

INTRODUCTION

Informatics, the maximization of data use and acquisition through the intersection of information and computer science, is becoming commonplace across a range of applications that interface with everyday life. Currently, researchers are challenged to document economic aspects of information across a vast array of decision-making contexts. There are important general lessons that can be applied across applications from the field of infonomics, but context can also drive the impact and evolution of information use in distributed business environments.

Healthcare is one such context uniquely poised for transformation based on informatics and the economic aspects of information-driven changes in the provision of healthcare. The delivery of health services represents one of the more complex examples of distributed decision making as multiple stakeholders - providers, patients, family caregivers, insurance payers, and government regulators - have interests in individuals' health decisions and treatments.

Prompted by rising healthcare costs and concerns over quality, there is significant pressure to reform healthcare in both developed and developing countries. Stakeholders are looking to a wide array of information technologies to address challenges in health delivery, including access to care, medical errors, cost efficiencies, health outcomes, patient and provider satisfaction, demographic challenges such as aging populations, and provider shortages. Such challenges are particularly pressing given the unprecedented strain the health care industry will face due to an aging global population. The United Nations projects that by 2050 the number of older people (60 years or older) will outnumber younger people worldwide, due to people around the world living longer and having fewer children (United Nations, 2002).

While informatics may not present a solution to every problem in healthcare, appropriate applications of new information technology to the provision of health can indeed present promising strategies for addressing shortcomings in the healthcare system or advancing the practice of medicine. The sheer quantity of information necessary to practice medicine and to be an informed patient is rapidly increasing. Health informatics systems can serve as gateways for this vast amount of information to be utilized and managed by both providers and patients.

In line with the recognition that information technology can be used as a tool to address the challenges in healthcare, there is also a growing movement for paradigmatic shifts in the very nature of healthcare provision. For example, the movement toward “patient-centered care” seeks to provide health services that explore a patient’s main reason for a health visit, concerns, and need for information; gain an integrated understanding of the patient’s emotional needs and life issues, find common understandings of the etiology of the problem, allow the patient and health provider to mutually agree on management; enhance prevention and health promotion; and reinforce the continuing relationship between the patient and health provider (Stewart, 2001). Health informatics can assist in this movement of patient-centered care, empowering patients and their communities so they can make informed decisions regarding their healthcare (Cornford & Klecun-Dabrowska, 2001). Operationalizing this concept calls for employing information technologies to meet the core goals of patient-centered care, namely (Sherer, 1993):

- Locating services as close as possible to patients
- Redefining work by desegregating job tasks and providing health workers with necessary support, skills, and training
- Meeting patient needs, rather than the needs of a department, discipline or field.

This chapter seeks to illustrate the evolution and impact of health informatics, review what research has taught us to date, and comment upon future directions to advance health informatics and infonomics research. The discussion will include the utilization of health informatics systems designed to assist healthcare providers in their work, technology to bring health services into patients’ homes, and population-based applications that can advance public health. A greater understanding of health informatics applications - what these systems are and how they could radically transform the healthcare system - can provide the foundation for studies of the economic impact of an information-driven revolution in healthcare delivery. While many of the statistics and examples cited in this chapter are drawn from the U.S., lessons learned and potential applications would be similar in international contexts. Differences between the U.S. and other countries are noted when relevant.

THE UNDERPINNINGS OF HEALTH INFORMATICS

Health informatics has emerged as a rapidly evolving scientific field that studies the interrelationship between information (e.g., computers and communications), science (e.g., engineering and technology) and health (practice, education, and research). Health informatics, by nature, encompasses multiple disciplines, including communication, economics, engineering, computer science, nursing, and medicine. This new academic domain includes multiple applications, such as:

- Development and delivery of public health information
- Design and analysis of electronic medical records and personal health records
- Evaluation of the impact of IT on the clinical processes, outcomes, and resources
- Telemedicine and remote monitoring
- Data management and database construction
- Development of terminology, coding, and classification schemes
- Process re-engineering
- Interactions and interfaces between technology, providers, and patients
- Implications for policy and ethics
- Bioinformatics
- Clinical decision tools and decision support systems
- Geographic Information systems

With its broad array of disciplines it should not be surprising that health informatics also encompasses a variety of terms referring to transferring data to maximize patient care. Terminology commonly used in the literature when discussion heath informatics includes electronic medical records (EMR), electronic health records (EHR), health information technology (HIT), health information network (HIN) and health information exchange (HIE).

Before EMRs, paper records were launched in the 19th century as the standard of recording patient data, treatments, and procedures (Shortliffe, 1999). Generally, EMRs simply refer to an individual record in which a healthcare provider records treatments, drugs, and future recommendations electronically. There are several advantages of an electronic record, including legible orders and the ability for quicker searches through the record (D. Bates, Ebell, Gotlieb, Zapp, & Mullins, 2003). While the terms EMR and EHR are often used synonymously, many consider EHRs to be more comprehensive (Busis & Hier, 2007). EHRs include individual patient information from a variety of sources, such as radiology (films), pharmacy (interaction checks), and specialist information (cardiologist, dermatologist, etc.).

Examining the broader scope of electronic health data management, HIT is defined by the Department of Health and Human Services as a "comprehensive management of medical information and its secure exchange between healthcare consumers and providers" (Department of Health and Human Services, 2008). HIT is being recognized as an extremely important tool for improving healthcare quality and outcomes, reducing costs, and improving access to care. HIEs or HINs are necessary when connecting all of the individual patient records across regions or organizations. Through the years these have also been coined CHINs (Community Health Information Network) or RHIOs (Regional Health Information Organization).

New health informatics applications are often cited in calls to improve the healthcare system, such as in the early 1990s when the Institute of Medicine called for the creation of computerized patient records nationally (Dick, Steen, & Detmer, 1991). While many healthcare professionals and policymakers at that point understood the benefit of sharing patient information among healthcare providers, a decade later it was necessary to produce more calls for the public to recognize the importance of information technology in healthcare as the Institute of Medicine published two additional reports *To Err is Human* (2000) and *Crossing the Quality Chasm* (2001). *To Err is Human* is now considered to be a seminal report on restructuring the healthcare system in order to improve health outcomes. That report declared that up to 98,000 people in the United States were dying due to medical errors each year. The report posited the entire healthcare system must be revised in order to meet six goals - to provide care that is safe, effective, patient-centered, timely, efficient, and equitable (Johnston, Pan, Walker, Bates, & Middleton, 2003; Kohn, Corrigan, & Donaldson, 2000). The report also asserted health informatics would be a key to resolving this crisis in healthcare (Johnston, et al., 2003; Kohn, et al., 2000). In *Crossing the Quality Chasm* a strategic plan was proposed to address the problems highlighted in *To Err is Human*. In it, health informatics is positioned as being able to facilitate in addressing all six goals of improving healthcare.

Three years later, in 2004, President George Bush declared by 2014, most Americans should have a national EHR and created the position of the National Health Information Technology Coordinator (Blumenthal & Glaser, 2007). Still, almost a decade after *Crossing the Quality Chasm*, researchers and practitioners are still no closer to implementing national EHRs (Miller & Sim, 2004). A study conducted through 2005, demonstrated less than twenty-four percent of physicians used EHRs in an ambulatory setting, only five percent of hospitals had a computerized physician order entry (CPOE) system, and less than two percent of the hospitals were actively using CPOE systems (Holbrook, 2006; Jha, et al., 2006). This is despite the fact that HIT has been found to improve patient care and quality (Chaudhry, et al., 2006). The challenges faced by implementation of a nationwide health network were also noted in the IOM's 2001 report, these issue consist of interoperability, standardization, privacy, regulatory, human factors and the large financial investment requires (Institute of Medicine, 2002). Even today these barriers remain as key hurdles facing IT diffusion in healthcare, though progress is being made - 29.2% of office-based physicians were using EMRs in 2006, a 22% increase from 2005 and 60% increase since 2001 (Hing, Burt, & Woodwell, 2007).

Some of the key challenges facing these projects include cost, lack of reimbursement, technical issues, system interoperability, legal and policy issues, and concerns over security, privacy, and confidentiality (Hersh, 2004; Schoenman, Keeler, Moiduddin, & Hamlin, 2006; Whitten, Buis, & Love, 2007). Physicians are often expected to front upwards of $24,000 to install and implement a HIT system with little return on investment (ROI) (Hersh, 2004; Johnston, et al., 2003; Kleinke, 2005). Insurers, laboratories, patients and others generally uninvolved in the payment for electronic systems assume the remainder of the ROI (Hersh, 2004; Whitten, Buis, & Love, 2007). Any type of health information technology application generally involves systems with high complexity that must be customized to a particular clinic or office (Whitten, Buis, & Mackert, 2007). Hersh (2004) suggested that health care facilities, especially those in rural or underserved areas, adopt a simple and inexpensive solution to HIT. System interoperability is also a concern regarding the adoption of HIT in the health field. Most information is inaccessible from one system to the next, making a cohesive record for patients impossible, lowering the incentives for single physician offices or small clinics to implement this type of technology (Hersh, 2004, 2006; Kleinke, 2005; Walker, et al., 2005). Security, privacy, and confidentiality are an important topic when dealing with HIT, as many studies report that electronic data have more security features than traditional paper records (Hersh, 2004). In general, patients do not perceive security issues as a major barrier, whereas clinicians are extremely concerned (Whitten, Buis, & Love, 2007).

Some of the challenges facing the rollout of health technology in the U.S., specifically the fragmented healthcare system, are not present in other countries. Indeed, many other countries, specifically those with more centralized systems of health care – the United Kingdom, Canada, Norway, Singapore, etc. – have been able to advance far ahead of the U.S. (E. Shortliffe, 2005). Overall, the governments of those countries have initiated programs to advance HIT and most are at least six years ahead of the United States (Anderson, Frogner, Johns, & Reinhardt, 2006). While many countries are further along in their implementation, they are still facing a myriad of hurdles to full adoption and diffusion. Many of these countries' programs started with disjointed and unstandardized systems but discovered that such a strategy hindered adoption. Some countries adopted standards set by the eEurope 2002 and eEurope 2005 Action Plans. Many other countries have adopted the Health Level Seven (HL7) standards, including Canada, Germany, the United Kindgom, and the U.S. (Anderson, et al., 2006). HL7 "provides standards for interoperability that improve care delivery, optimize workflow, reduce ambiguity and enhance knowledge transfer among …healthcare providers, government agencies, the vendor community" (HL7, 2009).

In the past, there has been a fundamental assumption that health informatics will inherently improve the quality of healthcare (Heathfield, Pitty, & Hanka, 1998; Kaplan, 2001). Above and beyond improvements potential improvements in healthcare, health informatics research involves understanding the implementation and utilization of these technologies while also examining the actual use by the healthcare workers in their health specialty (Kaplan, 2001; Lærum, Ellingsen, & Faxvaag, 2001). Many researchers studying health informatics now understand that human factors, organizational institutionalism, and medical specialty contribute in the overall diffusion and success of these tools. The following section provides an overview of recent research in health informatics.

CURRENT ISSUES IN HEALTH INFORMATICS

Health informatics systems span the healthcare system, from hospitals and doctors' offices to patients' homes to the efforts of public health officials to improve population-level health indicators. Informatics in health offers the opportunity to study large scale information systems based on human-centered considerations. As there are multiple types of large scale information systems in the health context, special consideration must be paid to the unique nuances of these information-based services. This section highlights study of US-based applications.

EHRs and Healthcare Quality

Widespread deployment and adoption of EHR systems is one important step toward improving healthcare in the U.S., an important goal given that U.S. adults only receive approximately half of the care they should (McGlynn, et al., 2006). As stated earlier, adoption of EHRs in the U.S. has been quite slow, however, with 25-30% of practices currently making use of such systems (Berner, Detmer, & Simborg, 2005; Burt & Sisk, 2005; Gans, Kralewski, Hammons, & Dowd, 2005).

There are numerous reasons that EHR adoption has been slow, including difficulty in making the business case for EHRs and incentive systems that do not reward healthcare providers for adopting EHRs (Middleton, Hammond, Brennan, & Cooper, 2005; E. Shortliffe, 2005). Additional structural barriers within the healthcare system provide further hurdles to EHR adoption, such as difficulties arriving at technical and administrative standards (E. Shortliffe, 2005); the U.S.'s relative lack of a national structure could be one reason that health systems that are more centrally coordinated (e.g., Sweden, Australia, and Denmark) have had comparatively greater success adopting EHR systems (Harris Interactive, 2002). Assuming the context within which EHR systems are implemented improves to favor adoption, studying current EHR efforts sheds light on additional issues likely to arise as healthcare organizations seek to install an EHR system. These include a fear among providers that EHRs might depersonalize the delivery of healthcare (Aydin, Rosen, & Felitti, 1994) and reluctance to spend sufficient time learning the actual technology (Overhage, Tierney, McDonald, & Pickett, 1991). It is important to recognize that such barriers are indeed significant and can impact the perceived benefits to widespread EHR adoption.

Providers are certainly aware of the benefits EHRs might offer, including quicker reviews of charts and improved patient privacy and security (Massachusetts Medical Society, 2003; E. H. Shortliffe, 2005). Other advantages to EHR deployment include cost savings for healthcare providers (Ash & Bates, 2005), increased continuity of care (Kibbe, Jr., & Green, 2004), and reduced medical errors (Hillestad, et al., 2005). Recent work has demonstrated that provider acceptance is largely dependent on providers' perceptions regarding the overall benefits of widespread EHR adoption – those providers who perceive the greatest benefits are most likely to endure temporary, personal troubles associated with EHR adoption in their own practices (Whitten, Buis, & Mackert, in press). Even if the current healthcare system is not driving health providers to adopt EHRs, that could change in the coming years as the Institute of Medicine has called for increased transparency, including public reporting of healthcare quality and increased payments to those providers offering superior care (Institute of Medicine, 2002).

In the end, of course, widespread EHR adoption will depend primarily on proving the success of such systems in improving patient outcomes. In providing the rationale for a study of EHR use on the quality of ambulatory care in the U.S., Linder et al. (2007) point to the often-conflicting results regarding impact of EHRs on healthcare quality. This could be due to the fact that many of the studies reporting positive findings come from a relatively small number of institutions that have developed internal EHR systems (Chaudhry, et al., 2006). As such, the basic justification of EHRs could be based on a shaky foundation.

Given the key role that widespread adoption of EHRs will play in a national effort to improve healthcare through the use of new health informatics systems, the current state of affairs leaves significant room for improvement. Continued improvements in design, research into impacts on healthcare quality, and better training projects are needed if EHRs are to fulfill their potential as a core element of healthcare systems.

E-Health and the Provision of Healthcare

Shifting from healthcare providers' use of health informatics to a patient-centered view, the spread of broadband Internet access has made possible two phenomena with particularly important implications for the U.S. healthcare system – widespread use of the Internet to obtain health information and the provision of healthcare services to the home via telemedicine.

One of the more accepted definitions of e-health is supplied by Eysenbach (2001):

> *e-health is an emerging field in the intersection of medical informatics, public health and business, referring to health services and information delivered or enhanced through the Internet and related technologies. In a broader sense, the term characterizes not only a technical development, but also a state-of-mind, a way of thinking, an attitude, and a commitment for networked, global thinking, to improve healthcare locally, regionally, and worldwide by using information and communication technology.*

With more than 70% of American adults going online in general, data also indicate that a whopping 80% of these users are specifically looking for health-related information e-health increasingly ubiquitous (Fox, 2006; Pew Internet and American Life Project, 2007). People venturing online can make use of a variety of e-health applications, from systems designed to connect patients and providers via e-mail to online support groups (Arrington, 2004; May, Finch, Mair, & Mort, 2005). For patients interested in maintaining their own Personal Health Record (PHR), e-health applications such as Google Health (Google, 2008) and Microsoft HealthVault (Microsoft, 2008) allow users to organize their health information in one central location. Such systems raise important questions regarding ownership and access to data, as well as the quality and accuracy of patient-entered information. Widespread adoption of PHRs does introduce a variety of patient privacy and data protection issues, though a majority of respondents in one recent survey expressed a willingness to share health information if it meant better healthcare (Ball & Gold, 2006; California HealthCare Foundation, 2005).

Health communication researchers have established significant benefits to these types of e-health applications in providing health interventions. Users benefit from increased access to information from a variety of sources, as well as the anonymity that some patients value when dealing with certain health issues (Willis, Demiris, & Oliver, 2007). Information providers can benefit from the ability to tailor information to better match the cultural values and needs of users (Oenema, Brug, & Lechner, 2001). Indeed, research has demonstrated e-health applications can educate low health literate individuals, and such interventions are useful and appreciated even among more literate audiences (Mackert, Whitten, & Garcia, 2008; Whitten, Love, Buis, & Mackert, in press).

At the same time, e-health applications permit healthcare consumers to reach out in search of effective strategies for managing their own health.. Telemedicine, one of those applications, makes it possible to provide healthcare services directly into patients' homes. Telemedicine, defined broadly, is the provision of healthcare services via telecommunication technology. The earliest work in telemedicine took place in the 1960s (Wittson, Affleck, & Johnson, 1961), and has since grown to the point that it is no longer possible to quantify the number of systems operating in the U.S.(Whitten & Kuwahara, 2003)

Initially, telemedicine typically employed some form of videoconferencing to link a health provider at a hospital to a patient at a remote clinical setting. Such videoconferencing could take place via low-bandwidth phone lines or higher-bandwidth Integrated Services Digital Network (ISDN), though advances in Internet Protocol (IP) networking solutions have dramatically increased the speed, flexibility, and cost-effectiveness of telemedicine systems in recent years.

Today, telemedicine has expanded beyond videoconferencing to include the exploding application of remote monitoring, the home-based monitoring of patients with chronic diseases; related systems let caregivers remotely monitor patients' compliance taking their medications. Telemedicine has demonstrated its efficacy in an assortment of medical applications, including dermatology (Chen, See, & Shumack, 2002), psychiatry (Kuulasmaa, Wahlberg, & Kuusimaki, 2004), and physical therapy (Rizzo, Strickland, & Bouchard, 2004), to name a few. Telemedicine researchers continue to explore innovative and efficacious methods of providing healthcare at a distance, so the capabilities of the technology and range of uses will continue to improve. This is particularly true as advances in information storage and transmission will make it easier, and more cost effective, to use telemedicine technology for store-and-forward imaging systems (e.g., teleradiology). Advances in mobile technology, such as cellular phones with built-in video cameras, will present telemedicine researchers with platforms on which they can build innovative telemedicine systems to meet patients' healthcare needs.

Above and beyond the technological capacity of existing and future e-health and telemedicine systems, the impact of these technologies on the doctor-patient relationship must be considered. Even within a single study, patients' perceptions of the interplay between online sources of information and the doctor-patient interaction can vary significantly (Kahlor & Mackert, in press). The takeaway lesson, as with the introduction of any technology into the healthcare system, appears to be that there is no simple answer; thus the more flexible that e-health and telemedicine systems can be designed, to let providers and patients customize their own experience with the technology, the more likely it is that such systems will achieve sustained usage.

Health Informatics and Public Health

The rationale for implementing new telemedicine and e-health systems in patients' homes often involves the goal of eliminating health disparities resulting from uneven access to healthcare services. There are a variety of reasons such disparities might be present, including significant differences that often exist between urban and rural areas. Improvements in Geographic Information Systems (GIS) tools have made it possible to further investigate the efficacy and equity of the healthcare system and public health efforts, moving beyond urban-rural disparities (Noor, Zurovac, Hay, Ochola, & Snow, 2003).

As an example of the application of GIS to public health, Gordon-Larsen et al. found that inequality in the built environment (e.g., parks and other recreational areas) resulted in disparities in physical activity and increased obesity among lower-income and minority populations (Gordon-Larsen, Nelson, Page, & Popkin, 2006). Such findings from GIS-based research can help public health professionals to design and effectively target interventions designed to reduce the prevalence and impact of health disparities. GIS systems can be used to track the spread of infectious and acute diseases, in addition to the incidence and distribution of chronic conditions (Croner, Sperling, & Broome, 1996).

Some of the more significant benefits to GIS-based research and interventions can only come about by sharing the information contained in databases by various state and national government agencies. Effectively merging the information managed by the Centers for Disease Control and the U.S. Environmental Protection Agency, for example, could make it possible to study the impact of pollution and environmental quality at the population-level.

Widespread deployment of EHRs and patient-controlled PHRs could provide invaluable information to researchers and healthcare agencies using GIS tools to investigate public health. While the benefits to public health are clear, there are indeed potential concerns regarding privacy and how such information might be used. Public health interventions based on GIS data are likely to be welcomed by the public, but concerns over how insurance companies could potentially use such information are valid and likely to counterbalance those benefits for some healthcare professionals and members of the general public for some time to come.

A RESEARCH AGENDA TO ADVANCE HEALTH INFORMATICS AND HEALTH INFONOMICS

As health informatics has the potential to alter the healthcare system in a variety of positive ways, it is imperative that scholars continue to advance research regarding health informatics as nations around the world struggle to improve services while managing costs to both healthcare consumers and national budgets. And while health informatics and practice moves forward, the ability to tease out the economic impact of new health information and strategies for managing that information will become more pronounced.

As EHRs can be viewed as the foundation upon which many other systems can be built, any research agenda to advance health informatics can productively begin with EHRs. Given the fact that many of the positive results from EHR deployments come from leading healthcare institutions and providers, it is important to expand studies of EHRs into a variety of other settings. If the only healthcare providers that can achieve significant economic or quality improvements through the use of EHRs are premier institutions, that could suggest some fundamental issues that need to be addressed as policymakers push for widespread adoption of EHRs. Related to this, comparative studies of different national programs for promoting EHR adoption are needed to codify and improve upon the best policies for promoting EHR adoption across national healthcare systems.

Healthcare providers and consumers are seeking new ways of improving access to health information for all. Some of these efforts are being advanced by healthcare providers (e.g., remote monitoring of patients in the home), while others are driven by consumers' desire to become active participants in their own health (e.g., e-health applications like HealthVault and Google Health). In either case, there is a real need for research into what factors most strongly influence provider and patient acceptance, in addition to elements of system design that might contribute significantly to successful deployment (e.g., interoperability with other e-health applications, perceived usefulness, perceived ease of use). Research from related fields, such as Information Systems can provide a starting point for such investigations. Similarly, work in economics, specifically Transaction Cost Economics, has the potential for direct application to the sharing of information among healthcare institutions (Coles & Hesterly, 1998; Hodgkin, Horgan, & Garnick, 1997; Williamson, 1996). Additionally, policy and ethics researchers could productively explore the privacy and security issues surrounding the widespread adoption of e-health applications, whether such technologies are embraced voluntarily by healthcare consumers or brought to them as standard care without their approval.

As EHRs and e-health systems begin to accumulate more and more data about populations - either nationally or at the local/regional level - the potential for GIS-based public health investigations will continue to grow. But the promise of improved health interventions must be balanced against less acceptable uses of such technology, such as insurers determining coverage based on GIS data and trends. How will healthcare consumers balance the positives and negatives of such technology? It is entirely possible – if not likely – that the average healthcare consumer is unqualified to have an informed opinion on such issues. Policy and ethics researchers must continue to debate the public health benefits that could result from widespread use of GIS-based systems and the potential downside to this information as it might impact individual people. Additionally, more work must be done to assess the public's understanding of health and privacy issues, as well as their willingness to share private health information in exchange for improvements in healthcare services. Of course, this is just one part of the much larger issue of healthcare decisions and responsibility in general being shifted to patients.

Another need, across all kinds of health informatics applications, is to study differences in how larger and smaller institutions adopt these systems, as well as how the economic costs and benefits of implementing informatics applications varies among different institutions. Bates (2009) recently suggested that some kinds of applications – such as order entry and decision support systems – are sufficiently mature to merit widespread adoption among larger healthcare institutions. The benefits of these systems in smaller healthcare institutions, as well as the benefits of other informatics applications, are less clear. As health infonomics research advances it must focus on helping to provide answers to practitioners on when a particular informatics application is likely to provide economic benefits to an institution - with the final answer depending on factors such as size of the institution, the particular application, and the designer of the system (vendor vs. in-house).

Finally, a significant need across all research areas in health is an increased focus on projects that, while perhaps not complete failures, certainly do not represent complete successes or examples of best practices. As important as it is to learn what works, it is equally vital that researchers and professionals have more opportunities to find out what has not worked. The *Journal of Telemedicine and Telecare*, an international journal focusing on telemedicine and e-health, dedicates a supplement each year specifically to successes and failures in this area. Topics covered include elements of projects that if neglected can virtually ensure significant problems (e.g., Mackert & Whitten, 2007) and systematic reviews of the quality of studies investigating both success and failures in telehealth projects (e.g., Bensink, Hailey, & Wootton, 2007). Researchers much continue to share the causes and results of less successful projects if the field is to advance as smoothly and quickly as possible.

As important as it is to pursue a productive research agenda in health informatics and infonomics, it must be recognized that these advances are dependent upon contributions from a variety of fields. Researchers from medicine, nursing, communication, information technology, economics, public health, and computer science are all essential to advancing the design and application of health informatics systems. Thorough studies of health informatics and infonomics almost by definition will be interdisciplinary, thus providing opportunities for collaboration among academics from a variety of specialties.

A LOOK TOWARD HEALTH INFORMATICS AND INFONOMICS OF THE FUTURE

A range of illustrious publications have called for investment and implementation of various health informatics solutions to address health quality, access and cost issues. Even though a host of barriers have impeded diffusion to date, there are few who doubt the inevitable transition to a wide-scale infonomics phenomenon in health. This evolution will not occur in isolation of the contextual factors that drive health services today and tomorrow.

Health infonomics must operate in a setting that serves more patients. In many developed countries, baby boomers are transitioning from middle to old age in record numbers. With this aging population comes increased disease incidence as well as expectations for prolonging life. Along with the increase in patients will come more technologies leading to increased amounts of information from which health providers and patients must manage health events. Electronic technologies offer a solution to improving efficiency for a new continuum of care. The role of the patient will change as we witness increased self-diagnosis and self-care as patients and their family caregivers obtain more information. We will see a shift as hospitals become the site for the extremely ill as more people are able to remain at home. The enhanced availability of data to the public and health providers will cause improvements in processes and outcomes. As a result, we may witness a significant change in the delivery model where care becomes more routinized for more common diseases.

Currently, health informatics systems for the exchange of information are typically designed and deployed with local utilization in mind. Typical exchange interoperability challenges are addressed through tailoring the software to address such issues as differences in the data structures and ambiguous interpretation from implied metadata. However, problems increase exponentially when a new party seeks access to the informatics-based data, the number of users and need for records increases, and when clinical structures evolve over time. All of these challenges will call for generic interfaces that can comply and adapt with these changes, as well as built in mechanisms to find the location of the needed data items. The bottom line is the future informatics solutions will differentiate the users and the data location. This infonomic infrastructure will require communication between the systems to be based on the needs of the healthcare worker and/or patient; however, the actual location of the information will be transparent and less important (van der Linden, Kalra, Hasman, & Talmon, 2008). Such large-scale infrastructure will also make it possible for health infonomics researchers to consider the economic tradeoffs evident in any health policy decision, such as the increased costs associated with a particular medical advance or the ability to maintain a particular level of care at a reduced cost.

Perhaps the most important future shift to be noted concerns the pattern and style of interactions rather then any technology-related detail. Healthcare workers in the early 21st century communicate in ways that parallel human conversation - one person defines and requests information. In fact, current information retrieval from established standards such as HL7 and archetype 13606 is based upon this paradigm. However, expectations and communication patterns are slowly shifting as we employ an Internet that makes it so simple to move from a one-to-one exchange to a one-to-many exchange. In addition, we are now recognizing the unnecessary need to store everything locally. Instead, health infonomics will demonstrate the enhanced efficiencies of retrieving all forms of data only when they are needed from any secure storage location.

CONCLUSION

Few dispute the inevitable shift to adoption and dependence of informatics to a degree that reshapes the very foundation of health infonomics. As presented in this paper, there are a range of specific applications to operationalize this shift such as EHRs, e-health activities, and GIS services to impact public health. Typically, arguments concerning positive impacts on costs and health outcomes dominate the call for adoption and diffusion of these technology-based solutions. We concur, noting the need for ongoing documentation of these important impacts. However, this essay must acknowledge the role and importance of human perceptions that will drive health infonomics. Indeed, attaining a deep understanding of the usage of health informatics systems, as well as challenges these systems face, is necessary before the full economic impact of information-driven healthcare can be pursued and recognized.

Health advocates commonly call for a revised role for the health consumer. For example, Garson and Levin (2001) predict that we are witnessing a shift whereby the patient will eventually be the ultimate consumer and measures of patient satisfaction and other patient-oriented report cards will assume growing importance. With this in mind, we wish to close by acknowledging the potential perceptions of patients who experience healthcare in an environment that makes wide use of information technology applications. Whitten and colleagues (2007) conducted a study where they investigated the relationship between investment in health information technology and patient satisfaction in the hospital context. This study analyzed patient satisfaction data for hospitals that were included in the 2005 *Hospitals & Health Networks* annual list of the “100 most wired hospitals and health systems.” Specifically, they assessed the level of satisfaction from multiple angles between patients from the most wired hospitals and patients who had used a hospital not included in this list. Analyses from this study found that patients from the most wired hospital group reported higher levels of global satisfaction than did patients from the other group of hospitals. Patients from the most wired hospitals also reported higher satisfaction related to the admission process, their experiences with physicians, and personal issues such as sensitivity and pain. In addition, higher satisfaction scores were associated with most wired hospital status more so than for any specific demographic variable tested. The results of this study suggest that among the longer-term benefits of IT investment in hospitals may actually be issues related to patient satisfaction. These data imply that IT enhancements affect the way patients receive and perceive their care.

As we move toward a new paradigm of health delivery necessitated by public and private desires to contain health costs and improve health outcomes, we are witnessing a reality where patients will be more knowledgeable about managing healthcare, better informed about the benefits, risks, costs and alternatives for treatments, more technologically savvy, and more engaged in decision-making. The implications for health infonomics are critical. The superhighway for health information exchange will be crowded with multiple stakeholders driving our future course in this crucial area of infonomics.

KEY TERMS AND DEFINITIONS

E-Health: Health services and information delivered or enhanced by the Internet and related technologies

Electronic Medical Record (EMR): Individual record in which healthcare providers record treatments, drugs, and future recommendations electronically

Electronic Health Record (EHR): Electronic record that includes patient information from a variety of sources, such as radiology (films), pharmacy (interaction checks), and specialist information (cardiologist, dermatologist, etc.)

Healthcare Information Technology (HIT): Technology used to store, manage, and transmit information between healthcare providers and consumers

Informatics: The intelligent management of information to maximize data acquisition and usage

Personal Health Record (PHR): E-health tools that let patients manage all of their health information in one location

Telemedicine: Provision of healthcare services via telecommunication technology

Chapter 1.9

Benefits and Barriers to Adoption of Information Technology in U.S. Healthcare

James G. Anderson
Purdue University, USA

ABSTRACT

Information technology such as electronic medical records (EMRs), electronic prescribing, and clinical decision support systems are recognized as essential tools in all developed countries. However, the U.S. lags significantly behind other countries that are members of the Organization for Economic Cooperation and Development (OECD). Significant barriers impede wide-scale adoption of these tools in the U.S., especially EMR systems. These barriers include lack of access to capital by healthcare providers, complex systems, and lack of data standards that permit exchange of clinical data, privacy concerns and legal barriers, and provider resistance. Overcoming these barriers will require subsidies and performance incentives by payers and government, certification and standardization of vendor applications that permit clinical data exchange, removal of legal barriers, and convincing evidence of the cost-effectiveness of these IT applications.

DOI: 10.4018/978-1-60566-356-2.ch014

INTRODUCTION

Information technology has been proposed as an essential tool in solving the problem of fragmented and inaccessible clinical information (Kohn, Corrigan & Donaldson, 1999). The current largely paper-based system adversely affects both the cost and quality of health care as well as compromises patient safety (Leaning, 1993; Dick & Steen, 1997; President's Information Technology Advisory Committee, 2004a,b). Information technologies (IT) such as electronic health records, e-prescribing, clinical decision support systems, electronic management of chronic disease, and bar coding of drugs and biological products have been proposed as ways to reduce health care costs and improve patient safety (Agency for Healthcare Research and Quality, 2001; Aspden, Corigan, Wolcott & Erickson, 2004) . For example, a Rand study estimated that the potential savings of widespread adoption of EMRs in the U.S. could be as much as $81 billion annually (Hillestad, Bigelow, Bower et al., 2005). However, critics question these estimates arguing that the reality of health care practice in the U.S. will make it difficult to realize savings of this magnitude (Goodman, 2005; Walker, 2005; Himmelstein & Woolhandler, 2005; Miller, West, Brown et al., 2005).

As many as three quarters of a million people are injured or die each year from adverse drug events (ADEs) (Bates, 1996; Lazarou, Pomeranz & Corey, 1998). It has been estimated that adverse drug events (ADEs) occur in from two to seven out of every 100 patients admitted to a hospital in the USA (Bates, Cullen, Laird, et al.., 1995; Classen, Pestotnik, Evans, Lloyd, & Burke, 1997). The annual cost of morbidity and mortality due to drug therapy in 1995 for the U.S. may be as much as $76.6 billion. (Bates, Spell, Cullen, et al., 1997; Johnson and Bootman, 1995).

ADEs also occur among outpatients. One study estimates a rate of 5.5 per 100 patients (Honigman, Lee, Rothschild, et al., 2001). Another analysis of hospital emergency departments in the U.S. estimated that ADEs account for 2.4 out of every 1,000 visits (Budnitz, Pollock, Weidenbach, Mendelsohn, Schroeder, & Annest, 2006).

Information technology has been shown to be effective in preventing serious medication errors (Anderson, Jay, Anderson &Hunt, 2002; Bates, Evans, Murff et al., 2003a,b; Bates & Gawande, 2003). A review of research of the effects of computerized physician order entry (CPOE) and clinical decision support systems (CDSSs) on medication error rates found evidence that both CPOE and CDSSs can substantially reduce medication error rates (Kaushal, Shojaania & Bates, 2003). Also electronic prescribing has been shown to reduce prescription errors and improve compliance with managed care formularies (Galanter, Didomenico, & Polikaitis, 2005). Point-of-care decision support tools can provide providers with alerts for contraindicated medications (Miller, Gardner, Johnson & Hripcsak, 2005).

A number of countries that are members of the Organization for Economic Cooperation and Development (OECD) have experienced widespread implementation of information technology. The Harvard School of Public Health and the Commonwealth Fund's International Symposium survey of primary care physicians in 2001 found the following use of electronic medical records among primary care physicians: U.S. (17%), Canada (14%), Australia (25%), New Zealand (52%), and the U.K. (59%). The use of electronic prescribing by primary care physicians was: U.S. (9%), Canada (8%), Australia (44%), New Zealand (52%), and the U.K. (87%) (Harris Interactive, 2001). Only three OECD countries, Portugal, France and Spain lag behind the U.S. (Harris Interactive, 2002).

By 2006, the gap between physicians in the U.S. and other OECD countries had widened. Table 1 shows the results of a survey of U.S. primary care physicians (Anderson & Balas, 2006). Overall only about one out of four primary care physicians reported that they had implemented electronic medical records or clinical decision support tools in their practices. Even fewer physicians surveyed reported using electronic prescribing (20.1%) in practice. Internists were the most likely to have implemented these information technology tools in their practices; obstetricians and gynecologists were the least likely.

When compared to the results of a recent study of primary care physicians in seven countries (Australia, Canada, Germany, New Zealand, the Netherlands and the U.K.), the U.S continues to trail European countries in the use of information technology in patient care. U.S. physicians were the least likely to have clinical information systems in their offices; while ninety percent or more of physicians in the Netherlands, New Zealand and the U.K. use electronic medical records in their practices (Schoen, Osborn, Huynh, Doty, Peugh, J. & Zapert, 2006). The majority of physicians in these countries also reported routinely using electronic prescribing and electronic access to test results. In contrast our survey found that only 28% of U.S. physicians reported using EMR; 20% used electronic prescribing of medications; and 22% accessed test results electronically. The functionality of these EMR systems varies

Table 1. Use of information technology by primary care specialty (%). Other = Geriatrics, Occupational Medicine, etc.

Application	Family Practice	Internal Medicine	Pediatrics	Obstetrics and Gynecology	Other	Total
Electronic Medical Records						
Implemented	23.2	31.2	23.0	16.4	40.6	25.8
Electronic Prescribing						
Implemented	17.7	26.4	20.4	13.3	24.0	20.1
Decision Support Tools						
Implemented	27.6	25.7	24.0	15.6	30.8	25.1
Electronic Communication						
Implemented	25.5	26.6	20.4	21.2	26.2	23.2

greatly from country to country. Physicians in the Netherlands were the most likely to report that their EMR systems enabled them to share patient records with other physicians; whereas physicians in New Zealand were the most likely to report that they could access patient records from outside of their offices. Utilization rates of all types of IT are lowest in Canada and the U.S. where EMRs are concentrated in larger physician groups.

Despite its potential to improve efficiency and quality of care, investment in information technology in health care lags behind other sectors of the economy in the U.S. Most of the $20 million invested in health care information technology in 2001 was used to computerize financial systems (Goldsmith, Blumenthal, & Rishel, 2003). In comparison to six countries, the U.S. total investment in health information technology per capita in 2005 was $0.43. This compares to $4.93 in Australia and $192.79 in the U.K. (Anderson, Frogner, Johns & Reinhardt, 2006).

All of these countries have well established federally coordinated and partially funded health information technology programs. Germany completed a national network in 2006. The Canadian government has invested $1.5 billion Canadian in health information technology in an effort to catalyze investment by requiring matching funds (Commission, 2003). Canada's Health Infoway program expects to implement electronic health records for half of its population by 2009. The U.K. has an ambitious IT project underway and hopes to have a network available to all health care providers by 2014. The United Kingdom's government has allocated 8 billion pounds to health information infrastructure (Brewin, 2003). The system will include electronic health records for everyone and an electronic prescription transmission system. The U.S. only recently passed the Wired for Health Care Quality Act that will establish collaboration and authorize grants to encourage the adoption of health information technology (Anderson, et al. 2006).

Adoption of information technology such as EMRs and computerized physician order entry by U.S. hospitals has also been limited (AHA, 2005). Surveys indicate that less than 15 percent of U.S. hospitals have implemented computerized physician order entry systems (CPOE) (Ash, Gorman & Hersh, 1998; Pederson, Schneider & Santell, 2001). A recent report commissioned by the Health Information Network Europe (HINE) indicates that hospitals in 15 European nations spend only 1.8% of total revenue on information technology. As a result IT use in hospitals in Europe is similar to the U.S. Only 2.2% of European hospitals have implemented computer-

Table 2. Perceived benefits of implementing IT applications (%)

Benefit	High/Medium	Low/None
Patients assume responsibility for monitoring symptoms/disease	62.3	37.7
Shorter consultations	46.1	53.9
Patients not seeking medical care when it was not needed	50.7	49.3
Patients coming in sooner for necessary treatment	63.4	36.6
Fewer unnecessary tests	57.3	42.7
Fewer unnecessary treatments	57.7	42.3
Fewer errors	74.8	25.2
Increased productivity	69.5	30.5
Reduced costs	63.0	37.0

ized physician order entry systems with clinical decision support compared to 2.5% of American hospitals (Versel, 2005).

Until recently, IT products available for healthcare providers were mostly designed for large organizations and were costly. Recent advances in technology have made IT applications more available to primary care physicians in smaller practices (McDonald & Metzger, 2002). Despite its potential to improve efficiency and quality of care, use of information technology in health care lags behind other sectors of the economy in the U.S. In 2001 most of the $20 million invested in health care information technology was used to computerize financial systems (Goldsmith, Blumenthal & Rishel, 2003). Less than 10 percent of U.S. hospitals had adopted electronic medical record systems and less than 5 percent had implemented computerized physician order entry by 2001.

The following section reviews the evidence regarding benefits from information technology. Potential benefits include reduced cost, increased productivity, improvements in patient safety, and the enhancement of patient responsibility for marinating their health.

BENEFITS OF HEALTH INFORMATION TECHNOLOGY

Physicians, in general, perceive potential benefits from implementing IT (Table 2). A recent survey of U.S. primary care physicians found that almost 75% indicated that these applications could reduce errors (Anderson & Balas, 2006). Almost 70% perceived information technology as potentially increasing their productivity; over 60% indicated that IT tools have the potential to reduce costs and help patients assume more responsibility. At the same time about half of the primary care physicians surveyed indicated that they did not perceive that information technology applications would result in shorter consultations, reduction in unnecessary care, patients seeking needed care earlier, and reduction in unnecessary tests and treatment.

There is evidence to support these perceptions. Balas and others (1996) reviewed 98 randomized clinical trials that examined the efficacy of clinical information systems. The review found evidence that provider reminders, computer-assisted treatment planners, interactive patient education and patient reminders all were effective in improving the outcomes of family medicine. A second review of controlled clinical trials of clinical decision support system (CDSSs) found positive effects on physician performance (Hunt, Haynes, Hanna &

Smith, 1998). In particular drug dosing systems, diagnostic aids and preventive care systems were found to enhance patient care.

There is additional evidence that information technology can significantly improve patient safety (Anderson (2004a,b; 2008; Bates, 2000; Bates, Cohen, Leape et al., 2001). The studies reviewed have demonstrated that information technology applications can detect and prevent medication errors and adverse drug events. The positive effects of information technology on medication safety in both inpatient and outpatient settings have been demonstrated. In particular studies have shown that computerized physician order entry can be effective in preventing medication errors. A study in a large tertiary care hospital found that the implementation of a computerized physician order entry (CPOE) on all hospital units decreased serious medication errors by 55%. The CPOE system included dose selection, drug allergy and drug-drug interaction checking, and required physicians to indicate route and frequency of doses (Bates, Leape, Cullen et al., 1998).

Other IT applications have been shown to be efficacious in preventing errors. Electronic prescribing systems that provide computer-based support for the creation, transmission, dispensing and monitoring of drug therapies have been shown to increase patient safety (Miller, Gardner, Johnson & Hripcsak, 2005). Alerts generated by a clinical decision support system were effective in decreasing the ordering and administering of drugs that were contraindicated due to renal insufficiency (Galanter, Diidomenico & Polikaitis, 2005).

Information technology has also been shown to improve care for chronic illness. One study reviewed 109 articles that described information systems designed to assist providers in the care of patients with diabetes, heart disease and mental illness (Dorr, Bonner, Cohen et al., 2007). These studies assessed the impact of IT applications on guideline adherence, visit frequency, documentation, treatment adherence, rates of referral, appropriateness of screening and testing, and cost. The majority of these studies revealed a positive impact of IT on the process of care for patients with chronic illnesses.

In the next section we discuss major barriers to the implementation and utilization of information technology in practice. Barriers include initial costs and uncertain financial benefits for providers, changes in practice patterns, technology, inadequate technical support, physician attitudes, privacy and security.

BARRIERS TO IMPLEMENTATION OF HEALTH INFORMATION TECHNOLOGY

A key barrier to implementation of electronic medical records and other clinical information technology applications appears to be the high initial costs and uncertain payoffs to physicians. Over 80% of primary care physicians surveyed reported the lack of financial support for IT applications as a major barrier to adoption (Anderson & Balas, 2006). Moreover, physicians who perceived lack of financial support and high investment costs required to implement IT were significantly less likely to have implemented EMRs, electronic prescribing and decision support tools. Upfront costs of EMRs in ambulatory care are estimated to range from $16,000 to $36,000 per physician. Additional costs are incurred for maintenance of the system and decreased revenue from patients during the transition from the paper chart to the EMR (Miller and Sim, 2004; Miller, Sim & Newman, 2003). Cost-benefit analyses have shown that physicians who invest in EMR systems derive little more than ten percent of the benefits. Most of the savings from improved efficiency go to payers and purchasers (Walker, Pan, Johnston et al., 2005; Wang et al., 2003).

Changes in practice patterns brought about by the implementation of electronic medical record also constitute a barrier to adoption. Many physicians report that they spend more time with each patient following the implementation of an EMR. This results in longer workdays and fewer patients seen during the initial period following implementation.

A second barrier is the complexity of EMRs and clinical IT applications. Our survey found that physicians cite the time and effort involved in learning to use these technologies as a significant barrier. Eighty-six percent of the physicians surveyed stated that vendor's inability to deliver acceptable products as a significant barrier to implementation of IT in their practices (Anderson & Balas, 2006). In general, physicians perceived these barriers as difficult to overcome. Almost two-thirds of the physicians surveyed also cited the lack of a strategic plan for implementing applications and difficulty in recruiting experienced IT personnel as major barriers while over one-half cited lack of sufficient knowledge of IT as a barrier to implementation. Other studies have found problems with usability of EMRs. Poorly designed screens and difficulties in entering progress notes require physicians to spend extra time entering patient data. Maintenance of IT systems is another concern for physicians. Small practices lack the technical support personnel needed to maintain the system. Also vendors in general provide relatively little support for their products or charge high maintenance fees. Because of the many vendors, interoperability represents another major barrier to implementation of EMRs and other IT applications. Lack of ability to exchange clinical data with laboratories and hospitals is a major impediment for smaller physician practices.

Unlike the health care systems of many western countries, the U.S. system is composed of private, independent individual and group providers, hospitals, ambulatory care and long term care centers that compete with one another. The system is non-centralized with multi-payers. Information technology adoption decisions are made independently and there are few if any incentives to share information concerning patient care. Moreover, there are many competing vendors each with their own products. In contrast, in the U.K. a research team developed the PRODIGY system specifications and knowledge base and the five largest General Practice system suppliers covering 85 percent of the market integrated the software into their clinical systems. Currently this system is being implemented by all 27, 000 General Practitioners in the U.K. (Purves, Sugden, Booth & Sowerby, 1999).

Privacy concerns are another barrier hindering implementation of IT. Both physicians and the public are concerned about potential breeches of confidentiality. Since many EMR systems are Web-based, many physicians and patients fear that medical records may not be secure. This is even more of a concern when wireless Internet is used to transmit records to multiple locations (Rash, 2005).

Security breaches of data banks are far more frequent in the U.S. than in Europe. This is due to the fact that European countries have a comprehensive set of national privacy laws and offices of data protection (Dash, 2005). In contrast the U.S. has a confusing, sometimes conflicting, patchwork of federal and state laws and agencies that deal with the protection of data. Also, the U.S. has a large private data collection industry with companies like ChoicePoint and Acxiom, that collect, analyze and sell consumer data. In Europe, private companies are severely restricted from collecting personal data without individual consent.

Legal barriers to IT adoption also exist in the U.S. (Bates, 1997) Various laws related to fraud and abuse, antitrust, federal income tax, intellectual property, liability and malpractice and state licensing create a climate of uncertainty for health care providers in implementing IT (U.S. Government Accountability Office, 2004). For example the physician self-referral law and the anti-kickback law present barriers to hospitals that would like to pay for electronic software for affiliated physicians. (See Table 3)

Table 3. Perceived barriers to implementing IT applications (%)

Barriers	No Barrier or Easily Overcome	Overcome with some or great effort or insurmountable
Lack of financial support	12.6	87.3
Vendors inability to deliver acceptable products	20.7	79.3
Acceptance by staff	41.7	58.3
Difficulty proving quantifiable benefits	32.8	67.2
Lack of strategic plan for implementing	34.9	65.1
Recruiting experienced IT personnel	39.6	60.4
Retaining experienced personnel	42.5	57.5
Insufficient knowledge of IT applications	37.5	62.5
Considerable investment in IT applications	13.0	87.0

OVERCOMING BARRIERS

Overcoming the cost barrier will be difficult and may require incentives by payers and the government. An example is New Zealand, Australia and the U.K. that have introduced government funding programs to stimulate adoption and use of EMRs (Harris Interactive, 2001). Canada and the U.K. have made significant investments in a health information infrastructure (Commission, 2003; Brewin, 2003). Professional associations can also facilitate adoption of IT. Professional physician organizations played a key role in the development and rapid implementation of the national electronic medical record system in the U.K. Currently over 95 percent of General Practitioner practices in the U.K. are computerized (Purves, 1998). In the U.S. the American Academy of Family Physicians through a nonprofit foundation is developing low-cost, open-source EMR software that will be available to physicians with no licensing fee.

Financial incentives may also accelerate adoption of EMRs and other IT applications. A 2006 survey of primary care physicians in seven countries found quality improvement efforts in all of the countries (Schoen et al, 2006). Pay-for-performance approaches to motivating physicians to improve care and to hold them accountable for the quality of care have been adopted in several countries. Doctors in the U.K. are significantly more likely to be participating in incentive programs than doctors in other countries. The U.K. program rewards performance on the basis of 146 indicators that measure clinical and preventive care, organization and patient satisfaction (Doran et al., 2006). Thirty percent of GPs' salaries are based on their performance on a set of measures computed by the EMR (NHS Connecting for Health). Financial incentives are also widespread in Australia and New Zealand.

The U.S. and Canada do not have national initiatives. A number of purchasers, health plans, and employers are initiating quality-based reimbursement programs. These plans encourage HIT adoption through additional payments and reimbursement for virtual physician visits (Health Strategies Consultancy, 2004). In Canada the Primary Health Care Transition Fund provides funds for the creation of new primary care models (Weatherill, 2006). House resolution 747 introduced into the 2005 U.S. Congress also would make zero interest loans available to provider groups and would reward those who use EMRs (Gonzalez et al., 2005).

Incentives could also be provided in the U.S. through Medicare, the national social insurance program that provides medical insurance coverage for over 41 million seniors aged sixty-five and over and people with disabilities in the U.S. Medicare is the largest purchaser of health services in the U.S. and has the power to promote adoption of health information technology (Rosenfeld, Bernasek & Mendelson, 2005; Hackbarth & Milgate, 2005). The Center for Medicare and Medicaid Services (CMS) could require participating physicians to adopt health information technology. Additional payments could be provided for physicians who use specific certified IT applications.

Certification of vendors' applications may help to overcome another barrier to implementation. Other countries have identified a few vendors for a region and required that they meet certain standards to facilitate transfer of clinical information among health care providers. The development of community-wide data exchanges also can stimulate the adoption of EMRs (Miller & Sim, 2004). These exchanges allow clinicians to view all of their patients' data regardless of provider and care site and thus decrease physicians' time and increasing financial benefits.

Despite the call for implementation of electronic medical records by the Institute of Medicine, adoption in practice in the U.S. has been slow (Dick & Steen, 1991). Acceptance of IT in practice depends on more than dissemination of information about their availability and potential benefits (Anderson, 1997, 1999, 2003). IT applications such as EMRs and CDSSs alter traditional practice patterns, work flow and relationships with other health care providers. They change the way that physicians care for their patients. Acceptance of these systems is shaped by physicians' perceptions of how they will affect the accomplishment of their professional goals. Several decades of experience suggest that physicians will accept applications that enhance their ability to manage patient care but will tend to oppose applications that they perceive as primarily benefiting health care organizations and payers.

Experience suggests several factors that may increaser acceptance and utilization of IT applications in practice. Broad participation of physicians in the selection and implementation of applications is essential. Systems that are implemented without broad physician involvement are likely to fail. Moreover, it is essential to consider in advance how the IT application will affect work flow and routine practice patterns. Physicians will use applications that assist them in providing better patient care. Applications that primarily benefit the administration of health care and/or payers will not motivate physicians to change their established practice behavior.

CONCLUSION

It has been estimated that the net cumulative savings from adopting EMR systems in U.S. hospitals over 15 years could be as much as $371 billion and the net cumulative savings from physician adoption could be $142 billion (Hillestad, Bigelow, Bower et al., 2005). But significant barriers impede wide-scale adoption and use of EMR systems (Leape &Berwick, 2005). These barriers include lack of access to capital by health care providers, complex systems and lack of data standards that permit exchange of clinical data, privacy concerns and legal barriers and provider resistance. Overcoming these barriers will require subsidies and performance incentives by payers and government. Currently costs of implementing health information technology are incurred by individual providers while the benefits accrue to many others. The private sector in the U.S. is unlikely to accelerate the adoption of IT unless there is significant public sector investment and incentives. It has been estimated that a national heath information network would cost $156 billion in capital investment over 5 years. Annual operating costs are estimated to be $48 billion (Kaushal et al. 2005).

Certification and standardization of vendor applications that permit clinical data exchange will be required to achieve greater interoperability.

Legal barriers will need to be removed and greater security of medical data must be guaranteed. Also, convincing evidence of the cost-benefit of these applications will need to be provided in order to convince practitioners and patients of the value of information technology in practice.

KEY TERMS AND DEFINITIONS

Adverse Drug Events (ADE): A medication that results in unintended harm to a patient

Computerized Decision Support Systems: A computer-based system that consists of a knowledge base and an inference engine that generates advice to the providers

Computerized Physician Order Entry (CPOE): Clinical systems that electronically relay the physician's or nurse practitioner's diagnostic and therapeutic plan for action

Electronic Health Record (EHR): An electronic repository of information about a patient's health care and clinical information management tools that provide alerts, reminders and tools for data analysis

This work was previously published in Handbook of Research on Information Technology Management and Clinical Data Administration in Healthcare, edited by A. Dwivedi, pp. 217-229, copyright 2009 by Medical Information Science Reference (an imprint of IGI Global).

Chapter 1.10

Ageing, Learning, Technology, and Health Management

ABSTRACT

The world's population is ageing rapidly. Ageing has an impact on all aspects of human life, including social, economic, cultural, and political. Understanding ageing is therefore an important issue for the 21st century. This chapter will consider the active ageing model. This model is based on optimising opportunities for health, participation, and security in order to enhance quality of life. There is a range of exciting options developing for personal health management, for and by the ageing population, that make use of computer technology, and these should support active ageing. Their use depends however on older people learning to use computer technology effectively. The ability to use such technology will allow them to access relevant health information, advice, and support independently from wherever they live. Such support should increase rapidly in the future. This chapter is a consideration of ageing and learning, ageing and use of computer technology, and personal health management using computers.

AGEING AND LEARNING[1]

Globally the population is ageing. Worldwide the proportion of people aged 60 and over is growing faster than any other age group. In 2025 there will be a total of 1.2 billion people over the age of 60 (World Health Organisation, WHO, 2002, p6). McFadden (2002) noted that this is now a portion of the life span never before experienced by so many people and that consequently we need new models of ageing to deal with this. The notion of active ageing has been proposed as one such model.

Active Ageing is a relatively recent global approach to older people achieving healthy, productive, safe and fulfilling lives. Active ageing is the 'process of optimising opportunities for health, participa-

DOI: 10.4018/978-1-60566-356-2.ch042

tion and security in order to enhance quality of life as people age' (World Health Organisation, WHO, 2002, p.12). Active ageing reflects not only the continuation of physical activity in later life, but also the continued participation in social, economic, cultural, spiritual, and civic affairs. WHO challenged all countries to implement the concept of active ageing within the cultural and demographic realities of their populations. In Australia two studies have recently explored the concept of active ageing: the Australian Active Ageing survey (National Seniors Productive Ageing Centre, 2005) investigated the contributors to and meaning of active ageing for older adults; and research undertaken by the Department for Community Development, Government of Western Australia (2006) developed and implemented an Active Ageing Benchmark Indicators. Both studies conceptualised active ageing for older people in terms of being proactive in keeping healthy, being physically and mentally active, engaging in learning, living in safe environments, working, and actively participating in family and community life. In the USA older adults themselves defined successful ageing as multidimensional including physical, functional, psychological and social health (Phelan, Anderson, LaCroix & Larson, 2004). In Britain, Bowling & Iliffe (2006) found that a multi dimensional lay model of ageing predicted quality of life more powerfully than unidimensional models (e.g. biomedical, sociological).

Learning

Education and learning are assumed to be important factors in facilitating participation and allowing adults to enjoy a positive quality of life as they age (WHO, 2002, p16). Participation within the broader community is important purely for enjoyment and recreation, and also to allow older people to adapt to changes within the environment in areas such as technology, lifestyle, finances and health. The ability to solve problems and adapt to change are strong predictors of active ageing and longevity according to Smits et al, (1999), cited in WHO (2002: 26). Butler (2002) cites the MacArthur Study on Aging as confirming that engagement in meaningful activities contributes to good health, satisfaction with life, and longevity as well as reducing the costs of physical and emotional illness. It is clear that learning plays an important role in productive ageing (Ardelt, 2000; Dench & Regan: 2000, Glendenning, 1997; Withnall, 2000) and therefore it is important for us to understand more about the phenomenon of learning by older people.

Barriers to Learning

Research in learning by older adults is, unfortunately, dominated by identification of obstacles to to the process caused by mental and physical deterioration. For example Driscoll, Hamilton, Petropoulos, Yeo, Books, Baumgartner & Sutherland (2003) described the ageing hippocampus and its effects on learning and memory. They reported in addition that cognitive tests to assess information-processing speed, working memory capability and declarative learning, administered to adults aged 17 to 86 years old, found significant age-related decrements in all three constructs (Kirasic, Allen, Dodson, & Binder, 1996). Boulton- Lewis (1997) concluded from a review of the literature 'that most adults, as they age usually process less information and do it in a slower and less efficient manner'. However 'knowledge that has been already acquired, the ability to retrieve it, as well as visual and auditory sensory capabilities are maintained for the most part, into the sixties' at least. Unfortunately, an outcome of the focus on problem-oriented research on ageing has helped create an image of older people as `being over the hill, out of date, out of touch, frail, sick and in need of services and support' (Kerschner & Pegues, 1998).

A Positive Approach to Learning

Taking a positive approach one can assert that older adults can and do acquire new knowledge outside of their domains of expertise. Researchers have found that with extra practice an older adult will perform as well as an unpractised younger adult (Charness 1992). For example, Rabbit, Diggle, Holland & McInnes (2004) found that on intelligence tests substantial practice effects counteracted true declines of ageing which remained significant even with intervals of seven years between tests. They also noted that variability between individuals was seen to increase as the sample aged. Charness (1992) suggested that the critical issue, in terms of age and performance is how the older person compensates for changes in processing speed and working memory to maintain performance. Boulton-Lewis (1997) proposed that given time and sufficient motivation older adults are able to achieve equivalent learning outcomes to younger learners. Obviously the nature and amount of learning achieved in early and middle life impacts significantly on the capacity of older adults when learning new skills and knowledge in later life.

Motivation to Learn as People Age

Motivation and confidence are critical to learning at any age, and particularly so as people become older. Purdie and Boulton-Lewis (2001) found that: the least important learning needs identified by older people were those associated with technology. They stated that their most important learning needs were associated with transportation, health and safety, In earlier interview data however participants had suggested that use of technology was an important area for new learning. The strongest barriers to such learning were those associated with physical disabilities; the weakest barriers were those associated with interaction with other people. In general participants were confident that they could successfully address the learning needs related to health, safety, leisure and transportation but not those associated with technology. Boulton-Lewis, Buys & Lovie-Kitchin (2006) asserted that older adults learn more slowly, need more practice, and their interests will vary, but in most cases motivation will be strong enough to learn new skills and to continue living fully through learning. They found that significant factors for learning activities were being female, having good physical health, level of prior education, good mental/emotional health, being younger, living in regional areas, not being retired, and being a high income earner. The Australian Active Ageing (Triple A) study (Buys, Lovie-Kitchin, Nayak, Boulton-Lewis, Tedman-Jones, Anderson, Edwards, Courtney, & Zlobicki, 2005) also found that in addition to good health an individual's attitude to learning was most important in active ageing; they generally agreed that they needed and wanted to learn about new things such as technology, new activities and leisure interests; respondents aged 50-64 were more likely to be interested, need and want to learn to keep up to date with new technology, and make an effort to learn new things. Therefore negative attitudes to learning by older people need to be examined. It should be generally acknowledged that older people are active and useful citizens who want to keep living their lives as fully as possible. If indeed learning keeps peoples' minds active and helps them in problem solving then it should make them less dependent and actually save governments money.

In summary learning is important to active ageing and there are some obstacles to learning as people age. However older adults can acquire new knowledge if they make the time and effort. If the motivation to learn is strong enough then we can assume that older people will effectively undertake new learning.

AGEING AND USE OF COMPUTER TECHNOLOGY[2]

A significant phenomenon of this century is the rapid and continuing increase in knowledge and the use of technology. For individual older users communication technologies have the potential to minimize social isolation and improve quality of life (Swindell, 1993). It is recognized in government and related documents that it is important for older adults to have abilities and opportunities to use new technologies to support and improve their quality of life and their participation in society (Department of Health and Ageing,The National Strategy for an Ageing Australia, 2001). These abilities would include allowing them to find and use information for personal health management.

Learning in a Modern Society

Health professionals express concern about connecting with older adults in new ways in order to increase their ability to engage in learning about health management (Kerschner & Pegues, 1998; Crane, 2001). Professionals are particularly concerned about the need for older people to learn about technology if they are to maintain their connections with community and societal developments, and to take advantage of the benefits technology offers. For example, inter alia, online management of health that becomes increasingly relevant to people as they age, is available only to those who have access to the Internet and have basic computer literacy.

Literacy, health literacy, and information literacy are three other related areas that must be considered when trying to encourage older adults to learn about and engage with, their personal health management in an online environment. Parjkh, Parker, Nurss, Baker and Williams (1996) interviewed 202 patients in a public hospital in Atlanta, Georgia, and reported that 42.6% had inadequate or marginal functional health literacy. They found that a significant number of these patients were ashamed to tell their family and that most of these patients actively sought to hide their low literacy skills. The patients with the lowest literacy were more likely to be males, over the age of 60, who had less than a high school education. A recent study by the Australian Bureau of Statistics (2006) confirmed that health literacy is a significant issue there also. A survey of over 9000 adults found that six in 10 people aged between 15 and 74 do not have the basic knowledge and skills to take care of their health and prevent disease. The findings revealed that many adults were not aware when they needed to contact a doctor, were unable to understand instructions on prescribed medication, and were unable to interpret food labels in order to follow a special diet such as low fat or low sugar. The health literacy problems of older adults are well documented. The 2003 US National Assessment of Adult Literacy (2007) included the first-ever national assessment of health literacy, which found that adults aged 65 and older have lower health literacy scores than all other age groups surveyed. Only 3 percent of the older adults who were surveyed were measured as proficient.

Linked to the issue of health literacy is that of information literacy. The Medical Library Association (MLA) has defined Health Information Literacy as the ‘set of abilities needed to recognize a health information need; identify likely information sources and use them to retrieve relevant information; assess the quality of the information and its applicability to a specific situation; and analyse, understand and use the information to make good health decisions’ (2003, para 5). Undoubtedly, much of the available health information that older adults need may require them to be able to use or access electronic tools and applications.

Older People and Computer Use

The current generation of older Australians has a relatively low rate of use of electronic tools and applications (COTA, 2004, p4). Factors such as education, income, age, ethnicity, and geographical location are likely to result in disadvantage for some groups (OECD, 2001). Issues of social exclusion have been identified in many investigations and commentaries about older people and information technology (Barnett & Adkins, 2001; Cameron, Marquis & Webster, 2001; Foskey, 2002; Scott, 1999; Steinberg, Walley, Najman& Donald, 1999; Tay, 2001). Lloyd and Hellwig (2000) found in Australia that retirees were the group most likely to remain without an Internet connection; 63% were unconnected compared with 29% of all groups who were not connected. This is similar to the figures for the United States where Rideout and Newman (2005) found that less than one-third of seniors have ever gone online and fewer than half have ever used a computer. In Europe in 2006 only 18% of people aged 65-74 had used a computer and only 13% had used the Internet within the past year (Ala-Mutka & Punie, 2007). It has been suggested that older adults were less likely than younger adults to use technology in general (Czaja, Charness, Fisk & Hertzog, 2006). Statistics show that, as age increases, the likelihood of using a computer decreases, yet in the age group 65 years and over, the number of adults accessing the Internet has more than doubled since 1999 (ABS, 2004). In 2002, for example, 13% of adults aged over 65 years accessed the Internet (Australian Bureau of Statistics, 2003). These older people used Internet technology mainly for the purpose of communication but should be able to learn to use it for many other purposes. The use of computers by older people should increase as the present generation of computer users age. However action needs to be taken to enable older people now to benefit from the use of technology.

Benefits of Using Computer Technology

Research confirms that there are beneficial outcomes of using a "home" computer for people who are likely to experience increased vulnerability as they age. In residential care situations, for instance, computer learning programs were associated positively with skills and confidence in spite of older adults own health perceptions; they were also beneficial in reducing depression (Timmermann, 1998; McConatha, McConatha, Deaner and Deigny, 1995). Computers in the homes of older people can provide significant benefits that improve their lives as they age. A study of frail older people's attitudes found that their use of a computer to maintain their home health care networks improved their self-esteem, particularly when they received appropriate training support in their own homes (Billipp, 2001). Studies that indicate positive outcomes for older people who use technology are particularly important to the policy of 'ageing in place'. Mynatt and Rogers (2002) found that technology use could potentially support the functional independence of older people and thus enable them to continue living independently in their own homes. Furlong (1997) described the creation of an online community for the third age where members would be able to address questions such as financial decisions, healthy lifestyle, management of disabilities and illness, friendships, relationships, passions, hobbies, work, and connection with family and friends. Billipp (2001) found however that while there were good reasons for including computers in home environments, some older people were more likely than others to respond positively to such an intervention strategy.

Attitudes to Computer Use

Some older people have a favourable disposition towards computers, while others may respond negatively to the design and operational features

(West, 2002). Zajicek (2004) suggests that age-related impairments such as vision, hearing and memory loss, and loss of mobility, contribute to "loss of confidence and difficulties in orientation and absorption of information". Barriers to such learning included attitudinal aspects such as being too old, embarrassment with lack of abilities, short-term memory loss, declines of manual dexterity and visual acuity (p. 62). Marqui, Jourdan-Boddaert & Huet (2002) studied young and old computer users and found that among the older group 'non-cognitive factors, such as fears of computerisation and its consequences in the workplace, age-related negative stereotypes, attitudes and lack of confidence' impacted on the success of their mastery of new computer technology. Purdie and Boulton-Lewis (2003) found, for adults over 70 years of age, that the most frequently mentioned learning *needs* were how to use a computer for e-mails and financial matters. However this ability was rated quite low as a priority for what they *wanted* to learn, probably because of a range of perceived difficulties. Respondents also indicated that they would prefer to learn in a one-to-one situation, preferably with a friend or family member rather than in a class. For some the cost of computer purchase and Internet access was also a problem. A study of older adults in South England and Wales found that, rather than resisting new computer technology, older people's non-use was mostly caused by the perceived irrelevance of ICT in their lives, with 78% of non users stating they had no need, and no interest in using computers (Selwyn, Gorard, Furlong and Madden, 2003).

A Hong Kong study by Lam and Lee (2006) found that Internet self-efficacy was the primary predictor in whether older adults used the Internet in a community ICT centre. Over 1000 adults aged 55 years and over participated in the study. A study by Partridge (2007a; 2007b) explored the factors that influence an individual's decision to use the Internet. Conducted in the US and Australia, the study found that Internet self-efficacy, or a belief in one's ability to use the Internet, was the only factor that predicted Internet use when socioeconomic variables were controlled (i.e. age, gender, income, education, employment). The study revealed that regardless of age an individual will use the Internet only if they have developed a high level of Internet self-efficacy. An individual can increase their Internet self-efficacy by watching similar others successfully use the Internet, being told that they can successfully use the Internet, and having past success in using the technology. Interestingly the study did find that age was a predictor on Internet self-efficacy, with younger individuals reporting higher levels of self-efficacy beliefs. Thus, the key to Internet use is self-efficacy not age but in instances where older adults have a low level of self-efficacy strategies can be implemented that will help them to increase their self-efficacy beliefs. In short, adults of all ages can learn how to integrate the Internet as part of their everyday life information worlds.

Boulton-Lewis, Buys, Lovie-Kitchin, Barnett, & David, (2007) in a study in Australia found that interest in learning, keeping up to date, valuing communication, being younger, and being male are predictors of learning about technology. Older adults used technology for a range of purposes but there was not much emphasis on its relevance to health management. On the other hand Campbell (2004) in the USA found that of 70 self-volunteers 58 were women; and that highly educated women who own or have access to a computer, have low levels of anxiety towards computers, strong feelings of self-efficacy towards computers and the Internet, and an internal locus of control are more willing than men to find medical information to manage a chronic health problem. The attitudes and needs described above present a challenge in terms of convincing older adults that they can benefit from and be comfortable with computer technology, in particular women, those with low incomes, little relevant education, or those from ethnic minorities.

However, many studies also attest to the capacities and abilities of older people to learn how to use the technology (Williamson, Bow & Wale, 1997; Scott, 2001). Older people have been encouraged to use ICT (Information Computer Technology) in specific settings such as computer clubs and libraries (Williamson et al, 1997). Such opportunities are often in provided in group situations and are not always accessible or suitable for older people. There are also a number of older people who are completely computer literate and keenly interested in promoting computer education and tuition among their peers (Hazzlewood & Kilpatrick, 2001; Swindell & Vassella, 1999). Groups such as ASCCA (the Australian Seniors' Computers Clubs Association), COTA (the Council on the Ageing), U3A (University of the Third Age), and SeniorNet in the US (Grodsky & Gilbert, 1998) for example, actively promote computer tuition by older people for older people. These approaches focus on complete beginners who may be fearful of the technology (Barker, 2000). There are initiatives also involving younger adults and children as computer tutors for older people.

The rate of computer use by older people is relatively low however there are well documented studies of the benefits of computer use by people as they age. Whether older people do in fact use computer technology will depend on their attitudes, needs, availability of tuition, willingness to learn, and their access to computers.

PERSONAL HEALTH MANAGEMENT THROUGH ONLINE ACTIVITY

One aspect threatening the quality of life of older people is exclusion from information in an increasingly digital world. This includes independent access to relevant health information, advice and support. Research described above confirms that there are beneficial outcomes from using a home computer for people who are likely to experience increased vulnerability as they age. Recent developments suggest that computers can be useful for health management for older people in creative ways such as obtaining medical data from patients, connecting to personal records, getting prescriptions online, and empowering patients to obtain health information in detail at their own pace in their own homes.

The Internet has rapidly become the primary vehicle for information and communication. It is therefore not surprising that it has become a common source for locating health information. A variety of media exist through which individuals can access health information online. These include websites, online support groups, chat rooms, instant messaging, e-lists and email. In many ways the Internet is an ideal tool for disseminating health information (Flynn, Smith & Freese, 2006). It provides individuals with privacy, immediacy, convenience, anonymity, a wide variety of information, and diversity of perspectives (Cotton & Gupta, 2004). Wagner and Wagner (2003) noted that older adults benefit by accessing health information online in three ways. Firstly, older adults may be more motivated to get health information because they are at greater risk than younger adults for illness. Secondly, because of retirement or a reduced workload, older adults may have more time than younger adults to examine health information. Finally, older adults may have only limited access to other health care sources and this difficulty in reaching a provider may be the result of limited mobility, remote location or loss of social network. Although there are many advantages to online health information seeking, disadvantages are also apparent. Credibility of the health information available is perhaps one of the more notable concerns (Cotton & Gupta, 2004). In recent years a small but growing number of studies have demonstrated that older adults are beginning to use computers and Internet technology to locate health information and to assist in the personal health management. (Moore, 2005; Morrell, Mayhorn & Bennett, 2000; Wagner & Wagner, 2003).

Technology Tools for Health Management

Siminerio (2005) asserts that as demands on today's health systems increase creative ways of using technology to explore health care are being explored. She describes those tools that are already possible in the USA at least. For example electronic medical records that collate information from a range of sources are replacing paper records. These save time and give prompts to doctors. Video setups can be used to beam doctors into patient's televisions and picture phones. Telephone modems can be used to feed information from blood glucose and blood pressure monitors directly to doctors and nurses. She suggests that the next steps might be: development of patient portals to allow a person to connect directly to their own records to get repeat prescriptions, check test results and get online advice; health cards which could be used to connect in a similar way to banking cards used in a ATM; and kiosk stations such as those in airports which could transmit blood pressure results directly to the doctor's records. Since this paper was released some of these technology tools have been developed, tools that will help patients and doctors to communicate better about health care issues as well as maintaining confidentiality, even between the office and the patients home (Reuters, 2008). Some of Siminerio's predictions remain fanciful but as similar technology exists for other purposes, the move of this into the health domain is highly likely. Bates and Komaroff (2006) also discuss paperless medicine that should allow people's records to be available wherever they are needed. They say that (in the USA): whilst only 24% of medical providers use electronic records in their offices the number is increasing and institutions are building systems with common coding that allows them to exchange data; technology is making it easier for patients to communicate with doctors and participate in their treatment; computers can provide doctors with up to date drug information; and that in the long term computerizing medical care will be expensive but it should provide savings, safety, and increased quality and efficiency. Bauer (2006) presents forecasts, implications and responses for the future of healthcare based on digital transformation. He suggests that the most powerful trend for healthcare is a revolution in medical science made possible by networked computers and that developments in technology will bring changes through new potentially beneficial tools. Whilst some of these tools do not at present allow older people to personally manage their own health needs some personal involvement is possible and should increase. Requardt (2006) argued that IT would be the biggest challenge in contemporary health care. IT will introduce a new paradigm shift in medicine and public health that will have many benefits. For example, 'the patient of the future will no longer rely just on the individual experience of his physician, but on the entire medical knowledge that is available' through intelligent patient databases (p. 22). IT will however also bring with it many new problems such as data protection and ethics that will need to be addressed.

Resources and Reliability

Anyone who can search the Web independently can find an enormous amount of information about health issues by themselves. A simple search for self help around health management in a search engine will provide thousands of links to self-help groups, self-help manuals, resources from health funds, or guides on how to lose weight and exercise. Some of this can be too detailed, depressing or from a non-reputable source. Cohen (2001) notes that the elderly can become adept Internet surfers; and whilst there are financial and physical obstacles, they can use this powerful tool to participate in their own healthcare; however seniors accessing this information need some personal guidelines about how much information they want, where the most dependable information is to be found, and how to judge the content of the Websites they visit. There are good and bad Websites in this respect and people can obtain and use information that is questionable unless they have some knowledge of medical matters or know how to evaluate the resources they find.

Becker (2004) notes that whilst the Internet provides an extraordinary opportunity for older adults to access health information, providing online health resources however does not guarantee that older adults will be successful at accessing or understanding the information they seek. Websites that do not meet the online needs of targeted users may pose virtual barriers that prevent the information seeker from attaining their goals. Using the National Institute of Ageing web guidelines Becker assessed the usability of 125 web sites offering health resources. The results of the study showed that many of the sites were not 'senior friendly' with specific improvements needed in order to accommodate the vision, cognition or motor skills of the older adult users.

Dishman (2004) describes Intel's Proactive Health lab that emerged from a study of householders who were early adopters of broadband technology. As a result of requests for help with care of ageing parents Intel is applying digital home technologies to the development of personal health systems for ageing in place. These applications include wireless sensors, adaptive interfaces, real-time data capture, and context aware feedback. They assert that they support an alternative to costly mainframe healthcare and help us all to personally manage our health better. There is also software available, accessible by the Internet, that allows patients and medical teams to access health records and assessment outcomes, consider treatment options, and communicate via e-mail (VisionTree Software).

Wilbert (2007) describes results from a survey of baby boomers in Minnesota, USA, that found many are actively ageing, planning to continue to live independently by investing in technology to help them. Businesses in the local area have already begun to respond, with a "senior-living community" of 325,000 square feet established, which includes common areas for socialization, housing for 250 people, a fitness center, plus the usual amenities of any housing community. The group is seeking to actively partner with health technology providers to equip and maintain these styles of communities on a broader scale, supporting the ageing baby boomers to continue living independently while properly supported in personal health management.

Gillaspy (2005) believes that recent changes have created an impact on libraries that provide consumer health information to the public. These include increased Internet connectivity, the quality and amount of consumer health information available, the realization that the American lifestyles could be causing health problems, maturation of the consumer health movement, and acceptance of it by health care professionals, emphasis on health literacy, and the events of September 11th. Whilst these changes are not specific to older consumers the issues of ageing baby boomers, their impact on health care financing, the lack of time for doctors and nurses to provide adequate health and patient information during scheduled visits, and the boom in complementary therapies all make it more important for public libraries to provide access to health information.

Strategies for Improving Computer Use and Applying Skills to Health Management

The purpose of this chapter has been to explore the range and use of the exciting options that are developing for personal health management by the ageing population, that make use of computer technology, and that should support active ageing. The exploration outlined in this chapter must be considered in light of its existing limitations. Firstly, whilst ageing is a global issue the exploration outlined in this chapter has focused solely on how the issue is experienced within developed countries. Secondly, research into ageing is many and varied, the breadth and depth of studies available has meant that the current chapter has only been able to provide a snap shot of some of the key commentaries in the field.

Active ageing promotes the continued engagement of older people in their communities in order to lead fulfilling lives. The more engaged people are and the more networks that they have, generally the better off they are as they age. There are strong links between participation, health and security. It is important make sure that older adults remain as healthy as possible, as good health is a significant variable in their ability to participate in wider activities. In order to stay healthy older people need to have access to health and health services. In the future many health services will be delivered through electronic methods and will require, at minimum, basic computer and technology literacy. This is where learning is involved. Older adults can and do learn. Most have a strong desire and ability to do so. They want to learn about a wide variety of things including technology operation. Learning basic computer literacy is within the capacity of most of the older population of developed countries at least. Thus we need to support programs that directly assist older adults to use technology, particularly in accessing information.

Boulton-Lewis, Buys, Lovie-Kitchin, Barnett and David (2007) found that the older people who use computer technology have a range of motivations to do so. The connection between learning and technology seems to be underpinned by a positive attitude towards the future and continued engagement with a range of learning issues. Men are more likely to feel at ease in using such technology. Given that it has been asserted that there is a close relationship between quality of life and use of computer technology with regard to issues including healthy lifestyle, management of disabilities and illness, it seems that there is a need to promote computer use with older people despite their possible fears and perceptions of lack of relevance in their lives. This is particularly important for women because they may be less inclined to use computers, generally live longer and often alone, and need to be able to personally manage their own health.

Facilitating Computer Use

There is a range of initiatives to promote access to computer use by older people. Computer companies and peer teaching (Grodsky and Gilbert, 1998) are two such activities. Many seniors' organisations in Australia such as ASCCA, COTA, University of the Third Age, and SeniorNet actively promote computer tuition by older people for older people. It seems that these programs are particularly important for females who want to learn generally, want to learn about technology and are not as likely to be currently using it (Boulton-Lewis et al., 2007). The need for access to computers for people with lower incomes also needs to be addressed.

Livingston (2007) described recent developments in ICT for older users allowing them to attend to solutions including health care. In a similar vein Czaja and Lee (2007) discussed the impact of ageing on access to technology and asserted that successful use of technology for older adults is predicated on systems that are designed to accommodate their needs and preferences. They suggest guidelines for system design based on assessing the cognitive and perceptual demands placed on the learner. Ala-Mutka and Punie (2007) suggest that older adults should be involved in the design of computer systems and programs that are suitable for them. They also suggest that older people could more easily take up a familiar tool such as digital television.

CONCLUSION

In summary this chapter has clearly shown that there are already developments that allow older adults to partially manage their personal health online. These are likely to increase exponentially. We are only just beginning to develop a picture of how the ageing population is using computer technology to manage their personal health. This chapter reveals the vibrant and diverse nature of active ageing research. Further research is needed to explore the main consequences and implications associated with older adults using an ever-changing array of technology (ie iPods, mobile phones) for their personal health care and management. Research in this field should be multi-disciplinary in nature, collaborative, and have a focus on learning.

Addressing the issue of healthy and productive ageing (Department of Health and Ageing, 2003, pi) has been cited as one of the crucial concerns for Australia's future and as such is a 'matter of highest national importance' (Howard 2001, cited in Andrews, 2002). The Australian government has challenged the Australian research and health care communities to generate 'high quality research in healthy ageing' (Department of Health and Ageing, 2003, p. 55). The active ageing model presented in this chapter helps fulfil the government's challenge. We are living in an information rich and technology driven world. More and more individuals are being called upon to obtain their own health information, and in doing so, are confronted with a plethora of health information resources from ebooks to blogs to youtube to databases. But many lack the ability to find their way through the spate of the ever increasing number and variety of health related IT resources available. In order for older people to make full use of the available health information resources and tools they need to be willing to learn. We should implement strategies and procedures that will motivate older people to learn to use IT to facilitate personal health management. The active ageing model and associated studies outlined in this chapter are unique because they place the focus on learning for individual empowerment. The active ageing model, if implemented, will help community health services reduce health inequalities and improve the health of ageing Australians. Promoting active ageing will enable ageing Australians to be proactive in their health and lifestyle choices.

KEY TERMS AND DEFINITIONS

Active Ageing: Refers to the process of enhancing quality of life as people age by ensuring opportunities exist for health, participation and security.

Ageing: Refers to the process of becoming older.

Computer Technology: Is a broad term that refers to computer software and hardware.

Learning: Refers to the process of acquiring or developing new skills, knowledge and attitudes.

Motivation to Learn: Refers to attitude, desire, will to learn.

Older Adults: Older people, ageing persons, usually over 65 years.

Personal Health Management: Refers to an individual taking active responsibility for managing their own health care.

Chapter 1.11

Evaluating Healthcare IT and Understanding the Work of Healthcare are Entangled Processes

Joseph Schulman
New York Presbyterian Hospital, USA

ABSTRACT

Parallel to the monumental problem of replacing paper- and pen-based patient information management systems with electronic ones is the problem of evaluating the extent to which the change represents an improvement. Meaningful and useful evaluation rests upon: a) explicitly conceptualizing the goals and tasks of the daily clinical work; b) thinking of electronic information management technology as a cognitive tool; c) explicitly representing in the tool the pertinent information elements; d) selecting among possibilities for representing a problem formulation so as to facilitate the solution; and e) appreciating the dynamic interaction between the work and the tool–that changing a tool necessarily changes the work. Anchored in the story of how one hospital committee learned to think about the purpose and impact of a patient information management system, this chapter gives practical insight to these evaluative considerations.

DOI: 10.4018/978-1-60566-030-1.ch002

INTRODUCTION

This chapter grew out of a story about how a committee of clinicians and information technology (IT) professionals learned to think more clearly about healthcare IT; to think about it in a somewhat deductive manner. Since healthcare IT is a tool to aid the work of healthcare, the group ultimately determined that critical reflection entails identifying what may be considered first principles that justify and inform the work itself. At the outset, the committee's task of characterizing IT success versus failure seemed perfectly clear. But only so until they began to understand the crucial distinction between healthcare system tasks and goals, and that activity without clarity of purpose may be activity without value. From these insights emerged an interrogative framework anchored in clear notions of purpose and designed to yield operational understanding. Over time, the essential idea became evident: clinical work and tools are calibrated to each other. The committee came to appreciate that a tool achieving quick user acceptance may be one that makes little use of its technological potential; and that workers may be unaware that their early opinions about new tools reflect their imposing the specifics of the previous work/tool interaction on the present one. The story of how this group learned to think about evaluating healthcare IT was originally published in the Journal of the American Medical Informatics Association and is reprinted here with permission: "Discovering how to think about a hospital patient information system by struggling to evaluate it: a committee's journal."(J. Schulman, G.J. Kuperman, A. Kharbanda, & R. Kaushal, 2007)

Of equal importance to understanding first principles that underpin the work of healthcare is an understanding of first principles for designing IT to aid that work. One such principle is the notion of a problem space – discussed in the committee's journal, later in this chapter. This chapter begins by examining additional foundational principles of IT design. These include the notion of a cognitive tool; exactly which information elements one ought to pay attention to; considerations for selecting among representational options so as to facilitate solving an information management problem; the vital importance of explicitly conceptualizing the bulk of the daily work in order to deftly manage it via database technology; and the idea that our tools generally determine how we think and work.

COGNITIVE TOOLS

IT is a cognitive tool. A cognitive tool is an artifact to represent and express what one knows; it may even help one to discover new knowledge. It is intended to aid human cognitive processing,(Jonassen) to extend and facilitate what one could otherwise achieve unaided. The point of such a tool is not to relieve health care providers of the actual task of cognitive processing, but to *extend* providers' cognitive abilities. Users should be able to process more information than if they had no tool. Note that whether or not such a tool is available, providers must think deeply about the information at hand. The tool should promote deeper, more critical reflection and help the user discover relevant ideas that might have been missed without the tool. Rather than solely make the current task array easier, cognitive tools should enable the user to perform additional tasks that were always pertinent to the work but otherwise unfeasible.(Jonassen) Moreover, since the truly intelligent system is the user – not the tool, the tool ought to be largely controlled by the user. In contrast, all too commonly current technology imposes constraints on exactly how the user may formulate and think about a problem.

WHICH ELEMENTS OF THE DAILY WORK SHALL WE ATTEND TO?

One way to think about IT as a tool to facilitate the daily clinical work – which largely entails formulating and solving problems – is to decompose the work into its component processes:(Robertson, Elliot, & Washington, 2007)

1. Seeking information
2. Presenting information
3. Organizing knowledge

Thus, IT affects cognition and ultimately action because it frames the way its users think. How does this happen? From a user perspective, a particular database software implementation is essentially a template of blanks to be filled in or to be viewed. Each template directs attention to particular aspects of work (formulating and solving problems) and to particular data elements – and discounts or ignores others. Templates underpin not only healthcare database software but also similarly intended word processor or spreadsheet applications; and to some extent, templates also underpin the mental models of providers who manage their patient information with pen and paper. In any case, rather than reflecting the real importance of the selected data elements, the framing and focus of such templates may derive from what is readily measured or represented or from what decision makers determine based on legacy and/or accepted belief. For some IT implementations, the framing and focus may be apropos for specific types of patients or pathophysiological conditions, but it may be uniformly applied to an inappropriately wide range of patients and conditions.

DOES HOW WE REPRESENT WHAT WE PAY ATTENTION TO, MATTER?

Whatever the framing and focus of an IT implementation, it amounts to a specific representational system; a map of the reality over which it is hoped the tool will provide greater mastery. Such a system includes:(Norman, 1993)

1. That which is to be represented
2. That which does the representing; symbols

This map – whether represented in consciousness or in a cognitive tool such as a database software application – must itself exist as a representation: a metarepresentation.(Norman, 1993) It is the meta-representation – the mental model of reality – that one tends to reflect upon.(Norman, 1993) Very importantly, often more than one way exists to represent the selected aspect of reality. So it is central to evaluative thinking to ask: How does one choose among the possibilities?

The answer entails evaluating the suitability of each representation for solving the associated problem. In the words of popular wisdom, "there's more than one way to skin a cat." It turns out that a problem's difficulty and its very nature are related to its representational or meta-representational specifics. This abstract idea becomes concrete and much clearer after considering two games: one called "15," and the second, the well-known "tic tac toe."(Guerlain, Hayes, Pritchett, & Smith, 2001; Norman, 1993)

The game of "15": Two players may select, without replacement, any of the nine digits – 1, 2, 3, 4, 5, 6, 7, 8, 9. A player may take one digit in turn. The aim is to be the first player to get any three digits that add up to 15.

Consider this game scenario:(Norman, 1993) Player A selects 8. Player B selects 2. On the second round, A selects 4 and B selects 3. On round three, A selects 5; now, what digit should B select next? Please pause and try to answer the question.

Most people find this a difficult problem to solve. It produces cognitive overload. Tasks include mentally keeping track of game rules; which player selected which digit; which digits remain; and which remaining combination is preferred: both players' numbers must be added in various combinations of three digits and then one must decide either to block the opponent or advance toward winning.

Now consider a second game.

The game of "tic tac toe": Most readers know this game from childhood. Played on a 3 X 3 matrix, the aim is to be the first player to position three identical symbols – either X's or O's – in a straight line.

Consider this game scenario: Player A uses X symbols and Player B uses O symbols. Figure 1 shows the game at round number 3; now, where should Player B place an O next? Again, please pause to answer the question.

Most readers (and children) find this problem easy to solve. They quickly determine that Player B should place an O in the lower right cell (Table 1).

Why does "15" seem difficult and "tic tac toe" easy? It is because the way the information about the "tic tac toe" game is represented enables one to see the solution "at a glance." No memory and little additional reflection are needed. In contrast, "15" as represented above provides no memory or other information processing aids.

But "15" need not be so difficult a game. As mentioned earlier, often more than one way exists to represent an aspect of reality; and that a task's

Table 1. Game scenario (Norman, 1993)

X	O	X
	X	
O		

difficulty and its very nature are related to its representation or meta-representation. The game “15” may be represented differently, graphically, as if it were “tic tac toe.” Imagine that player A and Player B played “15” such that they arranged the available digits as though they were X’s and O’s in “tic tac toe.” The upper portion of Table 2 illustrates one possible configuration reflecting the earlier game scenario:(Norman, 1993)

After referring to the matrix in the upper portion of Table 2 and the game in play in the lower right, it’s readily apparent that the digit Player B should select on round three is 6, in the lower right cell. The lower left portion of Table 2 highlights the parallel with “tic tac toe.”

PROBLEM ISOMORPHS

The games of “15” and “tic tac toe” illustrate a key first principle for healthcare IT design, the notion of problem isomorphs.(Norman, 1993; Simon, 1996) In each game, the problem, the essential question to be answered, is actually the same. The tasks involved in answering the essential question, and the attendant difficulty, differ greatly because of how the relevant aspect of reality was represented. For either “tic tac toe” or “15,” graphically representing the information as the matrix illustrated in Figure 2 aids the player by providing some “external memory.”(Guerlain et al., 2001) Note, however, that for a given problem the preferred representational choice may depend on whether a person or a computer is doing the data processing. Although it is easier for a person to solve “15” when graphically represented, it is easier for a computer to do so when it is arithmetically represented.(Norman, 1993) It is easier for a person to solve “tic tac toe” when spatially represented. However, many people would find it much more complicated and unintuitive to write a computer program for solving “tic tac toe.”(Norman, 1993) Thus, optimal representation depends on the available knowledge that may be brought to bear, the problem-solving algorithm applied, and the performance characteristics of the computational system.

The great variation in healthcare and the way it is documented, often with little association to outcomes (Blumenthal, 1994; The Center for the Evaluative Clinical Sciences, 1998), suggests that the notion of problem isomorphs could be

Table 2. Player A’s selections are bold; Player B’s selections are italics.

beneficial to usefully conceptualizing healthcare and evaluating healthcare IT. Eddy observed that "When different physicians are recommending different things for essentially the same patients, it is impossible to claim that they are all doing the right thing."(Eddy, 2005) Here is one elementary illustration of the relevance of problem isomorphs to healthcare IT evaluation. To answer a question or solve a problem, an IT user often must navigate among several windows on a computer monitor. This forces the user to rely on human memory and cancels some of the machine potential for leveraging recall. (Think again about the experience of playing the arithmetically represented game of "15.") In some software applications, once a particular view has opened the user can't go back to check another with related information without losing information already entered on the current screen view. Imagine how helpful it would be for clinicians if a specific array of data elements particularly pertinent to a patient's problem profile was available on a single screen view – something like the graphically represented game of "15."

In summary:

1. Try to discriminate bad representations that produce a cognitive quagmire from good representations that can point to the answer
2. Recognize that the very concept of the problem to be solved may change when workers have cognitive tools that expand their perceptual capability, their memory, and their computational skills

When the only tool you have is a hammer, everything looks like a nail ~Abraham Maslow

CAN WE RECOGNIZE IT SUCCESS WHEN WE LOOK AT IT?

Success vs. Failure: Is the Glass Half Empty or Half Full? (Reprinted from Schulman, 2006. Used with permission)

Van Der Meijden et al reviewed publications between 1991 and 2001 that evaluated inpatient information systems requiring data entry and retrieval by health care professionals.(Van Der Meijden, Tange, Troost, & Hasman, 2003) They found a plethora of studies extensively describing system failures but could find no study that explicitly defined system success. Indeed, health information systems are rather prone to failing. (Littlejohns, Wyatt, & Garvician, 2003) One fundamental for learning from an information system failure is to disentangle user resistance to change(Rogers, 1995) from suboptimal technical solutions. Those who protest the changes occurring in patient information technology must come to see that the real choice does not include the status quo.(Department of Health, 2002; Dick, Steen, Detmer, & eds., 1997) (Thompson & Brailer, 2004) Bearing in mind that user acceptance need not imply a problem successfully solved, see Lorenzi and Riley(Lorenzi & Riley, 2000) for a review of individual and organizational factors that influence people to accept new information technology.

Success/Failure Permutations

It is probably clear by now that "How to recognize IT success?" begs other questions: How well have the representations been matched to the tasks? Are the correct tasks being performed – how does one know? A variety of possibilities are possible:

1. A well-conceived and/or implemented software application of an adequately conceptualized work reality
2. A well-conceived and/or implemented software application of an inadequately conceptualized work reality
3. A poorly-conceived and/or implemented software application of an adequately conceptualized work reality
4. A poorly-conceived and/or implemented software application of an inadequately conceptualized work reality

A substantial portion of healthcare IT shortcomings may derive from the current work reality and how it is conceptualized.(C. Nemeth & Cook, 2005; C. P. Nemeth, Cook, & Woods, 2004) The daily work of healthcare may appear to unfold smoothly, but only because clinicians are doing many thing to make it appear so. Closer examination reveals an exceedingly complicated, vague, variable, inconsistent, and fast-paced reality.(C. Nemeth & Cook, 2005) Experienced clinicians know that clinical processes may be implicit or even ad hoc – and vary with each patient.(Joseph Schulman, 2004) These realities of under-conceptualization and procedural anarchy are "hiding in plain sight."(C. Nemeth & Cook, 2005) Those who cannot recognize what is actually unfolding before them cannot understand the work as it truly is and therefore cannot create appropriately supportive cognitive tools.(C. Nemeth & Cook, 2005) What is needed to move beyond this difficulty is to apply to healthcare IT cognitive engineering methods and meticulous observation of the clinical work as it actually is – in distinction to what workers would like to imagine it is.

A perhaps contrasting view is expressed in an intriguingly titled article, "Designs are hypotheses about how artifacts shape cognition and collaboration."(Woods, 1998) The author appears to assume that software designers begin with an adequately conceptualized work reality (possibilities #1 and #3 in the above list). He makes two points. First, our tools determine how we think and work – and how we do these things with our co-workers. Secondly, an implemented design's actual performance in aiding cognition and collaboration must be explicitly tested. Of course, testing the design hypothesis requires data describing appropriate outcome variables and predictor variables. This, in turn, requires a conceptual framework for that which we wish the tool to help us with.

Are we trapped in a conundrum of determining whether the chicken or the egg comes first? Here is how one group saw their way out.

DISCOVERING HOW TO THINK ABOUT A HOSPITAL PATIENT INFORMATION SYSTEM BY STRUGGLING TO EVALUATE IT: A COMMITTEE'S JOURNAL (REPRINTED FROM SCHULMAN, KUPERMAN, KHARBANDA, & KAUSHAL, 2007. USED WITH PERMISSION)

Alice came to a fork in the road. "Which road do I take?" she asked. "Where do you want to go?" responded the Cheshire cat. "I don't know," Alice answered. "Then," said the cat, "it doesn't matter." ~Lewis Carroll, Alice in Wonderland

As organizations transition from paper to electronic media for storing and managing patient information, front-line clinicians experience disquieting feelings that may range between vague distress and profound disruption of their world. These clinicians face "dilemmas of transformation in the age of the smart machine."(Zuboff, 1988) We think it is crucial that all involved in this transformation strive for clarity in understanding how technology restructures the work situation, how a computer-based patient information system can "abstract thought from action"(Zuboff, 1988) – not only automate but also *informate* (Zuboff, 1988) – reveal activities, events, entities, ideas, and information to some degree previously opaque; and how work tasks, work flow, and tools dynamically interact.

Hospital information technology (IT) committees represent a part of an organization's strategy for crossing the chasm separating the culture of paper media and the culture of electronic media. (Healthcare Information and Management Systems Society, 2006; Shortliffe, 2005; Wyatt, 1995) These committees commonly include front-line clinicians. These individuals may have little experience with either the potential or the pitfalls of the technology over which they adjudicate, and little experience in how to critically think about the issues. To draw attention to this aspect of the unfolding transformation and contribute to the conversation about how to make sense of it, we summarize our committee's early experience.

In the Beginning, the Task Seemed So Clear

We work at a large academic hospital. Our committee is comprised of administrators, clinicians including physicians, nurses and pharmacists, and IT specialists. Our charge is to improve our inpatient clinical IT systems by determining: desirable features for our electronic patient information management system; how to minimize work disruption during system implementation; and how to evaluate the consequences of replacing the previous technology. In particular, we were asked to suggest exactly what to measure in order to determine whether the IT system is successful. At the outset, this seemed rather straightforward to many members. So at the first meeting the group quickly crafted a list of "short term goals." These included assembling an inventory of resources from which we could obtain evaluation data, planning to assess the medical error reporting system for IT related events, and conducting an IT user survey.

Stepping Back

Then one of us spoke up. "These aren't goals. They're tasks. Before deciding what to do (task), shouldn't we say exactly what we want to achieve (goal)? For example, depending on our goal, we might prefer to track trigger events (sentinel metrics (Resar, Rozich, & Classen, 2003)) instead of analyzing data from the medical error reporting system."

Several of the clinicians, understandably, conceptualized the committee work as they do their clinical work. After a patient's history, physical exam, and ancillary data are presented on rounds, they often immediately rattle off the next lab studies and images to obtain. If pressed on this issue, they say they're so accustomed to their work that in the blink of an eye they (implicitly) determine the goals those labs and images are intended to promote. However, test this assertion by asking: "If the laboratory tests and images you need – for instance, a CBC, CRP, and a chest X-ray – provide the answers you seek, then precisely what is the question these answers inform?" Some workers simply respond with a puzzled look, some will articulate a reply; but the replies tend to vary among respondents – and infrequently are they framed as questions. Rarely, someone will articulate the question the studies, the "answers," indeed inform: "What is the estimated probability my patient has condition x, given the results of these studies?" Activity without clarity of purpose may be activity without value. If the estimated probability that a patient has condition x, given confirmatory study results, does not exceed a threshold value justifying the benefits/risks of treatment, the studies, the "answers," are unnecessary. Similarly, evaluation data should only be collected if they help to answer a specific question designed to explicitly probe goal achievement.

Identification of Purpose

At our next meeting, we tried again to articulate what we wanted to accomplish over the short-term: 1) We want to identify existing data sources that can inform evaluation of our work and to understand the sources' strengths and weaknesses. 2) As a foundation for evaluation, we want to enumerate the intended consequences of the current IT implementations and discover some of the unintended consequences. Although in hindsight #1 was still quite vague and #2 essentially stated that the goal was to create a list of goals, we pressed on.

"What are we trying to achieve in the long term?" 1) We want to be able to describe the effects of our clinical interventions, including otherwise unapparent effects we would not know of without analyzing aggregated patient data. 2) We want to use the potential of IT to improve the care we provide.

This sounded pretty good. Even so, we acknowledged the imprecision by following with the question embedded in our committee's charge: "How do we define success – how will we know when we have achieved these goals?" We did not appreciate at the time, that the idea we began to grapple with might be more usefully conceived as a continuous variable, a spectrum of "doing a good job," rather than binary, success/failure. (Aarts, Doorewaard, & Berg, 2004) Nor did we appreciate the need to operationally define "doing a good job"; or that crafting this definition was at the core of our measurement task; nor the need to consider the multiple evaluative perspectives from which achievement might be framed, for example, the committee's, the clinical staff's, the IT department, the organization. We did appreciate that answering the question entailed developing evaluative criteria for our information management tool, along with evaluative criteria for our clinical performance.

We were starting to get it: identifying what we measure comes *after* developing a clear, explicitly articulated idea of what we're trying to achieve. This idea of what we're trying to achieve must do more than sound lofty and laudable. It must describe what the system is to be about at the core. Without such clarity, we'd ultimately just collect lots of data without gaining knowledge. By this formulation we recognized too, that our work was enmeshed with that of another committee charged with developing clinical performance metrics. Although we actually were back where we started, we sensed that we could now make a more informed choice about the path to take.

Broad Goals

In discussing candidate goals, members indicated that IT was important because it represented a means for reducing errors. So we scrutinized a widely accepted definition of error:

"… all those occasions in which a planned sequence of mental or physical activities fails to achieve its intended outcome, and when these failures cannot be attributed to the intervention of some chance agency."(Reason, 1990)

Clearly, we needed to achieve much more conceptual clarity and specify our ideas in greater detail. The notion of error makes no sense until we precisely identify the intended outcome, i.e. the goal of the activity.

Our deliberations also led us to Norman's (Norman, 1993) and Zuboff's (Zuboff, 1988) notion of IT as a cognitive tool – something that should make us smarter than we are without it. Therefore, taking account of the various users at our hospital, we pondered how to think about the main features this cognitive tool should offer.

Herbert Simon helped point the way:

"Solving a problem simply means representing it so as to make the solution transparent… a problem space in which the search for the solution can take place… Focus of attention is the key to success –

focusing on the particular features of the situation that are relevant to the problem, then building a problem space containing these features but omitting the irrelevant ones." (Simon, 1996)

A new candidate goal and associated evaluative criteria were revealed. Now we asked, "To what extent does our tool aid in creating a productive problem space?"

By now, most of us had completely forgotten that we initially thought the committee's charge could be straightforwardly dispatched. We understood that it was so complex we must break it up into more manageable chunks. We identified broad categories within which to articulate hospital IT goals and problems

- Business, i.e. billing and collections
- Regulatory compliance
- Reporting
- Patient documentation
- Electronic prescribing
- Decision support and other cognitive enhancements
- Referrals
- Clinical performance evaluation and quality improvement
    - ◦ Exposure-outcome relationships
- Patient registries
- Workflow and efficiency

Criteria for Measures

We were beginning to share the view that collecting data is merely the tip of the iceberg that is IT measurement. Data collection is buoyed by a body of explicit performance questions whose answers have potential to advance our purpose. Proposed measures must plausibly inform those answers by withstanding rigorous and uniform scrutiny:

- What dimension of IT use or patient care does this measure inform us about?
    - ◦ With what overarching aim does this dimension resonate? That is, if a list of explicit aims and a fine-grained process map of our entire enterprise were spread before us, precisely which aim and process component(s) does this measure enable us to associate?
        - ▪ Such measurement activity should both derive from, and test hypotheses about causal sequences
- What results do we expect, i.e. what is our hypothesis?
- How would we interpret results that might be displayed? (This entails working with fabricated, "dummy data," during planning.)
- What might we do differently once we know this thing?
- What target performance range do we seek to achieve for this measurement variable?

This interrogative framework depends on clear notions of purpose, intended outcomes. However, systems may produce surprises: unintended, undesired outcomes. How might the committee learn about unintended consequences of IT? We discovered another daunting challenge. Sometimes, we wouldn't know in advance what to look for; even worse, we might not recognize what we were looking at after it occurred. As a first step, we would measure unintended IT consequences via some type of user survey. Practical considerations required that we draw a sample from all users. Therefore, we would have to determine how to sample. Our thoughts increasingly reflected our experience: "First, we should discuss detailed, explicit aims of the survey. That way, we'll have a clearer idea of what to do. For example, if one aim is to gain insight to whether responses might be biased by user's experience with antecedent technology, we might consider including complementary "fly-on-wall" observers' reports."

Learning from Others

We considered the wide range of IT already implemented – for which corresponding goals often appeared to be implicit at best. And we considered the practical reality that committee members could devote only a small fraction of their total work time to this effort. It seemed sensible to develop ever-more fine-grained goals in conjunction with accumulating insights via learning from what others have done in these areas. That is, we would start with others' evaluative frameworks, reflect on the goals they (at least implicitly) seek to establish, and over time, refine our own concept of our goals and how we determine that we achieve them.

We drew heavily from the excellent overview of Ash, Berg, and Coiera (Ash, Berg, & Coiera, 2004) to draft an extensive conceptual framework for probing clinicians' experience using our institution's patient information management system (Box 1). The work/tool interaction section of Box 1 merits additional discussion. The content and flow of the daily work – the tasks constituting the means of achieving the (hopefully explicit) aims – reflect what is possible and practical at the time. The tools are designed to facilitate the work, and similarly reflect what is possible and practical at the time. Thus the notion of what constitutes the daily work, operationally framed, varies over time. Note that the aims of the daily work tend to be more stable than the tasks selected to achieve the aims. To illustrate, in the days of paper-based patient records, clinicians would never dream of instantly computing a patient's post-test probability of a particular disease as soon as a test result is reported. Today, this is indeed possible. Although such Bayesian computation was always consistent with the aims of clinical work, it may become part of the daily work when it is possible and practical.

Our Revelation

The essential point is that clinical work and tools are calibrated to each other. If a tool is changed, the work flow and/or fine structure it is intended to support must necessarily change. (Aarts et al., 2004) Thus, stakeholders must consider as an aspect of progress the need to recalibrate work flow and/or fine structure to new tools' capabilities; ever mindful of the aims that motivate the work. A tool achieving quick user acceptance may be one that makes little use of its technological potential and correspondingly less likely to advance the goals or justify the investment. The "aha moment" arrives with the understanding that preserving existing problem solving approaches that suppress evident potential for more effectively and/or efficiently advancing the goals is antithetical to progress. A problem space with which workers are comfortable may, when new tasks are enabled, be rendered suboptimal. Therefore, in the context of the goals of the enterprise, we define user acceptance as a result of judging not a new tool in isolation, but a new work/tool dyad. A short "test drive" yields an answer to the wrong question.

Workers long accustomed to a particular way of working may have difficulty imagining new ways made possible by tools that enable things they never dreamed of. Indeed, workers may be unaware that their early opinions about new tools reflect their imposing the specifics of the previous work/tool interaction on the present one. To further illustrate this important idea of dynamically calibrating work and tools to each other, we invited members to consider this question: "If all you had to do was ask for it, what do you wish your patient information management tool could do?"

- Serve me new and relevant information without my having to open a specific patient's record – the information system should "find me" when necessary

- Support Bayesian decision making (compute post-test disease probability)
- Enable me to access it remotely (from home)
- Configure multiple windows into one coherent display, as I deem necessary
- Optimize the problem space in relation to the nature of the problem, rather than the same configuration for every patient
- Facilitate communication among consultants
- Improve communication efficiency; minimize interactions and interruptions
    - Communicate with other involved providers from within a patient record
        - Document communication and results
    - Prevent duplication of efforts, prevent memory lapse
- Promote an explicit list of patient-specific goals for the day, articulated as part of daily patient rounds
- Support a shared to-do list among all care providers

The point of this invitation was to illuminate the way one's conceptualization of work is molded by one's notion of what is possible. The aim was to highlight contrasts: the difference between the items enumerated on a current task list and a potential ideal task list; the gap between the way tasks are done and potentially more efficient/effective alternatives enabled by technological advancement. Pondering such contrasts promotes creativity in formulating a problem space and solution. (Simon, 1996) Although the invitation was not intended to encourage user expectations with which tool builders could not keep up, some low level of discord appears desirable for stoking the flame of continual improvement.

Lessons We Learned

In conclusion, although evaluating a clinical IT implementation is a daunting challenge, it is central to managing the organization. IT evaluation should be founded upon explicit understanding of the goals of the enterprise – *necessarily the first step in the process*, appreciating the incessant work/tool interaction, and expecting that these change over time. This view thus calls for:

- Persuading the user community that their choices do not include the status quo
- Discriminating user resistance to change from suboptimal technical solutions(Rogers, 1995; J. Schulman, 2006)
- Appreciating that user acceptance need not imply a problem successfully solved(Lorenzi & Riley, 2000; J. Schulman, 2006)
- Setting realistic expectations; understanding that early iterations of a solution may produce only tolerable or promising results, i.e. it is impossible to anticipate every issue that will arise after implementation.(J. Schulman, 2006)
- Appreciating that the appropriate evaluative study design may be a matter of controversy. Randomized controlled trials, though a gold-standard for discriminating an intervention effect, are typically infeasible. Some outcomes may not even be quantifiable; however, they may be analyzed using widely accepted qualitative methods.(Stoop, Heathfield, de Mul, & Berg, 2004)
- Periodically re-thinking the boundaries and elements of the problem space

Daunting as IT evaluation may be, it is unavoidable because, as our story illustrates, it is central to healthcare. Fortunately, as we engage with the challenge we become increasingly energized. We urge others to serve on committees such as ours

Box 1. Conceptual framework for probing clinicians' experience using a patient information management system

Dimension of IT tool use: Work Flow

- Data entry
    - Do we impose perceived additional work tasks?
    - Is information displayed in a visual format that facilitates the task?
        - Fonts
        - Background color
        - Content structure
        - Data retrieval
    - Individual patients
    - Aggregates of patients
    - How soon after creation is a record available?
- Interruptions: when distracted by a competing task, do users lose track of thoughts and where they were in the record by the time they return to it or does the tool remember for them?
- System response time; down time
- Ease of system access
- Feature navigation: ease, and possibility to toggle between features
- Juxtaposition error: is a data element so close to something else on the screen that the wrong option may easily be clicked or an item read in error?
- Have users devised workarounds? That is, have users devised strategies and tactics enabling them to live with the system despite demands they deem unrealistic, inefficient, or harmful?
- To what extent does this tool promote entering information only once, but enable presenting it in varied contexts?

Dimension of IT tool use: Cognitive enhancement/impedance

- Does this tool overwhelm users (cause cognitive overload) by overemphasizing
    - Structured and "complete" information entry
    - Alerts and reminders
    - If so, please provide detailed explanation
- Does this tool cleave information that belongs together, forcing users to switch between different screens, so that users feel deprived of the overview desired?
    - If so, please provide detailed explanation
- Standard phrases
    - Are readability and information value of reports diminished by over-use of standard phrases?
        - Does the availability of these standard phrases discourage users' composing thoughts and crafting meaning?
        - As users read a narrative, is understanding sometimes confounded by uncertainty whether a sentence or clause represents thoughtful word use – a spot-on description; or merely a conveniently available selection – a more or less apropos description?
- Have others over-used cut and paste or copy and paste text manipulation?
    - Redundant information
    - Inaccurate information
- Are data provided as abstract cues, or do they contain sufficient context to establish their referential function?(Zuboff, 1988)
- Do users feel they function more as data entry workers or as knowledge workers?

continued on following page

Box 1. Continued

  - Do users feel their identity as a professional has changed by using this tool?
    - If so, how?
- To what extent does this tool draw out users' intellect in working with the data and aid their creating meaning from it?(Zuboff, 1988)

Dimension of IT tool use: Communication

- To what extent do users think that another professional reviewing their entry will grasp the essence of what they intended to communicate?
  - Do users think that "entering" their contribution to the patient record replaces their previous means of initiating and communicating their plans?
  - Have users noticed a change in the amount of direct interaction among physicians, nurses, and pharmacy?
    - If so, in what direction?
    - Is this perceived to be in their patient's and their interests?
  - Has overall reliance on the computer system as a source of answers to clinical questions increased, decreased, or stayed the same?

Dimension of IT tool use: Work/tool interaction

- Does the tool seem to
  - Speed or slow the daily work?
  - Make users feel smarter or dumber?
  - Force users to change the way they think?
    - About the patient
    - About the work
    - If so, is the change good or bad?
- What do users need that they're not getting?
- What are users getting that they don't need?
- For each of the above, exactly how has the user determined this?

because the rewards of this arduous, often frustrating, endeavor are nothing less than greater clarity about the essence of our work in healthcare, greater mastery in achieving its purpose, and a greater sense of meaning in our daily tasks.

CONCLUSION

Evaluating healthcare IT and understanding the work of healthcare are entangled processes because clinical work and associated information management tools are calibrated to each other. The point of such tools is to extend providers' cognitive abilities: promote deeper, more critical reflection, and help the user discover relevant ideas that might have been missed without the tool; all the while speeding the flow of the component tasks constituting the daily work. However, healthcare IT can aid providers in their work only to the extent that providers and IT designers understand *exactly* what the work is to achieve and by what means. Lofty and laudable-sounding goals generally are uninformative for IT design. Explicit, operationally defined goals; work tasks designed to efficiently and effectively achieve the goals;

and clear ideas of what is meant by "efficiently" and "effectively"; these are the prerequisites for evaluative thinking.

Since one's concept of work is molded by one's notion of what is possible, the work of healthcare and IT tools to facilitate it exist in a dynamic, changeable relationship. This relationship resembles the evolutionary dynamic between biological organisms and their complex and ever-changing environment. The concept of a successful organism is meaningless without a specified environmental context. As that environment changes – and indeed it continually changes – so does the evaluative framework for determining what constitutes success.

KEY TERMS AND DEFINITIONS

Cognitive Tool: An artifact to represent and express what one knows; intended to aid human cognitive processing, to extend and facilitate what one could otherwise achieve unaided.

Electronic Information Management Technology (IT): Typically, a database software application (less sophisticated implementations occur in word-processing or spreadsheet software) running on some configuration of computer hardware

Goal, Aim, Purpose: That which one seeks to achieve via a particular work operation; a desired result.

IT Evaluation: The process of determining the degree to which an IT implementation facilitates the work of an individual or organization

Meta-Representation: The representation of the representational system – the explicit map of the portion of reality of interest. Reflection on the chosen map of reality actually tends to occur upon the meta-representation – the mental model of reality.

Patient Information Management System: A data management system that facilitates processing of patient information

Problem Isomorph: A single problem can be stated in various ways, and often therefore can be variously represented. The particular representation, or problem isomorph, can influence the difficulty of solving the problem.

Problem Space: The collection of possible information configurations and actions that may transform them, in order to advance toward a goal; i.e. the circumstances within which the search for the solution to a problem can take place.

Problem Solving: The process of moving from a starting point in the problem space to the goal.

Representational System: A map of the reality over which it is hoped the associated cognitive tool will provide greater mastery. Such a system includes both that which is to be represented and that which does the representing – symbols.

Task: One of a set of actions – specific steps in a process – contributing to achieving a goal.

Chapter 1.12

Healthcare Information Systems and the Semantic Web

David Parry
Auckland University of Technology, New Zealand

INTRODUCTION

The World Wide Web (WWW) is a critical source of information for health care. Because of this, systems for allowing increased efficiency and effectiveness of information retrieval and discovery are critical. Increased intelligence in Web pages will allow information sharing and discovery to become vastly more efficient .The semantic Web is an umbrella term for a series of standards and technologies that will support this development.

BACKGROUND

The Web and Healthcare Information Systems

The early development of the Internet, from ARPA developments and the Internet protocol in the 1960s and 1970s to increasing use of e-mail and text-based systems, led to the development of HTTP and HTML in the 1990s (Barry et al., 1997). The Web has become a critical source of information and communication among people in all domains. The world of medicine on the Web, including such concepts as eHealth, have become areas of great academic interest (Pagliari et al., 2005). Thus, the Web and health care are increasingly co-dependent.

Finding the required information in a search of HTML documents is difficult, as HTML is really a formatting language for humans rather than for indexing. Of course, Web-based systems such as search engines or digital libraries are available, but these rely on indexing either as a set of keywords drawn from a limited vocabulary or from sometimes unreliable parsing of the document. Knowing what information a Web page contains, whether it is a medical record, a clinical result, or an academic paper, is still difficult.

DOI: 10.4018/978-1-59904-889-5.ch083

The Semantic Web

Tim Berners-Lee has coined the term “Semantic Web” (Berners-Lee, Hendler, & Lassila, 2001). This term has been enthusiastically adopted and generally includes any work intended to allow the meaning of data contained in Web resources to be made accessible to software agents or humans.

In essence, a semantic Web document is a collection of three parts:

- The document that contains the information, marked up in a suitable way
- A document that contains the rules for interpreting the markup (Namespace)
- A document that links the information with the namespace (i.e., which set of interpretation rules is being used).

There has been a great deal of work under the auspices of W3C to develop standards for the semantic Web, in particular representations using XML. Two of the major efforts are the Web ontology language (OWL) (Smith, Welty, & McGuinness, 2004) and the resource description framework (RDF). In terms of information retrieval, the semantic Web will allow a user to express what they mean to find and find objects that satisfy that request without regard to the language or syntax of the request. The semantic Web implies ways of representing the meaning of documents and constructing queries to discover that meaning. If possible, such a process will be as automatic as possible and incorporate the advances in computing power available to users on the desktop and at the server.

An example may make this system clearer. The example is taken from the W3C example page (http://www.w3.org/2000/10/rdf-tests/)

The original RDF document is:

```
<?xml version=”1.0”?>
<rdf:RDF
xmlns:a=”http://description.org/
schema/”
xmlns:rdf=”http://www.
w3.org/1999/02/22-rdf-syntax-
ns#”
xmlns:oiled=”http://img.cs.man.
ac.uk/oil/oiled#”
xmlns:xsd=”http://www.
w3.org/2001/XMLSchema#”
xmlns:rdfs=”http://www.
w3.org/2000/01/rdf-schema#”
xmlns:daml=”http://www.daml.
org/2001/03/daml+oil#”
xml:base=”file:/C:/
downloads/RDF-Model-Syntax_1.0/
ms_4.1_1.rdf”>
<rdf:Statement>
<rdf:subject
rdf:resource=”http://www.w3.org/
Home/Lassila”/>
<rdf:predicate
rdf:resource=”http://descrip-
tion.org/schema/Creator”/>
<a:attributedTo>Ralph Swick</
a:attributedTo>
<rdf:object>Ora Lassila</
rdf:object>
</rdf:Statement>
</rdf:RDF>
```

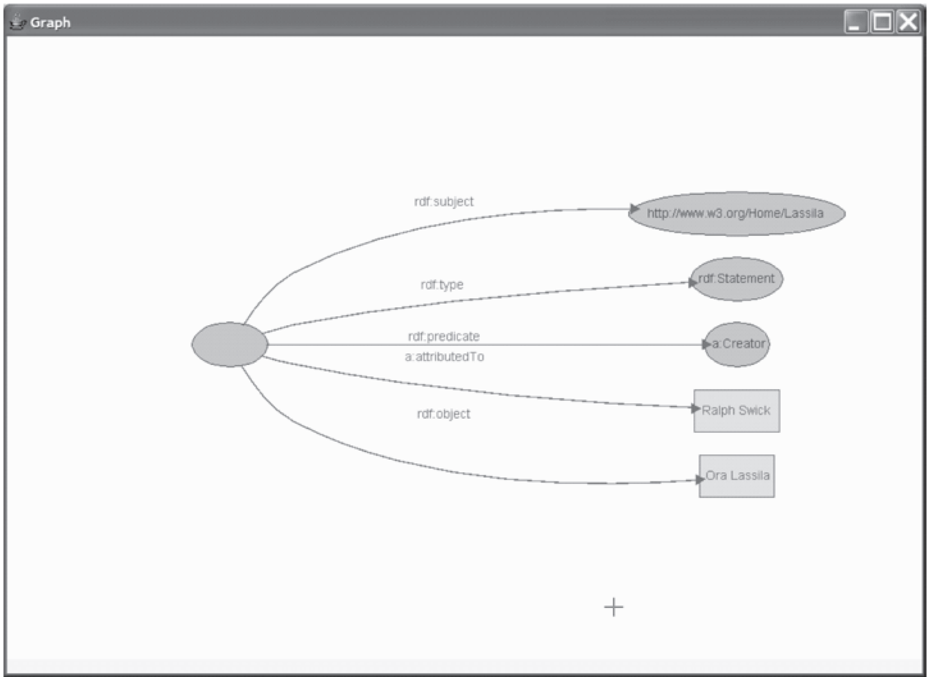
This can be displayed as shown in Figure 1.

This can be expressed in words as “Ralf Swick and Ora Lassila have the attributes of creators of RDF.”

The flexibility of this approach can be seen by the fact that the definitions of what RDF is and what “creator” means can be located in other files. Thus, agreed meanings can be used across multiple data files.

Often it may be useful to think of the meanings of items in documents as related to an ontology and that there is a standard for the expression of ontologies on the WWW. This standard—Ontology Web Language (OWL) (Smith, Welty, & McGuinness, 2004)—allows ontology relations to be coded in

Figure 1. XML document construction



a machine and human readable form within files that can be located on the WWW.

An example of an OWL statement is shown in Table 1 (the example is taken from Smith, Welty, & McGuinness, 2004.

This example shows the definition of an equivalent class—items that satisfy the conditions given in the equivalent class construction are regarded as equivalent. In this particular example, things from Texas are assigned to be “Texas things.” This project is still at a fairly early stage but obviously represents a potentially beneficial approach to standardization that may be useful for the deployment of the fuzzy ontology described later.

Table 1. OWL example

```
<owl:Class rdf:ID=”TexasThings”>
<owl:equivalentClass>
<owl:Restriction>
<owl:onProperty rdf:resource=”#locatedIn” />
<owl:someValuesFrom rdf:resource=”#TexasRegion” />
</owl:Restriction>
</owl:equivalentClass>
</owl:Class>
```

What both these approaches do is allow the page author to identify to agents or humans the intended meaning of various parts of the document. The RDF form does not need the existence of an underlying ontology, but in many cases, an ontology does exist, which makes consistent namespace creation easier. Of course, systems such as HL7 already have what are effectively namespaces, but the semantic Web approach means that the author provides the data, the possible values of the data, and the potential meaning of the data in a format that allows shared meanings. This makes the approach very powerful for semistructured information or approaches where only a subset of the information is needed.

Systems for encoding semantic information do not have to rely on XML or other general-purpose systems. An extremely general-purpose approach to adding semantic information to documents is the WorldNet approach described in Mihalcea and

Mihalcea (2001). In WorldNet, there is a number of keywords, each of which has a large potential set of attributes such as synonyms, hyponyms, related terms, and so forth, which are used for searching. Documents have their own schema that includes information about the position of e-words within the document.

HEALTH INFORMATICS AND THE SEMANTIC WEB

The use of semantically meaningful XML structures is not new in medicine. The entrez database that is used to access PubMed has a standard XML output that allows users and agents such as the entrez e-search tools to identify elements of a document record. Similar systems are available for gene and protein libraries.

The use of Semantic Web technologies for a health database is described in AnhÃ¸j, 2003. In many cases, the use of ontologies has predated the implementation of Semantic Web formulation in the medical domain. In the previous terms, the reference to namespace is implicit, as the namespace is determined by the ontology that is being used. This approach is more powerful in some respects, as extremely complex relations and workflow can be encoded into complex ontologies, but less flexible in that all the documents have to refer back to the same namespace.

Web-based ontologies can be seen as a part of implementing the Semantic Web. The Stamford medical informatics group suggest their language—PROTÉGÉ-2000 (Noy, Sintek, Decker, Crubézy, Ferguson & Musen, 2001)—as a means of representing ontologies on the Web. The central role of ontologies in knowledge management is emphasized by Staab and Maedche (2001).

A number of systems have been designed to allow communication between ontologies; for example, XOL, an ontology exchange language implemented in XML and developed from Ontolingua (Karp, Chaudhri, & Thomere, 2004). The Ontolingua server (Stanford University Knowledge Systems Laboratory, 2001) allows online collaborative editing of ontologies, and the knowledge system laboratory is also the home of a library of ontologies (e.g., the enterprise ontology and others).

The MeSH system also can be easily represented as an ontology, although in this case an object can be allowed to be a member of more than one leaf element at the lowest level. This is because a particular document can be "about" many different and closely related subjects. It is also possible to have the same leaf element incorporated in a number of different branches. This creates problems for some representation systems, and artificial distinctions have to be made between the same terms, depending on from which branch it has come.

A keyword or index term hierarchy can be seen as a particular class of ontology. At the same time, documents can be analyzed in terms of such ontologies. In this case, the attributes used to define a document are themselves divided by navigating the tree that represents possible classifiers. In the information retrieval case, it is highly likely that documents will possess many attributes, some of which may tend to place it in differing parts of the ontology. For example, a page produced by a sufferer's charity about a disease may have attributes such as brevity, low reading difficulty that indicates it would be located in a tree associated with public information, but it may have valuable links to research teams and means of getting funding that would make it suitable for researchers and located in that tree. An XML result from PubMed can be seen as an example of a Semantic Web document, where the namespace is not directly referenced but can be obtained from the publisher.

Not only knowledge sources can be represented in this way. The Electronic Health Record (EHR) can use Semantic Web technologies, for example, by identifying regions that correspond to patient ID, date of birth, or diagnosis.

Current Research Projects in this Area

The National Library of Medicine (http://www.nlm.nih.gov/healthit.html) runs a number of large-scale projects in this area; in particular, the UMLS work mentioned earlier. This forms a basis for a great deal of work. Underlying the concept of a Semantic Web is that of ontology. The protégé research group at Stanford (http://protege.stanford.edu/) is continuing to develop interactive tools and ontology products.

The WWW consortium (W3C) has active programs developing and promoting OWL and RDF (http://www.w3c.org). Research in ontology development includes the use of fuzzy ontologies to better match uncertain classifications (Parry, 2004; Tho, Hui, Fong & Tru Hoang, 2006) and the development of ontologies for specific areas such as the gene ontology machine (http://www.**geneontology**.org). Applications of Semantic Web approaches to health care include drug safety (Stephens, Morales & Quinlan, 2006) and the investigation of e-health quality and reliability (Eysenbach, Lampe, Cross & Brickley, 2000). A particularly strong effort is being made to use semantically enhanced web services in the medical domain in the Artemis project (Asuman et al., 2006).

FUTURE TRENDS

The Bioinformatics community has a number of applications ready for Semantic Web approaches (Wang, Gorlitsky & Almeida, 2005). The wide variety of interfaces to the various databases in this area remains difficult, and a standardized semantic approach seems particularly likely to arrive. The latest release of HL7, version 3 (Dolin et al., 2001) is explicitly based around semantics of documents. Many applications are based around data-sharing via XML documents and Web services, and standards are emerging. Semantic standards—what a particular piece of information means—is intrinsically more complex for more sophisticated information, and it may be that hybrid approaches are used. That is, items such as name, patient number, drug therapy, and so forth are easily standardized, but more abstruse concepts such as prognosis or lesion appearance may not be so easily represented. The Semantic Web architecture will become more attractive for purely internal projects as tools for XML and RDF become more effective.

In business terms, there appears to be a role for brokers and intermediaries between systems. There are potential issues with privacy of medical data in that Semantic Web storage should be more comprehensible than proprietary formats, but health care systems always have had this problem. It seems likely that the open source movement will be particularly adept at adopting this approach, which will lead to increased use of the EHR (Middleton, Hammond, Brennan & Cooper, 2005). In terms of health knowledge and information retrieval, interoperability between systems seems the greatest possible benefit and, in particular, the development of intelligent browsers with agent technology that can vastly increase the power of search by personalizing it and putting it in context.

CONCLUSION

The Semantic Web is based around a number of fairly simple standards, but adoption of those standards in the health care domain is sometimes difficult. It is possible that Web publishers will generally adopt Semantic Web coding standards to allow their documents to be used by increasingly sophisticated agent-based systems. The vision presented in Shadbolt, Hall & Berners-Lee (2006) is attractive and is happening for particular domains. The huge bulk of Web pages that have not been revised for ease of semantic understanding seems to pose a problem. However, HTML coding was seen as difficult in 1996, so as more editors become available and the utility of Semantic Web applications becomes obvious, this may not be a vain hope. Undoubtedly, Semantic Web approaches to information publishing and sharing are likely to be a key aspect of work in health care information in the future.

KEY TERMS

Electronic Health Record: A system of storing information about a patient to assist in diagnosis and treatment.

HL7: A medical message system standard.

MeSH: Medical Subject Headings. Index terms used by NLM.

Ontology: A rigorous and exhaustive organization of some knowledge domain that is usually hierarchical and contains all the relevant entities and their relations.

Semantic: Of or relating to meaning or the study of meaning.

PubMed: Web portal to the National Library of Medicine Bibliographic Database.

W3C: The World Wide Web steering committee.

WWW: The World Wide Web. A system using data and program protocols that allow simple publishing and transfer of information.

XML: Extensible Markup Language. A standard set by W3C for documents that can include description of the meanings of items.

ABSTRACT

Health data and knowledge had been structured through medical classifications and taxonomies long before ontologies had acquired their pivot status of the Semantic Web. Although there is no consensus on a common definition of an ontology, it is necessary to understand their main features to be able to use them in a pertinent and efficient manner for data mining purposes. This chapter introduces the basic notions about ontologies, presents a survey of their use in medicine and explores some related issues: knowledge bases, terminology, and information retrieval. It also addresses the issues of ontology design, ontology representation, and the possible interaction between data mining and ontologies.

DOI: 10.4018/978-1-60566-218-3.ch002

INTRODUCTION

Ontologies have become a privileged and almost unavoidable means to represent and exploit knowledge and data. This is true in many domains, and particularly in the health field. Health data and knowledge had been structured through medical classifications and taxonomies long before ontologies had acquired their pivot status of the semantic web. In the health field, there are still more than one hundred classifications (e.g., ICD10, MeSH, SNOMED), which makes it very difficult to exploit data coded according to one or the other, or several of these classifications. The UMLS (Unified Medical Language System) initiative tries to provide a unified access to these classifications, in the absence of an ontology of the whole medical domain - still to come.

In order to apprehend the interest of ontologies in data mining, especially in the health domain, it is necessary to have a clear view of what an ontology is. Unfortunately, there is no consensus within the scientific community on a common definition of an ontology, which is somewhat paradoxical, as one of the characteristics of an ontology is to represent a consensus of a community on a given domain. However, one does not need to enter the specialists' debate on ontologies to understand their main characteristics and therefore be able to use them in a pertinent and efficient manner for data mining purposes.

On a first level, one can think of an ontology as a means to name and structure the content of a domain. Among the numerous definitions that have been given, there is some kind of agreement that an ontology represents the concepts of a domain, the relationships between these concepts (IS-A and other relationships), the vocabulary used to designate them, and their definition (informal and/or formal). The IS-A relationship plays a central role, as it provides the (tree-like) skeleton of an ontology. This structure need not be a tree, as a concept may specialize several upper concepts, contrary to a taxonomy. Compared with a thesaurus, an ontology is freed from a particular language: an ontology deals with concepts, independently from the (natural) language that is used to designate them, while a thesaurus deals with terms that are expressed in a particular language. Moreover, a thesaurus does not enable the creation of new relationships between terms, whereas ontologies do.

There is no strict boundary between taxonomies, thesauri and ontologies, and a taxonomy may be considered as a particular case of an ontology. In practice, most ontologies rely on a taxonomic skeleton which is enriched with ontology-specific features. One can also notice that the conceptual schema of a database, expressed in object form, is close to an ontology (a micro-ontology) of the application domain of the database. Therefore, most people dealing with health data have been dealing with ontologies, either explicitly or implicitly – most often implicitly. However, making explicit the notion of ontology has made it possible to formalize and unite various formalisms and practices. The current ontology standard in the web universe, namely OWL[1], might not be the final standard for ontologies, but it has initiated a movement towards the need for an agreement for such a standard.

Ontologies have their roots in Aristotle's categories, and particularly in Porphyry's tree-like representation (3rd century), which laid the foundations for modern ontologies. This tree-like structure is still present in ontologies and in most knowledge representation systems through the IS-A relationship. The attributes in object or frame-based systems and the roles in Description Logics provide the other relationships of a possibly corresponding ontology. However, the introduction of ontologies in the field of Computer Science by Gruber in the 90's was not motivated by philosophical considerations but by the need of a representation in first-order logic of knowledge-based systems in order to facilitate their interoperability (Gruber, 1991). Today's ontologies are still strongly linked to first-order logic, either through Description Logics, which constitute the main stream in the ontology domain, or through conceptual graphs, which also have a strong logic background. Ontologies have also become an unavoidable support to knowledge and data integration.

In order to provide a level of understanding of ontologies that enables the reader to comprehend their interest in data mining, we first present two examples to introduce the basic notions related to ontologies. We then make a short historical presentation of the notion of ontology, with its philosophical background and its introduction in the computer field in the 90's for knowledge sharing purposes. In the following section, we make a survey of classifications and ontologies in the medical and biological fields. We then address some issues related to ontologies: knowledge bases, terminology, information retrieval, and finally ontology building. We conclude by presenting a summary of recent and ongoing work on data mining with ontologies and mention some perspectives.

ONTOLOGY ESSENTIALS, ORIGIN AND DEFINITIONS

The basic notions necessary to approach ontologies are concepts, relations, vocabulary and definitions. We illustrate them through two examples taken from ongoing work involving ontology building and use.

Basic Concepts and Examples

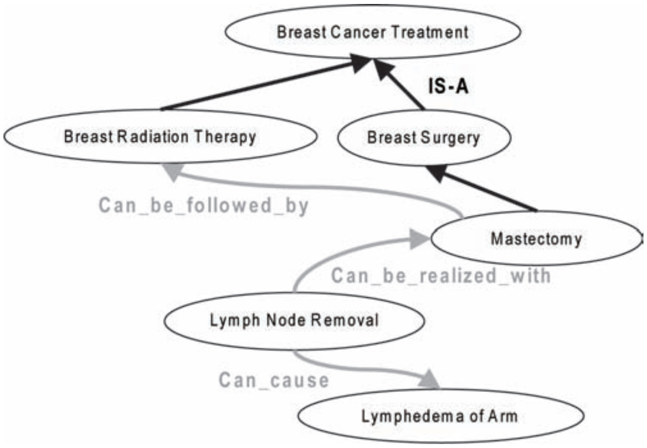
A Concept-Based Terminology in the Field of Breast Cancer

The first example introduces the notions of concept and relationships, and illustrates the terminological aspects of ontologies. Some authors consider that an ontology does not contain any vocabulary, only universals describing "reality" (Smith, 2003). Such universals, anchored in "reality", are different from concepts, which are creations of the human mind. *Absent nipple* is an example of *concept* that is found in medical classifications. According to B. Smith, such a concept is not a universal, as an absent nipple does not exist in reality but is a creation of the human mind. Universals have to be named, but this name is conventional and the various terms used to designate an ontology component (usually called a concept) should be dealt with outside the ontology. Although we understand this view, which implies considering a *terminology* associated with - but not part of - the ontology, throughout this chapter we will adopt the common view of ontologies and consider the vocabulary associated with concepts as part of an ontology.

The problem addressed by the work presented below is that of the language used in medicine by different categories of users, namely health professionals and lay people. Most health professionals recognize that patients and other lay people are not familiar with medical terms. As these terms are used in health-related documents (texts, web sites) it makes it difficult for patients, and more generally for lay people, firstly to find these documents through queries, as their *natural* language is not the language used in the documents themselves, and secondly to understand them. Moreover, much of the health-related scientific literature is in English, which increases the problem of querying the web for some; this is also true for health professionals, who are not always familiar with the English language. One solution to this problem is to create an ontology of the considered domain (ideally the whole medical domain) and to associate with its concepts the terms in the relevant languages, e.g., professional-English, lay-English, professional-French, lay-French. This is the objective of the work undertaken by R. Messai for breast cancer in her PhD work (Messai et al., 2006). The ontology fragment presented in Figure 1 shows an example of a conceptual structure. *BREAST SURGERY*, *MASTECTOMY* and *LYMPH NODE REMOVAL* are concepts. The concept *MASTECTOMY* is linked to the concept *BREAST SURGERY* by the hierarchic relation *IS_A*. This means that the concept *MASTECTOMY* is more specific than the concept *BREAST SURGERY* (conversely, the concept *BREAST SURGERY* is more generic than the concept *MASTECTOMY*). Figure 1 shows three occurrences of pairs of concepts linked by the IS_A relationship:

- BREAST RADIATION THERAPY IS_A BREAST CANCER TREATMENT
- BREAST SURGERY IS_A BREAST CANCER TREATMENT
- MASTECTOMY IS_A BREAST SURGERYand three occurrences of non-IS_A relationships:
- MASTECTOMY *Can_be_realized_ with* LYMPH NODE REMOVAL
- MASTECTOMY *Can_be_followed_by* BREAST RADIATION THERAPY

Figure 1. An example of a conceptual structure in the breast cancer field



- LYMPH NODE REMOVAL *Can_cause* LYMPHEDEMA OF ARM

The IS_A relationship provides the skeleton of the ontology (its taxonomic part), while other relationships provide information about the domain that can be exploited through logical reasoning, for example for information retrieval or question-answering purposes.

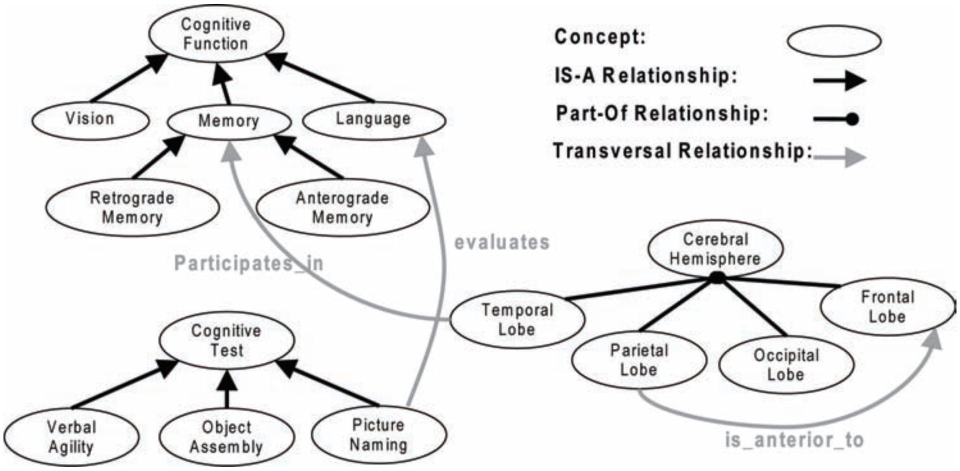
Although the concept names are in english, the concepts themselves are independent from the language, as is the ontology[2]. The name chosen to designate the concept in a given situation among several possible terms is somewhat arbitrary (for a presentation in french, french names would be chosen). Moreover, several terms can be used in the same language to designate a concept, e.G., mastectomy, mammectomy and breast removal, for the concept MASTECTOMY. These terms can be considered as synonyms and any of them could be used to designate the concept MASTECTOMY. However, it is common usage to choose a preferred term among these synonyms, in order to facilitate the communication between the different users of the ontology. In the context of the current project a preferred term has been chosen for each category of users considered: professional-English, lay-English, professional-French and lay-French. Examples of terms associated with the concepts of Figure 1 are given below (the preferred term is underlined).Lymphedema of arm:

- *Lymphedema of arm*, *arm lymphedema*, *edema of arm* (professional-English)
- *Arm swelling* (lay-English)
- *Lymphœdème du bras, œdème lymphatique du bras* (professional-French)
- *Gros bras, gonflement du bras* (lay-French)

One important objective of this ontology is to support multilingual Information Retrieval. It is established that patients' query formulation leads to poor results since most health-related information is available in English and uses a specialized medical terminology. It is likely that they will search for "heart attack" rather than "myocardial infarction", "rash" rather than "exanthema" or "hair loss" rather than "alopecia" (McCray et al., 2003). Therefore, breast cancer terminology for lay people should contain terms specific to the patients' language, such as *"breast pain"* for *"mastodynia"* and *"breast removal"* for "*mastectomy"*, but also medical terms such as *"pyrexia"*, which they can encounter.

Through an ontology with a rich terminology covering English and French, professional and lay languages in the domain of breast cancer,

Figure 2. An example of a conceptual structure in the brain field



lay people will be able to access and understand health-related data and knowledge in the breast cancer field, while using their own words and language. In order that access to web-based medical content be independent from the language and the scientific skill of the user, an ontology associated with a multilingual terminology will be used to index and query documents. Such an Information Retrieval system can also be used by health professionals, as their language has also been employed in the indexing process, through the concept-based indexing approach that is applied (see §4.3).

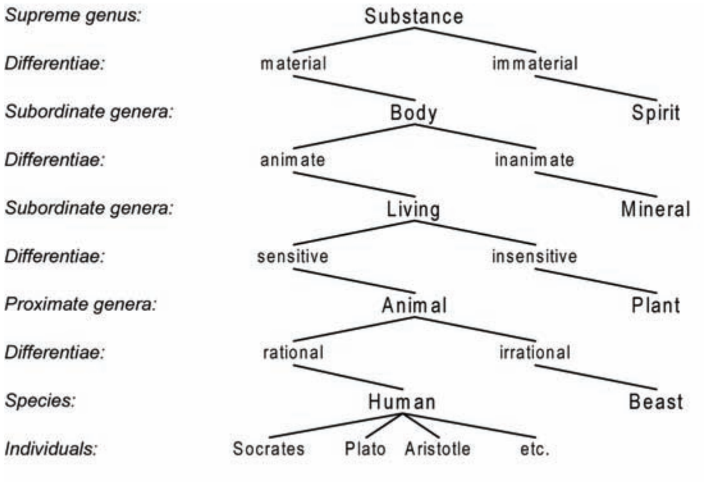
The second example is taken from a former national French project on the mining of brain data (Bonnevay et al., 2003). This project aimed at discovering relationships between brain regions and cognitive functions through the results of cognitive tests performed on patients with brain injuries. To achieve this goal, knowledge about both the anatomical and functional aspects of the brain has been formalised through an anatomical ontology, a functional ontology and an ontology of cognitive tests. The knowledge about the brain domain (a.k.a. anatomo-functional ontology) is expressed through semantic relationships between the concepts of the three ontologies. Generally speaking, a given cognitive function (e.g., *memory, language*) is evaluated by a set of cognitive tests or subtests (e.g., *verbal agility test, picture naming test*). A particular area or region of the brain participates in the execution of a given cognitive function. For example, the *temporal lobe* is involved in *memory*. Figure 2 presents an example taken from the ontology built in this project. It illustrates two basic notions of ontologies: concepts and relationships. It also shows the use of a particular relation, namely *Part_Of*, which play with the *IS-A* relationships a key role in biomedical ontologies such as the Digital Anatomist Foundational Model of Anatomy (FMA) and the Gene (GO) ontology (§3.1). The *Part_Of* relation links an entity and its components, and is intended to be transitive.

This ontology has been used to support the discovery of relationships between the cognitive function and the anatomical regions of the brain in the French national project BC3 (Brain and Health Knowledge Base) (Bonnevay et al., 2003).

Basic Notions

The two previous examples have illustrated the notions of *concepts*, *relations* and *terminology*, which can be considered as the main constituents of an ontology. The IS_A relationship, which is

Figure 3. Porphyry tree[4]



central to ontologies, provides the taxonomic skeleton of the ontology.

In the above examples, definitions were not associated with concepts. As an ontology aims at establishing a consensus within a community on a (general or specific) domain, it is necessary, during ontological engineering, i.e., the design and the building of the ontology, to provide definitions in natural language. Such definitions are often sufficient to reveal dissentions in the understanding of concepts, which often have different meanings in different groups, thus leading the group to look for a consensus.

Associating formal definitions with concepts and relationships requires the use of a formal language. First-order logic is well suited for that purpose, and was indeed used in the first formal work on ontologies, in the KIF/Ontolingua environments (Gruber, 1993). Today, Description Logics (DL), a meaningful subset of First-Order Logic, is the formalism most widely used to support formal ontological work. OWL, the current recommendation of W3C for ontology description, is based on Description Logics. The first and most well known formal work in medicine using DLs is the GALEN system (Rector et al., 1993). It uses a specific DL, namely GRAIL, whose author, I. Horrocks, is one of the designers of the OWL language.

Origins and Definitions

Aristotle's categories may be considered as the first tentative to build an ontology of what exists. It consisted in identifying and naming ten categories[3] into which any existing thing or being can be classified. These categories may seem awkward to us today but it was indeed an original and remarkable work at the time. They were provided as a flat list, but five centuries later, Porphyry (234?-305?) organized them into a tree structure and provided basic principles to differentiate child and parent nodes, as well as nodes at the same level (Figure 3).

These principles consist in identifying sets of characteristics that distinguish two close nodes. This principle is known as the differentia principle and it is the basis of contemporary approaches to ontology construction (Roche, 2003) (Troncy et al., 2002).

The Latin work *ontologia* first appeared in a text in 1613. The word "ontology" itself (in English) first appeared in a text in 1721 in *An Universal Etymological English Dictionary* by

Nathaniel Bailey: *An Account of Being in the Abstract*. It first appeared in a title of a book in 1733 (Notes on the history of ontology http://www.formalontology.it/history.htm). It referred to the philosophical usage of the term. Barry Smith, a philosopher who is now working on ontologies in the biomedical field, gives the following definition: "Ontology as a branch of philosophy is the science of what is, of the kinds and structures of the objects, properties and relations in every area of reality … In simple terms it seeks the classification of entities. Each scientific field will of course have its own preferred ontology, defined by the field's vocabulary and by the canonical formulations of its theories" (Smith, 2003).

The contemporary use of the word "ontology" in computer science and particularly in the semantic web area originates in the work of the Knowledge Systems Laboratory at Stanford in the late 80's to provide a clear and logically defined meaning of knowledge bases, and as a consequence provide a methodology to ensure their sharing and reuse (Gruber, 1991). This resulted in the KIF (Knowledge Interchange Language) language and the Ontolingua language and project (Gruber, 1993).

The first definition referred to in Computer Science comes from the above group: " an ontology defines the basic terms and relations comprising the vocabulary of a topic area as well as the rules for combining terms and relations to define extensions to the vocabulary " (Neches et al., 1991). The most generally referred to definition of an ontology is that given by Grüber: *"an ontology is an explicit specification of a conceptualization"* (Gruber, 1993).

It should be emphasized that there is currently no definition of an ontology that is agreed upon by the computer science community. A fairly complete list of the many other definitions provided since the early 90's, can be found in (Corcho et al., 2003), as well as a survey of methodologies, tools and languages for building ontologies. The question of what is a good or sound ontology remains the subject of an intense debate. Reference authors in this domain are B Smith (http://ontology.buffalo.edu/smith), N Guarino (Guarino et al., 1995) (http://www.loa-cnr.it/guarino.html). In France the work on ontology is centered on terminology (Baneyx et al., 2005), (Roche, 2005).

ONTOLOGIES IN MEDICINE

Medical Classifications

Since Linne's classification of species in 1735, there has been an explosion of the number of classifications in the biomedical field, which poses the problem of reusing data based on different classification systems. With the proliferation of computer tools, this problem has become particularly acute in data mining, where the size of the data set plays an important role; hence, the need to group sets of data from different origins, which is impossible if these data sets use different coding systems. Among the best known and most used we can cite[5]:

- **ICD** (International Statistical Classification of Diseases and Related Health Problems), has been developed by The United Nations World Health Organization (WHO) in Geneva, in collaboration with 10 international centres. It is regularly revised to reflect advances in medicine. The main focus of this classification is *"to promote international comparability in the collection, classification, processing, and presentation of mortality statistics"*[6].
- **SNOMED CT** (Systematized NOmenclature of MEDicine – Clinical Terms) is a clinical terminology. It results from a merging between SNOMED-RT (Reference Terminology) developed by the College of American Pathologists (CAP) and the England and Wales National Health Service's Clinical Terms (a UK-

based terminology for primary care previously known as the Read Codes). It was designed to give a common framework to capture and code information about a patient's history, illness and treatment. A new international organisation, the Health Terminology Standards Development Organisation (IHTSDO, also known as SNOMED SDO) acquired the ownership of SNOMED CT on 26 April 2007 and will be responsible for future maintenance and development.

- **MeSH** (Medical Subject Headings) is a medical Thesaurus used to index, catalogue and retrieve the world's medical literature, by PubMed, the NLM's interface to the MEDLINE database. There are 24,767 descriptors in the 2008 edition of the MeSH thesaurus. In addition to these headings, there are more than 172,000 headings called Supplementary Concept Records (formerly Supplementary Chemical Records) within a separate thesaurus. There are also over 97,000 entry terms that assist in finding the most appropriate MeSH Heading; for example, Vitamin C is an entry term to Ascorbic Acid[7].
- **The FMA** (Foundational Model of Anatomy) is a reference ontology in the field of anatomy. Its main focus is to represent anatomical entities, ranging from biological macromolecules to cells, tissues, organs, organ systems, and major body parts, including the entire body (Rosse, 2003). The different parts of the human body and their relationships are described in such a way that they are understandable to humans and can also be browsed, processed and interpreted by machines. The FMA currently contains around 75,000 anatomical items (concepts) and 120,000 terms.
- **GO**, the Gene Ontology, aims "to describe gene and gene product attributes in any organism". It can be broadly split into two parts. The first is the ontology itself (actually three ontologies), each representing a key concept in Molecular Biology: the molecular function of gene products; their role in multi-step biological processes; and their localization to cellular components. The ontologies are continuously updated, and the new version is made available on a monthly basis. The second part is annotation, the characterization of gene products using terms from the ontology. The members of the GO Consortium submit their data and it is publicly available through the GO website[8].

While most classifications in the biomedical field were designed to answer specific needs, FMA and GO offer a more declarative view of the domain they cover, respectively anatomy and genetics. As a consequence, they are more open to a wide variety of applications.

UMLS[9]

To try to solve the problem of the explosion of biomedical classifications, the National Library of Medicine launched in 1986 the ambitious UMLS program. UMLS stands for Unified Medical Language System and aims at providing a unique entry point for any biomedical item that can be referred to in scientific medical and biological texts or studies. To do so, a so-called meta-thesaurus has been built – and is constantly evolving – in order to cover the whole medical and biological domain. An entry in the meta-thesaurus is a concept with a unique *CUI* (Concept Unique Identifier). The number of concepts in the meta-thesaurus is constantly growing and the 2006 AA release contains 1 276 301 concepts. This size makes it very difficult to manage and it is almost impossible to guarantee the consistency of this set of concepts. The concepts of the meta-thesaurus are linked through the IS_A relationship, which is the main relation, and through other relations such as *Associated_with* and *Occurs_in*. The 2006 version contains 57 different relations. Each UMLS concept is linked to the *same* concept in other classifications. UMLS considers currently 149 classifications. Therefore, it becomes possible, through UMLS, to use data from sources using different classifications, provided that each reference to a data item in a classification is transformed into its corresponding UMLS concept and the UMLS *cui* is used in the global study.

The UMLS program is still active. However, consistency issues are becoming more and more difficult to manage, due to the constantly growing size of the metathesaurus and the poor ontological quality of the UMLS structure. Currently, the OBO initiative appears to be one of the most promising enterprises in the domain of health-related ontologies.

OBO (Open Biology Ontologies)

Data need to be integrated for a better and easier access. One way to achieve data integration is to use ontologies or other terminological resources to annotate data. The absence of a solid theoretical background in the building and the formalization of ontologies have led to a proliferation of ontologies, which itself creates obstacles to integration.

In 2001, Ashburner and Lewis initiated a strategy in order to address the question of: *"how best to represent the proteins, organisms, diseases or drug interactions that are of primary interest in biomedical research"* (Smith et al., 2007) by creating OBO (Open Biology Ontologies), an organization that aims at gathering developers of life-science ontologies. OBO has established the key-principles of sound ontology building and sharing. According to these principles, ontologies must be open and available without any constraint or restriction; they must be scalable and receptive to modification as a result of community debate; they must be orthogonal to other ontologies to facilitate the combination of different ontologies through additional relationships and modular development; they must share the same syntax to facilitate shared software implementation; and they must employ a unique identifier space to enable backward compatibility with legacy annotations as the ontologies evolve.

OBO now holds over 60 ontologies, including the GO and the FMA. It is supported by the NIH Roadmap National Center for Biomedical Ontology (NCBO) through its BioPortal. A group of OBO ontologies developers have initiated the OBO Foundry, a collaborative experiment based on the voluntary acceptance by its participants of an evolving set of principles (available at http://obofoundry.org) that extend those of the original OBO by requiring in addition that ontologies must be developed in a collaborative effort, must use common relations that are unambiguously defined, have to provide procedures for user feedback and for identifying successive versions and have a clearly bounded subject-matter.

RELATED ISSUES

Ontologies and Knowledge Bases

The development of ontologies in Computer Science is anchored in that of Knowledge Bases. In Ross Quillian's PhD thesis (1966 - unpublished), the central theme was "What sort of representational format can permit the *meanings* of words to be stored, so that humanlike use of these meanings is possible? " (Ringland et al., 1987). This sounds today almost as an objective of the Semantic Web, and ontologies appear as an answer to this question. Quillian's answer was Semantic Networks, which made an intensive use of the IS_A relationship, now at the heart of ontologies. However, there was not a clear distinction between concept and instance nodes, and the IS_A relationship could hold between concepts (MALE IS_A HUMAN) as well as between an instance and a concept (John IS_A

HUMAN). This made automatic reasoning complex, and Minsky's frames made a clear distinction between classes and instances (Minsky, 1975). The main reasoning process with frame-based systems was *instance classification*. A frame (class) is characterized by attributes (named *slots*) and by range constraints over these attributes. An instance is classified into a given frame (class), if and only if its own attribute values satisfy the range constraints of the same attribute in this frame. For example, the instance *John* with attribute *Age=40* is classified into the class ADULT as it satisfies the constraint Age>18 associated with this class.

In the same decade, the 70's, rule-based systems were developed independently. Their main function was also *instance classification* although this term was not explicitly used. Instead, their role was described as the process of deriving *conclusions* from initial values called *facts*. The experts who designed the Mycin rules, for example, clearly had in mind an underlying taxonomy, which can be guessed at through the rules (Buchanan et al., 1984). Considering the initial *facts* as the attribute values of an instance, the reasoning process supported by the Mycin set of rules can be understood as the classification of this instance in this implicit taxonomy. This was made explicit in the Centaur system, which was a re-writing of the former rule-based system Puff, replacing some rules by the corresponding taxonomy of classes, while other rules were used to calculate the value of an attribute from other attributes (Aikins, 1983).

Frame systems were much criticized because a hierarchy of frames could contradict the set inclusion property inherent to the IS_A relationship. For example, a class OSTRICH could be defined as a subclass of the class BIRD, with the class BIRD defined with the property *flies=true* and an exception *flies=false* attached to the class OSTRICH. This made sound reasoning with frames impossible and the KL-ONE language was designed to overcome this drawback (Brachman et al., 1985). Although the KL-ONE system was never fully implemented because of the complexity of the logic operations involved, it laid the foundations for Description Logics (initially called Terminological Logics). Description Logics are themselves the most widely used support today to represent formal ontologies, in particular through OWL (Ontology Web Language), which is the standard proposed by the W3C (World Wide Web Consortium) for ontology representation.

The two most important reasoning operations (also called inference) supported by Description Logics are *concept classification* and *instance classification*. Concept classification is the process of identifying the inclusion property between two concepts through their logical definition. For example, given the following two definitions:

- ADULT ≡ PERSON and Age>18
- SENIOR ≡ PERSON and Age>65

Concept classification will establish that SENIOR IS_A ADULT, which can also be read as SENIOR → ADULT, SENIOR *implies* ADULT, ADULT *subsumes*-SENIOR, or SENIOR *is subsumed by* ADULT. *Concept classification* is the discovery of the IS_A relationship (also called *subsumption*) between two concepts from their sole definition.

Instance classification can be seen as a particular case of concept classification and was dealt with in this way in the first DL systems. Given the instance defined by *John≡ PERSON and Age=40*, considering it as a concept (the concept *JOHN* with the single instance *John*) would establish that *JOHN is subsumed by* ADULT. This is instance classification (the classification of the instance *John* into the class ADULT).

However, implementing instance classification through the concept classification process was too expensive, as concept classification is a complex operation, while instance classification can be implemented in a simpler and more efficient manner. Current DL systems distinguish the two operations, as does RACER, one of the most widely used reasoners associated with the implementation of the OWL language in the Protégé environment.

Consistency checking of a set of concepts in a DL is also a side effect of concept classification. If a concept is subsumed by no other concept, either it is a concept at the top of a hierarchy, or its definition is inconsistent (he cannot have a parent concept, due to an inconsistent definition).

Within the Noesis project (www.noesis-eu.org) we have implemented a subset of the MeSH thesaurus in OWL. Although the MeSH thesaurus cannot claim an ontology status, implementing it in OWL and applying the concept classification scheme made possible the discovery of a cycle in the taxonomy of concepts in the first version of the 2007 MeSH. This cycle has been removed in the following version.

One can see the advantages of a formal definition of an ontology, for example through a DL formalism. Non-explicit IS_A relationships between concepts can be discovered automatically, and the whole set of concepts can be checked for consistency. However, implementing an ontology in a formal language can be a difficult task, especially for large ontologies. This was done in the Galen project (Rector et al., 1993) for a subset of the medical field, using the GRAIL DL. The OWL language now offers the possibility of choosing three degrees of complexity in the description of an ontology, by proposing three sublanguages:

- **OWL lite**, which is syntactically simple and adapted to the description of simple hierarchies with simple constraints.
- **OWL DL**, based on Description Logics, which enables automated reasoning and checking for inconsistencies.
- **OWL Full**, which is highly expressive but which cannot guarantee decidability.

Ontology and Terminology

Terminologies focus on *words* and their relationships; where the main relationships are hyperonymy and its inverse, hyponymy. Ontologies focus on *concepts* and their relationships. Concepts are mainly organized through the *subsumption* (or IS_A) relationship, which corresponds to the hyperonymy/hyponymy relationships in terminologies and in thesauri. It organizes concepts by abstracting common characteristics, leading to a hierarchy of concepts corresponding to a taxonomic organization of objects (Roche, 2005). Moreover, ontologies offer the possibility to create new relationships, thus increasing their expressive power.

Ontologies and terminologies are used for the main purpose of providing a shared conceptualization of a specific part of the world to a community of users, aiming to facilitate knowledge communication. Gamper provides four criteria to distinguish the two notions (Gamper et al., 1999):

- **The formal framework of their definition:** The science of Terminology uses the plain text in the natural language to define the meaning of terms. The correct interpretation of the intended meaning depends on the user. Ontologies explicitly specify the conceptual knowledge by the use of a formal language with a clear semantic, which avoids ambiguous interpretation of terms;
- **Computational support:** The available tools differ for the two disciplines: most currently used terminologies provide little or no semantics for both an explicit representation of knowledge and for data maintenance. While for ontologies, through the use of formal representation language, e.g., Description Logics (Nardi and Brachman, 2003), it is possible to check their consistency, and to infer new knowledge.
- **Users:** terminologies are human user-oriented (translators and domain experts are

their primary users). Ontologies are mainly developed for knowledge sharing between agents (human and machines);

- **Natural language usage:** The terminology focuses on knowledge transfer as a linguistic activity, i.e., natural language exploration in order to identify all terms used by people to talk about underlying concepts, whereas ontologies are intended mainly for computational use and can often ignore the importance of naming concepts with "understandable" terms (e.g., UMLS CUI)

In France, the ontology work is much anchored in terminology (Rousselo et al., 2002) (Roche, 2005).

Ontologies and Information Retrieval

Traditional information retrieval systems mostly rely on keyword-based search. They only take into account the co-occurrence of words to represent the documents and the query. However, a relevant document does not always contain the same words as the query. One of the promising solutions to this problem is the use of an external semantic resource in the information retrieval process. Such systems are characterized by the notion of a conceptual space in which documents and queries are represented, in opposition to the word space found in traditional models (Baeza-Yates et al., 99). Since the end of the nineties, ontologies offer this conceptual space upon which these systems depend to retrieve a part of the semantics of both documents and queries.

The identification of concepts in a document (concept mapping) is not an easy task. Moreover, one of the limitations of this approach is that the quality of the search depends on the coverage of the ontology. In order to support concept-based Information Retrieval, an ontology should contain all the terms that can be found in the documents searched for, and also the terms and the expressions used in the queries by people searching these documents.

Using the ontology of breast cancer presented in §2.1.1 to index documents and to interpret queries, any of the terms associated with the concept LYMPHEDEMA OF ARM would be equivalent in a user query. For instance, asking for *lymphedema of arm*, *arm lymphedema*, *edema of arm, arm edema, arm swelling, lymphœdème du bras, œdème lymphatique du bras, gros bras, gonflement du bras* would result in the same set of documents.

In the Noesis project, where objectives included concept-based Information Retrieval and annotation, a significant effort was made for the enrichment of the vocabulary of the concept-based terminology[10] that was used, in order to ensure a good coverage of texts to be indexed by this terminology (Simonet et al., 2006).

Ontology Design

Ontology building is not an easy task and one of the major bottlenecks in developing bio-ontologies is the lack of a unified methodology. Different methodologies have been proposed for different scenarios, but there is no agreed-upon standard methodology for building ontologies, contrary to the database domain, for example, with the Entity-Relationship Model. The building process usually involves domain experts to reflect current knowledge about the concerned domain.

Projects about ontology building started in the early 90's. In 1995, Ushold and King proposed a method to build an ontology from scratch (Ushold et al., 1995), which comprises four steps: identify the purpose, build the ontology by the identification of the key concepts and relationships in the domain of interest, evaluate it, and document it.

Literature scanning for deciding on the basic concepts and relationships to insert in the ontology may be useful to help building an ontology. However, since building an ontology from a huge amount of literature data is a difficult and time-consuming task, a number of tools such as

TextToOnto (Maedche, 2004) and its successor Text2Onto (Cimiano, 2005), TERMINAE (Biebow et al., 1999), the ASIUM system (Faure, 1998), Ontologos (Roche, 2003) OntoLearn (Velardi, 2005) or OntoLT (Buitelaar, 2003) have been developed in order to support the user in constructing ontologies from a given set of (textual) data. The common element to these frameworks is the use of natural language processing for providing features to be used to learn ontological structures. For instance, OntoLT is an ontology learning plug-in for the Protégé ontology editor which basically makes use of the internal structure of noun phrases to derive ontological knowledge from texts. The OntoLearn framework (Velardi et al., 2005) mainly focuses on the problem of word sense disambiguation, i.e., finding the correct sense of a word with respect to a general ontology or lexical database. TextToOnto and Text2Onto are frameworks implementing a variety of algorithms for diverse ontology learning subtasks: relevance measures for term extraction, algorithms for taxonomy construction as well as techniques for learning relations between concepts. Text2Onto also takes into account the fact that the document collection can change and thus avoids starting the whole learning process from scratch every time a change occurs (Cimiano, 2005). TERMINAE is a tool that integrates the design and editing steps. It brings together both Natural Language Processing (NLP) Tools and Knowledge Engineering tools. NLP tools support the extraction of all the occurrences of the different terms, and the definition of the different meanings, called notions, of each term. Knowledge engineering tools associate concepts with terms and insert them into the ontology.

Ontology Representation

Several languages, based on the XML syntax, have been developed for the use of ontologies within the Semantic Web infrastructure. The most representative are RDF/RDFS, the W3C recommendation for metadata representation, OIL, DAML+OIL and now OWL which is the W3C recommendation for ontology representation.

SKOS is an area of work developing specifications and standards to support the use of knowledge organization systems (KOS) such as thesauri, classification schemes, subject heading systems and taxonomies within the framework of the Semantic Web. SKOS provides a standard way to represent knowledge organization systems using RDF, which allows it to be passed between computer applications in an interoperable way. The SKOS specifications are currently published as W3C Working Drafts but they will soon become a W3C recommendation. In the Noesis project, the OWL representation of the MeSH thesaurus also used SKOS elements that were necessary to represent multilingual aspects of the associated vocabulary (e.g., choose a preferred term for each language), which could not be easily achieved in pure OWL.

The Protégé environment is the most used ontology editor. However, its poor user-friendliness has led the OBO group to design their own ontology editor and format, better suited for use by non-IT people.

Although they are currently less in fashion than Description Logics, Conceptual Graphs offer a graphical representation formalism to implement ontologies (Sowa: Building, sharing and merging ontologies, http://www.jfsowa.com/ontology/ontoshar.htm).

DATA MINING AND ONTOLOGIES

The interaction between data mining and ontologies can be considered in two ways:

1. The use of ontologies in data mining processes, either to include domain knowledge in the input information or to represent the results.

2. The use of data mining techniques to build ontologies.

In both cases, it is mainly text mining that is concerned. Text mining aims to extract useful knowledge from textual data or documents (Chen, 2001) (Hearst, 1999). In the biomedical domain, this process is very useful since the huge and rapidly increasing volume of scientific literature makes finding relevant information increasingly difficult. For example, the identification of relationships among different biological entities, e.g., genes, proteins, diseases, drugs and chemicals, etc, is an important concern for biological researchers. While such information can be extracted from different types of biological data (e.g., gene and protein sequences, protein structures), a significant source of such knowledge is the biological textual research literature which is increasingly being made available as large-scale public-domain electronic databases (e.g., the Medline database). Automated extraction of such relationships (e.g., gene A *inhibits* protein B) from textual data can significantly enhance biological research productivity in several ways: by keeping researchers up-to-date with the state-of-the-art in their research domain, by helping them visualize biological pathways, and by generating likely new hypotheses concerning novel interactions, some of which may be good candidates for further biological research and validation (Palakal et al., 2005).

Examples of text mining applications include document classification, document clustering, concept extraction, information extraction and summarization. Using an ontology for document clustering has several advantages: it is possible to cluster documents written in several languages since concepts are *language-independent* and the use of concepts helps reduce the size of data, which, in turn, reduces processing time (Pham et al., 2007). Ontologies also offer a natural support to the extraction of semantic relations between entities. For example, the Genescene system utilizes an ontology-based approach to relation extraction by integrating the Gene Ontology, the Human Genome Nomenclature, and the UMLS (Leroy and Chen, 2005).

Ontologies offer a natural support to data mining in that they provide semantically sound classes to collect and organize data. One important principle behind the use of ontologies to represent the input data in data mining processes is that, by increasing the conceptual level of input data, one can also expect to obtain results at a higher conceptual level. This has been demonstrated in several papers. (Hotho et al., 2003) have shown that using ontologies as filters in term selection, prior to the application of the K-means clustering algorithm, increases the tightness and relative isolation of document clusters as a measure of improvement. Other examples can be found in a new book on data mining with ontologies that presents recent and ongoing research and industrial work in this domain (Nigro et al., 2007).

Text mining is also used in the construction and enrichment of ontologies (Mothe et al., 2007). The statistical analysis of texts of a domain may help exhibit clusters of terms that are candidate concepts for this domain (Karoui et al., 2006), and the discovery of relationships between such clusters of terms can evoke possible relationships between concepts. Although much work is done on the automation of ontology construction (Cimiano et al., 2005), the use of knowledge discovery in texts may help the ontology designer to identify concepts and structure them through IS_A and other relationships, in a semi-automatic way. Ontologos and Terminae are examples of such systems that use linguistic techniques to support the building of ontologies (Roche, 2003) (Biebow et al., 1999).

CONCLUSION

In this chapter, we have provided an overview of ontologies with the objective of helping people involved in Data Mining in the biological field to apprehend the possible contribution of ontologies to their discipline. We did not answer explicitly the question “What is an ontology” and this question is still open to debate. An ontology of ontologies would be needed to organize the various points of view on this question. The same problem arises concerning the term Knowledge Base, and the two notions are strongly related. We have shed some light on some aspects of ontologies that seem important to us. Some of these aspects would justify further developments and we have tried to provide references to major publications in the relevant fields.

Integration aspects are of vital importance in data mining as data from various sources can be used in the input data set. The principle of using an ontology to unify input data from different sources via the concepts of this ontology now appears obvious. However, its implementation with real and heterogeneous databases is not so simple and constitutes the matter of active research and technical work (Lenzerini, 2002). Database integration requires establishing mappings between the schemas of the constituent databases or between these schemas and a global schema built for that purpose and which reflects the conceptual structure of the ontology. Such mappings can be represented as SQL views but recent approaches use Description Logics to implement an ontology-based representation of them (Dejing et al., 2006). We can also note that integrating database schemas is a problem similar to that of integrating different ontologies on the same domain; this problem is known as ontology alignment (Euzenat et al., 2004).

Data mining aims at extracting knowledge from data, thus creating *a posteriori* knowledge, whereas ontologies provide *a priori* knowledge that can be used in the data mining process, as well at its start by providing semantically sound classes to collect and organize data, as at its end to represent the results. One key of the success of ontologies in many domains, including the biomedical field, is that they provide semantics of domain knowledge in a human as well as in a computer-readable form. Data mining techniques can also be used to help building ontologies from texts. Note that some concept-based terminology, e.g., wordnet, which is sometimes (improperly) considered as an ontology, could be used to process the input data by replacing words by low-level concepts of this ontology in the texts to be analyzed. This ontology represents *a priori* knowledge, while the ontology obtained through text mining constitutes *a posteriori* knowledge, and one expects the resulting ontology to provide a description of the domain at a higher conceptual level than the initial one.

We conclude by quoting the editors of a recent book, Data Mining with Ontologies (Nigro et al., 2007) where they recall that: “One of the most important and challenging problems in data mining is the definition of the prior knowledge: this can be originated from the process or the domain. This contextual information may help select the appropriate information, features or techniques, decrease the space of hypothesis, represent the output in a most comprehensible way and improve the whole process. Therefore we need a conceptual model to help represent this knowledge … As a result, ontological foundation is a precondition for efficient automated usage of knowledge discovery information”.

KEY TERMS

Data Mining: Data mining, also referred to as knowledge discovery in databases (KDD), is a process of finding new, interesting, previously unknown, potentially useful, and ultimately understandable patterns from very large volumes of data (Nigro et al., 2007)

Information Retrieval: Information Retrieval (IR) is concerned with the indexing and retrieval of information in documents. Although any kind of document can be indexed and searched for, IR has been first and mainly applied to texts. Active research is currently devoted to content-based indexing of other types of documents such as images, videos and audio content. Automatic indexing of texts relies on a thesaurus. Contemporary IR tends to use ontologies associated with multilingual terminologies in order to make the search less language-dependent (e.g., English documents can be returned for queries posed in French, provided they refer to the same concept).

Knowledge Base: The term "Knowledge Base" was first used in the seventies to designate a set of expert rules to be processed by an "inference engine" along with the " facts " that represent the current situation that the (expert) system is to identify though the chaining of expert rules. In modern systems, starting with frame-based systems, this operation is known as *instance classification*. The most recent KB systems, based upon Description Logics, also consider *concept classification*, which consists in ordering concepts through the subsumption (inclusion) relation.

Medical Classification: Medical classifications provide the terminology of the medical domain (or a part of it). There are more than 100 medical classifications currently in use, most of them being specific of a subdomain (e.g., brain) or oriented towards a specific usage (e.g., MeSH for bibliographical indexing).

Ontology: An ontology is a structured description of a domain under the form of concepts and relations between these concepts. The IS-A relationship provides a taxonomic skeleton while other relations reflect the semantics of the domain. Definitions (either formal or informal) can be associated with concepts, as well as terminological variants, possibly in different languages. Usual definitions are: "An ontology is a specification of conceptualization" (Gruber) and "An ontology describes the concepts and relationships that can exist and formalizes the terminology in a domain" (Gruninger & Lee)

Terminology: Terminology deals with terms definition and usage, in general or in a specific context (e.g., medical terminology). According to authors, the definition of terminology vary from the study of terms to the actual sets of terms of a domain, possibly structured, which brings terminological work near to ontological work. This closeness is illustrated by the neologism "ontoterminology" which has been proposed by C. Roche at the TOTh conference in 2007.

ENDNOTES

[1] The Ontology Web Language: http://www.w3.org/2004/OWL/

[2] This is not strictly true, as there are concepts that exist only in some culture and in a given language. However, in the scientific domain such an approximation is usually considered as valid.

Chapter 1.14

Quality of Health Information on the Internet

Kleopatra Alamantariotou
City University London, UK

ABSTRACT

Recent statistics show that the World Wide Web has now grown to over 100 million sites: a phenomenal expansion in only 15 years (Mulligan 2007). It has been estimated that there are 100,000 sites offering health related information (Wilson 2002). As the amount of health information increases, the public find it increasingly difficult to decide what to accept and what to reject (Burgess 2007). Searching for information on the internet is both deceptively easy and the same time frustratingly difficult (Kiley 2002). The challenge for consumers is to find high quality, relevant information as quickly as possible. There has been ongoing debate about the quality of information aimed at patients and the general public and opinions differ on how it can be improved (Stepperd 1999). The purpose of this chapter is to provide a brief overview of the different perspectives on information quality and to review the main criteria for assessing the quality of health information on the internet. Pointers are provided to enable both clinicians and patients find high quality information sources. An understanding of these issues should help health professionals and patients to make effective use of the internet. .

INTRODUCTION

> *Health information includes information for staying healthy, preventing and managing disease, and making other decisions related to health and health care. It includes information for making decisions about health products and health services. It may be in the form of data, text, audio, and/or video.* (Dzenowagis 2001)

The Internet provides a powerful tool for patients seeking medical information. It offers consumers access to a wealth of health and medical information that can enable them to take responsibility for their own health (Linkous 1999). Information is the communication or reception of knowledge. Such communication occurs in great part through the recording of knowledge (Taylor 2004). Some commentators predict that in the near future the Internet will be an important vehicle for delivering information and medical care. Tom Ferguson coined the term "e Patients" to define those people who were empowered to find medical answers for themselves, rather than rely on any single individual's opinion or interpretation. Virtual children's Hospital based the Internet's first medical Web site since 1993(Risk 2003).

The number of health related Web sites is rising with more 70,000 sites available to patients in 2000. A 2006 survey of 5,007 U.S. adults found that 84% of consumers claimed to have researched a health-related topic online in the past 12 months. (Fox 2006). Another survey reported that eighty percent of American Internet users (some 113 million adults) have searched for information on at least one of seventeen health topics. (Fox 2006). 75% of all adults on line (47% of all adults) use the Internet to look for health information. This amounts to 98 million adults nationwide. (David 2003). On average those who look for health information online do so on average 3.3 times every month(Fox 2006).

Faced with this explosion of online information the main challenge facing today's information consumer is how to find high quality information that meets their personal needs, within an acceptable time frame. But whilst everyone agrees that information quality is an important consideration, the concept of quality is problematic since in medicine there are often gray areas where the evidence-base is poor, making it difficult to determine a gold standard (Lewis 2005) Quality is an inherently subjective assessment, which depends on the type of the information needed, the type of the information searched for, and the particular qualities of the consumer (Wilson 2002). Experts believe that formal methods are needed to describe and assess information quality. Naumann maintains that "quality is the main discriminator of data and data sources on the Web" (Naumann 2001).

The paradox of quality as Robert Pirsing notes is the fact that "even though quality cannot be defined, you know what quality is" (Pirsing 1974). Although the typical consumer may be able to produce and define what quality means to them, each individual's perception of the quality of health information will vary depending upon their current circumstances and quality requirements (Burgess 2007).

A recurrent concern about online health information is that anyone is free to publish. Websites are set up by individuals, patient, charities, activist groups, commercial bodies either selling a product, as well as by health care professionals. The overwhelming majority of these resources are informal, quite often with no clinical input (Potts 2006).

RISKS POSED BY POOR QUALITY INFORMATION

It has never been easier for members of the public to access health information. In the twenty-first century it is taken for granted that patients may browse the Internet for the information about their condition, contact other patients by e-mail, send e-mails to their doctor or use touch screen kiosks in order to get health information (Jones et al 2005). But many believe there is a downside to this development. They fear that while the quantity of information has expanded exponentially, the same is not true for its quality. There is a concern in many professional groups about the potential harm associated with the use of poor quality health information. The quality of health information is of a particular concern because misinformation could be a matter of life and death (McClung 1998, Crocco 2002).

Harm in this context may be defined as adverse events or bad outcomes, either physical or emotional or financial, that occur from acting on materials or information and medication obtained from a Web site. On the other hand Crocco and collegues found only a few cases in the literature of harm associated with poor quality of health information on the Internet. In particular the authors report on a systematic review of peer-reviewed literature, to evaluate the number and characteristics, of reported cases of harm associated with the use of health information obtain on the Internet. (Crocco 2002).

In addition one way to demonstrate the amount of dubious health information online is to carry out a free text search using the phrase 'cancer cure'. The Web sites retrieved from this search contain cure-all remedies, based on scant or no medical evidence. At http://www.1cure4cancer.com for example, visitors are informed that Vitamin B17 kills cancer cells. The site fails to disclose the results of clinical trials into the effectiveness of this treatment. Ekman (2005) has investigated the prevalence and quality of interactive risk sites on the Internet. He found that the number of cancer risk sites increased by 50% between 2001-2002. Ekman's research study found that that the overall quality of the documentation on the cancer risk sites was poor. The majority of the cancer risk sites do not give reliable risks estimates. Similarly Lee et al (2003) found that thirty two percent of bladder cancer information sites contained inaccurate information. One critical problem was outdated data, rather than incurrent information.

Many of those searching for health information are looking for advice not about illness but ways of staying healthy or improving health. Furthermore disease information, material about weight control, and facts about prescription drugs top the lists of interests for health seekers. Many Website dealing with lifestyle choices and health are scams, particularly sites which shortcuts to weight loss and improvements in personal performance. Such sites frequently are devoid of scientific evidence, relying instead on anecdotes where personal experiences are presented as facts without references. Quite often sites with biased information only present one side of the argument. (Kiley 2003).

A longitudinal study (Pandolfini 2002). concluded that the quality of health information on the Internet had improved over the last 5 years. Nonetheless, the author concluded that people should continue to be alert as online information is not always accurate. In the absence of editorial controls, information may be of low quality and potentially harmful (Bower 1996). Poor interpretation of written information on medicines has been shown to lead to anxiety and poor compliancy to therapy. Therefore there is a need for promoting and educating consumer search and appraisal skills when using this information. For instance as Peterson(2003) indicated educating customer to find information on medicines may help them use their medicines in safer and more effective way(Peterson 2003).

There are various Internet sites which monitor health frauds and quackery. These are summarised in Table 1.

Table 1. Wesite monitoring health frauds and quackery

Quackwatch — http://www.quackwatch.com
- A member of Consumer Federation of America
- A nonprofit corporation whose purpose is to combat health-related frauds, myths, fads, fallacies, and misconduct.

National Council Against Health Fraud — http://www.ncahf.org
- A private, non-profit, voluntary health agency that focuses upon health misinformation, fraud and quackery as public health problems (NCAHF 2007).

Health Care Reality Checked and alternative medicine — http://www.hcrc.org
(Kiley 2003).

American Council on Science and Health (ACSH) — http://www.acsh.org
- A consumer education consortium concerned with issues related to food, nutrition, chemicals, pharmaceuticals, lifestyle, the environment and health
- An independent, nonprofit organization (ACSH 2003).

REVIEW OF INITIATIVES TO IMPROVE QUALITY OF HEALTH INFORMATION

The quality of health information on the Internet became a subject of interest to healthcare professionals and consumers groups in the mid-1990s (Gagliardi 2002). This concern is prompted by a desire to prevent of physical, mental, and emotional harm caused by wrong, misleading, inappropriate, false, information to member of the public who use the Internet to seek or receive health information, products, and services (Dzenowagis 2001).

There have been a host of initiatives aimed at establishing criteria for judging the quality of online health information. These have produced policy document, tools to assist the development, implementation and evaluation process and various methods to determine how well Web-sites comply with the standards(in which case they can display a kitemark). The hope is that if developers adhere to the quality criteria, end users will be able to readily identify reputable sites (Ekman 2005). The European Union has also drafted guidelines on quality criteria for health Websites. However, there is no international consensus for how to deal with the quality issue problem (Jadad 1998, Eysenbach 1998).

The organizations who have created guidelines for evaluating health related Websites include

- Health On the Net (HON)
- American Medical Association
- Internet Health Care
- Coalition Hi-Ethics
- MedCertain

None of these guidelines have been systematically applied to a broad set of Web pages and conditions. Furthermore little research has been conducted to empirical assess what a consumer might find while searching on Internet (Berland et al 2002).

In conclusion the emphasis of the responsibility for the future access and quality of health information is placed on the medical informatics leaders who must understand: medicine and information disciplines. Health professionals need to be able to direct patients of good quality health information included health related Websites (Shepperd 1999).

The Judge Health guidelines were developed in partnership between Contact a Family (a UK charity) and the Information Society Research and Consultancy Group at Northumbria University (www.northumbria.ac.uk/isrc).

In addition the Judge project, supported by the Health Foundation developed guidelines in order to judge the quality of health information Web sites. Two sets of guidelines were produced: (i) to help health consumers make informed choice about Web sites.(ii) to assist some support groups to produce good quality Web sites. These were made available via www.judgehealth.org.uk.

The guidelines comprise four sections:

i. How to produce good quality information;
ii. How to design good quality Web sites;
iii. How to market Web sites;
iv. How to help consumers use health information (Barnett 2006).

One of the more successful quality initiatives schemes has been developed by the Geneva based Health On Net Foundation (HON). The initiative is an expression of a self-regulatory mechanism. Self-regulation of the health Internet remains a powerful driver of the pursuit of quality standards for health information on the Internet (Dzenowagis 2001).

The HON code originally consisted of eight broad principles for medical Webmasters. Central to this code is the principle that any medical information must only be given by medically trained and qualified professionals. Where this condition cannot be met there must be clear confirmed that a piece of advice was given from a non-medically qualified individual or organization (HON 2007). To some extend other principles of the code are concerned with how clearly the source of both data and funding for a site can be determined. HON has stepwise taken a more active approach in actually "reviewing" and verifying applications. It is certain that sites displaying a HONcode are not necessary better than those do not comply with these criteria (Lewis 2005).

In 2002 the European commission published a communication called "quality Criteria for Health related Web site" based on a workshop in Brussels . The Quality criteria include Transparency and Honesty, Authority, Privacy and Data protection, Accountability, Responsible Up dating information, Editorial policy and accessibility (E-europe 2002).

According to (e-Europe 2002) quality criteria should address issues of both supplier and user education. In particular one document that simultaneously tell suppliers how to comply with key quality criteria and in order to educate users what to expect from a good health Web site. Needless to say that the quality criteria should address both passive information-giving sites as well as sites that allow for transactions between service or users and information providers.

Moreover the Health Summit Working Group selected defined and evaluated seven major criteria for assessing the health quality information: Credibility, content, disclosure, links, design, interactivity, and Caveats.

Criteria for Evaluating Internet Health Information (Health Summit Working Group H.S.W.G):

- **Credibility:** Includes the source, currency, relevance/utility, and editorial review process for the information. A site should display the name and logo of the institution or organization responsible for the information. Furthermore the date of the original information is based and the date that post on the Web.
- **Content:** Must be accurate and complete, and disclaimer provided. In particular clinical or scientific evidence that supports a position should be clear and understandable. Also a disclaimer describing the purpose and scope authority and currency of the information should be provided.
- **Disclosure:** Web sites is important to provide disclosure including the purpose of the Web site and the profile as result user can understand the intent of the organization or individual . In particular includes informing the user of the purpose of the site, as well as any profiling or collection of information associated with using the site.
- **Links:** Evaluated according to selection, architecture, content, and back linkages. Especially critical to the quality of an Internet Web site are its external resources and links connections to other Web sites that confirm the information that provided .
- **Design:** Encompasses accessibility, logical organization (navigability), and internal search capability. In particular the Web sites must be easy to use. The design including graphics, text and links is important in order to delivery and use of any Web information.
- **Interactivity:** Web sites should include a feedback mechanism for users in order to offer their comment, corrections, and criticisms, and as result raise questions about the information provide. This make the Web site accountable to its user and allowing information exchanged to many individuals.
- **Caveats:** Clarification of whether site function is to market products and services or is a primary information content provider (HSWG 1999).

In addition The eHealth Code of Ethics is developed as a set of guiding principles aimed at health Internet stakeholders worldwide. In January 2000, about 50 experts in providing health information on line attended the "e-health" summit on the ethics providing information on the Internet in Washington. The code of ethics addresses issues of quality, privacy security and confidentiality and commercial behaviour (Eysenbach 2004). The goal of the E-health code of ethics is to ensure that people can confidently and with full understanding of know risks realize the potential of the Internet in managing their own health (Dzenowagis 2001). In conclusion the e-health code of ethics places a border on other organization developing quality standards for Internet health information.

Hi-Ethics Code of Conduct consisted of 14 principles, and was developed by a group of leading for-profit consumer health information Web sites (Lewis 2005). Established on May 2000 current members is 15 companies and current membership fee are 6000 dollars. The rules developed are intended to assure that Internet health services reflect high quality criteria and ethical standards. Also health information is trustworthy and protected. Needless to say that consumers are able to distinguish on line health services that follow the Hi-Ethics principles from those that do not (Hi-Ethics 2007, Dzenowagis 2001). Sustainability of the Hi-Ethics Code of Conduct is Vulnerable to the burdens placed on member companies, citizens and the ability of Hi-Ethics to maintain the currency of the principles. (Dzenowagis 2001). Furthermore AMA code of America Medical Association (Winker 2000). The mission of AMA is to promote the art and science of medicine and the betterment of public health. Guidelines for Medical and health information site on the Internet and Principles Govern AMA Web sites has been established since 2000 by AMA. Providers are Web site of the American Medical Association Medem (www.medem.com) The development of guidelines begin in 1999 where health information on the Web are based on those that govern medical journals, including peer-review process, authorship, sponsorship and the principles of privacy and confidentiality (Dzenowagis 2001, AMA 2007). These are governance tools indended for use by the developers of AMA . Also other organizations have adopted these guidelines for use.

It is certain that all the sets of criteria derive from similar roots. These roots are the principles of privacy, honesty, confidentiality, currency, accuracy, prevalence, consent, disclose and accountability. Quality criteria for patients decision and health information are relevant to patients and health care professionals, health care services and policy makers, all of whom is necessary to be confident about the developing and testing quality tools that undergone before their release (Elwyn 2006). For instance factors affecting the quality of an information source, the issues associated with the accessibility of a resource, the overall design and layout of the information and the ease of using of materials are secondary to the content issues (Intute 2006). At that point that we may be able to understand and examine in more depth the goal of helping patients to have the best quality information in order to take the best health decisions.

Promoting quality criteria for health information means better health. The benefits and outcomes of using health information are many. According to David et al (2003) on line questionnaire produced by the British Life and Internet Project, a total of 93 per cent said that the information had helped in understanding more about an illness or injury and a relatively high 57 per cent of responders said that that the information found was sufficient for them to act upon to improve their health. Moreover a total 26 per cent said that the information found had affected their decision about whether to see a doctor. In conclusion what have we learned from quality of health information on Internet is that consensus is important, collaboration and dissemination are crucial. Furthermore the cost of implementation is too high, also user and provider indifference is real. Moreover citizens education is a difficult and important task. In addition quality criteria are not enough and technology and understanding need to be promoted. As result more research needs to be done on: poor quality and health outcomes, on consumers behaviour, and better international collaboration and dissemination(Risk 2003).

EXAMPLES OF TOOLS FOR ASSESSING THE QUALITY OF CONSUMER HEALTH INFORMATION

Several groups have developed interactive Internet tools to educate consumers. These tools help users to assess the quality themselves(Eysenbach 2004).A further application of the code of good conduct takes the form of a user guidance tool. In particular with a code is demonstrated not by a label, but by a link to a guidance tool which invites the user to check if a site comply the quality criteria. Such tools may be specific to a particular type of information, such as DISCERN **(**http://www.discern.org.uk/**)** where developed to assess the quality of health information on treatment choices (Charnock 1998, Charnock 1999) Areas covered are: bias in the material, a clear statement of aims, references and additional sources of support and information, uncertainty, risks and benefits (including those of opting for no treatment), and treatment options. Moreover DISCERN (http://discern.org.uk) provides a brief questionnaire through which users gain a valid and reliable way of assessing the quality of written information on treatment choices. Similarly NETSCORING which uses a questionnaire of 49 criteria falling into eight categories: credibility, content, links, design, interactivity, quantitative aspects, ethics, and accessibility (e-Europe 2002). In conclusion another user guidance system is QUICK (www.quick.org) where provides children with a step by step guide to assessing health related information on Internet (Eysenbach 2002).

The Health Information Quality Assessment Tool **(hitiWeb.mitretek.org/iq)** — the Health Summit Working Group in North America (hitiWeb.mitretek.org/hswg) is currently developing a reliable and valid appraisal tool for users of health information on the Internet (Mitretek 1999). The main areas currently covered are credibility, content, disclosure, links, design, interactivity, and caveats (information on the function of the site). When looking for health information most Internet users start with a generic search engine. Very few check the source and date of the information they find (Fox 2006).

HEALTH WEBSITES AND SEARCH ENGINES

Health information can be extremely useful, empowering us to make important health decisions. Given the wealthy of information available through the Internet and other sources it is important to be able to assess its quality. This can be difficult because health information is constantly changing.

Web sites should provide clear and conspicuous notice of their information practices. It was thought that the greater the number of sites visited, the greater the like hood of a healthy behavior outcome. This based on an information model that argues that not all sites will present the information in the same way and design. Users benefit from collecting information from a number of sites. In particular they find it easier to collect the information and because jumping from site to site means that users can compare the information and become more knowledgeable (David 2003).

Below we provided some searchable catalogues to good quality health Web sites .

EXAMPLES OF HIGH QUALITY HEALTH WEB SITES

NHS Direct on line (http://www.nhsdirect.nhs.uk**):** The forefront of 24 hour health care delivery telephone and e-health information services during day and night. Provide information and advice about health and based in United Kingdom.

Healthfinder (http://www.healthfinder.gov/**):** Is a gateway consumer health information Web site whose goal is to improve consumer access to selected health information from a government agencies. The developer and sponsor of this site is the office of Disease Prevention and Health Promotion.

In particular is a US government site that provides access to health information from a range of sources, including government agencies and professionals organizations.

HON Health on Net Foundation (http://www.hon.ch/**):** An international not profit organization. It provides a databases of evaluation health materials and also provides the use of the HON Code and help unify the quality of medical and health information available.

MEDLINE PLUS (http://www.nlm.nih.gov/medlineplus**):** Is the National Library of Medicine, and part of National institute of Health. Provides access to a wide range of databases and health related organizations.

Patient UK (http://www.patient.co.uk**):** Designed to direct non-medical people in the United Kingdom to information about health related issue.

Organising Medical Networked Information (OMNI) (http://www.omni.ac.uk**):** OMNI provides access to good quality biomedical and health information Websites worldwide. It has been developed for medical professionals first and it based at the university of Nottingham in United Kingdom.

Provide good quality biomedical and health information by the Internet worldwide.

HealthWeb (http://healthWeb.org): Is a site established by librarians and information professionals from major academic medical institution in the Midwest. The site also provides "user Guides" developed to help consumers use Internet resources more effectively.

National Electronic Library for Health (NeLH) (http://www.nelh.nhs.uk**):** Extend Nhs library service to patient and the public. Provide easy access to health information and to the best current knowledge.

HebsWeb Health education Board of Scotland (http://www.hebs.scot.nhs.uk**):** The Web site for the Health Education Board of Scotland. In particular the site provide access to a wide range of consumer health information resources.

NOAH: New York Online Access to Health (http//:www.noah-health.org/**):** Is a unique collection of state local, and federal health resources for consumers. NOAH'S mission is to provide hifh quality, full term information for consumers, timely and relevant.

National Institutes of Health (http://www.nih.gov/health/consumer**):** Provides access to database of consumer health information published by the US National Institute of Health.

NHS in England (http://www.nhs.uk/**):** Health Web site is based in England, in particular is giving straightforward information presented in words, pictures video and audio about health living.

Best Treatments (http://www.besttreatments.co.uk/**):** In association with BMJ(British Medical Journal clinical evidence is a Web site for patients and doctors. In particular is providing the best research evidence about the treatments for many medical conditions.

Medem (http://medem.com): A new site launched in the fall of 2000, is a project of the leading medical societies in the United States. The site was developed to provide a trust online source for credible, comprehensive, and clinical healthcare information secure and confidential.

National Women's Health Information center (http://www.4women.gov/**):** Is gateway to selected women's health information resources. Its purpose to provide information about prevention, diagnosis and treatment of the illnesses and health conditions that affect them. Is sponsored by the U.S public Health Services office on women's Health.

IPEX (http://www.dipex.org**):** Is a Web site based in Oxford in England. Has a wide variety of personal experience of health and illness. People talking about their experience of illness and health issues.

Diabetes123 (http://www.Diabetes123.com/**):** Is an organization whose mission is give information in online diabetes care, improving quality and reducing the cost of care by increasing the understanding of providing traditional products and services for the treatment of diabetes.

Contact a family (http://www.cafamily.org.uk**):** Is the only United Kingdom wide charity providing advice, information and support to the parents of all disabled children. Also parents can get in contact with other families both on a local and national basis.

StartHere (http://www.starthere.org/bigpage1.htm**):** Offer a variable service to citizens, providing useful information across a broad range of health topics.

EQUIP (Electronic Quality Information for Patients) (http://www.equip.nhs.uk/index.html#top**):** The Web site is based in west Midlands region NHS England and offer a variable links health Web sites. It was created in response to government requirements for improvements in information available to patients.

Health Education Board Scotland (http://www.healthscotland.com/**):** Is a National agency for health improvement from gathering evidence, to planning delivery and evaluation of a range of health topics and life stages.

Clinical Evidence (http://www.clinicalevidence.com**):** Is a new kind of decision support resource. BMJ clinical evidence systematic reviews summarise the current state of knowledge and uncertainty about the prevention and treatment of clinical conditions, based on searches and appraisal of the literature.

PathCAL (http://www.pathcal.ac.uk/**):** Is a set of 129 Web-based tutorials in order to help students understand the basic pathological principles of disease exploiting techniques in learning psychology

National Patient Safety Foundation (NPSF) (http://www.npsf.org/**)**/(www.centreforhig.demon.co.uk**):** Is a central resource in order to facilitated the production and dissemination of high quality patient information for health services users. The trust provides information as part of the health information services and NHS direct include large library information and databases.

Center of Disease Control and prevention(http://www.cdc.gov/**):** An agency of the department of Health and Human services is dedicated to promoting health quality of life by preventing and controlling disease, there are also sections on health topics in the news and health hoaxes (Williamson 2006, Killey 2003, Childs 2003, Shepperd 1999, Fox 2002).

SEARCH ENGINES

According to Fox(2002) A typical health seeker goes on line to see what can find without getting advice about where or how to search from anyone including medical professionals or friends.

You can use some search engines if you can not find what you need from the gateways. Here are some examples of search engines.

- **Google** (http://www.google.co.uk)
- **AlltheWeb** (http://www.alltheWeb.com)
- **Yahoo** (http://www.yahoo.com)
- **MedHunt** (http://www.hon.ch/MedHunt)
- **Mirago** (http://www.mirago.co.uk)
- **Excite** (http://www.Excite.com)
- **Allsearchengines.com** (http://www.Allsearchengines.com)
- **Medstory** (http://www.medstory.com)

LEARNING HOW TO SEARCH

There are free on line tutorials by organizations or libraries. Here are some sites that provide free on line tutorial in order to develop Internet skills:

- The online Netskills Interactive Course (TONIC) Since 1995 Netskills has delivered high quality professional training services to the education public in the UK and beyond (http://www.netskills.ac.uk/onlinecourses/tonic/).
- Resource Discovery Network (RDN) Virtual Training Suite (http://www.rts.rdn.ac.uk) or http://www.intute.ac.uk is a free on line service providing you with access to the very best Web resources for education and research. In particular the service is created by a networked of UK universities and partners. The databases characterized of high quality information.
- Quality information checklist: www.quick.org.uk/menu.htm provides children with a step by step guide to assessing health related information on the Internet.
- DISCERN www.discern.org.uk is a brief questionnaire for users to validate information or treatment choice. (Childs 2003).

CONCLUSION

Health information has been variously described as the foundation for better health. The complexity of the issues surrounding quality of health information in the context of the health Internet has been shown (Dzenowagis 2001).

On demand side, there are different users of information. The usual position searching for information based on quality is to find the best available item that meet patient needs (Burgess 2007). The existence of the pseudo-health segment of information producers and users complicates efforts to introduce quality standards for health information on the Internet. Trustworthy health information from well known source on the Internet needed for the growing user population (Ekman 2005). Qualitative data are needed to design educational and technological innovations to guide consumers to high quality information (Eysenbach 2002).

Since no international consensus for quality criteria exists has as impact the responsibility falls on the medical organizations institutions and societies. It is important that organizations such as medical universities and governmental agencies to provide trustworthy high quality health information on Internet (e-Europe 2002) Experts from around the world will be invited to share their knowledge and experience. The international partnership for health informatics education(IPHIE) dares from 1999 and seeks to maintain, improve and promote medical and health informatics training and education through international collaboration(Murphy 2007).

It is now to be expected that national and regional health authorities, and private medical Web sites owners will implement the quality criteria and to develop information campaigns to educate site developer and citizens about minimum quality standards for health related Web sites.

KEY TERMS AND DEFINITIONS

Consumer Health Informatics: Consumer health informatics is the branch of medical informatics that analyses consumers' needs for information; studies and implements methods of making information accessible to consumers; and models and integrates consumers' preferences into medical information systems. Consumer informatics stands at the crossroads of other disciplines, such as nursing informatics, public health, health promotion, health education, library science, and communication science, and is perhaps the most challenging and rapidly expanding field in medical informatics; it is paving the way for health care in the information age.

Health Information: Health information is required for a wide variety of purposes, including building knowledge and understanding of health conditions; helping people to decide when they need to seek specialist help; supporting choices in relation to treatment, management or social care options; identifying, choosing and accessing appropriate healthcare providers; and educating patients and the public about public health risks and about primary and secondary prevention.

Internet: The Internet is a world wide, publicly accessible series of interconnected computer networks that transmit data by packet switching using the standard Internet protocol (IP). It is a "network of networks" that consists of millions of smaller domestic, academic, business, and government networks, which together carry various information and services, such as electronic mail, online chat, file transfer, and the interlinked Web pages and other resources of the World Wide Web (WWW).

Quality: Quality is an inherently subjective assessment, which depends on the type of the information needed, the type of the information searched for, and the particular qualities of the consumer. Experts believe that formal methods are needed to describe and assess information quality.

Chapter 1.15

Improving Data Quality in Health Care

Karolyn Kerr
Simpl, New Zealand

Tony Norris
Massey University, New Zealand

INTRODUCTION

The increasingly information intensive nature of health care demands a proactive and strategic approach to data quality to ensure the right information is available to the right person at the right time in the right format. The approach must also encompass the rights of the patient to have their health data protected and used in an ethical way. This article describes the principles to establish good practice and overcome practical barriers that define and control data quality in health data collections and the mechanisms and frameworks that can be developed to achieve and sustain quality. The experience of a national health data quality project in New Zealand is used to illustrate the issues.

DOI: 10.4018/978-1-60566-026-4.ch295

BACKGROUND

Tayi and Ballou (1998) define data as "the raw material for the information age." English (1999) builds on the idea of information as being data in context, with knowledge being information in context, where you know the significance of the information. Translating information into knowledge requires experience and reflection.

Klein and Rossin (1999) note there is no *single* definition of data quality accepted by researchers and those working in the discipline. Data quality takes a consumer-focused view (consumers being people or groups who have experience in using organisational data to make business decisions) that quality data are "data that are fit for use" (Loshin, 2001; Redman, 2001; Wang, Strong, & Guarascio, 1996). Data quality is 'contextual'; the user defines what is good data quality for each proposed use of the data, within its context of use (Pringle, Wilson, & Grol, 2002; Strong, Lee, & Wang, 1997). Therefore:

Data are of high quality if they are fit for their intended uses in operations, decision-making, and planning. Data are fit for use if they are free of defects and possess desired features (Redman, 2001).

Data quality is now emerging as a discipline, with specific research programmes underway within universities, the most significant being that of the Sloan School of Management Information Quality Programme at the Massachusetts Institute of Technology (MIT)[1]. The field is based upon the well-established Quality Discipline, drawing on the work of Deming (1982) and the adaptation of the "*plan-do-check-ac*" cycle (the Deming Cycle). It also draws upon the "*quality is free*" concept of Crosby (1980) arising from the notion that doing things wrong is costly, and imports the ideas behind the Six Sigma approach and Total Quality Management (Juran & Godfrey, 1999) adapted to Total Data Quality Management (TDQM) and the management of information as a product (Wang, Lee, Pipino, & Strong, 1998).

The research programmes are developing ways to combine TDQM with the strategic direction of the organization, aligning the data quality requirements with overall goals. At present, there is little research published in this area, although some organizations do have data quality programmes with some strategic alignment to the business requirements.

Data quality is also becoming an increasingly important issue for health care providers, managers and government departments. The movement towards total quality management in health care to improve patient safety and health care efficiency is demanding high quality information. Further, evidenced based care requires the assimilation of large amounts of relevant and reliable research data available at the point of clinical decision making. Strategic prevention, national consistency of improvement practices, evolving data standards, and targeted improvements with increasing consumer involvement are all moving health care towards a TDQM model of data quality management.

Using the TDQM model, many of the methods developed in other industries can be useful for improving health care data. However, health data differ from data that arise in other fields in several ways. For example, the complex and multidisciplinary nature of medicine means that, unlike other sciences, health care data have no internationally standardized terminologies. This lack of standardization produces many homonyms, where the same term can mean different things depending on context, and synonyms, where there are several ways of expressing the same meaning. Added to these sources of ambiguity is the plethora of healthcare abbreviations which have no agreed format. The required longevity, privacy, and confidentiality concerns associated with health data are also distinguishing characteristics. Combine these inherent features with the need to share and integrate the data across distributed and disparate entities such as the Ministry or Department of Health, regional health boards, hospitals, general practices, and individual specialists, and it is hardly surprising that the improvement of healthcare data quality is multifaceted and more involved than in many other domains.

THE DEVELOPMENT OF A DATA QUALITY EVALUATION FRAMEWORK

A common imperative in the health sector is the need to structure and improve the management of data quality within regional or national health data collections that aggregate patient health data and use the combined data for epidemiological and service planning purposes. Clinicians and managers recognize the need for assessment tools that indicate the level of data quality, identify where the problems are, and who should be accountable. This information can then be used to construct a strategy for quality improvement. This was recently the situation in New Zealand where previous work to develop the Ministry of Health information systems strategic plan, and a current state analysis of data quality, provided further support for the commencement of a programme of data quality improvement.

The starting point for any Data Quality Evaluation Framework (DQEF) in the health sector is the pioneering work of the Canadian Institute for Health Information (CIHI) (2003a, 2003b) The CIHI has developed a comprehensive data quality framework based on a hierarchy of quality attributes ranging from criteria at the base level that are grouped into characteristics, and then further reduced into a small number of high-level dimensions[2]. The CIHI framework is of course developed for Canadian conditions and must be adapted for local circumstances to ensure applicability. This can be done by engaging data custodians and stakeholders in an iterative sequence of focus group, interviews, and discussions that modify the data attributes at each level to reflect existing organizational structures and practice. The iterative process is most readily facilitated by action research using grounded theory (Strauss & Corbin, 1998) to structure the analysis of qualitative data through inductive coding and comparison.

In the New Zealand project, for example, analysis confirmed the utility of the Canadian quality dimensions of accuracy, relevancy, timeliness, usability, and comparability, but found it necessary to add a dimension of privacy and security to ensure that this aspect is explicitly managed to meet New Zealander's expectations for national data collections. The project also revealed that New Zealand's unique patient identifier, the National Health Index (NHI), is a powerful tool for the location of poor quality (e.g., redundant or incorrect) database entries.

The New Zealand project also revealed the advantages of the action research approach. Discussion and feedback, coupled with rigorous analysis, raises awareness of the importance of data quality, an issue which is frequently underrated at all levels by data users and managers. The approach similarly creates a common understanding of terminology and recognition of the importance that quality improvement is an ongoing venture needing continued support and clear lines of accountability. Thus, in developing and applying a data quality evaluation framework, it is important to:

- define the underpinning data quality criteria carefully involving all stakeholders to ensure common understanding and direction;
- consider the critical quality dimensions that reflect how the organization uses data and how data flow throughout the business processes;
- document business processes identifying data sources and their reliability;
- appreciate that the framework requires practical supporting tools, for example, documentation, to make it effective;
- customize the language of user guidelines or manuals with regard to the level and experience of the intended users;
- be aware of the importance of both education and training at all necessary stages and levels – training is essential to affect the culture change that must accompany the realization of the importance of data quality; and
- be aware that application of the framework is an iterative, on-going process – the required outcomes cannot be achieved in a single-pass.

THE DEVELOPMENT OF A DATA QUALITY IMPROVEMENT STRATEGY

Porter (1991) states that the function of a strategy is to integrate the activities of diverse functional departments to ensure consistency within an organization with explicit, reinforcing goals and policies when senior management cannot participate or monitor all decisions directly. It will be apparent from the above discussion that a Data Quality Evaluation Framework will not, by itself, automatically lead to required improvements and that a strategy, as defined by Porter, is critical to its successful implementation. Robson (1997) also notes that a successful strategy "exploits opportunities and fits the circumstances at the time" with a requirement, therefore, to undertake a systematic, skillful, accurate and realistic assessment of the opportunities and to re-evaluate them. The design and execution of a Data Quality Improvement Strategy (DQIS) in health care therefore begins with a current state analysis followed by an assessment of the capability and maturity of the relevant health care organizations to effect the necessary improvements and understand the implications. Benchmarking against international organizations and other business sectors also helps to root the strategy so that it identifies local priorities and exploits current capabilities.

As is typical of many health systems at the present time, an extensive analysis of practices in New Zealand found that data quality management is entirely initiated through "bottom up" processes, in general through information services or information technology teams. Management has not yet taken responsibility, and indeed does not understand their role in the data quality process. Data quality improvement tends to occur when staff become frustrated with their inability to use the data for its intended purpose and there is no one else in the organization responsible for overall data quality management. This bottom up approach introduces silos of data quality improvements that can lead to even more quality issues by increasing discrepancies and producing conflicting reports from the same source. The New Zealand analysis shows that this situation is evident in all types of health sector organizations. It confirms that TDQM and the strategic management of data quality are relatively new phenomena, still rarely found across organizations in either New Zealand or overseas. New Zealand health care is certainly not lagging behind in the management of data quality but its political system, national public sector provision, structured assessment tool, and the NHI suggest that it has the infrastructure and capability to become a world leader in the implementation of a strategic data quality programme based on TDQM principles.

The New Zealand DQIS thus provides the Ministry of Health and the sector with detailed guidelines on how to develop and implement TDQM at all levels of the health sector. Roles and responsibilities are clearly defined, along with data ownership. A series of projects provides the required development for "business as usual" initiatives that institutionalize data quality into every day practice and make use of existing sector knowledge through the development and dissemination of best practice guidelines. For a data quality improvement strategy, it is important therefore to:

- derive and impose standards that facilitate data and information transfer whilst preserving quality;
- re-engineer the business processes to deliver the quality data needed for efficient service planning and the effective practice of integrated patient care;
- identify and disseminate best practice to reduce the development time needed to improve data quality;
- ensure data quality levels are not unnecessarily rigorous to maintain user ownership and workloads at reasonable levels;
- define user accountabilities for data quality and the mechanisms to enforce them; and

- seek to embed the search for data quality in normal working practices and recognize its achievement in appropriate ways such as accreditation.

As these requirements suggest, the strategic management of data quality requires wide ranging skills from practitioners with experience in many different areas. The challenge is, therefore, to encourage these practitioners to develop an interest and ownership in data quality and then to undertake further study to apply their skills to the development of the necessary strategic programmes.

There is considerable theory available in disciplines outside of data quality to support the New Zealand findings that organization wide teams enhance the learning and innovation of those who participate leading to improvements throughout the organization as a whole. Encouraging staff to develop solutions themselves helps to institutionalize data quality in the organization, through the development of emergent strategy. Data quality practitioners are empowered to implement "business as usual" initiatives that they themselves believe work. This emergent strategy is guided by the overarching organizational or national strategy that provides the simple rules that encourage the seeds of innovation and maintain momentum towards the defined vision.

Whilst comparison with data quality initiatives in other sectors is important, the development of a data quality framework and strategy for health care must always recognize the inherent complexity of the "business" of health. Plsek and Greenhalgh (2001) introduce the science of Complex Adaptive Systems (CAS) to help understand and bring about change in the health care environment. A complex system is defined as "a system with many independent agents, each of which can interact with others" (Penchas, 2003), that can behave very sensitively and be influenced by small initial differences (Champagne, 2002). Health care systems are just such systems creating complex adaptive interactions that contain emergent learning and change potential (Penchas, 2003).

In summary, the management and improvement of data quality in health care relies on an action research approach through collaborative groups to understand the relevant issues, an organization wide data quality team to develop the maturity capability of the organization, and an awareness of the inherent complexity of health care that demands multidisciplinary solutions to multidisciplinary problems.

CONCLUSION AND FUTURE DIRECTIONS

The development of a Data Quality Evaluation Framework and a Data Quality Improvement Strategy as described in this article provide clear direction for a holistic and "whole of health sector" way of viewing data quality, enabling organizations to implement local innovations through locally developed strategies and data quality improvement programmes. Simple rules, such as the TDQM process and the data quality dimensions guide the change, leaving room for innovation. With these essential features in place, practitioners can use a range of other devices to embed data quality awareness and accountability in normal practice and facilitate further change.

For example, experience in using the DQEF and the benefits of better data quality information will help to generate appropriate data quality metrics. Suitable metrics are paramount to the success of the DQEF and to provide data suppliers with applicable key performance indicators for expected levels of data quality. The New Zealand research referred to provided an embryonic methodology for metrics development via its ethnicity data collections but the methodology needs further refinement and validation through empirical testing.

Organizationally, data quality practitioners should have a pivotal role in the development and implementation of new systems, including ongoing training of data collection staff on the impact of errors and the downstream uses of the data. Further, the importance of data quality, and the staff who work in this area, needs to be recognized by management teams. Recruitment of staff should include those with the skills of strategic thinking and analysis. Providing such a team with a structured programme of data quality management, with clear roles and responsibilities for the organization to manage their data from a whole of system view, will enable data quality practitioners to concentrate on improvement initiatives.

Other valuable approaches include change management theories such as appreciative enquiry (Fry, 2002), which can help to encourage the utilization of existing organizational knowledge and enact change with a minimum period of diminished performance (Elrod, 2002). The theory of "complex systems of adjustment" (Champagne, 2002; Stacey, 1993) can be instilled in the organization to encourage change through the constant interaction of people throughout the organization. Champagne (2002) notes the similarities between complexity and learning theories. Both see change in a global, integrated way as forming part of the routine life of organizations, with the change process a collective one.

This research that underpins this article was undertaken in New Zealand, but the many similarities between international health care systems and the correspondence in data quality capabilities suggest strongly that the results are generally applicable. This raises the possibility of external benchmarking (Hamel & Prahalad, 1994) between international healthcare organizations to compare performance, develop best practice, and identify key challenges. Even so, the health sector environment has some way to go before reaching second and third generation data quality management as discussed by Redman (2001). Continued research into the prevention of poor quality data through process management could lead to a health sector where all data quality is managed through prevention rather than "find and fix." This may be a difficult, even elusive, goal but its pursuit will bring benefits to all citizens.

KEY TERMS AND DEFINITIONS

Complex Adaptive System: A system with many independent agents, each of which can interact with others.

Data Quality Dimensions: Quality properties or attributes of data; a set of data quality attributes that most data consumers react to in a fairly consistent way.

Data Quality Framework: A tool for the assessment of data quality within an organization; a vehicle that an organization can use to define a model of its data environment, identify relevant data quality attributes, analyse data quality attributes in their current or future context, and provide guidance for data quality improvement.

Data Quality Improvement Strategy: A cluster of decisions centered on organizational data quality goals that determine the data processes to improve, solutions to implement, and people to engage.

Datum: A fact or value assigned to a variable; single observational point that characterises a relationship. Data is the plural noun of datum

Emergent Strategy: A series of actions converges into patterns that become deliberate when the pattern is recognized and legitimized by senior management.

Grounded Theory: A method of extracting meaning and theories from data by systematically and intensively analysing and coding the data, sentence-by-sentence, or phrase-by-phrase.

Total Data Quality Management: An approach that manages data proactively as the outcome of a process, a valuable asset rather than the traditional view of data as an incidental by-product.

ENDNOTES

Chapter 1.16

Literature Review in Computational Linguistics Issues in the Developing Field of Consumer Informatics:

Finding the Right Information for Consumer's Health Information Need

Ki Jung Lee
Drexel University, USA

ABSTRACT

With the increased use of Internet, a large number of consumers first consult on line resources for their healthcare decisions. The problem of the existing information structure primarily lies in the fact that the vocabulary used in consumer queries is intrinsically different from the vocabulary represented in medical literature. Consequently, the medical information retrieval often provides poor search results. Since consumers make medical decisions based on the search results, building an effective information retrieval system becomes an essential issue. By reviewing the foundational concepts and application components of medical information retrieval, this paper will contribute to a body of research that seeks appropriate answers to a question like "How can we design a medical information retrieval system that can satisfy consumer's information needs?"

DOI: 10.4018/978-1-59904-990-8.ch043

INTRODUCTION

The Internet functions as a family physician as more and more people seek medical information on line and make subsequent healthcare decisions based on the acquired medical information. Consequently, one of the perspectives in biomedical informatics defended by the statistics of (1) significant increase in the prevalence of Internet, (2) increased concern of healthcare among general population, and (3) sheer growth in the number of medical literature available in public concentrates on the use of biomedical information by consumers. Denoted as consumer informatics, this emerging perspective focuses on the consumer's information need, access to the information, and modeling their information need for system integration (Haux, 1997; Lange, 1996; Logana & Tse, 2007; Nelson & Ball, 2004; Soergel, Tse, & Slaughter, 2004; Warner, 1995). However, simple statistics does not secure it as a robust academic discipline since the significance of healthcare information is rather determined by what's in the information and how the information can be used in addition to how users acquire the information. The core problem, in addressing this matter, is the discrepancy between user vocabulary, used by a "lay person", and professional vocabulary used by clinical professionals. While consumers search medical information on the Internet using their everyday terms, medical literature on the Internet is represented in professional terms. Consequently, key words in consumers' queries do not match the medical key words in medical documents (or match the wrong ones). This can cause a significant problem since misinformed healthcare decision is directly related to consumer's health issues. In the field of consumer informatics, therefore, a trend of research has burgeoned in designing the map that can translate (in effect "mapping" one vocabulary to another) consumer vocabulary to professional vocabulary.

The objective of this paper is to discuss concepts of consumer health vocabulary and review research endeavors to reduce the gap between consumer vocabulary and professional vocabulary. Primarily, it aims at examining current methodological approaches to map consumer vocabulary to professional vocabulary, critically reviewing them, and suggesting expanded perspective. With this literature review, researchers in the field of consumer informatics will be able to set a basis for further exploration of healthcare information system design. In addition, concepts and methods regarding vocabulary mapping reviewed here will provide the researchers with critical viewpoints to approach methodological problems and help them identify and gain insights into the system design to reduce discrepancy between consumer information need and medical domain knowledge.

The rest of the paper is structured as follows: Background concept section discusses conceptual background of consumer healthcare vocabulary and how it can be explored and developed to better facilitate links between consumer information needs and medical domain knowledge. In related work section, research studies that contribute to practical solutions of mapping consumer terms to professional terms are reviewed and analyzed. In discussion section, along with critiques for current studies, different perspectives to approach the problem are discussed. The discussion includes a brief review of semantic approach to design consumer vocabulary. Lastly, conclusion section concludes this paper.

BACKGROUND CONCEPT: CONSUMER VOCABULARY

In this section, the concept of consumer health vocabulary is discussed. The definition of consumer health vocabulary, current issues of consumer health vocabulary, and the problems of consumer health vocabulary in regards to information retrieval system are main topics of discussion in this section.

Consumer health vocabulary is a set of terms that is used by the general population when they refer to specific healthcare information needs. In a more practical sense, Zeng and Tse (2006) conceptualize it as a "combination of everyday language, technical terms (with or without knowledge of the underlying concepts), and various explanatory models, all influenced by psychosocial and cultural variations, in discourses about health topics" (p. 24). This definition implies a few major points in understanding the concept of consumer health vocabulary. First, there is a gap between consumer vocabulary and technical vocabulary, not only in lexical collections but also in the conceptualization of the overlapping vocabulary; and second, interpretation of the same term can vary among consumers with different experiences and cultural background.

A series of research studies shows examples of consumer vocabulary issues in particular healthcare situations; Chapman, Abraham, Jenkins, and Fallowfield (2003), in a cancer consultation situation, report that about half the participants in their survey study understood expressions for the "metastatic spread of cancer", e.g., 'seedlings' and 'spots in the liver'. While 63 percent correctly identified that the term 'metastasis' meant that the cancer was spreading, only 52 percent understood that the phrase 'the tumor is progressing' has a negative implication. Lerner and colleagues (2000), in the emergency department situation, describe that patients have limited understanding of medical terms. In their study, the participants were asked to answer whether 6 pairs of terms had the same or different meaning. Individual score was measured based on the number of right answers. The mean number of correct responses was 2.8 (SD = 1.2). Among the incorrect answers, the proportion of patients that did not recognize analogous terms was 79 percent for bleeding versus hemorrhage, 78 percent for broken versus fractured bone, 74 percent for heart attack versus myocardial infarction, and 38 percent for stitches versus sutures. Non-analogous terms were not also correctly recognized; 37 percent for diarrhea versus loose stools, and 10 percent for cast versus splint. Although the situation varied their studies share a common theme of problem addressing that communication between patients and doctors is not well-facilitated due to the language barrier. It is more serious in a situation where a patient does not have a medical professional to interact with, i.e., on line medical search. Making medical decision without proper information can cause a serious danger to patients. Therefore, a system that can virtually aid patients with searching for what they really want is required.

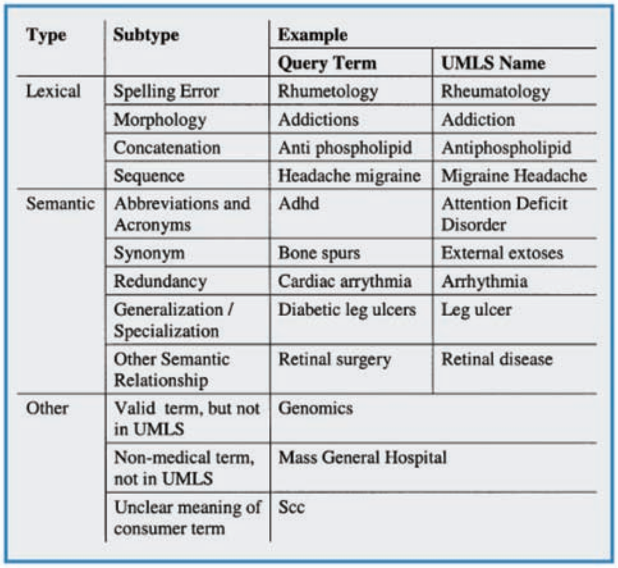
A translation mechanism can be embedded in current medical information retrieval systems so that consumers can search for what they need using their own vocabulary. Since conventional mechanism of best match information retrieval depends intensively on exact matching between user query (i.e., representation of user's information need) and pre-designed information structure of system (i.e., representation of stored texts), mapping consumer vocabulary to professional vocabulary (i.e., system vocabulary) will provide a method to reduce the communication gap. Therefore, the "development of a consumer vocabulary should be based on research that includes consumer information needs and consumers' ways of talking about and expressing those needs" (Lewis, Brennan, McCray, Tuttle, & Bachman, 2001, p. 1530), i.e., representation of consumer needs reflecting cultural context or specification.

RELATED WORK: DESIGNING A COMMUNICATION MAP BETWEEN CONSUMERS AND PROFESSIONALS

A growing number of studies identify that interterritory communication between consumers and healthcare professionals sustain a serious language barrier in terms of understanding terms and concepts. In attempting to overcome the roadblock, researchers design methods to offer links between consumer vocabulary and professional vocabulary. In this section, research studies that contribute to methodological approach of mapping consumer terms to professional terms are reviewed and analyzed.

McCray and colleagues (1999) use UMLS (Unified Medical Language System) Knowledge source server to map user queries put to National Library of Medicine Web site. They report that 41 percent of the 225,164 unique, normalized queries mapped successfully to the UMLS Metathesaurus. Mapped terms were mostly corresponding to

Figure 1. Classification of mismatches between consumer terms and UMLS (Q. T. Zeng et al., 2002)



Type	Subtype	Example	
		Query Term	UMLS Name
Lexical	Spelling Error	Rhumetology	Rheumatology
	Morphology	Addictions	Addiction
	Concatenation	Anti phospholipid	Antiphospholipid
	Sequence	Headache migraine	Migraine Headache
Semantic	Abbreviations and Acronyms	Adhd	Attention Deficit Disorder
	Synonym	Bone spurs	External extoses
	Redundancy	Cardiac arrythmia	Arrhythmia
	Generalization / Specialization	Diabetic leg ulcers	Leg ulcer
	Other Semantic Relationship	Retinal surgery	Retinal disease
Other	Valid term, but not in UMLS	Genomics	
	Non-medical term, not in UMLS	Mass General Hospital	
	Unclear meaning of consumer term	Scc	

concepts of diseases, other types of disorders, and drugs. According to their analysis, term mismatch was caused mainly by user query formulation. In other words, they noticed that user queries are in very specific level that their database may not contain or may only provide indirect information. Moreover, user queries with partial words or abbreviations which are not represented in UMLS were not also efficiently matched. The authors also identify that query length was not sufficient to fully represent consumers' information needs.

Zeng and colleagues (2002) also use UMLS function of conceptual analysis. They collected free text query terms entered into the "clinical interests" section of the Find-a-Doctor function of the Brigham and Women's hospital Web site and free text query terms entered in the MEDLINEplus site. The collected consumer terms were mapped to the UMLS 2000 edition, containing a set of concepts from various vocabularies such as MeSH, ICD-9, and SNOMED. Exact matching method resulted in mapping rate of 49 percent for the unique Find-a-Doctor query terms and 45 percent for the MEDLINEplus unique query terms to UMLS concepts. They identified unmapped terms and classified them into 12 different categories (Figure 1). The categories include spelling error, morphology, concatenation, sequence, abbreviations, synonym, redundancy, generalization, other semantic relationships, valid term not in UMLS, invalid term not in UMLS, and unclear meaning of consumer term. Among them, they also report that, lexical mismatch and conceptual mismatch constituted over 90 percent.

Smith, Stavri, and Chapman (2002) collected features and findings identified in 139 e-mail messages which were submitted to the University of Pittsburgh Cancer Institute's Cancer Information and Referral Service. The e-mail messages were coded and mapped to the 2001 UMLS Metathesaurus. Among 504 unique terms that were identified, 36 percent were exact matches to concepts in the 2001 UMLS Metathesaurus; 35 percent were partial string matches consisting of 24 percent of known synonyms for the metathesaurus concepts and 1 percent was lexical variants. 4 percent of the total terms, were not mapped to the UMLS.

Tse and Soergel (2003) collected 1,936 postings from 12 Web-based health discussion forums for consumer vocabulary corpus. They also collected 208 documents from magazines, newspapers, commercial ads, government publications, and patient pamphlets for mediator corpus. In order to control for various consumer types 14 "lay persons" identified medical expressions from the documents. According to the provided guideline, they selected terms on the basis of their personal experience, knowledge, judgment, and context in the document. The extracted terms were spelling corrected, expanded, normalized, and then mapped to concepts in the 2000-2001 UMLS Metathesaurus using MetaMap and the Knowledge Source Server. Terms that were not mapped automatically were manually mapped to the UMLS with assistance from a physician consultant. Terms were mapped 36 percent for consumer vocabulary, and 43 percent for mediator vocabulary to UMLS.

As reviewed, present technology that enables translation of consumer vocabulary to professional vocabulary is to put existing consumer vocabulary into a formal infrastructure (e.g., UMLS). With this technology consumers will be able to see familiar language and behavior on the system interface level, while requesting complex medical information to satisfy their needs.

DISCUSSION: TOWARDS SEMANTICS

Some studies have examined aspects of controlled medical vocabularies and identified the discrepancy between consumer medical terms and professional medical terms. There are also endeavors to make proper connection between those two groups of terms so that consumers can search for medical information without learning the professional terms. However, it may be also the case that consumers may not be able to distinguish useful information from the search result without proper conceptual understanding. Therefore, in addition to a solid mechanism that can translate consumer terms to professional terms, a repository of semantic definitions and relationships among those definitions is required to help consumers with reliable search. In this section, a need of semantic application for medical information retrieval system is discussed.

Queries formulated by healthcare consumers usually contain multiple concepts resulting in deeper level of information structure in search results. A pivotal point in organizing information from the search result is to understand equivalent or semantically close concept and make subsequent selection. As Lorence and Spink (2004) argue, one-to-one mapping of a term in consumer vocabulary to a term in professional one is likely to be problematic since it does not identify complex relationships among terms, e.g., relationship through specialization hierarchy. As a consequence, consumer, while seeking medical information on line, can be overwhelmed by the cognitive challenges of estimating the semantic distances between a term and various possible meanings of the term. In other words, search results through one-to-one mapping "translator" do not provide contextual cues that can aid satisfy consumer's medical information need, hence enrich the search result.

Biomedical vocabularies and ontology can play a critical role in the process of integrating healthcare information with appropriate semantics. Not only in academics but also in commercial domains, efforts are underway toward integrating biomedical information with proper context of consumer needs. For example, a healthcare application in relation to this area is designed and analyzed, e.g., the Semantic Knowledge Representation Project (National Library of Medicine, n.d.), providing scalable semantic representation of biomedical free text. Internet-based medical search technologies for consumers, in conjunction with their specific level of healthcare inquiries, is evolving to fulfill increasing need to examine the use of language in less strict way with less cultural differences. Therefore, defining and storing semantic relationships among consumer and professional vocabularies can be the next step of system design in medical information retrieval.

CONCLUSION

Designing consumer information retrieval system in the domain of biomedical informatics poses a tremendous challenge in that there are so many variables that have to be counted in the functional logic of such systems. This paper has discussed an overview of consumer informatics, consumer vocabulary mapping, in relation to consumer's medical information search on the Internet. Some studies mentioned in earlier sections examined the mismatch of consumer vocabulary with professional vocabulary while the studies reviewed in later sections have investigated term mapping. Growing opportunities for consumers to gain knowledge about specific health conditions on the Internet offers a significant implication for the design of medical information retrieval system. This paper contended that defining and storing relationships among the consumer and professional terms is required to better facilitate retrieval functions of medical information.

KEY TERMS AND DEFINITIONS

Consumer Informatics: A branch of medical informatics that concerns healthcare consumers' information need, concentrating on their access to medical information through studying methods and models of healthcare consumers' use of information system.

Information Retrieval: A discipline that concerns effective transfer of information between creator of information and user of information. In the system perspective, representation, storage, organization, access, and distribution of information are studied, while, in the user perspective, various information seeking models and how to satisfy users' information need are studied.

Medical Literature Analysis and Retrieval System Online (MEDLINE): A database of literature in life science and medical informatics.

Medical Subject Headings (MeSH): A controlled vocabulary and/or metadata system of medical subjects for the purpose of indexing life science literature.

Ontology: Structural model that represents concepts and relations of the concepts within a domain to reason about objects in the domain.

Unified Medical Language System (UMLS): A controlled medical vocabulary with defined terms and structured mapping amongst the terms.

Vocabulary Mapping: A translation mechanism that links one language to another to promote communication between the users of different languages.

Chapter 1.17

Better Knowledge for Better Health Services:

Discovering Guideline Compliance

Stefano De Luca
Evodevo s.r.l., Italy

Enrico Memo
Ca' Foscari University, Italy

ABSTRACT

The expenses in Health Care are an important portion of the overall expenses of every country, so it is very important to determine if the given cares are the right ones. This work is about a methodology, Health Discoverer, and a consequent software, aimed to disease management and to the measure of appropriateness of cares, and in particular is about the data mining techniques used to verify Clinical Practice Guidelines (CPGs) compliance and the discovery of new, better guidelines. The work is based on Quality Records, episode parsing using Ontologies and Hidden Markov Models.

INTRODUCTION

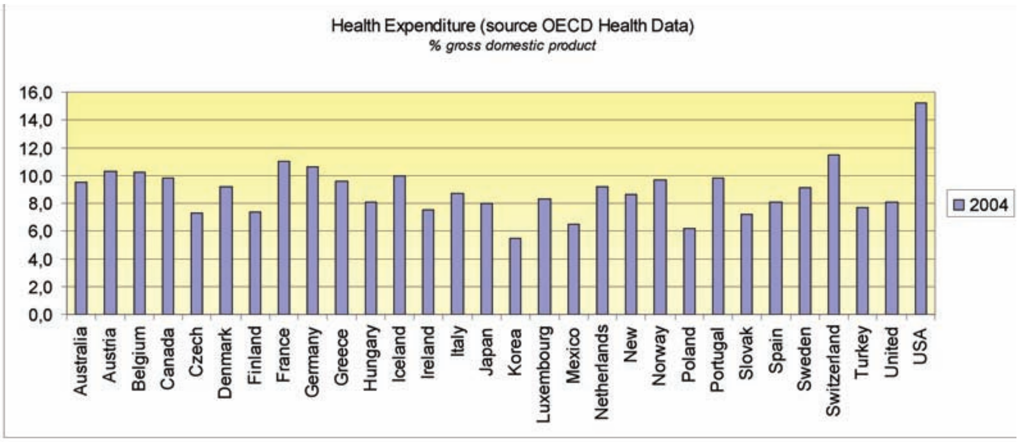
The importance of health and social services is constantly increasing as global societies grow older and the awareness of a proper care is spreading between citizens. Central point of this issue is the increasing cost of maintaining such health and social care systems. As reported by OECD (OECD Health Data 2007), the GDP (Gross Domestic Product) used in the health care varies from 5.5% (Korea) up to 15.5% (USA), in Italy we score a 8.7%. This research used the last complete data, on year 2004. In 2005, 2006 and 2007 this research assisted to a substantial growth, in Italy itexpect a raise from 8.7% up to 9%.

The research's purpose was to reach the definition of a valid and applicable method for inappropriateness reduction in medical praxis. Being sanitary economy a relatively young science, authors were sure that the quest wouldn't be easy and, being the *inappropriateness* recognized as one of the main resource waste causes within health care services, they were also sure that their search wouldn't be a trivial one.

The measure of appropriateness is strongly related to the use of Health Information Technology

DOI: 10.4018/978-1-60566-230-5.ch005

Figure 1 Health Expenditure %GDP



(HIT); use of HIT is seen as a way to increase the general quality of medical care and a way to reduce its cost (Welch et al. 2007); the clinical decision support systems increase guideline adherence in the clinical practice, thus improving health status and improving the financial elements on the long term.

The EPR (Electronic Patient Records, or Electronic Health Records) are the most discussed form of HIT. USA's Institute of Medicine (www.iom.edu) states eight core functionalities describing EPR:

- health information and data storage,
- management of results from laboratory and imagingtests,
- electronic ordering (e.g., prescription drugs and referrals),
- clinical decision support (e.g., guideline reminders),
- interoperability, and
- administrative processes such as billing.

The research intend to start from existing EPR software systems by improving their ability to manage guidelines and to discover important health properties, hidden in the health data.

This chapter describes the process and technologies authors used to approach the inappropriateness, choosing within different instruments the more suitable one, and presents the model developed starting from their consideration.

Because it is very hard to define when a care is appropriate, guidelines usage has been selecedas a metric to measure the appropriateness. The way a care is given mainly depends on the processes defined by medical institution as the correct one, and formalized as medical guidelines. So it is very important to know if the medics are following one of the possible guideline, because if it is so there are strong chances that the given care are appropriate, with greater results for the patient and lower expense for the medical institution (and typically for the government).

In section 2 it'll be discussed the process followed to establish an acceptable (by medics, institutions, government) way to measure care rightness and other, yet established metrics; this section is very important because there is a strong resistance bye medics and medical institution to measure the quality of given cares. Hence in section 3 it'll be proposeda generalized software architecture able to cope with the problems shown in section 2. Section 4 is focused on the clinical guidelines, entering in the core of thispaper, i.e., how to determine if the medics are following them. Section 5 introduces data mining techniques and process (CRISP-DM) when is applied to medical data. Section 6, Guidelines adherence discovery using Markov Chains, describes in detail the new algorithms and tools realized to effectively answer the goal: discovering guideline compliance. Last section 7 draws some conclusion.

THE PROCESS

The study started on 2004 with a project named *Health Mining* (Bei, A., De Luca, S., Ruscitti, G. and Salamon, D., 2005, De Luca S., Memo, E. et al. 2005). The goal of this study was to define a disease management methodology acceptable and approvable by the government levels and by doctors and their structures. Being disease management, and inappropriateness computation in particular, an important element in economic rate of hospitals' work, it was essential to count on a large base to support the methodology, otherwise it'd be easy to experience a reject of the entire process.

National and international instruments recognition represented the first step of followed process. The survey emphasized the following instruments:

- **PRUO:** Protocol for Hospital's Usage Revision and his American version AEP (Appropriateness Evaluation Protocol) are two measure/classification instruments aimed to split the days spent in the hospital in "appropriate" and "inappropriate";
- **Disease Staging:** a classification system for in-patients developed in the USA by prof. Gonnella, from Thomas Jefferson's University of Philadelphia. The classification algorithm evaluates patient's pathological condition and its gravity homogeneously and strictness;
- **AP Pro:** evaluates acute patient's admissions on the basis of discharge forms, it discovers low-complex assistance admissions and minimal severity admissions that, for their characteristics, are suitable for a Day Hospital treatment;
- **LEA:** Essential Assistance Levels are Italian limits established by National Sanitary Service (SSN), defining uniformity for granted cares, based on the constitutional principle that enacts health right for all citizens.

All these instruments, variously used on the Italian territory, missed one of the main characteristics we were searching for: the usefulness of the method for many different user levels.

That's why it has been chosen to proceed with an international comparison, arranging three different expert commissions coming from Sweden, United Kingdom and Germany and asking them which kind of instruments the three different nations were using to cope with inappropriateness at a national and local level. Thanks to this comparison an extremely interesting instrument used by Sweden Health Ministry at a national level since the 80's was discovered: the national quality registers.

National Quality Registers: The Swedish Model

Sweden started more than 15 years ago a specific process trying to answer the following questions: how to enhance quality? How to reduce medical practice variability? How to reduce costs?

The answer has been mainly found in the institution of pathology-specific digital registers. These registers collect data on patients, treatments and subsequent results and outcome. At the present days Sweden can count on over 40 registers and call them "Quality Registers", emphasizing the scope they are built for. National Quality Registers are basically databases collecting:

- Patient personal data
- Diagnosis
- Treatments
- Results

These kinds of data, variously aggregated and statistically analyzed, represent a precious instrument to promote and to monitor the quality enhancing in national health systems.Different registers can all provide the following data:

- Register starting date
- Approximate volume of interventions
- Register's Patient Coverage on Total Patient for a given pathology
- Register's patient inclusion criteria
- Brief list of register's variables
- Feedbacks: data reports and statistical analysis of data
- Results: conclusions emerging from reports and statistics
- Publications
- Contact information for data insertion referent and data transfer criteria

The greatest register value comes from the large amount of homogenous data collected yearly on all the national territory on different pathologies. These data analysis permits the easy, immediate and economic dissemination of new best practices. Registers can also provide a sort of alarm system for defects causing problems to patients, representing a learning and medical decision support system.

Registers are useful if, and only if, each single health unit can monitor provided services' quality in time, comparing reached level with other structures and national average. Many Swedish registers still show great variability moving from region to region: however these kind of instruments can emphasize and disseminate the best performing regional model.

In Sweden Quality Registers are not obligatory, Swedish strategy is to maintain the register participation free and voluntary-based, while maintaining anonymous the data input and publication. In these way non-excellent health units are not discriminated, but fostered in register participation (free and useful for guideline design and best practices individuation).

Registers were born at a local level, but nowadays have been adopted at a national and centralized level. Few, but essential are the register creation and maintenance rules, they must:

- Contain individual data on diagnosis, medical intervention and relative results;
- Preview doctor participation;
- Preview meetings and feedback procedures;
- Facilitate collaboration between health structures;
- Face nationally relevant themes;
- Try to involve private structures;
- Be able to generate relevant and credited information.

In Sweden registers are public and can count on a common system and software, all the data must be inputted immediately and only the complications are lately inserted. Periodically, all data are transmitted from the local database to the national one and yearly each single health unit receives his own report. General data are published yearly and used in national and international meetings.

These were the reason to focus on this instrument, but enriching it at a new level. This process ended his first run with a web based, emphasized version of a quality register based on pacemaker and AICD (Automatic Implantable Cardioverter Defibrillators) implants.Main features of the system were:

- **Web based interface:** no need for installing software on different PC and possibility of older hardware systems utilization;
- **Different user level access:** we previewed Regional, Hospital and single Doctor access to data, each level was characterized by different statistical tools;

Figure 2. Disease Management Process

- **Architecture flexibility:** for an easy application to any disease.

Health Mining project evolved then in a new project, **Health Discoverer**, that enhanced Health Mining with a Service Oriented Architecture, a stronger data mining level and ontology support.

Expected Outcome

The quality register model, based on international standards, lets surgeons to input detailed data regarding patients, symptoms, implants, administered drugs and follow-up. In the original Health Mining, we used CARDS data standard for cardiology audit.

The system offers a large range of statistical analysis on recorded data and previews different user levels: region, hospital and single doctor. The register has been thought to assure regional statistics on the observed medical care and to foster a sharper phenomenon perception; at the hospital level, statistics may be used to compare values with regional averages and to support budget making. Last but not least, the systematic data recording and the statistics availability may be able to cope with medical praxis variability, reducing it.

Process Components

The main process components are the followings:

Disease selection: while Disease Management can be applied to all kind of diseases, the assuption is that it's better to mainly cope with the most interesting illness, in term of social relevance and cost reduction, notwithstanding more managed diseases mean more reuse of medical data and better context for data mining extractions.

Guidelines selection: after a specific disease selection, this step involves the selection of (a set of) field-relevant international guidelines.

Quality records selection and adaptation: given the guidelines, variables referred by inappropriateness studies have been chosen, in order to compose a quality record; the system can use existing international quality records, but they must be localized and adapted to Disease Management purposes.

Business intelligence, Data Mining and rule extraction, new guidelines discovery: after the process phase, the technical ones. Here data are collected and used to calculate statistical groups and process/results variance, to extract rules about the care process and new approach to guidelines or part of them.

Given the task complexity, different tools were used: statistical analysis of deviance is useful to turn off the noise, while Knowledge Discovery in Database (KDD) is critical to extract valuable insights about the best practice or problems in the managed context; so typical business intelligence, statistical tools, specific data mining and rule inference tools were used. **Health Discoverer** adds to this layer an ontological discoverer that enable the model to use logical inference reasoners.

Results evaluation: the last step consists in Evidence Based Medicine usage, exploiting the results to re-plan actions, changing (if necessary) the used guidelines and improving the general process. At this stage the system is ready to re-start the process, with better confidence and control over the way health care can be managed.

All the above phases involve a validation by the scientific committee in order to avoid naïve choices or to avoid confusion between localized improvements and general ones. In this way the system is able to produce a higher quality process, to minimize the possible physicians resistance to the control tool, to design the DM tool in a doctors' positively perceived way.

SOFTWARE ARCHITECTURE

Main goal of Health Discoverer is the collection of all the relevant medical data and their analysis by data mining tools and techniques to discover Clinical Practice Guidelines (CPG) adherence and the reasons resulting in good or bad disease management. In doing so, the interest focuses in sharing knowledge on existing or discovered Guidelines and in the other kinds of knowledge, in particular derived rules, clusters and simpler statistics – including Key Performance Indicators (KPI) as usual in Business Intelligence.

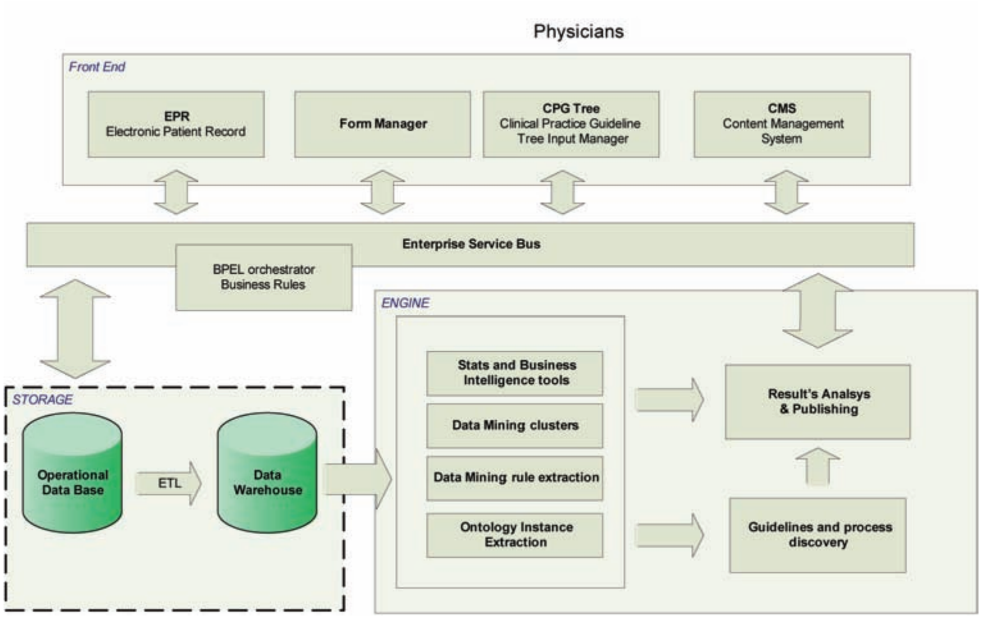
Health Discoverer has three main components: the Input Front-End sub-system, that collects all the information and give users the possibility to input data and view discovered results, the Storage sub-systems, where a Medical Data Warehouse is built, the Engine sub-system, where multiple data mining algorithms and the Guidelines discovery are applied. Health Discoverer is based on a Service Oriented Architecture (SOA), where all components are joined by an Enterprise Service Bus (ESB); the communications are carried out by standard web services and specific medical protocols, as DICOM or HL7 (e.g., for Electronic Patient Record data gathering). The flow of information and services is managed by a standard BPEL engine and a rule engine, both driving the ESB communications.The architecture is based on these macro components:

- **Front end:** is a web based front-end for input patient data and dissemination of the results. It receives data from:
    - **Forms,** generated by a generalized Form Management System which allows to rapidly create a web based way to obtain quality record data;
    - **EPR data stored in HIS system,** usingweb service and HL7/DICOM protocols to pass on EPR, this way supporting the interoperability with other products;
    - **Tree Input Management,** to manage the disease's process tree created by the guidelines, graphically represented in the front-end; the user can select the branch related to the real process of the illness cure and indicate the possible divergence. In this way alternate guidelines can be discovered or, if the guideline does not exists for the chosen illness, it can be anew created.

A **CMS** is used to disseminate results.

- **Storage:** receive the information from the Front End and collected them through an ETL (Extract, Transform and Load); once

Figure 3. Health Discoverer Architecture



in the sub-system, the data will be used to populate a data warehouse, optimized for statistical and data mining purposes.

- **Engine:** core of Health Discoverer, includes the statistical components, the data mining tools, the ontology instance extraction and guideline and process discovery.

Clinical Practice Guidelines (CPGs

Clinical Practice Guidelines (CPGs) are a method for standardization and uniform improvement of the quality of medical care. CPGs describe plans and processes aimed to cure a specific illness.

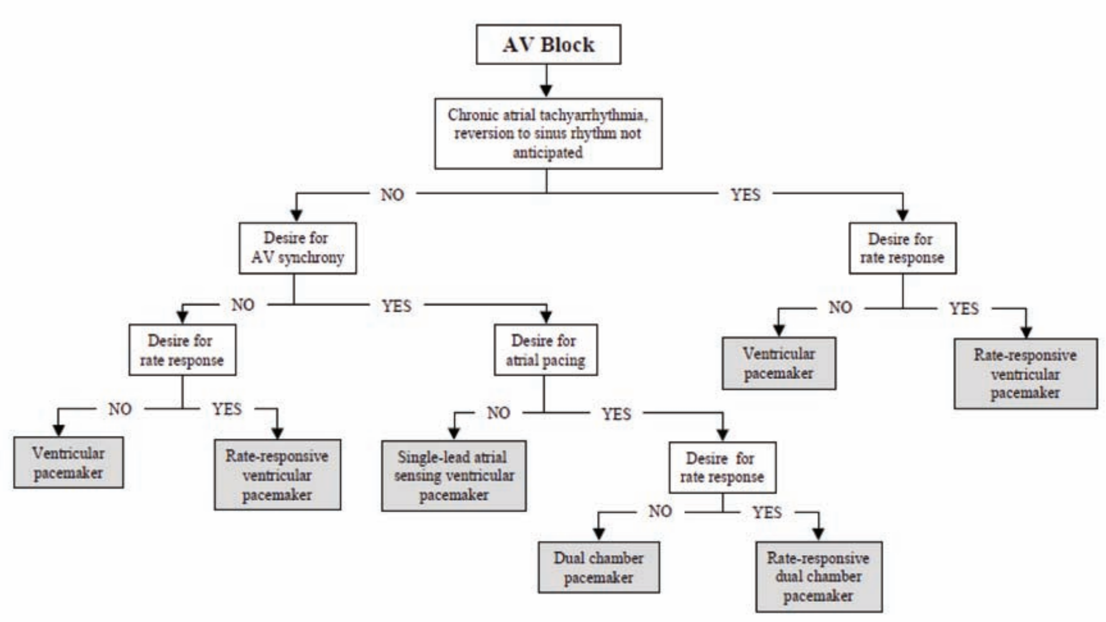
As stated by the International Organization OpenClinical (URL: www.openclinical.org), "Guidelines are designed to support the decision-making processes in patient care. The content of a guideline is based on a systematic review of clinical evidence - the main source for evidence-based care."

According the Institute of Medicine definition, clinical guidelines are "systematically developed statements to assist practitioner and patient decisions about appropriate health care for specific clinical circumstances''.

The guidelines are composed by decision trees, as in *Figure 3*, and descriptive text as "*Under certain circumstances, an implanted pacemaker may be useful for treating patients with recurrent symptomatic ventricular and supraventricu-lartachycardias*". Both the examples are from (ACC/AHA 2002), the ACC/AHA guideline for pacemaker installation.

Guidelines usage is in line with the trend towards evidence-based medicine (EBM) and healthcare, that has ever-greater support, motivated by clinicians, politicians and management concerned about quality, consistency and costs. CPGs are based on standardized medical best practice, and have been shown to be capable of supporting improvements in quality and consistency in healthcare. Many have been developed, though the process is time and resource-consuming. Many have been disseminated, though largely in the relatively difficult to use format of narrative text.

Figure 4. Selection of pacemaker systems for patients with atrioventricular (AV) block (excerpt ACC/ AHA Pacemaker Installation Guideline)



The importance of CPGs is growing, although the relatively low diffusion of EPR limits the impact on the medical practice.

Indeed, CPGs are mostly in textual form, that is impracticable by the EPR and by automatic system able to verify guideline' application. There are several systems aimed to formalize CPGs: Arden, PROforma, USAM, GEM, Helen and GLIF.

Arden Syntax (cf. URL) is a guideline specification standard widely used in Clinical Decision Support Systems; it is based on a procedural language able to encode medical knowledge and logic. Knowledge is defined in *Medical Logic Modules* that use if-then rules to describe the medical process.

PROForma (Fox, Johns & Rahmanzadeh 1998) is aimed to represent clinical knowledge in form of set of tasks; it is a language for modelling clinical processes, along with associated tools and methods for creating clinical decision support, care planning, workflow and other applications. PROforma proposes a standard, computer executable language and interchange format for clinical decisions and processes modeling, and it is used in several commercial DSS, e.g., Arezzo or Cocoon.

The Guideline Elements Model (GEM) is an XML-based guideline document model designed to organize all the life-cycle of guidelines. It is intended to facilitate translation of natural language guideline documents (i.e., the "natural" form of CPGs) into a format that can be automatically processed by machines. GEM is intended to be used throughout the entire guideline lifecycle to model information pertaining to guideline development, dissemination, implementation, and maintenance. GEM is document-centric and want to use the guideline document as a knowledge source to promotes authentic translation of domain knowledge.GLIF is being described just below, 'cause it has been choosedas a standard for this work.

All these standards, and hence the guidelines "formally" described using them, start from the idea that there are persons designing them, and so are unable to encode the knowledge extracted from data mining algorithms (as acknowledged too by Kazemzadeh et al. 2006).

GLIF

The Guideline Interchange Format (GLIF) is a language for structured representation of guidelines, developed to facilitate sharing clinical guidelines.

The GLIF model (Peleg et al. 2000) allows the specification ofa guideline as a flowchart of temporally ordered steps, representing *clinical decision* and *action steps*. Concurrency was modeled using branch and synchronization steps. GLIF's guideline class also can manage authoring information, as the author, the status, the modification date and version, the scope of the guideline, eligibility criteria, and so on.

While developing a guideline, it is important to model not only the knowledge and the task involved in the care giving, but also to manage the guideline maintenance and the instantiation of a CPG in a real clinical environment, e.g., how to get patient data from EPR or to alert medics in case of problems, and, last but not the least, the retrospective assessment of the quality of the application of the guidelines.

The modeling language of GLIF, in particular GLIF3 – its current version, permits to model the actions needed to describe a clinical guideline, using as a low level language a form of XML and an UML-like object oriented structure that permits to have different levels of description, using *classes*. In particular, GLIF3 offers:

- **Action steps:** recommendations for clinical actions to be performed (e.g., prescribe a medicine, order a test, start a treatment).
- **Decision steps:** decision criteria for conditional flowchart traversal (e.g., if-then decisions, as *if patient has high fever then do this*).
- **Branch and synchronization steps:** allow concurrency starting two or more concurrent decision flows, e.g., prescribing a medicine and a laboratory test at the same time. Synchronization reunify different branches in one single flow, e.g., receiving different tests in order to chose the next step.
- **Patient-state step:** characterizes patient's clinical state, the clinical history and diagnoses etc.

Indeed, to extract knowledge from the clinical database and then verify the adherence to the CPGs, GLIF3 has been used to model a flowchart diagram or, better, a finite state automaton with these basic modeling constructs, derived by the GLIF3 steps. This approach is similar to that of Kazemzadeh and Sartipi (2006), although the built automaton is needed to compare with discovered one and not (or at least *not only*), as in cited paper, to incorporate data mining task in a formal guideline.

Using these constructs, a CPG can be represented as a flowchart representation of a temporal sequence of clinical steps. In the following, these steps will be related to *events* to be discovered by the data mining process.

GLIF has three Representation levels: the *Author/viewer*, meant to describe the medical guideline for human understanding; the *Abstract machine*, that can be executed by an interpreter and used to analyze the correctness of guideline application; the *Integration into application environments*, to adapt to specific environments and contexts.

In this work, only the Abstract machine is mainly used, it is defined by logical expressions and actions that refer to defined concepts (medical ontology). The ontology can be formally defined by using the semantic web standards, as RDF and, more interesting, OWL (Web Ontology Language) that supersedes RDF including Description Language constructs and then allowing logical reasoning.

The GLIF standard has been chosen 'cause it is based on ontology, has a clear semantic and it can be based on OWL, that permits to extend the initial knowledge with new rules, although limited by the expressivity of Description Logic (a subset of First Order Logic).

Data Mining in Clinical Context

There is not a shared view of the adequacy of therapy, nor there is sufficient evidence of the right way to manage health care. Hence there is a strong need in having predictive modeling on Disease Management and data mining from the collected clinical work is proposed to start the process. On the other hand, this process needs to be an iterative, human-controlled one to permit the physician the evaluation of automatically generated results (clusters, trends, rules).

To remark the importance of knowledge discovery and modeling, the important Disease Management Association of America (DMAA) has a specific committee named "predictive modeling": "The mission […] is to educate the health care community about analytic tools available for increasing the efficiency and effectiveness of disease management programs." (May, J. (2006), pg. 374).

Data mining is mainly used in the process of guidelines evaluation and new best practice process discovery, although, once the needed data warehouse is complete, it is possible to work on other goals too.

An interesting improvement area is the use of temporal data mining for extraction of long processes and geographical data mining for insights from the hospitals and patients geographical positioning. This is a new frontier of data mining, and there are virtually no works on the health area (except for Rohan. B et al. (2001)).

At last, the goal is to unify the results of the data mining rule extraction with an ontology description of the guidelines; these are formalized by GLIF (GuideLine Interchange Format, for a description see (Kazemzadeh and Sartipi 2006)). The outcome consists in enriching the ontology with logic rules descriptions derived by data mining, so that inference engines, i.e., reasoners, can use them to extend the knowledge discovered by the data mining process.

Definitions

Hand, Mannila& Smyth, in their *Principles of Data Mining*, define Data Mining (DM) as "*the analysis of (often large) observational data sets to find unsuspected relationships and to summarize the data in novel ways that are both understandable and useful to the data owner.*"

In this case, clinical data are used to verify the appropriateness of the given cares, and in particular if these cares are following standard guidelines or, in case the cares are particularly successful, to extract a better guidelines. So, the goal is the building of a Clinical Decision Support System that, by interpreting the patient data using the mined knowledge within the context of the clinical guidelines, will be able to assist the decision makers and the medics to evaluate the current way of giving care and then make better decision about the process and the enforcement of the following standard CPGs.

Applying data mining in health care is not a novelty. However, there are some issues that make DM in this scientific field particular. Medical data sets are typically too large or too sparse. When data from medical machines (e.g., an ECG or a PET) or from an epidemiological study on a country are collected, millions of records, typically low-detailed, may result; for instance, in Italy all the implantations of pacemakers and AICD are registered in a large National records, but the information are limited to the initial diagnosis, personal data and the model of pacemaker installed – really too few information to state care appropriateness. On the other side, if we collect detailed data within a single Hospital, we will have lots of columns, but a small patient populations – in this study more than 300 columns (fields) are filled, but only about a hundred of patients recorded.Both cases require pushing data mining algorithms and processes to their limits (Roddick 2003).

All the most typical data mining techniques were applied to clinical data, in particular the macro areas of classification, clustery analysis and rule discovery. CRISP-DM process manages the application of these algorithms.

KDD Process: CRISP-DM

The KDD process is formalized in an industrial standard, CRISP-DM, that models the life cycle of a data mining project.The steps of CRISP's life cycle, are:

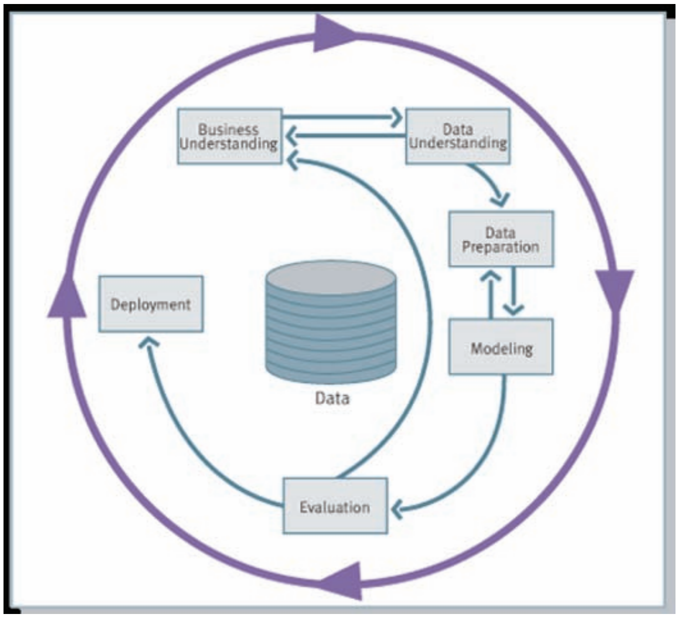
Business Understanding: Understanding the project objectives and requirements from a business perspective, then converting this knowledge into a data mining problem definition and a preliminary plan. The steps in this phase are: Determine the Business Objectives, Determine Data requirements for Business Objectives, Translate Business questions into Data Mining Objective.

Data Understanding: characterize data available for modelling. Provide assessment and verification for data.

Data Preparation: In this phase a set of examples is generated (choose sampling method, consider sample complexity, deal with volume bias issues), the attribute dimensionality is reduced (remove redundant and/or correlating attributes, combine attributes e.g. sum, multiply, difference etc.) attribute value ranges are reduced (group symbolic discrete values, quantify continuous numeric values), data are transformed (de-correlate and normalize values, map time-series data to static representation).

***Modelling*:** In this phase, various modelling techniques are selected and applied and their parameters are calibrated to optimal values. Typically, there are several techniques for the same data mining problem type. Some techniques have specific requirements on the form of data. Therefore, stepping back to the data preparation phase is often necessary.

Figure 5.CRISP-DM life cycle



***Evaluation**:* At this stage in the project a model (or models) appearing to have high quality from a data analysis perspective is built. The model must be evaluated and reviewed to be certain it properly achieves the business objectives. A key objective is to determine if there is some important business issue that has not been sufficiently considered.

Deployment: The knowledge gained will need to be organized and presented in a way that the customer can use it. It often involves applying "live" models within an organization's decision making processes, for example in real-time personalization of Web pages or repeated scoring of marketing databases. It can be as simple as generating a report or as complex as implementing a repeatable data mining process across the enterprise. In many cases it is the customer, not the data analyst, who carries out the deployment steps.

In the following subsection, the main DM techniques in health care are reviewed. An interesting more lengthy source is the paper "Selected techniques for data mining in medicine"(Lavra, 1999).

Classification

In classification the interest is focused in modelling the boundaries between classes (Hand et al. 2001). The act of classification is the training of a function to classify data item into, usually pre-defined, classes. Most popular algorithms in this class are: probabilistic learners as the Naïve Bayesian classifiers, decision tree learner as C4.5, Artificial Neural Networks.

In medicine, an evident use of classification is the partition of the all-patient group in affected and not affected by a disease. This group of algorithms are widely used in medicine, for instance in (Huang et al. 2007) to classify diabetic patients, or (Delen et al. 2005) in predicting breast cancer survivability.

Cluster Analysis

The idea in cluster analysis is to partition data (related to patients, to diseases etc.) to identify groups with a mapping function from a training sample to one of the identified groups. The algorithms in this group usually minimize a distance measure between a new item to be clusterized and the item in the yet classified cluster (e.g., using centroids). Although the goal is the same of classification, usually classification is supervised (i.e., the classification for the training samples is known) while clustering is unsupervised (the algorithms discover *per sé* the groups).

Popular algorithms for clustering are KNN – K-nearest neighbour algorithm, Kohonen maps – or SOM – Self Organizing Maps.

As stated by (Kazemzadeh. and Sartipi 2006), an application of clustering in the clinical care domain might be to perform risk analysis and assess patients' risk factors. (Churilov et al. 2004) have carried out a similar study to assign patients to three disjoint clusters of high, intermediate, and low risk patients.

Association Rules

The goal of association rule mining is the extraction of *if… then…* rules from the data, where *if A then B* will means that items of group A implies items of group B with a certain percentage *confidence*.

Association rules are very general, and can be employed in healthcare for identify patterns in data set; you can say that association rules *explain* the reasons of data, e.g., identify that a disease arises from two composed symptoms. association rules are employed for detecting when medics used a particular type of pacemaker, and then the soundness of the choice can be evaluated.

Each rule of the form $A \rightarrow B$ is characterized by the rule support, i.e., the total number of occurrence of the rule, and the confidence, i.e., the ratio of occurrence where A and B applies to the number of occurrence where only A applies. High confidence will mean that the causal relation between A and B is strong; high support will mean that the given rule that there are many sample of them can be trusted.

Rules are a form of knowledge stating the hidden relations, and so they are very important in clinical data mining. Figure 6 shows some rules extracted with C4.5 algorithm to identify the type of pacemaker medics will use and why.

There are lots of works on this subject; a new interesting one is by (Feng et al., 2006), on rule extraction in traditional Chinese medicine.

Temporal and Spatial Data Mining

Another important point is the need in analysing data within a spatial and temporal framework. This is very important in case of epidemiological studies or syndromic surveillance (cf. URL: www.syndromic.org). This type of surveillance involves collecting and analyzing statistical data on health trends – such as symptoms reported by people seeking care in emergency rooms or other health care settings – or even sales of medicines to early detection of bio terrorism attacks or diffusion of epidemics. Within the context of appropriateness, it is very interesting to discover if there are local differences in managing a specific clinical illness.

Temporal analysis is even more important, given that is important to study the order in which cares are provided. E.g., an important case of inappropriateness arises from two sequential hospital admissions related to the same illness: if the patient was correctly healed in the first admission, there were no raison to admit him again, so it is evident the care from the first admission were faulty.

Usually, in data mining temporal data are flattened in a single row that presents all the data together. This is a oversimplification that can hinder the discover of temporal relationships between cares, and it is inherently hard given the wide degree of freedom in giving care also for the same clinical condition. On the other hands, *real* temporal and spatial mining involves algorithms and processes that are heavy in computation time and not yet so reliable.

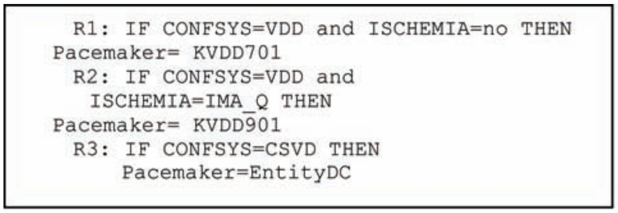
An intermediate way to approach temporal data is the segmentation in discrete *episode events*.Of course, to discover guidelines application,temporal analysisis *needed*, so the choicefallen on episode estimation that permits us to really discover CPGs uses.

Episodes

Episodes are well known in healthcare, and are the base of popular instruments as Diagnosis-Related Group (DRG) or Episode Treatment Groups (ETGs).

Diagnosis-related groups (DRGs) are a classification of hospital case types into groups expected to have similar hospital resource use. Medicare uses this classification to pay for inpatient hospital care. The groupings are based on diagnoses, procedures, age, sex, and the presence of complications or comorbidities. The DRGs may be assigned using

Figure 6. Example of extracted rule



```
  R1: IF CONFSYS=VDD and ISCHEMIA=no THEN
Pacemaker= KVDD701
  R2: IF CONFSYS=VDD and
   ISCHEMIA=IMA_Q THEN
Pacemaker= KVDD901
  R3: IF CONFSYS=CSVD THEN
      Pacemaker=EntityDC
```

different grouper, besides comparisons among different DRG versions should be done with caution since criteria are revised periodically.

Following Williams and Solon (Williams et al., 2002 - Solon et. al., 1967)episodes of care can be defined as "*A block of one or more medical services, received by an individual during a period of relatively continuous contact with one or moreproviders of service, in relation to a particular medical problem or situation*".

Although the definition is very general, it is still useful for defining how to partition the semi-continuous data found in the database. To define a block of cares as a single episode it is necessary to know the specific cares applied to the monitored disease: different diseases can have different way to compute blocks and episodes.

A transformation phase computing episodes from the database is applied. To define an episode a *key element* that identify a clinician (medic, nursery) giving an evaluation or a treatment to a patient is needed; to this key element we can link other elements (as drug prescriptions, tests and so on). In this way a fixed frame window is not used, but the construction of the episode on the relevance of care. This work is based on inpatient cares, so the construction starts from the admission to the hospital and ends with the discharge from the hospital and the subsequent patient recalls – the idea is that the sequence is relative to a complete disease management.

This is coherent with the quality records too, so we have a long sequence of more simpler episodes, each one can be atomic or a simple composition of atomic acts. The episodes are chosen to match the steps in the guidelines.

To have a sound appropriateness instrument, relevant aspects must be included in the episodes, as complications, comorbidities, important treatment as surgery.

Clinical complications: are complications arising during disease treatment that can change significantly the cares; complications can be related to the main disease, and described by the CPG. For instance, after a pacemaker installation can arose a haematoma; complication of a bronchitis can result in a pneumonia.

Comorbidities: it describes the effect of all other diseases or previous medical history (treatment, drugs etc.) an individual patient might have other than the primary disease of interest. For instance, a patient that needs a pacemaker implants *and*have HIV, requires different treatment from a patient without HIV. Comorbidities can impact heavily on the care plans, and it is important to record all the elements that can permit to differentiate patients with or without comorbidities, otherwise data mining will produce incorrect results.

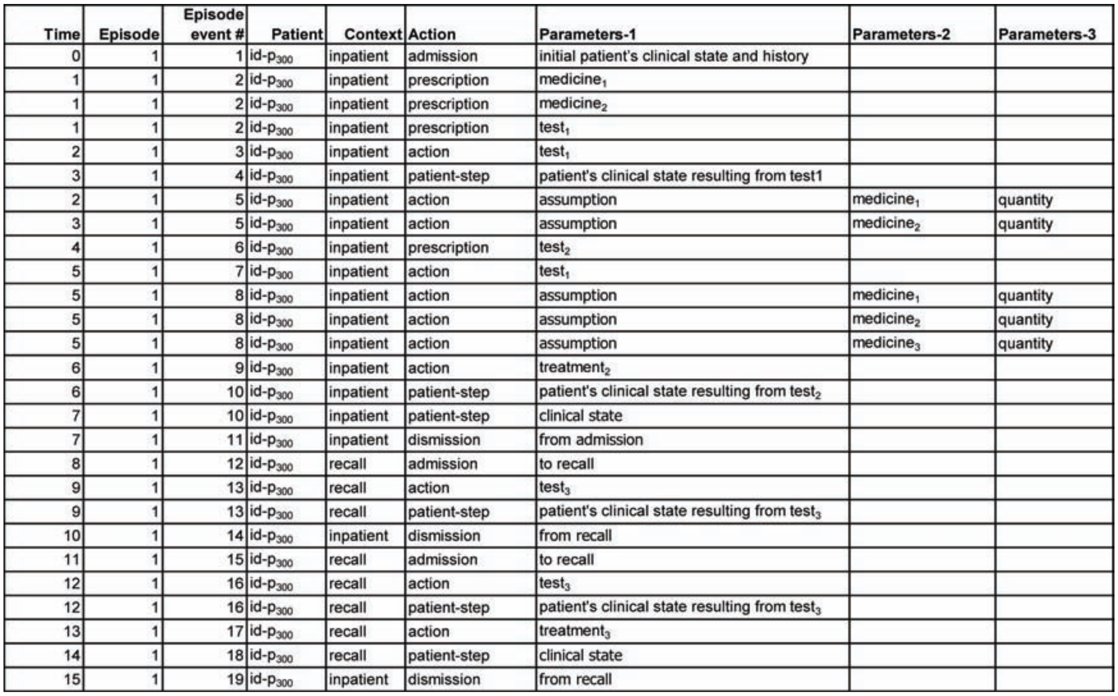
Surgery and other important treatments: in this case, surgery can be considered as a single step in the main guideline, while a specific protocol or guideline are applied to the surgery itself. So the analysis is simplified by managing this sequence of care not a single, complex, one but as the sum of two simpler sequences.

Figure 7 shows a simplified view of the data at the beginning of episode event counting process: each row contains the time when information are recorded, patient id (for privacy reason, his/her name is not used but an id only), the action type, the action parameters.

The data table contains information about a patient (id-p_{300}) admitted to the hospital, the relative given cares and two sequences of recall, the first with only a test and the second with a treatment too.

A tool is applied to this initial table to determine the episodes, *E^2T* or *Episode Extraction Tool*. E^2T uses episode discrimination criteria borrowed by the CPGs and by the medical ontology used as reference. It is useful to note that the column "action" is not present in the initial data, but was derived from the ontology too. This ontology permits to derive that to take a drug or make a test are all "action", while the test results or a screening are "patient-step"; as you can see, the concept "action", "patient-step" and so on come from GLIF3 ontology, extended to suite the needs.

Figure 7. Action records of patient cares



Time	Episode	Episode event #	Patient	Context	Action	Parameters-1	Parameters-2	Parameters-3
0	1	1	id-p_{300}	inpatient	admission	initial patient's clinical state and history		
1	1	2	id-p_{300}	inpatient	prescription	$medicine_1$		
1	1	2	id-p_{300}	inpatient	prescription	$medicine_2$		
1	1	2	id-p_{300}	inpatient	prescription	$test_1$		
2	1	3	id-p_{300}	inpatient	action	$test_1$		
3	1	4	id-p_{300}	inpatient	patient-step	patient's clinical state resulting from test1		
2	1	5	id-p_{300}	inpatient	action	assumption	$medicine_1$	quantity
3	1	5	id-p_{300}	inpatient	action	assumption	$medicine_2$	quantity
4	1	6	id-p_{300}	inpatient	prescription	$test_2$		
5	1	7	id-p_{300}	inpatient	action	$test_1$		
5	1	8	id-p_{300}	inpatient	action	assumption	$medicine_1$	quantity
5	1	8	id-p_{300}	inpatient	action	assumption	$medicine_2$	quantity
5	1	8	id-p_{300}	inpatient	action	assumption	$medicine_3$	quantity
6	1	9	id-p_{300}	inpatient	action	$treatment_2$		
6	1	10	id-p_{300}	inpatient	patient-step	patient's clinical state resulting from $test_2$		
7	1	10	id-p_{300}	inpatient	patient-step	clinical state		
7	1	11	id-p_{300}	inpatient	dismission	from admission		
8	1	12	id-p_{300}	recall	admission	to recall		
9	1	13	id-p_{300}	recall	action	$test_3$		
9	1	13	id-p_{300}	recall	patient-step	patient's clinical state resulting from $test_3$		
10	1	14	id-p_{300}	inpatient	dismission	from recall		
11	1	15	id-p_{300}	recall	admission	to recall		
12	1	16	id-p_{300}	recall	action	$test_3$		
12	1	16	id-p_{300}	recall	patient-step	patient's clinical state resulting from $test_3$		
13	1	17	id-p_{300}	recall	action	$treatment_3$		
14	1	18	id-p_{300}	recall	patient-step	clinical state		
15	1	19	id-p_{300}	inpatient	dismission	from recall		

In the database, we don't find the "branch step" and the "synchronization steps", because there are no explicit data to identify the start of parallel actions (*branch*) and the subsequent unification (*synchronization*); how explained below, this void has impact in the next step.

Once E^2T computed the episodes and its events in the clinical lifetime of a patient, the adherence to the applied therapy to official guidelines can be extracted.

Guidelines Adherence Discovery Using Markov Chains

All the elements needed to compute the guideline adherence by medics are now defined. Indeed we have:

- **databases** with all recorded cares for each patients; these databases are derived by EPR, quality records, doctors' annotations and so on;
- **a data warehouse** that unify all the collected data in homogeneous views (data marts) and permits to analyze data efficiently and with focus the subsequent data mining operations; ETL tools are used to create the data warehouse and in the process inconsistencies are cleaned and reduced and errors in the datacleared;
- **rules and clustering** computed by "traditional" data mining; these results can be used *per se* or as annotation of the discovered CPGs;
- **episodes**, extracted by a parser in accord to events and episode definition; these sequences are specific to each patient cares (in this case, the inpatient cares plus the hospital recalls);
- **formalized clinical practice guidelines**, in GLIF3 format; we can have more than one CPG for each disease, for instance we can have an European, Italian, USA, specific medical association guidelines: these

guidelines are all correct, and a medic can chose one of them or no one, preferring to decide itself.

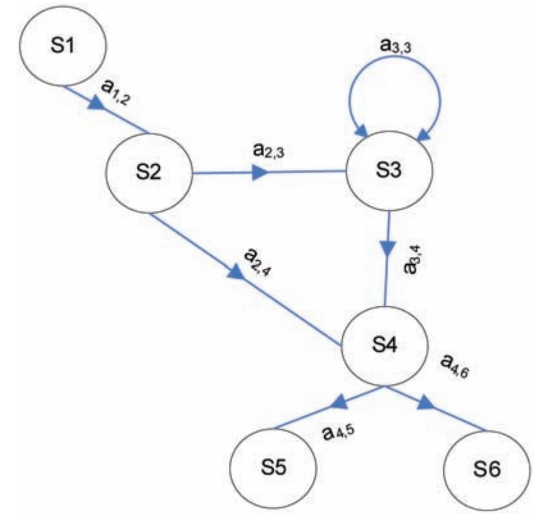
From these key elements, a way to compute the adherence to each possible guideline and, in case is needed, the *real* guideline that the hospital (or the medic) is *really* using.

Hidden Markov Models

As noticed in last paragraph, database shows only the episode events (and hence the episodes), but has no information on the process flow. The moments when clinical personal (medics, nurses and so on) operates a choice is *hidden*: we can watch the observable output of a black box, but we have no (direct) knowledge of how the box operates, i.e. we don't know the *model* of the black box. This is common situation, and there is a strong formalism used to model it: Markov Hidden Models (HMM).

HMM are related to Markov chains. The idea is to have a system that can be modelled any time as being in one of *n* distinct states $s_1, s_2, \ldots, s_n$, as illustrated by Figure 8. The system changes from a state to another according to a set of probabilities associated with each state. The time associated with state changes is denoted as $t = 1, 2, \ldots, m$ and the actual state at time t is denoted as q_t. To have a sound probabilistic description of this system the current state at time t and all the predecessor states are needed; for Markov chains, this probabilistic description is reduced to the current and the predecessor state only (Rabiner 1988, a very good introduction to Markov chains and Hidden Markov Models).

Figure 8



$$P[q_t = S_j \mid q_{t-1} = S_j, q_{t-2} = S_k, \ldots]$$
$$= P[q_t = S_j \mid q_{t-1} = S_i] \tag{1}$$

Only the process in which the right hand side of previous equation is independent of time is considered, and so the probability of the transition a_{ij}, i.e., moving from state s_i to state s_j is:

$$a_{ij} = P[q_t = S_j \mid q_{t-1} = S_i] \tag{2}$$

where

$$a_{ij} \geq 0 \tag{3}$$

and

$$\sum_{j=1}^{N} a_{ij} = 1 \tag{4}$$

Formally, a Markov chain is a triple $\left\langle E, \{p(p_1 = s)\}, A \right\rangle$ where:

- *E={1,2,...,k}* is finite set of states (or events); each state is a symbol generated by the alphabet *S*
- *p* is the set of the initial probabilities;
- *A* is the set of transition probability a_{st} for each *s*, *t* in *E*; as it said, the transition probability a_{st} is $a_{st} = P(p_i = t | p_{i-1} = s)$

More informally, a (first order) Markov chain is a probabilistic automaton where the probability of state change is related only to the previous state. A Markov chain is also an *observable* Markov model, because each state is related to an observable world event (an event of the world being modelled).

Hidden Markov Models deal with the modeling of situation where the world events cannot be observed; this is our case, because the transition is known, i.e., the effects of the state changing, but not the states themselves.

A HMM is a stochastic process determined by the two interdependent mechanisms, an underlying Markov chain having a finite number of states and a set of random functions (the black box). At each time step, the process modelled by the HMM is in a specific state and an observation is given by the random functions related to the current state. The Markov chain that is hidden to the observer changes state in accord to the transition probability from the current state to the next (using the probability matrix that describe each transition from *i* to *j*). The observer sees only the output of the random functions associated with each state and so cannot observer the Markov chain and does not observe its states – indeed, the chain is *hidden* to the observer, while the outputs are known.A formal definition of a HMM, using Rabiner notations is:

1. N is the number of states in the model; although the states are hidden, a certain correspondence between these states and world events can be assumed, in this case states of a CPG;
2. M is the number of distinct observation symbols per state, i.e., the discrete alphabet size; in this case, the types of given cares, the types of tests and so on;
3. A the transition probability matrix $A = \{a_{ij}\}$, where a_{ij} is the transition probability of the underlying Markov chain to move to state j from the (current) state i, as in eq. 2.
4. B the observation symbol probability distribution matrix $B = \{b_j(k)\}$ where $b_j(k)$ is the random function associated with state j and where

$$b_j(k) = P[v_k \text{ at } t \,|\, q_t = S_j]\ 1 \le j \le N \text{ and } 1 \le k \le M \tag{5}$$

5. Initial distribution $\pi = \{\pi_i\}$ where

$$\pi_i = P[q_1\ S_j]\ 1 \le j \le N \tag{6}$$

Hence the elements of an HMM are the model parameters of N, M, A, B, and π.N and M, that are implicit in the dimensions of the matrices A and B, can be removed simplifying the formula. So, a HMM is defined by the notation $\lambda = (A, B, \pi)$.

In conclusion, HMM is used to model the data collected about the CPGs use and discover real practice adherence, using the principles of Evidence Based Medicine: data evidence is exploited to extract knowledge about the appropriateness of (hospital) practice cares and their compliance with one of the CPGs designed by healthcare associations.

Last step to reach the goal is the computation of CPG adherence, as described in the next subsection

Chain Discoverer Tool (CDT)

In the last step in compliance discovering, there are two distinct problems: the first is computing how specific CPG are compliant with the training set, i.e., the collected data marked with episodes and episode events; the second is the discover of the best, possibly new, CPG as determined by the clinical follows up.

There is an important difference in the formalism used in the two problems: the first is a known Markov model, and so known is the underlying Markov chain, i.e., the probabilistic automaton derived by the CPG. Looking at the segment of a hearth CPG in *Figure 3*, it emerges an evidence of a tree that is the base of such automaton: remember, the only observable elements in database are the grey boxes while the branches (e.g., "Deside for rate response") are used by medics but otherwise hidden.

However, if only the compliance must be checked, known sources (from the patient-state step nodes) can be used to verify if the medic followed this particular guideline; e.g., the "chronic a trial tachyarrhythmia" can be verified by the state of the patient, and so the hidden elements are known, and a "simple" Markov chain can be used instead of an HMM.

In the second case, the free search for a good CPG, there is no prepared CPG, and so a full HMM must be used (no CPG, hence no evident Markov chain).

The *Chain Discoverer Tool* (CDT) is used to accomplish both these operations. From the E^{2}T the care data labelled with episodes are discovered, and CDT emits the percentage of compliance with a set of CPGs, and, if requested, the real automaton that describes (probabilistically) the cares given in accord to the database.

Compliance of a Specific CPG

Verification of the degree of compliance with some CPG is a useful tool to verify if a medic and his team are following one of the official guideline; it is important to remember that each disease can have more that a CPG, produced by European medic associations, or American ones or a National associations; hence, while the protocols are mandatory, the guidelines are discretionary. However, for a Clinical Decisional Support System, it is important to know if a medic are using one of the official guidelines or a new (possibly better) guideline.

To compute the distance between a specific care and one of the possible CPGs Laxman's work (Laxman et al. 2005) can be useful, talking about the discover of frequent episodes and learning hidden Markov models. An episode sequence is an ordered tuple of event types, with a time label, for instance:

$$\left\langle (E_1, t_1), (E_2, t_2), \dots, (E_n, t_n) \right\rangle$$

Removing the time label, an episode can b defined as a sequence of events

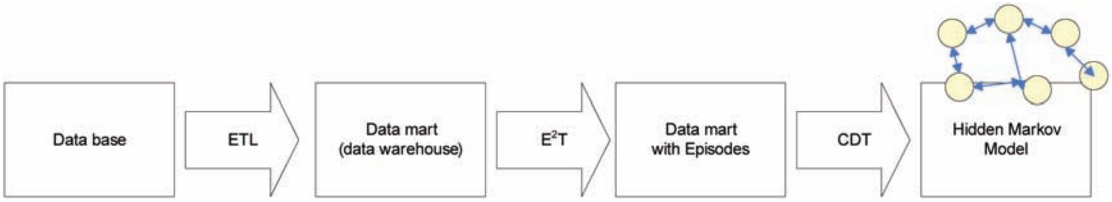
$$E_1 \to E_2 \to \dots \to E_n$$

First step is the counting of non-overlapping episode frequency. Two occurrences of an episode are said to be non-overlapping if no event associated with one appears in between the events associated with the other. The *frequency* of an episode is defined as the maximum number of non-overlapping occurrences of the episode in the event sequence.

The overlapping can happen in clinical data if a patient receive care for two distinct diseases: the two event sequences are overlapping but they belongs to distinct process and CPGs; this differentiation is carried out by the E$_2$T tool.

To determine the adherence to a CPG, the counting of episodes compatible with each CPG must be measured, that is given by algorithm 1:

Figure 9. CPG compliance discovery



```
Algorithm 1 CPGs episode occurrence counting
INPUT: C is the set of candidate episodes, i.e., the training data for a single episode
for all episodes e[i] in C
    for all event A[j] in e[i] do
        for all possible automaton $\alpha_k$
            if A[j] is acceptable by the automaton $\alpha_k$ at step j then increment $freq_{\alpha k}$
OUTPUT: frequencies $freq_{\alpha k}$ for all automata $a_k$ (i.e., all the computed CPGs)
```

This algorithm is a much simplified version of that in (Laxman et al. 2005), because we split the episode counting in the two tools, one step in E^2T and one in CDT.

Discovery of a New CPG

The discovery of a new CPG is equivalent to the discovery of the parameters of a HMM. The parameters that we are looking for are the number N of states, the transition probabilities matrix A – for each a_{ij} and hence the topology of the Markov chain, i.e., starting to a full connected graph, we want to remove the connections a_{ij} where the probability of the transition a_{ij} is 0. The topology of the HMM is defined by the type and the size of the HMM (Kwong et al. 2001). The type of HMM describes the connections between the states in the HMM and the size of HMM is the number of states used in the HMM.

There are several algorithm to compute and optimize the model parameters (the a_{ij}), in particular the Baum-Welch algorithm (Baum 2003), a specialized version of hill climbing. "Optimize" means to discover the most fit parameters compliant with the training set, i.e., the observed data.

This task is a simplified version of the general one. We can estimate the number N of states deriving it from the existing guidelines, and then start from a random probabilities matrix. We used a standard Baum-Welch algorithm although it suffer by sub-optimal optimization (given his hill-climbing derivation). A better, although more complex, solution is to use genetic algorithm that are able to optimize the model parameter *and* the topology at same time; details of such methods are described in (Kwong et al. 2001). We have planned the switch to genetic algorithms in the next version of CDT.

We can derive different HMM from the initial data. We are interested in these cases:

- **The totality of the training sample,** i.e., collected data: this experiment gives us an idea of the real process flow medics are using.
- **Only the training sample with a positive outcomes,** i.e., resulting in a successful disease management and less expensive cares; this is a very important process description, because it can be better than the "official" CPGs.
- **Only the training sample with a negative outcomes,** the inverse of the last case, i.e., resulting in unsuccessful disease management and/or expensive cares; this model is important too, because it gives us hint of how improve the cares.

The data set can be computed using filters as:

- Specific hospital;
- Specific department;
- Specific region etc.

For privacy and legal reason, it is impossible to apply the algorithm to one specific medic/team, although the instrument can be used as an improvement tool by the interested medic (and only from him/her).

CONCLUSIONS AND FUTURE RESEARCH

This research has moved from a Health-Mining project that gave interesting results, especially thanks to wide consensus gained among physicians. The objective was to put the basis for a generic disease management support system, establishing the workflow process and the needed software tools, directly reusable when moving to other diseases. In this sense, Health-Mining was a generalized framework involving not only software elements but also actors (physicians, managers, etc.).

Assuming the process has been correctly developed, actively involving relevant actors, we set-up appropriate instruments to harvest data, copying with frequent and well-known issues related to medical data collection.

Authors were sure that classical statistical analysis of patient records (as in Swedish National Quality Register) would provided us with a large amount of useful information, but they knew that this kind of process is human driven and, being a simple mechanism, would have not been able to discover unknown, probably useful, Guidelines. In fact, thanks to Gödel proof (K. Gödel, 1931), authors know that in a logic-formal system not all the true sentences can be deducted using the given rules. So, they used appropriate languages and algorithms to implement a system free to search for different kind of associations in a given database. Thanks to appropriate interpreters and Clinical Practice Guidelines discoverers they build a system able to focus data mining discovery into understandable and applicable Guidelines, going far beyond the simple statistical analysis of data and avoiding both incompleteness problems and user driven limitations. Concluding, Health Discoverer adds to Health-Mining project new temporal data mining algorithms, ontology extraction capabilities, and a better integration with standard data format for Guidelines.

As future works, authors expect to incorporate this system in the management process of large hospitals. The application to a larger set of illnesses has a direct managerial implication, because the system can act a meter and recommender on a larger audience, and can strengthen the algorithm too, because it will be challenged by more data, and they know how noise, missing data etc. can impact on an algorithm performance.

For the management side, this research has experimented the system (a simpler version) on a real project (pacemaker installation, as reported above), and it got some important results – especially for the extraction rule. Now the researchers want to measure how the system really impacts on the care and cost improvement, and if it is possible to extract better guidelines from the concrete hospital life: it has been theoretically supposed, but a concrete proof will represent a success for the entire theory.

ABSTRACT

As the number of open source software (OSS) projects in healthcare grows rapidly, researchers are faced with the challenge of understanding and explaining the success of the open source phenomenon. This article proposes a research framework that examines the roles of project sponsorship, license type, development status and technological complements in the success of open source health information technology (HIT) projects and it develops a systematic method for classifying projects based on their success potential. Drawing from economic theory, a novel proposition in the authors' framework suggests that higher project-license restrictiveness will increase OSS adoption, because organizations will be more confident that the OSS project will remain open source in the future. Applying the framework to a sample of open source software projects in healthcare, the authors find that although project sponsorship and license restrictiveness influence

project metrics, they are not significant predictors of project success categorization. On the other hand, development status, operating system and programming language are significant predictors of an OSS project's success categorization. Application implications and future research directions are discussed.

INTRODUCTION

"Rapidly rising healthcare costs and an epidemic of inferior healthcare quality over the past decade" (Brailer, 2005) call for an urgent and aggressive adoption of health information technology (HIT). HIT has the potential to transform the healthcare industry by increasing productivity, reducing errors and costs, facilitating information sharing and improving the quality of healthcare services (Brailer, 2005), effectively transforming the healthcare system. Yet, adoption of HIT has been slow and appears to lag the effective application of IT and related transformations seen in other industries (Goulde & Brown, 2006).

With the renewed urgency to adopt HIT, open source approaches are gaining attention (Goulde & Brown, 2006, Kantor et al, 2003, McDonald et al, 2003, Raghupathi & Gao, 2007). For example, under development in Europe is the open source project Care2X, an application with four components: hospital information system, practice management, a central data server and a health exchange protocol. The software is distributed under the GPL license. Another initiative, OpenEHR, funded primarily by the U.S. Department of Health and Human Services, is an open source application that will support health record exchange and access control services in rural Mendocino County, California. These and other similar initiatives have the potential to create low cost tools for physicians.

On a larger scale, government agencies (the predominant payers of healthcare bills) are looking for open source to meet their primary objectives of lowering costs and enabling connectivity. Canada Health InfoWay, funded by federal and provincial grants, started an open source initiative in 2005 to develop software that hospitals and HIT developers could use to ensure the reliable exchange of patient health records among various entities. The U.S. government already has placed its VistaA integrated hospital software package in the public domain to provide adopters with open source software (Goulde & Brown, 2006).

The most significant open source healthcare application is OpenVista, the open source version of Vista, developed and used by all medical centers of the U.S. department of Veterans Affairs. The Vista software and its EMR module can be purchased for $25.00 or less1, are open source by virtue of the Freedom of Information Act, and are being actively marketed by new vendors. Other open source applications include TORCH, a web-enabled EHR application believed to be usable in single practitioner offices and scalable to multi-site practices. Written in an interpreted language, TORCH is therefore operating system independent. Another clinical medical records type application is tkFP, which was implemented using a number of languages including C, C++, Python and Perl. OSCAR, an application from McMaster University, Canada, comprises several modules including an electronic patient record system, billing, referrals and secure messaging. The system requirements include Linux, Java2 SDK, MySQL and Jakarta Tomcat. GnuMED is yet another EMR built using a cross platform WxPython GUI and the Postgres relational database. FreeMed, on the other hand, uses the popular LAMP (Linux, Apache, MySQL and PHP) platform, to provide web browser-based interface.

These advances suggest that the open source development approach is a viable means to developing HIT applications. Considering these activities, OSS, itself a transformative force in the software industry, may have a significant role in this hoped-for HIT revolution, potentially affecting the development and adoption of HIT and the strategic positioning of HIT vendors. For example, a recent joint venture of Red Hat Inc. and McKesson Corp. is aiming to push IT further into U.S. healthcare through open source software (Babcock & McGee, 2007), thereby intensifying competition between Linux and Microsoft Windows (Economides & Katsamakas, 2006).

And yet while several applications have been reported in the literature (Raghupathi & Gao, 2007), primarily in the bio informatics field, hardly any rigorous studies exist to advance the understanding of OSS development in healthcare. For example, we do not have sufficient insight into the current level and speed of development of OSS in different types of healthcare organizations, and the factors that influence development and adoption.

Therefore, it is important to identify the characteristics and factors that influence software development and adoption in HIT, explain the forces behind them (e.g. sponsorship, licensing, technologies used), evaluate the effect of potential policies, and suggest the targets of such policies. To that end, this article is the first rigorous quantitative study based on objective data. A detailed analysis of open source development is one of the most overlooked aspects of HIT literature. Several HIT applications, including electronic medical record systems, are listed on the SourceForge web site, a good starting point for a comprehensive study of OSS in healthcare.

The rest of the article is organized as follows: section 2 describes the research framework for our study, drawing on work in the OSS and information systems fields. Section 3 describes the methodology and section 4 discusses the results. Finally, section 5 discusses the scope, limitations, conclusions and future research directions of our study.

RESEARCH FRAMEWORK

The primary objective of this research is to classify open source HIT projects into distinct groups based on their success and to explore the antecedents of those groups. Prior research in information systems proposed project metrics and identified antecedents of project success (Crowston & Howison, 2006, Crowston *et al*, 2006, Stewart *et al*, 2006), but there is limited research on classification frameworks that would provide more insight into open source projects (English & Schweik, 2007). For instance, Crowston & Howison (2006) discuss the need to explore the community of developers, leaders, and active users behind OSS to make decisions regarding software viability and suitability for user needs. They suggest looking at sponsorship (as a measure of success). In addition, understanding a project's life cycle and its developers' motivations is a critical basis for the open source community's impact on a project's success. Crowston *et al.* (2007) provide empirical evidence regarding the management practices of OSS teams. Specifically, the authors identify how OSS teams organize their work (focusing in particular on practices for assigning work), how these practices differ from those of conventional software development groups and thus suggest what others might learn from OSS communities.

Crowston *et al.* (2003, 2006) identified measures that could be applied to calculate the success of OSS projects based on a brief review of the literature, a consideration of the OSS development process, and an analysis of the opinions of OSS developers. They suggest that the development of success measures for OSS is important for two reasons. One, such measures would be useful to OSS project managers in assessing their projects. In many cases, third parties sponsor OSS projects so measures would help sponsors estimate a return on their investment. Two, OSS is an increasingly visible and copied method of systems development.

Drawing on prior literature in OSS and information systems we identify the relevant metrics of project success in HIT such as downloads and activity (Crowston *et al*, 2006, Stewart *et* *al*, 2006) and combine them with two extended metrics of success namely, the project rank and participation to create project clusters. Upon the creation of clusters, we explore the antecedents of such clusters. In addition to the effects of project sponsorship and license type, our framework focuses on the effect of such explanatory variables as development status, intended audience and technological factors (database environment, operating system, and programming language) on project success.

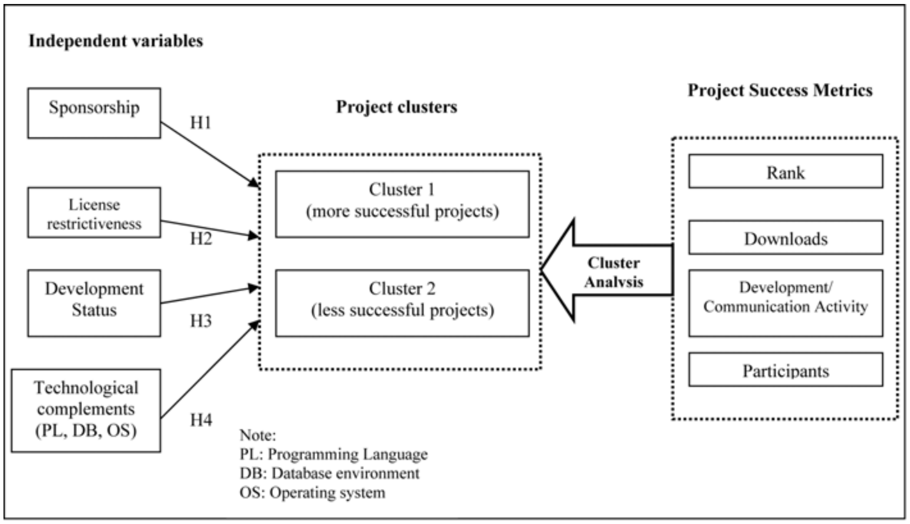
Our research framework is shown in Figure 1. The primary independent variables are *project sponsorship* and *license type.* Other variables considered in the framework are development status and technological variables such as programming language, operating system and database environment. The primary dependent variables are the success measures namely, *activity, downloads, rank, and participants.* Clusters of projects are derived using cluster analysis based on these dependent variables. Once the clusters are identified, we also examine *project sponsorship, license type*, and the other independent variables as antecedents of these clusters. Below we describe the main variables and provide the theoretical justification for the research hypotheses. Our choice of variables is consistent with previous studies on open source project success (e.g. Lerner & Tirole, 2005, Stewart *et al*, 2006). More detailed descriptions can also be found on the Sourceforge website.

DEPENDENT VARIABLES

Project rank**:** As per the SourceForge website, project rank measures the rank of a project within SourceForge database. The measure captures information about traffic, communication and development of each project.[2] Traffic reflects downloads and visits to project page. Development reflects commits to CVS repository and age of last release. Communication reflects tracker, mailing list and discussion forum activity.

- **Downloads:** This metric measures downloads' of a project's code from the project's page, as reported on SourceForge web site. Downloads reflect the popularity of a project to users and is also a proxy of use. Note that downloads are also captured in the *rank* dependent variable.

Figure 1. Research framework



- **Communication and development activity:** It refers to communication activity (tracker, mailing list, and discussion forum activity) and development activity (commits to CVS repository). Note that these are also captured in the *rank* dependent variable. Typically all projects are ranked on a percentile basis; the higher the percentile the greater the activity.
- **Participants:** As reported on SourceForge and in the context of our research framework, the participants metric refers to developers that participate in the project, not the end users. Since we are indirectly capturing the user participation from downloads metric and activity on the project website, focusing on developers' involvement is considered more important here.

Stewart *et al.* (2006) comment that project success in the context of OSS projects is a concept that varies in meaning across projects and stakeholders. Different stakeholders view success differently and are influenced by time, need, use, risk management, and a multitude of other similar context specific variables. Given the nature of OSS projects, where work is performed free of charge by voluntary developers without rigid deadlines or implementation schedules, traditional metrics of "on time and within budget completion" or "revenue generation" are not appropriate to measure the success of these projects. Alternative non-traditional metrics have emerged as indicators of success in OSS projects. These metrics may reflect the perspectives of particular stakeholders or they may have been explored in prior research. For example, (Crowston *et al*, 2003) submits that success or lack thereof is indicated by volume of traffic on the project web site, quantity of code downloads, and the number of people monitoring project activity. The attraction of voluntary developers to join and contribute to an ongoing OSS project, too, is an indicator of OSS project success, as argued by (Stewart *et al*, 2006).

INDEPENDENT VARIABLES

Sponsorship: A project is sponsored when it is initiated and/or actively supported by a healthcare organization or a firm providing health related software. We draw from economic theory in proposing that sponsorship increases a project's likelihood of success. This effect of sponsorship on success may occur because of the provision of resources such as non-volunteer developers, code (Henkel, 2006), or tools. Commitment to a process that is otherwise self-organizing as well as the signaling effect that attracts other developers and users imply that sponsorship should increase the likelihood of project success. Jeppesen & Frederiksen (2006) find that innovative users who contribute to business-hosted communities are either hobbyists or they are responsive to firm recognition. Sponsorship is a categorical variable.

The hypothesis related to sponsorship is as follows:

H1: *Project sponsorship is positively related to higher probability of project being classified into a cluster of more successful projects*

- **License type:** A software license defines the use, modification and distribution rights assigned to users. The invention of GPL (General Public License) by the Free Software Foundation was followed by a large number of open source licenses[3]. The major licenses among them are GPL, LGPL, BSD, MIT and the Mozilla Public License. Compared to closed (proprietary) licenses, GPL provides users with the right to use, modify and redistribute software. There are three main types of licenses (Lerner et al, 2003, Nelson et al, 2002), namely, strong copyleft (highly restrictive, such as GPL); weak copyleft (restrictive, such as LGPL); and non-copyleft (non-restrictive, such as BSD). Highly restrictive licenses are less likely to be usurped by an organization that takes the open source code, modifies it, and then commercializes the result. Prior research (Lerner & Tirole, 2005) examined the choice of open source license and found that restrictive licenses are used for projects targeted to end-users rather than developers, and for projects attractive to consumers, such as games. Earlier research has also argued that projects with restrictive licenses should attract more contributors (Lerner & Tirole, 2005, Stewart *et al*, 2006) but fewer users because of the restrictions and license uncertainty (Stewart *et al*, 2006).

We offer a novel interpretation of the role of licenses in open source development. We propose that a more restrictive license is positively related to higher user downloads. An organization adopting open source at the outset of a project, perceives benefits if it is assured that the project will remain open source in the future. On the other hand, users may perceive that projects with less restrictive licenses will not remain open source in the long run. Stricter licenses are convincing indicators that these projects will not get usurped and will remain open source in the future. Healthcare organizations, the predominant users of health software listed on SourceForge, usually are not interested in commercializing open source code, and for various reasons should find this assurance appealing (for instance, they can avoid commercial vendor lock-in). Projects with higher restrictiveness should also attract developers interested in protecting the openness of their work in the future.

The hypothesis pertaining to license restrictiveness is as follows:

H2: *The higher the license restrictiveness, the greater the probability of the project being classified into a cluster of more successful projects*

- **Development status:** This variable captures the software development status (e.g. pre-planning, alpha, beta, etc.). The development status pinpoints stages of the lifecycle of software development and should affect the success metrics of a project. It stands to reason that the project activity at various stages of development of an OSS project is bound of be varied. Since project success metrics (rank, downloads and activity percentile) all depend heavily on the activity of the project, implicit in our logistics regression of clusters is the hypothesis that development status does have a positive impact on the project classification into successful cluster. Formally, the hypothesis related to project development status is,

H3: *The more advanced the project development status the higher the probability of project classification into a cluster of more successful projects*

- **Technological complements:** We also explore the relationship between each of programming language (PL), operating system (OS), and database environment (DB) and project success measures. The motivation for this comparison is that these technologies are complements to the project output in the sense that output requires a PL and is deployed in a DB/OS environment. Therefore, these technologies are likely to affect the success metrics of a project. For instance, a project targeting a popular OS or DB environment may increase its success potential. Likewise a project using a popular PL in the health domain should attract developers easily as well as organizations that will use this particular PL to customize the OSS. So formally, the hypothesis related to project technological complements is,

H4: *Projects associated with successful technological complements are more likely to be classified into a cluster of more successful projects*

METHODOLOGY

Data Collection

We searched SourceForge for projects using the various keywords pertaining to health, medical, and bioinformatics applications. This search identified 607 projects related to HIT. We then excluded all indirectly related projects, such as those pertaining to pure medical sciences and medical devices. This filter narrowed the field to 258 projects. We excluded 79 of these on the basis of their not being considered typical HIT as per Institute of Medicine classification of HIT applications. An additional 5 projects were deleted because of duplication. The final sample of 174 projects was considered mainstream HIT falling as they did into such categories as health record systems, health office support, and utilities (such as interoperability). In addition, we gathered from the Internet sponsorship information on each project and integrated this data into the SourceForge dataset. A Java program was written to extract data from the web pages of each of the 174 healthcare open source projects. All extracted data were stored in a CSV (Comma Separated Values) text file that could be loaded easily into other applications, such as Excel and SPSS, for further analysis.

Data Preparation and Transformation

The variables in the research framework were coded appropriately to fit our analysis. For example, project licenses were coded as highly restrictive, restrictive and non-restrictive. Three variables that had over 15% missing data were dropped from the dataset and not considered further. SVN Repository Commits (82.7%) SVN Repository Reads (83.2%) and Mailing lists (25.7%) were the three variables that were dropped from the dataset. With regard to other variables, missing values were replaced with "0" or the median of the population (which incidentally was "0").

A large number of variables we studied had "severe positive" skew distributions. To reduce skewness, those variable values were transformed using "Inverse" transformation. Typically, inverse transformation produces values that are ranked in reverse order. It is not difficult to visualize this transformation: 10 becomes 0.1, 100 becomes 0.01, and so on. While 10 is less than 100 (10<100), the resulting 0.1 is greater than 0.01 (0.1>0.01). So we used INVerse REFlect transformation. In other words, we computed the inverse and then reflected by subtracting the inverse value from one ("1"). So an INVREF transformation of 10 results in 0.9 (or 1- 0.1) and INVREF transformation of 100 produces a 0.99 (or 1 - 0.01). The resulting numbers were ranked in the same order as they were originally. This retention of original ranking of transformed variable values made interpretation of subsequent results less confusing. With the INVREF transformation, the severity in the skewness was reduced but not removed altogether. However, the subsequent statistical processes were not overly sensitive to moderate levels of skewness, so the results are meaningful as well as useful.

Descriptive Statistics

Table 1 presents an overview of the project statistics over the past 12 months (the 12-month mean is the value for each metric by project). The mean column represents the grand mean, or the mean of each project's 12-month mean. In a few cases, data was available for fewer than 12 months; they may have been registered within the past year. All the projects were active as of May 2007.

The mean of activity percentile for the projects is 71.84, a positive indicator for the average activity. The average number of developers is 4, but there are projects with as many as 110 developers. It is interesting to note that activity percentiles range from a low of 16.31 to a high

Table 1. Project statistics

Project Activity metrics	Minimum	Maximum	Mean	Std. Deviation
Developers	0	110	4.09	9.267
Activity Percentile (last week)	16.31	99.86	71.8383	22.28214
Forum Messages	.00	3973.00	28.2414	301.15120

Total Feature Requests	.00	58.00	1.4885	6.06205
Total Pages	14.67	58007.42	1473.55	5609.67
Down loads	.00	10234.25	182.13	859.86
Project Web Hits	0	40825	1580.63	5369.411
Tracker opened	.00	8.75	.15	.83
Tracker closed	0	6	.08	.552
Forum Posts	0	15	.21	1.534
Rank (Mean)	123.92	141852.50	48488.69	33776.82

of 99.86. The total pages in a project ranges from 14.67 to 58,007.

Table 2 presents the descriptive statistics for the main independent and dependent variables. The most common type of license is restrictive, followed by highly restrictive and non-restrictive. The Highly Restrictive and Restrictive licenses do have some overlap, which can be ascertained easily as follows: The mean of Non Restrictive licenses is 0.17, that is, 17% of the projects belong to the Non Restrictive license type. Therefore, 83% (100 - 17) are of the Restrictive type. The means of Highly Restrictive and Restrictive license types add up to 1.12 (0.47 + 0.65) for a total of 112%; therefore, 29% (112 - 83) of the licenses fall under both Highly Restrictive and Restrictive categories.

The prefix DB_ stands for Database Environment, IA_ for Intended Audience, OS_ for Operating System, PL_ for Programming Language, and DS_ for Development Status. To facilitate useful insight and easy interpretation, the dummy variables under each of the categories with these prefixes were first sorted in the order of descending mean values. Then we generated correlations. For example, DB_Unspecified (mean = 0.5805) is listed at the top followed by DB_OS (mean = 0.3448), DB_NOS (mean = 0.0862), and DB_Other (mean = 0.0517) in that order for the Database Environment category. This implies 58% of the projects had not specified the database environment. Additionally, approximately, 34% had employed Open Source (OS) database technologies, while 8% of projects used Non-Open Source database technologies. Approximately 6% of projects employed two or more database technologies concurrently. (Overlapping classifications can be spotted easily when, as in this case, the total of mean values for classifications

Table 2. Descriptive statistics for independent and dependent variables

exceeds unity.) Additional insights include the fact that the mean of Sponsorship (0 = No; 1 = Yes) is 0.37, implying 37% of projects had sponsors and the remaining 63% did not. As for the intended audience classification, 38.51% of the projects targeted Industry, Science, Organizations and Research (ISOR), while 27.59% targeted Developers. Because the intended audience categories are mutually exclusive, the sum of their mean adds up to unity. While independent operating systems were preferred by 32.18% of the projects, 41.38% employ Java as the preferred programming language. These observations and others in Table 2 would be of interest to such OSS stakeholders as developers, sponsors, and users.

However, one factor limited our statistical analysis: some projects had missing data or reported none under various dummy variables, currently classified at DB_unspecified, IA_unspecified, OS_unspecifed, PL_unspecified, and DS_unspecifed. If certain data values had been reported for those projects, some of the results could potentially change.

ANALYSIS AND DISCUSSION OF RESULTS

The steps included the following: first, we incorporated select success metrics (see figure 1) as dimensions of cluster analysis to identify the project cluster; and second, we used logistic regression to analyze the antecedents of project participation in each cluster.

Cluster Analysis

Given that our model includes several types of variables including continuous (Downloads, Activity percentile), categorical (Dev_status, License Restrictiveness), and binary (Sponsorship yes/no, other dummy variables), it became necessary to employ two-step clustering unless we could find some transformations to change all of our data into continuous data types. Our solution for this research was to combine cluster analysis and logistic regression. First, we used cluster analysis to group projects into more successful and less successful groups. Then, binary logistic regression was used to understand the impact of attendant independent variables and complementary factors on the increase or decrease in the probability of each project being classified into either of the designated groups.

For the first step, we used two-step clustering to create clusters in SPSS. We let the system create the best number of clusters. Because the focus of clustering is to demarcate projects into successful or otherwise, we specified three criteria:

downloads, rank, and activity percentile for the creation of the clusters. These three dependent variables were chosen primarily because each of them is an alternative measure of project success in different perspectives (Crowston *et al*, 2003, Stewart *et al*, 2006). Dependent variable "developers" is left out of cluster creation process since the prior research didn't conclusively find association with developer participation and project success (Krishnamurthy, 2002). Typically, downloads and activity percentile are positively associated with the success of projects, while rank is negatively associated with the success since lower ranks denote greater success. Table 3 summarizes the cluster distributions for system-picked (two clusters) and user- specified (three clusters).

There is no difference in the first cluster for the system-picked or user-specified cluster creations. It is clear that Cluster 1 (which gives similar results under both processes) is distinct compared to the rest of the data. Consider the following plots of confidence intervals of three key characteristics of clusters that we used as criteria in creating the clusters. Figures 2a, 2b, and 2c show that "downloads" for the first cluster is the main characteristic that differentiates that cluster from the other two in the data set.

The reason for creating two alternate sets of clusters—first a set of two "best clusters" selected by the system and then a set of three "user-requested" clusters—was to compare the sets for developing possible insights. One important discovery was immediately evident: the first cluster remained the same with each approach. This finding suggests the occurrence of a natural cluster on the prescribed dimension viz. the chosen indicators of project success. Descriptive statistics of the best clusters picked by the system are presented in Table 4 below.

The mean values of downloads and activity percentile for cluster 1 at 0.9562 and 83.5743 were higher than those of cluster 2 at .0000 and 57.3941, respectively. Similarly the mean of rank for Cluster 1 at 27742.9737 was substantially lower than the rank of Cluster 2 at 74021.8789 (because the lower ranks indicate higher success). Downloads, Activity Percentile and Rank indicate the predictable behavior because they were used as the basis for defining the clusters in the first place.

It's significant to note that the sponsorship mean for Cluster 1 is a 0.47, indicating that 47% of projects were sponsored. However, only 27% of Cluster 2 projects had sponsors. This finding supports the framing of hypothesis H1. Restrictive and Highly Restrictive license types recorded a higher mean for the Cluster 1 than Cluster 2, supporting the framing of hypothesis H2 that the higher the license restrictiveness the greater the chance a project will be classified as successful. It is interesting to note the mean of Non-restrictive licenses for Cluster 1 is lower than that of Cluster 2, consistent with other findings.

To summarize, Cluster 1 encompasses the most successful open source projects in HIT. These projects are characterized by relatively

Table 3. Cluster distribution

	Best clusters picked by system			**Three cluster request result**		
		N	% of Total		N	% of Total
Clusters	1	96	55.2%	1	96	55.2%

(Note: there is no difference in the profile of the first cluster compared to the first cluster under best clusters picked by the system).

high downloads, high rank, and more developers. Cluster 1 projects are also more likely to be sponsored, and they have more restrictive licenses. These observations are consistent with our research framework.

Table 5 presents the descriptive statistics for the three-cluster definition.

The combination of the means of the first three variables in the table defines the centroid of each cluster. The mean of total bugs is higher for successful projects than it is for less successful projects. If one infers that the improvements to projects are based on total bugs reported, then we can surmise that reporting of more bugs indicates higher activity levels and better quality patronage. Sponsorship and license restrictiveness across the three clusters were generally consistent with prior research findings.

Logistic Regression

According to Mertler & Vannatta (2002), "logistic regression has the same basic purpose as discriminant analysis—the classification of individuals into groups." They go on to elaborate that "logistics regression seeks to identify a combination of IVs (independent variables)—which are limited in few, if any, ways—that best predicts membership in a particular group, as measured by a categorical DV (dependent variables)."

One advantage is that no assumption need be made that the predictors are normally distributed, linearly related, or have equal variances within the groups. Accordingly, we do not specifically screen the data for normality, linearity or homoskedasticity in preparation for the logistic regression. Further, since we have used "inverse reflect" transformation on the continuous variables to facilitate other statistical models, and most of the predictors are either categorical or binary, we have effectively avoided the problems with outliers. A preliminary multiple regression was performed to examine multicollinearity among the predictor variables and revealed the tolerance for all variables to be greater than 0.2, the recommended tolerance as per (Field, 2005).

As explained under cluster analysis section, Downloads emerged as the single most dominant factor in the creation of clusters. We left "downloads" out of the binary logistic regressions so that we might understand the impact of other predictors. Since the system picked only two clusters as best clusters, we limit the logistic regression discussion to the two clusters picked by the system. Instead of a single categorical variable "Development Status" (Dev_status) on a scale of 1-7 (denoting Planning, Pre-Alpha, Alpha, etc.), we coded binary 0/1 for each development status stage. Similarly, we coded binary dummy variables for the intended audience and programming language and other categorical variables as discussed above.

A Backward Stepwise Binary Logistic Regression was conducted to determine the independent variables that are significant predictors of the classification of projects into best cluster categories. The regression results indicate that the overall model of 11 predictors and a constant is significant in distinguishing between "successful" and less "successful" projects. (- 2 Log likelihood = 153.774; χ^2 (11) = 85.576; p<.0001). The model correctly classified 81.6% of the cases. Regression coefficients that are significant in the equation that predicts the cluster membership are presented in Table 6 below. Since the Wald statistic is considered to be very conservative and by adopting a liberal significance level (p<.05 or p<.1), nine of the 11 variables are found to be significant contributors to predicting the project category.

Hypotheses Testing

The results obtained from a logistic regression are somewhat different from the other types of regression equations in that, what is predicted in a logistic regression is the probability of a case being classified into a category rather than the value of a DV. The odds ratio or the Exp (B) indicates increase (or decrease if the B value is negative) in odds of being classified in a category when the predictor variable increases by 1. Therefore, the Exp (B), the odd ratio for programming language (PL_CPlusPlus) at 7.736, indicates that for an increase of 1 unit (in this case the flip of 0 to 1 of the dummy variable) there is 7.736 times likelihood of the project being successful for every 1 time of likelihood of project being unsuccessful.

Surprisingly, sponsorship is not indicated at all as a significant predictor of a project success. Therefore, Hypothesis H1 doesn't find support. However, non restrictive license does appear as a

Table 6. Regression coefficient obtained under binary logistic regression

Variable	B	Wald	Df	Sig.	Exp(B)
DS_ProdnStable	1.933	9.645	1	.002	6.912
DS_Planning	-3.403	8.233	1	.004	.033
TotalBugs_INVREF	-2.289	7.739	1	.005	.101
PL_PHP	-1.618	7.535	1	.006	.198
OS_Proprietary	1.334	7.397	1	.007	3.797
DS_Multiple	1.930	5.334	1	.021	6.888

PL_CPlusPlus	2.046	3.157	1	.076	7.736
NonRestrictive	-.939	2.783	1	.095	.391

Dependent variable: Cluster Number (1 or 2)

significant factor having an effect on project classification. Our hypothesis concerning the project licensing was that the higher restrictive licenses lead to project success. To support this hypothesis, one would like to have seen highly restrictive license obtaining a higher Exp (B) than restrictive license and non restrictive license's Exp (B) values respectively. But that was not the case here. So hypothesis H2 also fails to find support.

Three development status levels, including in order Production Stable, Multiple and Beta, have high odds ratios for indicating greater influences of those variables in influencing the probability of the project classification. This evidence provides support for hypothesis H3.

Programming language (PHP, C++), operating system (Proprietary) are predictors of project classification. Providing support for H4, these findings suggest that the success of a project is related to the availability of complementary assets, such as programming skills of developers and operating systems employed by users. Thus, technological factors such as choice of programming language and choice of target operating system strongly influence project success, and should be carefully chosen by project leaders.

Project leaders should carefully analyze and understand the impact of these variables (factors) and their tradeoffs. To summarize, while sponsorship encourages developer participation and higher activity in a project (based on past research findings), it does not guarantee the translation of these positive effects into higher downloads or a higher rank for the project. It is surprising that sponsorship did not influence project success. With regards to license restrictiveness, while it attracts more downloads and consequently results is a higher project rank and higher activity percentile (based on past research findings), we found in Table 6 that license restrictiveness does not guarantee the project classification into the successful projects cluster. This last finding is somewhat inconsistent with the increased downloads and higher activity percentile.

Several inferences can be drawn. While project sponsorship and license restrictiveness had significant influence on project success metrics, they did not directly impact project classification as successful or less than successful. Project development status indeed finds a prominent place in the logistics regression results. This suggests that the stages of development status have significant impact on project classification. Further, it is noted that programming language and operating system also have significant impact on project classification.

CONCLUSION AND FUTURE RESEARCH

This study proposed a research framework that explains open source project success and developed a method of classifying open source HIT projects. That identification of project classes provides useful insights to all OSS stakeholders in terms of project success and the drivers of that success. The study illustrates the usefulness of this approach in the context of HIT projects, while future research can leverage this method to other open source settings. Interestingly, development status, programming language (PHP, C++), and operating system (proprietary) are predictors of project classification. These findings suggest that the success of a project is related to such complementary assets as programming skills of developers and operating systems used by users. Thus, not only legal/social factors (such as license, organizational sponsorship) but also technological factors (such as choice of programming language and target operating system) strongly influence project success. Leaders of future projects should carefully consider the tradeoffs between these variables.

Before we emphasize the contributions, a number of limitations should become explicit. Since data from SourceForge was gathered at a specific time, this study is a snapshot in time. We recognize, too, that not all open source HIT projects are registered with SourceForge; many are registered at Freshmeat and at other related web sites. And many high profile projects maintain their own developer sites. Another limitation is that some projects may have outdated or erroneous data in their listings, not to mention those projects for which there was missing data. We assume that the HIT-related projects found on SourceForge, given the sites popularity and the large number of projects and developers registered there, are representative of the overall open source movement in healthcare.

The study makes a number of important contributions. First, we use cluster analysis to identify groups of successful and unsuccessful projects on SourceForge and find predictors of participation in each group. This systematic approach can benefit future studies that attempt to identify different types of projects in other domains. Second, we develop a theoretical framework that examines the role of technological complements, project sponsorship, development status and license type in the pattern of open source development projects and we test related hypotheses. Drawing from economic theory, a novel proposition in our framework suggests that higher project-license restrictiveness will increase OSS adoption, because organizations will be more confident that the OSS project will remain open source in the future. Third, we demonstrate how open source development may be better understood in the context of a specific domain—healthcare, and we provide insights on the status of open source development in that domain.

Project sponsors, such as firms or organizations, too can benefit from our insights. These findings have the potential to help sponsors identify projects worthy of their time and resource investments, whose success would enhance both brand recognition and market presence. Further, the programming language, database technology, and operating system preferences of developers and users of open source software projects are useful information to IT firms related with these technologies.

Regarding HIT, future research should consider the open source development dynamics (Katsamakas & Georgantzas, 2007) in the HIT context. The impact of OSS on HIT diffusion is another area worth investigating. A time series analysis and longitudinal studies may provide more sophisticated insights into the OSS development process.

Future research might consider a study that compares generic OSS (e.g. projects listed on

SourceForge and Freshmeat) and those developed in-house (e.g. bioinformatics applications). Detailed case studies of important development projects should provide a richer understanding of open source development in healthcare. A related problem to be examined is the adoption of open source software by healthcare organizations. While OSS applications development in health has great potential, the research framework, classification approach and findings presented here may be applied to other industries and organizations. But clearly open source development, especially with regard to healthcare, is a growing field. This is good and timely news given the need for HIT, wherein lies the opportunity to transform an entire industry.

Chapter 1.19

Cybermedicine, Telemedicine, and Data Protection in the United States

Karin Mika
Cleveland State University, USA

Barbara J. Tyler
Cleveland State University, USA

ABSTRACT

This chapter provides an overview of law relating to online and Internet medical practice, data protection, and consumer information privacy. It provides a comprehensive overview of federal (HIPAA) and state privacy laws, concluding that both those legal resources leave gaps in consumer protection and provide no real penalties for violating the laws. The authors educate the readers to the legal and data protection problems consumers will encounter in purchasing medical and health services on the Internet. Furthermore, the authors recount some actual case studies and follow those with expert advice for those Internet consumers who wish to be not merely informed, but also safe. The authors not only educate the readers to the lack of protection afforded to them but also advocate throughout the chapter that the United States must enact more federal protection for the consumer in order to deter privacy violations and punish criminal, negligent, and wilful violations of personal consumer privacy.

DOI: 10.4018/978-1-60566-012-7.ch018

INTRODUCTION

The practice of medicine is not immune from the information age. The use of the Internet, including e-mail, in medical practice is altering the traditional method of delivering medical care. Millions of Americans now rely upon the Internet as a primary source of medical information or education about their own symptoms, conditions, diagnoses, and treatments. The practice of **telemedicine,** consulting with another physician by using technology, is constantly evolving and expanding into areas never before imagined. Physicians are establishing their own Web sites and some few are now practicing medicine on the Internet.

The progression of the traditional practice of medicine in cyberspace has brought with it many issues related to privacy and **online data protection**. No longer is the **physician-patient relationship** limited to an in-person office consultation that carries with it the legal protections of doctor-patient privilege. Rather, the practice of medicine has evolved to include interactions that might not have ordinarily been considered a **physician-patient relationship**, and these contacts may stretch across both real and virtual boundaries. In fact, the interactions are, at times, both real and virtual, and the consumer-patient is now in a situation where it is difficult to identify exactly who is the party on the other end.

This chapter will provide an overview of the law relating to **cybermedicine,** medicine practiced without traditional in-person contact, and **telemedicine,** in terms of data protection and other legal complications related to licensing and a conflict of state laws. The chapter will examine the laws applicable to Web sites where medical diagnosis or the purchase of medical services (including prescriptions) is available. The chapter will discuss how the new methodology of acquiring medical care is at odds with traditional notions of state regulation and how current laws, both federal and state, leave many gaps related to any consumer protections or potential causes of action when privacy is compromised.

This chapter will proceed with an overview of the federal **Health Insurance Portability and Accountability Act of 1996** (**HIPAA**), an act promulgated to ensure privacy of health information as well as access to health care. It will review **HIPAA**'s application to medical practice conducted on the Internet. It will, in brief, discuss the plethora of sites available over which American citizens may purchase prescription drugs without a prescription from a licensed United States physician or merely through an overseas Web site with no physician to monitor the transaction. We then will examine current federal laws which are not set up to regulate these international transactions. The chapter will explore potential legal complications with **personal data** and privacy issues related to purchasing medical treatment or services on the Internet and describe what, if any legal recourse consumers might have when the outcome of an Internet medical transaction turns out to be undesirable. The chapter will posit some expert advice for consumers regarding using websites for medical purposes as well as protecting their own privacy. Lastly, this chapter advocates a federal law more punitive that **HIPAA;** one that regulates and protects patient information, medical transactions, and interactions on the Internet and deters violations of **patient privacy** by mandating significant fines and imprisonment for negligent or criminal and willful violations of that privacy.

THE TRADITIONAL PRACTICE OF MEDICINE IN THE UNITED STATES

Physician's State Licensure

The study and practice of medicine is core to mankind's need to extend and preserve life. The evolution of medical practice over the centuries from prehistoric times has involved the study of the human body and its mechanisms, disease processes, surgery, and natural herbal and manufactured drugs, to the present time, with its focus on modern genetic testing and techniques. While modern medicine and medical education had its genesis in the 19th century, the 20th century has made incomparable strides in clinical practice, immunology, and pharmacology.

Practicing medicine is not regarded by the law as an inherent right of an individual. Rather, it is regarded as a privilege that is granted by the people in a state acting through their elected representatives. Because it is considered a privilege to practice medicine, each state protects health care consumers by licensing and regulating physicians. As a report to Congress stated, "The purpose of licensing health care professionals is to protect the public from incompetent or impaired practitioners" (Telemedical Report to Congress, 1996). Licensure authority defines who has the legal responsibility to grant health professionals the permission to practice their profession. Physicians, dentists, registered nurses, and pharmacists are subject to mandatory licensing in all 50 states. Many other types of health care professionals are also licensed in most states. The federal government licenses some individual health care providers, for example, those professionals who manufacture, distribute, prescribe, and dispense controlled substances must be registered with the Drug Enforcement Administration (Miller, 2006).

Historically, under the Tenth Amendment to the United States Constitution, states have the authority to regulate activities that affect the health, safety, and welfare of the citizens within their borders, including the practice of medicine. The United States Supreme Court has recognized that states have a "compelling interest in the practice of professions within their boundaries" (Goldfarb v. Virginia State Bar, 1975).

In response to this amendment, each state has created a Medical Practice Act that defines the proper practice of medicine and mandates the duties of the state medical board to regulate medical practice. Every state and United States territory has a medical board. The primary means through which the state medical boards promote sound medical practice and keep consumers safe is through licensing and regulating of physicians.

The federal government plays little role in setting standards for the medical field except to the extent that the Food and Drug Administration is responsible for determining what prescription drugs are available, and setting safety standards for drugs and packaging. Retail pharmacies are highly regulated. All states require pharmacies have a license. Some states regulate hospital pharmacies through hospital licensing, exempting those pharmacies from the pharmacy licensing system. Pharmacy regulations often require staffing requirements as well that limit the hiring of those who are unlicensed. Standards of practice can be found in many places such as state statutes, agency regulations, and county or municipal ordinances.

Pharmacists fall into the category of coverage by state law as well. All states require licensing of pharmacists. The National Association of Boards of Pharmacy (NABP) is the independent group that assists member boards and jurisdictions in developing, implementing, and enforcing uniform standards. This group provides an Electronic Licensure Transfer Program (ELTP) listing all 50 states, the District of Columbia, Puerto Rico, and the Virgin Islands and the requirements for licensed pharmacists to transfer an existing license from one state or jurisdiction to another, as well as the fee for processing the preliminary application (NABP Web site, 2007). The federal government, under the Drug Enforcement Administration, licenses professionals who manufacture, prescribe, dispense, or distribute controlled substances.

Board Certification

Traditional **medical licensing** has changed in recent years to require more education for those physicians or specialists who wish to acquire **board certification** beyond the traditional state medical license. A seachange has occurred in the medical sciences as a direct result of exponential advances in electronics, chemistry, physics, computer sciences, engineering, and clinical medicine. Medical practice today requires so much knowledge, it is virtually impossible for any physician to become an expert in every field. Thus, many current clinical practices require advanced, specifically focused knowledge and extra years of training and education in specific fields of study.

According to the American Board of Medical Specialties (ABMS), there are more than 130 medical specialties and subspecialties. There are 24 member boards listed as members of the ABMS. If a physician is **board certified** it means that the physician has not merely completed medical school and holds a valid state license but has also completed an appropriate residency from 3 to 7 years and been examined using the criteria informing the physician's specific field.

As medicine and its practice become infinitely more complicated to practice, the licensure system within the United States discourages interstate practice (Johnson, 2006). There are some exceptions to requiring an actual physician's state license in each state: one such exception is the consulting exception. Physicians may practice medicine in another state by acting in consultation with a state-licensed referring physician. Even this exception varies from state to state and this exception preceded the advent of the practice of **telemedicine**. To remedy this discouraging of interstate practice, specialists who complete residencies should be considered for federal licensing. This licensing would allow the best and brightest to practice within the United States in all jurisdictions, regardless of state boundaries and not be hindered by local restrictions on consulting and practice.

Establishing the Physician-Patient Relationship

Whether express or implied, the traditional **physician-patient relationship** is contractual in nature and grounded in the premise that the physician is a learned individual, skilled and experienced in subjects about which the patient knows little or nothing but things that are of vital interest to the patient since they determine his health (Miller, 2006; Kohlman, 2006). This relationship is a fiduciary one, requiring the highest ethical obligation from the treating physician. Generally, the relationship may be created from an express or implied agreement. It is an express agreement when actual written forms are signed, the patient agreeing to pay for services in exchange for the performance of a specific service from the physician. In most cases, however, the agreement is implied. The patient finds a physician or is referred, makes an appointment, and travels to the physician's office. When the physician accepts the patient or undertakes to treat him, and the patient accepts the services, the relationship is created. Generally, a physician or other independent practitioner has the right to accept or decline to establish a professional relationship with any person (Miller, 2006).

Even though the existence of a **physician-patient relationship** usually depends upon whether a physician has examined, diagnosed, and treated a patient, the relationship must first be consensual for the purposes of **doctor-patient** privity. The relationship is considered consensual when the patient knowingly seeks the services of the physician and the physician knowingly accepts treatment of the patient (Kohlman, 2006). Certainly, such a relationship exists when a patient makes an appointment with and sees a practitioner in her office. In addition, physicians and surgeons on a hospital staff enter into a **physician-patient relationship** with every patient that they treat in the hospital, whether the patient has been admitted for emergency treatment or is even conscious or able to consent. Once the relationship is established, it is a fiduciary relationship in which mutual trust and confidence are absolutely essential. The practitioner incurs a duty of due care to the patient that is always measured by a professional standard for rendering professional services—one that is usually monitored by the state in which the physician is licensed (Johnson, 2006).

Informed Consent

In general, consent for most treatment must be an **informed consent**. This type of consent means that the treating provider is required to give the patient or decision maker several elements of information before the decision on treatment is made. As the American Medical Association states so eloquently on its Web site: "Informed consent is more than simply getting a patient to sign a written consent form. It is a process of communication between a patient and physician that results in the patient's authorization or agreement to undergo a specific medical intervention" (AMA, 2007). To establish a cause of action based upon lack of **informed consent**, the patient must prove that a practitioner failed to disclose to the patient the various alternatives and the reasonably foreseeable risks and benefits involved which a reasonable medical practitioner under similar circumstances would have disclosed (AMA, 2007). The ethical obligation to communicate certain information to the patient exists in statutes and case law all 50 states.

In 2007, Medicare and Medicaid circulated new interpretive guidelines contained in the Code of the Federal Regulations that significantly expanded the scope and documentation of **informed consent** that must be obtained by hospitals prior to performing surgical procedures. For example, the new Medicare/Medicaid guidelines require that patients be informed if a practitioner, other than the primary surgeon, would perform important parts of the procedure, even when the person is performing under the supervision of the primary surgeon. Additionally, where surgery is concerned, the consent form must specify the "specific significant surgical tasks" that would be conducted by surgeons other than the primary surgeon (42 C.F.R. § 482.51). This requirement gives more transparency to the long-held ability of an experienced surgeon to allow a resident who is learning to gain experience in doing surgical procedures by requiring the patient be informed of that fact in advance.

Liability-Battery and Negligence

Because of the way in which the traditional medical relationship is established, the liability imposed for breaches of duty can be contractual in nature or based on tort law. Tort liability is civil in nature, not criminal, and is imposed by the common law and some statutes for injuries caused by breaches of duty not based on the contract. Tort liability is almost always based on fault, whether the fault be intentional, reckless, or negligent. The most frequent type of liability for health care professionals and institutions is the negligent tort. The five elements required to establish negligence or malpractice are the following: (1) a duty, that means what should have been done; (2) a breach of duty, or a deviation from the required standards of care; (3) injury to a party; (4) causation, that means an injury directly and legally caused by the deviation from what should have been done. To determine negligence, it is foremost important to be informed regarding the duty required by the practitioner in the jurisdiction.

Once the existence of a duty is established, the scope of the duty must be determined. This scope is often referred to as the *standard of care*. The standard of care for individual health care professionals is what a reasonably prudent health care professional engaged in a similar practice would have done under the circumstances (Miller, 2006). Thus, the standard of care may differ for one who is an internist, a pediatrician, an obstetrician, or a thoracic surgeon based upon each physician's special education and training. **Board certified** and trained specialists would owe a higher duty of care because of their advanced education, training and skill.

When there is no **informed consent** or authorization for a procedure, the physician or other practitioner can be liable for battery even if the procedure is properly performed, beneficial, and has no negative consequences for the patient. The touching of the patient alone leads to the liability (*Fox v. Smith*, 1992; *Bommardy v. Superior Court*, 1990). Early court cases provided that giving the patient incorrect or incomplete information about a procedure or treatment could invalidate the consent and make the practitioner liable for a battery (*Bang v. Miller*, 1958; *Moser v. Stallings*, 1986). The majority of jurisdictions now rule that failure to disclose or to fully inform the patient is a separate cause of action from a battery.

Jurisdiction, Venue, and Conflict of Laws

In the practice of traditional medicine, there has been little question as to where a particular cause of action might be brought against a medical practitioner or when that action might be brought. The traditional patient/physician privilege has existed on a personal level with a patient physically seeing a physician. That physician may not practice medicine unless licensed in that particular state. Thus, were there to be a cause of action brought against the physician, the action would be brought in the state where the relationship existed, and the laws of that state regarding proving a cause of action would be applied. The state would necessarily provide a statute of limitations for bringing a malpractice or other legal action against the physician.

There would be exceptions, however, if the individual seeking medical attention was not from a particular state but sought expertise medical help or particularized treatment. Nonetheless, in a traditional **physician-patient relationship** in which each party is physically present during the treatment phase, the theory of where the lawsuit is brought and what laws are applied remains essentially the same. If a patient seeks treatment in a state in which she is not domiciled, that patient is still seeking treatment from a physician who must adhere to the licensing requirements and standards of the second state. Thus, it would be those laws that would apply should the patient be injured in the course of medical treatment or determine to bring a cause of action at a later date. No federal laws would apply, except to the extent that a patient might possibly be bringing an action based on an inappropriate action taken by the FDA related to a controlled substance or other type of drug (McGrath, 2005).

THE INTEGRATION OF FEDERAL LAW INTO THE TRADITIONAL PRACTICE OF MEDICINE: HIPAA

The landscape of state domination of the medical profession changed somewhat with the enactment, in 1996, of the federal Health Insurance Portability and Accountability Act commonly referred to as "**HIPAA**." The enactment of **HIPAA** has also had implications concerning the burgeoning business of providing medical advice and treatment electronically.

HIPAA was originally enacted to provide for the "portability" of health care coverage for workers who had lost jobs or were changing jobs (Metz, 2004). Ideally, **HIPAA** sought to implement a more unified system of medical information storage such that medical information could be easily transmitted electronically (Chiang & Starren, 2002).

Because **HIPAA** contemplated the use of a unified electronic storage system, there was a demand that there be provisions enacted that would ensure the privacy of electronically transmitted material. Thus, included within **HIPAA** are protections covering the privacy of an individual's medical records. The privacy provisions of **HIPAA** are intended to allow a patient to limit who will have access to medical records and further provides a limitation on the internal use of sharing information for purposes of diagnosis in that it restricts the disclosure of health information to the "minimum amount necessary" required for the intended purpose (Schmidt, 2000).

HIPAA specifically covers health information "oral or recorded in any form or element that:

a. Is created or received by a health care provider, health plan, public health authority, employer, life insurer, school or university, or health care clearing house; and
b. Relates to the past, present, or future, physical or mental health condition of an individual; the provision of health care towards an individual; or the past, present, or future payment for the provision of health care to an individual. *(Health Insurance Portability and Accountability Act of 1996)*

HIPAA essentially applies to three specific health entities: health care providers (such as doctors and hospitals), health care plans, and health care clearing houses, which include such entities as third party billing services that may be hired to "code" certain medical procedures for insurance companies (Public Welfare. 45 C.F.R. § 160.102). **HIPAA** also applies to "employers, insurance companies, and public agencies that deliver social security or welfare benefits" to the extent that they work with or necessarily disseminate information related to an employee's medical records (§§ 160,164). **HIPAA** applies to all individual health information that is "maintained or transmitted" and includes "health claims, health plan eligibility, enrollment and disenrollment, payments for care and health plan premiums, claim status, first injury reports, coordination of benefits, and related transactions" (Metz, 20004). Thus, the purpose of **HIPAA**, to provide health care portability for the patient while protecting privacy concerns, has broad and far-reaching consequences and regulations affecting the practitioner, the health care institution, and the insuring entity.

In addition to **HIPAA**, federal privacy law also has been enacted to protect the confidentiality of information concerning patients who are referred or treated for alcoholism and drug abuse (42 U.S.C. § 290dd-2). The rules apply to any specialized programs to treat substance abuse in any facility that receives federal funds, including Medicare and Medicaid.

State Law and HIPAA

The United States Constitution provides that federal law is the "supreme law of the land." Ordinarily, that clause would be interpreted to mean that when the federal legislature has passed a law on a particular issue, that federal law would take precedence over state laws on similar issues. Indeed, the enactment of **HIPAA** "mandated" that all state-licensed medical entities and professionals be "**HIPAA** compliant" within a certain period of time regardless of any state laws on the issue (Privacy Rights Clearing House, 2003).

However, the Supreme Court has determined that when there are both federal laws and state laws covering the same issues, federal laws will not supersede a state law if the state law provides more "protections" than the federal law. It is said that a federal law may provide a "floor" for the rights of an individual while a state may provide a "ceiling" (Kramer, 2007). As applied to **HIPAA**, an individual is certain to enjoy the privacy protections set out in the federal statute, but may enjoy *more* privacy protections if his/her home state has enacted additional privacy requirements for medical practitioners. Examples of state laws that provide greater privacy protection than **HIPAA** are those state laws regulating the release of a patient's mental health information and HIV/AIDS test results **(**Miller, 2006). In cases in which the state protections are greater, the state law trumps any federal law.

Civil Liability for Violations of HIPAA

Currently, **HIPAA** has no civil liability provisions for any violations of the statute. Thus, an individual who has been harmed in some way by a practitioner or entity that fails to protect them has no legal recourse for damages under the federal law. The law does provide criminal consequences in the form of fines and jail time. **HIPAA** provides that a "person who knowingly… uses or causes to be used a unique health identifier [e.g., names, addresses, social security numbers], . . .obtains individually identifiable health information relating to an individual," or "discloses individually identifiable health information to another person" may:

1. Be fined not more than $50,000, imprisoned not more than 1 year, or both;
2. If the offense is committed under false pretenses, be fined not more than $100,000, imprisoned not more than 5 years, or both; and
3. If the offense is committed with intent to sell, transfer, or use individually identifiable health information for commercial advantage, personal gain, or malicious harm, be fined not more than $250,000, imprisoned not more than 10 years, or both. (45 C.F.R. § 160.102)

HIPAA appears to specifically limit enforcement actions may be brought by only the respective states or the secretary of health and human services (42 U.S.C. § 300gg-22(a); *O'Donnell v. Blue Cross Blue Shield of Wyo.*, 2001). Thus, reporting a **HIPAA** violation might be the best that an individual harmed by the release of data can do. However, some plaintiffs have attempted to bring indirect causes of action for a **HIPAA** violation by bringing a common law invasion of privacy action against the offending party. In fact, **HIPAA** does not always pre-empt state litigation practices (Beck & Hermann, 2007). Moreover, some states specifically allow causes of action for the dissemination of private medical information (*Pettus v. Cole*, 1996).

TELEMEDICINE, CYBERMEDICINE, AND INFORMATIONAL WEB SITES

The Basics

When determining the complications related to medical practice and privacy on the Internet, it is important to understand the distinction between the types of medical Web sites that one might encounter, and the medical interactions that one might have. Like the traditional "in person" patient/physician relationship, some "virtual" interactions between patients and physicians are between known individuals who might actually "see" each other, although far removed from each other geographically (Harrington, 1999). In other interactions, however, the person logging into a website might have no idea who is on the other end, or even if the person on the other end is a physician. Thus, these relationships make the definitions of "patient" and "physician" hazy when attempting to discern the application of any existing privacy laws to Internet or telemedical transactions (Lewis, 2004).

Telemedicine

Telemedicine is defined as the "use of telecommunications technology to provide health care services to patients who are distant from a physician or other health care provider" (Granade & Sanders, 1996). Generally, a consultant is used to medically diagnose a patient's condition via two-way interactive television, remote sensing equipment, and computers. Such medical practice has advantages, not only for improving access to medical specialties, but for primary care for patients and cost reduction (Johnson, 2006). For example, in rural Arkansas, a pregnant patient with a family history of spina bifida, a congenital abnormality of the spine, living in a rural area whose obstetrician has just performed a prenatal ultrasound, can have her test transmitted to a specialist in maternal-fetal medicine in a large medical center who can review the test and opine the fetus is developing normally and immediately reassure the patient (Johnson, 2006). The benefits of using technology of the rich to diagnose and treat the poor has substantially increased the opportunities of those who would not otherwise receive health care and allowed them to receive specialized treatment (Tyler, 1998). Moreover, the availability of **telemedicine** has enabled the sharing of both information and expertise which has enhanced the development of the medical profession in general.

Cybermedicine

A. Patient Treatment

An offspring of the information and technology revolution, **cybermedicine** is the embodiment of a discipline that applies the Internet to medicine. The field uses global networking technologies to educate, innovate and communicate in ways that enhance and promote medical practice, rapidly transforming medicine into a different discipline. In many respects, **cybermedicine** is broadly defined as the practice of medicine without the necessity of any physical in-person consultation or examination (Scott, 2001).

Cybermedicine is a relatively new phenomenon that has been around for less than 15 years. On Friday, October 4, 1996, the news announced the first virtual real live doctor's office on the World-Wide-Web had opened (Cyberdocs Today, 1996). On this site, for a reasonable fee of $65, a patient could enter her name and vital statistics, her medical problem, send the service her symptoms, provide credit card information, and within a few minutes—without ever being examined—receive treatment and possibly a prescription. This first site located in Massachusetts, required that the patients either be physically in the state of Massachusetts or traveling abroad in a foreign country. These two location safeguards, allowed the site creators to circumvent the problem of state licensing laws for liability purposes (Tyler, 1998). If the patient was traveling in a foreign country, the patient who needed a medication refill could have one sent by fax machine to a local overseas pharmacy within a few hours. The reach of **cybermedicine** has since extended beyond the boundaries of a home state.

B. Prescription Drug Purchasing

An "offshoot" of the **cybermedicine** industry is a new generation of Web sites that provide prescription drug delivery to consumers. Estimates of the number of **Internet pharmacies** operating in the United States have reached as high as 1400 (Gregg, 2007). In 1 year, one article estimates that 135% more Web sites have offered controlled substances such as Xanax, Vicodin, and Ritalin. Investigators found 394 Web sites advertising controlled prescription drugs and 7% of the sites, or about 187, offered to sell the controlled drugs. The vast majority of those Web sites offered to sell the drugs *without a prescription* (DeNoon, 2007).

While most **Internet pharmacies** are legitimate businesses that offer customers an attractive and convenient option to purchase affordable medicine in accordance with state and federal law, these new **online pharmacies** present many problems for drug companies, consumers, and physicians. Consumers find it very attractive to order from the privacy of their own homes and find that such pharmacies offer privacy and convenience for them based upon medical consultation with a physician.

In some instances, the "privacy" aspects making many sites attractive are problematic in and of themselves. Individuals can often order drugs by a brief description of symptoms—symptoms that they may or may not have (FDA FAQ's, 2007). In addition, because the Internet guarantees near anonymity, there is no way for the "Web site" to tell that the person ordering on line is the person actually on the other end of the transaction. Although this type of scenario raises the specter of fraud, it raises other issues related to privacy.

The truth is that anyone who owns a credit card and a computer can order controlled substances or any other drugs online. Pharmacies that do not require a faxed or mailed prescription from a licensed physician present serious concerns for not only privacy but life itself. Drugs offering help for erectile dysfunction, Viagra, Cialis, and Levitra, rank among the top 10 drugs bought online. Other drugs in the top 10 sought after online are Propecia, for baldness, as well as drugs for acid reflux, cholesterol, and bone density (Lade, 2007). Anonymity seems to be the deciding factor in ordering such drugs online. Legitimate pharmacies functioning online can be problematic for privacy concerns. An FDA advisory was issued in spring 2007 after examining foreign drug purchases and finding drugs with potentially dangerous side effects were easily ordered online, without a prescription. Two deadly examples of resulting problems with online ordering of drugs follow.

C. A Suicide Case

In what is believed to be the first lawsuit of its kind, the parents of John McKay have sued an Internet site, a Colorado physician, and a pharmacy in Mississippi in federal court in California for wrongful death and negligence in the suicide of their son (Ostrov, 2007). John McKay was a Stanford University freshman and debating champion who used a credit card to order 90 tablets of the anti-depressant Prozac (generically called fluoxetine) from an **online pharmacy**. The pharmacy McKay used does not require a faxed or mailed prescription from a licensed physician. Instead, the prescription site asks only that the patients fill out an online questionnaire about their health history. McKay noted on his application that he had moderate depression, had taken the drug before, and was not suicidal. The doctor who wrote the prescription had a restricted **medical license** and was not allowed to prescribe drugs.

Less than 7 weeks after ordering Prozac, John McKay killed himself. He was 19 years old. Articles reveal that neither the web prescribing doctor nor the **online pharmacy** accepted any responsibility for McKay's death (Ostrov, 2007; Lade, 2007). California law requires that prescriptions must be written by a licensed California physician after a physical examination of the patient (Ostrov). Prozac and similar antidepressants carry the FDA's strongest warning that notes the link between taking the drug and suicide in children and adolescents. The warning urges physicians to closely monitor young patients on these drugs especially at the start of treatments.

Expert Advice in Light of McKay

- Parents must monitor the Internet use of children and young adults.
- Parents should check the family mail for suspicious packages.
- Parents should keep credit cards and any documents with credit card numbers away from children.
- Parents should make certain young people who are treated for depression are consistently monitored by a physician.

D. An Overdose Case

Christopher Smith made over $24 million dollars selling prescription painkillers illegally through his **Internet pharmacy** before he was indicted (Unze, 2007). Minneapolis court documents show that Smith sold prescription painkillers to Justin Pearson at least 12 times in 2004-05. Justin accidentally overdosed on Christmas Day, 2006. Two other individuals listed in the government's filing bought drugs from Smith and committed suicide or died of medical complications from prolonged controlled substance abuse within 18 months of purchasing drugs on the Web site. Smith was convicted of conspiracy to sell drugs illegally, misbranding drugs, and money laundering. He was sentenced to 30 years in federal prison August 1, 2007 (Unze). Pearson's family members petitioned the state legislature to change the law on **Internet pharmacies**. Minnesota law now prohibits doctors from writing prescriptions for Minnesota clients based solely upon an online questionnaire.

Expert Advice for Finding Safe Internet Pharmacies Online

- Use a pharmacy in the United States, not Canada or Europe.
- A safe pharmacy has a phone number and address listed.
- A safe pharmacy is one that is licensed by a government agency or certified by a reliable organization. (The National Board of Pharmacy has a Web site verifying U.S. pharmacies have met state and federal regulations. See www.vipps.info).
- A safe pharmacy has a clear privacy policy. Read it. Make certain it is easy to understand and explicitly states it will not share your personal information with others unless you agree.
- Always have a prescription from a physician or health care professional who has examined you.
- Make certain a licensed pharmacist is available to answer any questions you have.
- Price comparisons can be found at Pharmacy Checker, a company that certifies online pharmacies. See www.pharmacychecker.com.

INFORMATIONAL AND SELF-HELP SITES

A third category of electronically available medical Web sites are those that are purely for information, or provide forums for discussing medical problems. Web sites proliferate that are available for educating the public about everything imaginable in health care from routine procedures to rare diseases. Because of the availability of these sites, patients can now read excellent articles and research dealing with a rare disease that they, or a family member, may suffer from. There are many stories regarding individuals who diagnosed their own or others' illnesses by using the Internet.

Hospitals as prestigious as the Mayo and Cleveland Clinic also routinely set up Web sites that not only provide information about the hospital, but provide information on disease processes and give health care consumers preoperative and postoperative instructions. In addition, these Web sites often provide links to articles about particular diseases, or even have informational charts concerning drug interactions. Sites such as WebMD allow individuals to look up symptoms or ask medical questions of certain practitioners in an effort to get feedback on a particular ailment. Finally, listservs and chatrooms provide individuals the opportunity to share information about particular medical ailments or seek advice or support from others dealing with the same problems. As an example, ACOR.org provides those afflicted with various cancers to share information with an international contingency about their conditions.

PRIVACY CONCERNS RELATED TO ELECTRONIC SITES IN GENERAL

Since the inception of the Internet and the ability to enter personal information into a Web site, there have been problems with ensuring that **personal data** remains secure. Today, there are burgeoning problems with credit card fraud and **identity theft** in the best of circumstances. Connecting to a virtual site in which information must travel along millions of shared lines compounds the problem, even in situations where an individual believes she is entering into a transaction onto a trusted site. Even if a company takes the opportunity to employ encryption methodology (such as Verisign), the opportunity for data stealing remains in situations where hackers lurk. It is impossible to say with certainty that any electronic transaction will remain completely private (Mencik, 1999).

Unfortunately or fortunately, depending upon personal point of view, there is no overarching regulation of the Internet. The Internet is not a place, nor is it contained within a certain jurisdictional boundary. Those setting up Web sites do not have to sign up with a central authority or conform to certain rules and regulations. There is no central place to register domain names and no periodic reporting that must be done to maintain a Web site.

Some regulation of business on the Internet has begun. There are some laws that govern some types of Internet business and/or transactions; however, most of these laws draw upon principles that are more appropriately applied to land-based businesses and not cyberspace entities. For instance, the Federal Trade Commission is charged with enforcing various consumer protection laws such as preventing false advertising and deceptive trade practices (Granfield, 2000). Both state and federal law enforcement agencies are charged with preventing fraud occurring over the Internet, and there are various statutes, both state and federal, that deal with preventing the dissemination of spam (Controlling the Assault of Non-Solicited Pornography and Marketing Act of 2003).

Nonetheless, no law now in existence is able to prevent the stealing of **personal data**, and few laws can protect individuals whose **personal data** is used unknowingly by a Web site for uses such as targeted advertising. The only way for individuals to protect themselves to the highest degree possible is to be aware of the privacy policies of the Web site with which they are dealing. Financial data should be logged only into trusted Web sites that have **encryption** methodology in place, and **personal data** (such as names and addresses) should be shared only on websites that have a similar **encryption** data or on those that have privacies policies with which the individual agrees. Most consumers should be aware that the Internet makes it very easy to share data with other businesses, and that most businesses would prefer to engage in quick, targeted advertising. Any registration with any type of Web site may make the consumer part of a larger database that will not only result in unwanted email solicitations, but will make the consumer more susceptible to scam advertising.

Consumers should be aware that Web sites, even those related directly to the medical profession, have different types of privacy policies. Some highlights from these privacy policies are included in Table 1.

When accessing any Web site where personal information is disclosed, consumers who have any privacy concerns at all should be aware of the privacy policies related to the Websites. As the examples indicate, not all information that might be thought to be private or even protected by **HIPAA** is necessarily private. For instance, there are many pharmaceutical Web sites that are not United States Web sites and not subject to United States laws. Although many of these websites have "American" sounding names, the consumer should be aware that when logging in, entering data, and ordering, that information entered might not be as private as the consumer thought.

In addition, many Web sites contain somewhat of a "caveat emptor" proviso indicating to the consumer that if there are any links accessed from the first website, the consumer should understand that the privacy policies of the first Web site do not apply. Further, various Web sites disclose that private data may be accessed by a company doing business with the first party and that the company is required by federal law to enter into contracts ensuring the privacy of data. However, most Web sites are vague about what data is protected and do not provide the consumer access to the actual contract and listing of data that is being disclosed and how it will be protected.

Finally, various Web sites provide for the disclosure of data in certain instances—such as, in numerous pharmacy sites, disclosure to a friend or family member who is the caretaker of

Table 1.

Web Md	**There is a lengthy privacy policy that includes information about what cookies are collected. The policy also provides that personally identifiable information will not be disclosed except 1) to meet legal requirements and 2) when there is a threat requiring disclosure. The site informs the consumer that the consumer will be informed of "material changes" to the policy and provides that complaints may be lodged with TRUSTe privacy watchdog**
American Academy of Family Physicians (AAFP)	A shorter privacy policy discloses use of cookies and states that member information may be provided to "constituent" chapters. The policy also provides that some information may be disclosed for purposes of targeted sales. There is a disclaimer providing that some information may be disclosed when legally required. The site also "forewarns" the consumer that it cannot be held responsible for the actions of third parties whom have links within the site.
Merck.com	Merck provides that consumers may elect a level of privacy protection. The policy states that, "Personal information about you will be accessible to Merck, including its subsidiaries, divisions, and groups worldwide, and to individuals and organizations that use personal information solely for and at the direction of Merck," and further provides that information will be disclosed only to those "working on its behalf."
American Heart Association	Policy gives consumer ability to "opt out" of disclosure, but also provides that "aggregate information" is sometimes disclosed for research purposes. There may be disclosure as "required by law."
Revolutionhealth	Policy provides that the information provided by the consumer may be used to acquire information about other people in your demographic area for targeted advertising. The policy states that information may be disclosed for legal reasons, or when a "threat" is involved (e.g., national security). The site has a disclaimer that if third party sites are accessed, the privacy policies of the third party sites should be reviewed. Consumers have an opportunity to "opt out" of particular disclosures.
MedRx-One (No prescription necessary site)	Non U.S. company; one line privacy policy: "medrx-one pledges that the information you enter will not be shared with any parties not directly involved with the ordering or delivery process without your expressed consent (except for fraud cases) and that any e-mails you receive from medrx-one will be related to your order." The terms of use indicate that "local laws" (i.e., country of origin) will apply to any legal issues.
CVS	Provides state specific privacy policies in addition to an extensive privacy policies that mirrors the **HIPAA** regulations. Provides that information may be disclosed to "business associates" provided an appropriate contract exists that safeguards privacy. Sets out that information may be disclosed in some instances to an individual (friend or family member) involved in your care, "if we can reasonably infer that you agree."
Walmart	Walmart's privacy policy provides, "We may use or disclose your PHI for prescription refill reminders, to tell you about health-related products or services, or to recommend possible treatment alternatives that may be of interest to you," and, "We may disclose your PHI to a family member or friend who is involved in your medical care or payment for your care, provided you agree to this disclosure, or we give you an opportunity to object to the disclosure. If you are unavailable or are unable to object, we will use our best judgment to decide whether this disclosure is in your best interests."

the individual seeking a prescription. Although this proviso may make it more convenient for a caretaker to access information about meds for an individual unable to access the data herself, there is also a potential for abuse. In many situations, an individual has sought out the Internet for purposes of enhanced privacy for the very reason that she does not want family members to be aware of certain health information. Without any verification procedures in place, many individuals may have their medical privacy compromised even though a website is legitimate, well-respected, and has various privacy protection procedures in place that a consumer believes are absolute.

Although there is sometimes recourse when there has been an alleged breach of privacy occurring by way of an Internet transaction, this recourse may be limited in scope. As previously discussed, various federal entities are responsible for ensuring the enforcement of some laws; however, the

Internet provides opportunities for businesses to both form and disappear overnight making it not only impossible to find the target of the investigation, but to determine what would be the appropriate jurisdiction to handle any complaint. Furthermore, although there are various actions that might be brought against Web site companies that do business in the United States and technically exist in the United States, there is virtually no recourse available against website companies that exist outside the boundaries of the United States. These sites may not have even minimal privacy protections for consumers. Certainly, the speed with which Web sites may be formed and disbanded will serve to hinder any sanctions or penalties that may be geared toward the enforcement of privacy rights.

Finally, the varying privacy policies in place on Web sites make it difficult for consumers to even know what their rights are, or what rights were violated. Although most legitimate companies dealing with medical data have privacy safeguards in place, there are various “loopholes” that consumers must be aware of whenever transacting business on the Internet. These include releases for targeted marketing in some instances, disclosure to third party companies with which the original company does business, disclosure to caretakers, and disclosures for law enforcement purposes (and when “threats” are involved).

CONCERNS RELATED TO THE DISCLOSURE OF MEDICAL INFORMATION

A. Patient Rights and State Remedies

Medical information is often the most private and intimate information about an individual. Health information privacy is based upon two principles: 1) the patient should be entitled to know what is contained in her own record; and 2) the patient should be able to control who has access to that information. States, individually, have long been the principle regulators of health information. While physicians have always been obliged under their ethical obligations and the Hippocratic Oath to protect health care information, other secondary users in the health chain such as insurers, the government, and employers have, in the past, not always had the obligation to keep information confidential when storing or transmitting it. Only recently, the federal government has promulgated, through **HIPAA**, the Federal Health Privacy Rule to even out and establish a floor of privacy protection to all citizens.

While all states have constitutions that may give rise to a right of privacy, explicit guarantees of privacy in state constitutions are rare. Applying privacy protections to health information has occurred in piecemeal fashion with little consistency from entity to entity and state to state. Thus, the right of privacy in state law provisions is a patchwork varying from legislative protection to only common law provisions.

While every state has a statute restricting the use and disclosure of medical information, few states have taken a broad or uniform approach. Rather, the protection afforded to the information tends either to be specific to a certain condition or fails to cover much of the information collected. Most states have some type of statutory provider-patient privilege that affords to the consumer limited protection of one’s health information. But states vary widely in the scope of the provisions that are enacted restricting the use of medical information (Pritts, 2002).

Most states allow health care providers to use and disclose patient identifying information for treatment, payment, peer review, and research purposes. For any use or disclosure of information, not specified by state statute, the patient’s written permission is required. Patients should be informed regarding the information divulging practices of their health care providers. They are entitled to receive and review their medical records. In addition, the security of their medical information should be protected from unauthorized use or disclosure.

To be effective, the state privacy statutes must provide remedies and penalties for violating them. Thus, if personal health care records are not provided to a patient, there must be a sanction for failure to do so. In addition, if health care providers can divulge information with impunity, there is no real benefit to consumers.

States run the gamut in the remedies in their statutory provisions to protect the health consumer. Some states have expressly granted rights to patients to bring suit for equitable relief and attorney fees. Other states hold a violator liable for actual and punitive damages (Pritts, 2002). If a person can show the privacy violation was made with knowledge or was made intentionally, many states allow for criminal penalties including fines and imprisonment.

B. Need for Remedies & Uniformity

The problem remains that there is no uniform comprehensive state approach to violations of health care consumer privacy. Most states have allowed only some elements of fair and uniform disclosure into their codes. Many have no remedy for violations. California has crafted some of the most privacy-oriented consumer protection laws in the nation (Cal. Civ. Code 56-56.37). California's code affords patients by law rights to most of the major holders of health information. And the code restricts disclosures by health care providers, HMOs, and even employers. The California code also gives patients the right sue to enforce their rights. Yet, even California's law is lacking because there is no provision to require notice of the health care providers' practices and policies to patients. Individual states have a long way to go to offer real solutions to the problem of privacy.

FEDERAL PRIVACY PROTECTIONS

Applicability of HIPAA to Cybermedicine and Telemedicine

With the recent issuance of federal government regulations governing the use and disclosure of health information by the Department of Health and Human Services, the role and importance of state government remedies has changed. While **HIPAA** is the first federal health privacy law, it does not pre-empt stronger state laws. So state law can offer greater protection than **HIPAA** provides especially with remedies for abuse (Pritts, 2002).

Unlike many laws that do not contemplate the incorporation of technology into every day life, **HIPAA** was originally enacted for the specific purpose of integrating the use of computer technology in the dissemination of information. Thus, after the enactment of **HIPAA**, traditional forms of communication were added to coverage so that there would be no loopholes regarding the dissemination of information through such avenues of communication as oral and written communications. As a result, the application of **HIPAA** appears to be broad-based covering traditional forms and both cyber and **telemedicine**, at least in large measure (Wachter, 2001).

For example, **HIPAA**'s "Privacy Rule" is broad-based in its application and protects individualized medical information transmitted "in any form or medium." It extends to all patients whose information is collected. The Rule imposes responsibilities on all employees and volunteers and requires health care institutions to receive contractual assurances that business associates that will be handling individualized medical information will keep that data private (pp. 1-4).

Also required, **HIPAA** mandates that those dealing with providing health care provide a Notice of Privacy Practices that will set out how the organization will protect health-related information and specify a patient's rights including:

- How to gain access to the patient's health records.
- How to request corrections to errors in a patient's health records (or voice a disagreement with a medical conclusion).
- How to determine where medical information has been disclosed.
- How to request additional confidentiality for particular health information.
- How to keep information confidential by providing alternate contact numbers such that information will not be given to members of a household.
- How to complain about a breach of privacy protocol.
- How to contact the U.S. Department of Health and Human Services to follow up about a complaint regarding a breach of privacy protocol (University of Miami School of Medicine, 2005).

Additionally, the Privacy Rule requires supplemental authorization if a health care provider intends to disseminate any private information for the purpose of research, some types of marketing, or fundraising. Information related to psychotherapy is also considered overly sensitive, and **HIPAA** requires supplemental authorization for the dissemination of this type of information. There are, however, some types of medical information that are not considered completely private. This information may be disclosed in limited circumstances without there being a **HIPAA** release. These categories include:

- Information related to public health issues.
- Information related to abuse or domestic violence situations.
- Information related to law enforcement, or some judicial proceedings.
- Information that might prevent an imminent threat to public safety.
- Specialized information as required by particular state or federal statutes.

In addition, not all forms of communication of medical information fall into the category of marketing. For instance, it is not considered marketing for a covered entity to use personal information to tailor a health-related communication to that individual, when the communication is:

- Part of a provider's treatment of the patient and for the purpose of furthering that treatment, such as the recommendation of a particular medication.
- Made in the course of managing the treatment, such as reminders of appointments (Privacy Rights Clearinghouse).

In many instances, individual state laws will govern what must be disclosed regardless of the fact that **HIPAA** is a federal statute. And one author has argued that states should not rely solely on the Federal Health and Privacy Rule to protect citizens, but that they should "at a bare minimum . . . mirror the federal protections, thereby allowing enforcement to occur at the state level" (Pritts, 2002). Thus, states are encouraged to enact legislation spelling out health consumers' rights and remedies. In addition, those states that have already enacted comprehensive health privacy rules should reevaluate their statutes so they fill in gaps that may exist. For example, use of health information for marketing purposes is often ignored in state laws, while some states have enacted more stringent standards than the federal law (Boyer, 2004).

Whereas **HIPAA**'s Privacy Rule protects against the disclosure of certain information, **HIPAA**'s Security Rule sets out regulations related to the electronic transmission of data and thus imposes security requirements on the electronic systems themselves. Moreover, the Rule imposes these restrictions on the "covered entities" of health care providers, health plans, and health care clearinghouses. Neither in-person nor hand-written communications are covered by the Security Rule, but do fall under the Privacy

Rule which covers "any mode" of communication (University of Miami Medical School; 45 C.F.R § 164.302, 45 CFR § 164.306).

Given that **telemedicine** stems from a traditional doctor-patient relationship in which consultations are theoretically done remotely, technically, the criteria related to HIPAA would apply to those practicing **telemedicine**. However, there would be some complications related to **HIPAA** and privacy in general depending on what type of **telemedicine** relationship is established.

In a situation where a patient sees her own physician and there is a consultation that is done while her physician is in the room, there is the opportunity for the original physician to ensure that the consultant is bound, in writing, by the prescriptions of **HIPAA** and that the patient is informed of her rights under **HIPAA** should there be such a consultation. If, however, there is a remote consultation being done without the involvement of an initial more primary care physician, there is less of an opportunity to verify privacy rights, especially if there is some immediacy to the teleconference.

Although it is unlikely, and currently uncommon for an individual to log on to a Web site and visually present an injury for diagnosis, it is likely that this type of doctor/patient interaction will increase in the future. With such an immediate relationship, there might be little opportunity for the patient to be told of the website's privacy practices, and there would unlikely be any opportunity to review and sign appropriate forms.

Thus, although any type of **telemedicine** practitioner would be bound by HIPAA, the patients would be well-advised to know the policies of the particular practitioner before going ahead with a consultation. In the case where a primary care physician would be involved in a **telemedicine** conference, the patient would be well-advised to know what privacy policies have been established between the two entities.

The practice of **cybermedicine** is similar to **telemedicine** and, for the most part, those who practice **cybermedicine** are bound by HIPAA as are those involved with **telemedicine**. However, **cybermedicine** may present more opportunities for compromising privacy because there are various forms of what might be considered the practice of **cybermedicine** that are not subject to the **HIPAA** regulations (Lewis, 2004).

Cybermedicine is often associated with prescription drugs, and, true enough, pharmacists and pharmacies are subject to the regulations of **HIPAA** as are the parent companies that might be engaged in the pharmaceutical business (such as Rite Aid or CVS). However, **cybermedicine** is also associated with such Web sites as "Ask a Physician," "Self-Help," or "General Advice" Web sites. Even in the case of "Asking a Physician," one might not establish a doctor/patient relationship necessary to bind the doctor in question to **HIPAA** as a health care provider.

Although many individuals might ordinarily believe that information is confidential because there is a person's medical condition being discussed, that is not the case (Nath, 2006). Many people routinely log into Web sites to find out information concerning symptoms, or request information about a particular drug. Some sites require information such that a response might go to an email address, or may even require information such as an address. Because these sites are not health care providers, there is no prohibition that would prevent continuous emailings, or postal mailings that a person may not want about a condition that a person may not want others to know about. Because there is no health care provider relationship, there is nothing prohibiting any of these sites from selling information to other entities.

There are numerous privacy concerns that may develop by virtue of the fact that lines blur as the electronic trail becomes more extensive. In an ordinary situation, a health care provider deals with secretaries who may deal with insurance companies, who may deal with other insurance companies, who may deal with outsourcing of billing and/or data processing, who may ultimately deal with collection agencies for unpaid bills. Although each of these entities would technically be bound to keep data private under an initial business entity and employee agreement, the more people involved, the more difficult it is to control who has what data.

Where **telemedicine** and **cybermedicine** are concerned, the trail goes out even farther. In **telemedicine** situations, there may be staff in a room unseen by a patient having nothing to do with the procedure or medical consultation (such janitors, computer technicians, or camera operators). For both **telemedicine** and **cybermedicine**, there are Web designers and engineers who may have access to information in databases within the Web site. None of these ancillary workers are generally bound to keep health information private.

When the Web site itself is set up to work as a place where health care is provided, there is a good argument that these technical employees are bound by **HIPAA** as employees dealing with health treatment information; however, that characterization is debatable if dealing with a third party Web administrator (i.e., an independent contractor), or when the Web administrators are part of a larger conglomerate, such as when a retailer (e.g., Walmart) has a site where prescriptions may be filled. There is also some uncertainty as to what is the status of a third-party owner of a website when that owner is not in the health care field but rather has purchased the website for investment purposes, or even when the Web site itself is a subsidiary of a health care company (Nath, 2006).

In all instances involving use of the Internet for medical care, the consumer must not assume that whatever **personal data** is being handled will be kept confidential. If the consumer is attempting to protect private data, that consumer must be aware of the policies of the entity from wherever any type of medical information is shared.

Problems with Privacy Liability

While **HIPAA** pre-empts any state law that provides less protection than it does, state laws that provide greater or equal protections than **HIPAA** remain in effect. Certainly, **HIPAA** privacy rules allow providers to share private information as long as it is used for allowable purposes such as billing and treatment. Most states have placed significantly more limitations on the scope of courts to order release of personal health information. Several areas of personal medical information, including mental health and HIV/AIDS cases also are protected by state statutes that restrict disclosure of such information.

There is a common law cause of action that consumers may have based upon the **physician-patient relationship** and privacy (Miller, 2006). Two examples of such actions include:

1. A New York court legally enjoined a psychoanalyst from circulation a book in which detailed information concerning a patient was written (*Doe v. Roe*, 1977).
2. The Oregon Supreme Court ruled that a physician was liable for revealing his patient's identity to the patient's natural child who had been adopted (*Humphers v. Inter. Bank*, 1985). This breach was held to be a breach of professional responsibility.

Thus, state law may statutorily and at common law offer greater privacy protection than does **HIPAA** privacy rules.

PRIVACY CONCERNS FOR THE FUTURE

The future of medicine and healthcare necessarily must contain a prediction for the increased utilization of computer information and the Internet. Any such discussion will contain the exponential increase in the use of national and international markets with more chances for individual privacy to be compromised. There is an increasing focus on computerized medical records. The Veterans Administration has adopted computerized record keeping (*Schmidt v. Dept. of Veterans Affairs*, 2003). An executive order in 2004 established the Office of Health Information Technology. Thus, the federal government is moving forward in its efforts to use technology in health record keeping.

The advantages for such record keeping systems are better patient care information and fewer iatrogenic illnesses, drug interactions, and prescribing mistakes. The disadvantage is the security risk. Each day, the newspaper contains stories of computer records being stolen or compromised. The **HIPAA** privacy rules do pertain to all computerized records and e-mail. Records and communications of this sort must be protected with **encryption** and other security steps. Computerized records have been accidentally posted on the Internet (Pillar, 2001).

E-mail communications should be handled with the same discretion that other methods of communication are treated. E-mails can be requested in discovery and may be used in civil and criminal actions: e-mails tend to exist in cyberspace forever. Stories abound regarding health care information emails that have accidentally been sent to hundreds of the wrong recipients (Salganik, 2000). The law relating to computers, e-mails, and the Internet is still developing.

Individuals deserve privacy in their dealings with physicians, health maintenance organizations, billing agencies, pharmacies, and other entities. The remedies, both civil and criminal, offered to consumers for breaches of privacy are piecemeal at this time and consist largely of common law actions or those statutorily provided by each state.

The federal **HIPAA** law articulates the minimum protection that may be afforded to individuals. There is no uniform consistent statutory scheme to protect individual privacy of medical information nationally. Each state is free to create its own legislation. It is important to minimize the accidental release of private information. The law is continually developing in the area of privacy, the Internet, e-mails, and computer-stored information. New legal issues emerge each day that need attention in this ever expanding area. Federal law must be enacted to deal with Internet privacy violations uniformly and provide deterrents for violating the law with significant fines and criminal penalties for the full range of patients' privacy violations from merely negligent to that purposeful criminal violation of patients' privacy. Web sites that provide drugs to all comers with no physician oversight should be illegal.

Chapter 1.20

Health Technology Assessment and Health Economics

Steven Simoens
Katholieke Universiteit Leuven, Belgium

ABSTRACT

This chapter introduces health technology assessment and health economics as tools for decision makers to allocate scarce resources in the healthcare sector. It argues that information about the safety, efficacy and effectiveness, organizational implications, social and ethical consequences, legal considerations, and health economic aspects of the application of a health technology needs to be taken into account with a view to informing decisions about the registration and reimbursement of a health technology. Also, the author hopes that understanding the methodology and use of health technology assessment and health economics will persuade the reader of the added value of such studies and promote the application of health technologies that support further health improvements, whilst containing health expenditure.

DOI: 10.4018/978-1-60566-356-2.ch005

INTRODUCTION

Over the past decades, health technology has made a major contribution to improving the health status of populations. At the same time, countries of the Organisation for Economic Co-operation and Development (OECD) witnessed an annual average growth in health expenditure per capita of 4% during the 1995-2005 period. Growth in health expenditure outpaced economic growth of 2.2% during the same period. Health expenditure growth can be attributed to a number of factors, including ageing populations, the increasing prevalence of chronic conditions, healthcare resource use price inflation, technological advances, and increased expenditure on drugs. With respect to the latter, annual average growth in pharmaceutical expenditure per capita of 4.6% during the 1995-2005 period exceeded the annual rise in health expenditure (Organisation for Economic Co-operation and Development, 2007).

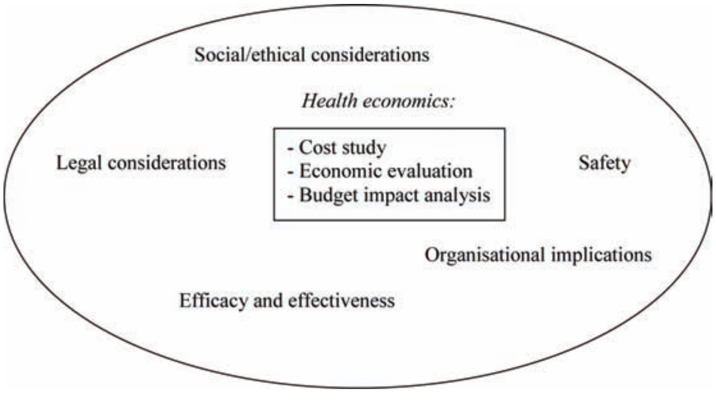
In response to this, Governments seek instruments that can aid the implementation of safe and effective health technologies that support further health improvements, whilst containing health expenditure. Health technology assessment and health economics provide such tools (Carlsson, 2004). Evidence derived from health technology assessments and health economics is used to inform decisions about the registration and reimbursement of health technologies in an increasing number of countries. The requirement for health technology assessment and health economics fits within an overall trend towards evidence-based decision making in healthcare (Perleth et al., 2001).

By carrying out a health technology assessment and a health economic evaluation, companies can demonstrate the value of their health technologies with a view to obtaining registration and reimbursement. For instance, in order to obtain registration and reimbursement, drugs need to overcome a number of so-called hurdles. A new drug needs to demonstrate its quality (first hurdle), safety (second hurdle) and efficacy (third hurdle) with a view to obtaining a *registration*. *Reimbursement* may depend on the value for money of the drug at the time of the reimbursement application (fourth hurdle) and after a number of years following the admission to the reimbursement system (fifth hurdle).

The aim of this chapter is to provide an introduction to the science underlying the assessment of a health technology. This chapter serves as a resource for readers who want a succinct overview of the methodology and use of health technology assessment and health economics. Particular attention is paid to defining the fundamental concepts and terms that are relevant to health technology assessment and health economics. Key references are added for those readers who wish a more advanced understanding of these topics. The chapter concludes with providing some additional resources (suggested readings, scientific journals, international societies and databases) related to health technology assessment and health economics.

Figure 1 presents the conceptual framework for this chapter. In its broadest form, a health technology assessment evaluates a health technology in terms of multiple criteria, one of which consists of a health economic assessment. The different criteria of a health technology assessment and the different forms of a health economic assessment are described in detail in the remainder of this chapter.

Figure 1. Health technology assessment and health economics



HEALTH TECHNOLOGY ASSESSMENT

Health technology assessment can be defined as a type of policy research that explores the safety; efficacy and effectiveness; organizational implications; social and ethical consequences; legal considerations; and health economic aspects of the application of a health technology. For instance, a health technology assessment of orthoses in Belgium covered the following aspects: a critical appraisal of the literature on effectiveness, costs and cost-effectiveness of orthoses; an international comparison of policy regulations on orthoses; a market analysis of orthoses; an international price comparison and production cost analysis of selected orthoses; and policy recommendations (Simoens et al., 2007).

The definition of a health technology assessment identifies three elements. First, health technology assessment seeks to support decision making by formulating recommendations for safe, effective health policies that are patient focused and achieve best value. Second, all relevant implications of a technology are evaluated. This requires a multidisciplinary approach involving physicians, economists, statisticians, ethicists, lawyers, engineers, social scientists, manufacturers and patients. Third, any technology can be the subject of an assessment. In general, a health technology refers to all measures for prevention, diagnosis, treatment and rehabilitation of a disease, including vaccines, drugs, medical and surgical procedures, and medical devices. It also refers to the organisational and support systems in which health care is provided.

The different aspects that are considered by a health technology assessment are now outlined (Goodman, 1998; Busse et al., 2002).

Safety

Safety judges the risks associated with using a technology. A health technology assessment should report the frequency and severity of adverse effects, the impact of the adverse effect on patient morbidity and mortality, and the risk of adverse effects among different groups of patients. A description should be provided of how the adverse effects were caused. Attention also needs to be paid to contextual factors (e.g. learning curve of surgeons) that may influence safety outcomes.

Regulatory authorities, such as the Food and Drug Administration (FDA) and the European Medicines Agency (EMEA), play a role in monitoring safety outcomes. Information about safety can also be gathered from the medical literature. Randomized controlled trials routinely measure safety outcomes, although this study design may not identify all possible harms of a technology. For instance, the time horizon of a randomized controlled trial may be too short to pick up rare adverse effects. Also, patients experiencing adverse effects may be excluded from a randomized controlled trial. Therefore, other study designs, such as observational studies and case reports, may provide valuable information about the occurrence of adverse effects.

Efficacy and Effectiveness

Efficacy and effectiveness both refer to the impact of a health technology on patient health. *Efficacy* refers to the clinical impact of a technology under ideal circumstances of use. *Effectiveness* measures the clinical impact of a technology under conditions of day-to-day practice and use. The effectiveness of a health technology tends to be lower than its efficacy because the clinical impact in daily practice may be influenced by such factors as the skills of the surgeon or patient compliance with drug therapy. For instance, a literature review concluded that the success of antimicrobial treatment of respiratory tract infections depended on patient compliance, with compliance being affected by the frequency of dosing, duration of treatment, adverse events, ease of administering drugs, ease of packaging, and price (Simoens, Decramer, & Laekeman, 2007).

With a view to providing a comprehensive overview of the clinical efficacy and effectiveness of a technology, a health technology assessment typically conducts a systematic literature review. Systematic reviews of the medical literature should be carried out following the guidelines of the Cochrane Collaboration® (Higgins, & Green, 2006). A good review formulates a well-defined research question; implements a search strategy for identification of studies; assesses the methodological quality of studies; extracts data from studies; summarises and interprets results.

Organizational Implications

A health technology assessment needs to examine the organisational issues specific to the local healthcare system that are related to the acquisition and operation of a technology. More specifically, the use of a technology may have implications for the training of staff (e.g. if staff need to have specific skills to apply the technology); for communication channels (e.g. if the technology requires communication between primary care and secondary care physicians), for the location of treatment (e.g. if the technology enables a patient to be treated in general practice rather than in hospital), for the utilization of healthcare services (e.g. if the introduction of a new drug therapy reduces surgical interventions), and for healthcare infrastructure (e.g. if the implementation of the technology reduces hospital length of stay or the need for hospital beds).

Social and Ethical Considerations

The perspective of patients and society can be incorporated in a health technology assessment by considering the social and ethical impact of a technology. Health technologies tend to raise social and ethical questions given that many technologies intervene at the start or the end of a patient's life. Technologies such as genetic testing, use of stem cells to grow new tissues and organ transplantation challenge societal norms and values.

A variety of approaches can be followed to elicit social and ethical issues related to the introduction of a health technology. Social and ethical aspects of a technology can be assessed by reviewing the social sciences literature. The public perspective can also be included in a health technology assessment by carrying out a patient survey; by organizing a focus group discussion with patients; by consulting patient organization websites; or by holding roundtables with ethicists and sociologists.

Legal Considerations

The introduction of a health technology has legal implications for the organization and financing of the healthcare sector and for the rights of stakeholders such as patients, healthcare professionals and manufacturers. For instance, a health technology assessment of weight-loss interventions explicitly took account of the regulation surrounding liability claims initiated by patients who experienced damage or injury following an intervention; the duty for supervision and information following weight loss surgery; patient rights (e.g. the right to informed consent); advertisement on weight-loss interventions; and legal aspects of cross-border healthcare in the domain of weight-loss interventions (Lambert et al., 2006). Consideration of legal aspects in a health technology assessment requires the input from lawyers.

Health Economic Aspects

The *health economic* aspects can be explored by carrying out a cost study, an economic evaluation and a budget impact analysis of the health technology. These three aspects are examined in more detail in the remainder of this chapter.

COST STUDY

A *cost study* can serve multiple purposes. Cost estimates can underline the importance of a disease to society when considered alongside its impact on morbidity and mortality and when compared with the economic burden of other diseases. Furthermore, cost studies may allow the identification of the drivers of diagnosis and treatment costs. Finally, cost data can be fed into economic evaluations, so that decision makers can ascertain the efficiency of various approaches to diagnosing and treating a disease by examining their consequences in relation to their costs.

Information about costs can be derived from a cost-of-illness analysis or from a cost analysis. A *cost-of-illness analysis* quantifies the economic burden of a disease to society by measuring the costs of diagnosing and treating a disease as well as the costs arising as a result of the disease (for instance, productivity loss due to time taken off work). A *cost analysis* compares the costs of two or more approaches to diagnosis and treatment of a disease (for instance, medical versus surgical therapy).

The following categories of costs can be distinguished. Direct healthcare costs refer to the costs of healthcare services such as costs of drugs, physician visits and hospitalisation. Direct non-healthcare costs are related to the provision of healthcare, but are of a non-medical nature. Examples of direct non-healthcare costs are the costs of transportation to the hospital and the costs of child care while the patient is receiving treatment. If healthcare services keep a patient alive, the patient is likely to fall ill in the future and require additional healthcare services. Healthcare costs in the added years of life as a result of keeping patients alive are denoted by indirect healthcare costs. Finally, indirect non-healthcare costs reflect the costs of productivity loss as a result of the disease. These costs not only consist of the productivity loss of the patient, but also of the productivity loss of family or friends who take time off work to care for the patient. The productivity loss may take the form of time lost from work ('absenteeism') or reduced productivity at work ('presenteeism').

Costs originate in the healthcare sector and in other sectors. For instance, treatment of opiate-dependent drug users involves the health sector (through the provision of maintenance or detoxification programmes), but also relies on the input from social care agencies. Furthermore, some studies have demonstrated that treatment costs are offset by savings arising from the prevention of future healthcare use and the reduction in criminal justice expenditure (Simoens, Ludbrook, Matheson, & Bond, 2006). Costs are incurred by the health care payer (i.e. insurance funds or national health service), the patient / family (e.g. drug co-payment, costs of home adaptation) and by the society at large (e.g. costs of productivity loss).

Once the relevant resource use has been identified, measured and valued, costs can be calculated (Jacobs, Ohinmaa, & Brady, 2005). These four steps are now described in detail in the following sections.

Identification of Resource Use

The perspective of the study determines which items of resource use need to be taken into account. A cost study can take a societal perspective by considering all (in)direct (non-)healthcare resource use. Alternatively, the more narrow perspective of the Ministry of Health, health care payer, hospital or patient can be adopted. In these instances, the cost study considers those items of resource use that are relevant from the perspective of the study. For instance, productivity loss as a result of illness is included in a cost study from the societal perspective. However, productivity loss is not relevant to the Ministry of Health and is, thus, excluded from a study with such a perspective.

The time horizon of a cost study needs to cover all relevant resource use. This applies to cost analyses, particularly those of immunization or vaccination programmes. Such programmes are associated with the use of drugs in the short-term, but may lead to savings from reduced healthcare resource use and from less productivity loss in the future. The time horizon needs to be sufficiently long to be able to investigate whether present drug costs are offset by future cost savings. The time horizon is also relevant to cost-of-illness analyses. A cost-of-illness analysis may take the form of a prevalence-based study, which measures costs attributable to a group of patients suffering from a disease during a given time interval. For instance, a literature review indicated that cost-of-illness analyses of endometriosis measured costs during a time period varying from six months to five years. This period was too short to account for the chronic nature of endometriosis which may afflict women during their reproductive years (Simoens, Hummelshoj, & D'Hooghe, 2007). Therefore, cost-of-illness analyses need to take the form of an incidence-based study, quantifying costs of a disease from onset to end.

Measurement of Resource Use

Two approaches can be adopted to measure the volume of resource use. On the one hand, a micro-costing or bottom-up approach identifies and measures each relevant item of resource use. This approach generates estimates of resource use with a high level of precision. However, this approach is time-intensive, expensive, and may yield estimates that are context-specific. On the other hand, a gross-costing or top-down approach measures resource use at the aggregate level (e.g. at the level of diagnosis-related groups) without specifying individual items. Such estimates benefit from increased generalisability and improve comparability of cost studies, but are less precise.

In terms of data sources, resource use can be measured in a sample of patients (primary data collection). A cost study can follow up patients suffering from a specific disease. Such case series that focus on identified patients only may be misleading in the case of diseases where diagnosis is complex and attribution of resource use to the disease is difficult. Studies comparing patients with/without a disease are better suited in that they allow identification of additional resource use related to the disease. Resource use can also be derived from existing sources such as patient medical records, a health care payer claims database or the published literature (secondary data collection). Patient medical records provide detailed information about healthcare resource use. However, such data tend to pertain to a specific institution(s), thus limiting the generalisability of cost estimates. An analysis of claims data benefits from comprehensiveness of information on healthcare resource use, but may suffer from missing data and incorrect diagnostic coding of claims. Resource use data can be gathered from the literature, although differences in the design of primary studies may restrict comparability of estimates.

Valuation of Resource Use

The valuation of resource use puts a monetary value on the resources depleted by the disease and its treatment. To this effect, the volume of resource use is multiplied by market prices. However, market prices do not always exist. For instance, drug prices may be negotiated between the government and the pharmaceutical company. Therefore, researchers use official list prices to calculate charges. Caution needs to be exercised when calculating charges as these do not necessarily reflect the worth of resource use. For instance, charges of surgical treatment in hospital may not accurately measure actual expenditure on administration, billing, capital depreciation, maintenance, laundry and other hospital services related to the surgical procedure.

Alternatively, shadow prices can be used to value resource use in the absence of market prices. This can be illustrated with the valuation of productivity loss. If the patient is an employee, his/her wage can be used to value lost productivity. If the patient is a housewife, this approach cannot be used as a housewife does not receive a wage. Instead, researchers need to draw on a shadow price, i.e. the market price of a similar activity. In this example, the market wage of a professional housekeeper could serve as the shadow price and could be used to value the productivity loss of the housewife.

Calculation of Costs

When calculating the costs of a healthcare programme, the question arises of whether to compute marginal or average costs. Dividing total costs by the number of units generates average costs. Average costs include fixed costs (e.g. costs of hospital infrastructure) as well as variable costs. Marginal costs represent the costs of producing one additional unit and, therefore, include variable costs only. As our interest is in the additional costs incurred by the healthcare programme, a cost study needs to calculate marginal costs. However, if the national implementation of a healthcare programme involves building a new hospital, the use of average costs is recommended as these represent the additional costs imposed by the programme.

ECONOMIC EVALUATION

An *economic evaluation* is in essence a comparative analysis of at least two health technologies in terms of both their costs and outcomes. Figure 2 portrays the components of an economic evaluation of a new drug therapy vis-à-vis a comparator. The comparator is generally chosen to reflect common clinical practice in the setting where the economic evaluation is undertaken. In our example of a new drug therapy, the comparator can be an older drug or a surgical intervention. If the new drug represents the first technology that is available to treat a specific disease, the relevant comparator may be no active therapy.

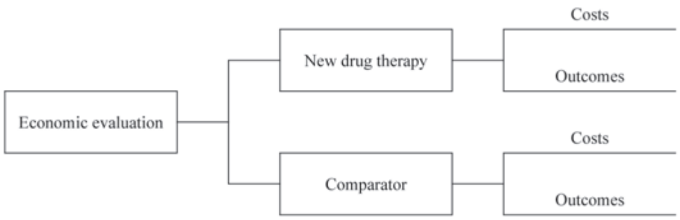
An economic evaluation enables us to answer *efficiency* questions by relating the costs to the effectiveness of alternative health technologies. An *incremental analysis* is carried out to express the results of an economic evaluation. This means that, for meaningful comparison, an economic evaluation expresses the additional costs incurred by one health technology vis-à-vis the comparator in relation to the additional outcomes of the technology vis-à-vis the comparator.

Types of Economic Evaluation

An economic evaluation can take a number of forms.

A *cost-minimisation analysis* is appropriate when the alternative health technologies produce equivalent outcomes (i.e. effectiveness and safety). In this case, a cost-minimisation analysis identifies

Figure 2. Components of an economic evaluation



the least costly health technology. For instance, an economic evaluation examined the efficiency of two antibiotics (teicoplanin and vancomycin) used in the treatment of intensive care unit patients with catheter-related infections (Simoens, De Corte, & Laekeman, 2006). Comparative trials of teicoplanin and vancomycin reported no significant differences in their effectiveness. Therefore, a cost-minimisation analysis compared costs of drug acquisition, materials required for preparation and administration of antibiotics, laboratory tests and nursing time. Treatment with teicoplanin turned out to be more expensive than vancomycin. This was because lower costs of laboratory tests with teicoplanin only partially offset higher drug acquisition costs.

A *cost-effectiveness analysis* denotes an economic evaluation that measures costs in a monetary unit and quantifies a single outcome in a physical or natural unit (e.g. the number of successfully treated patients, the number of life years gained, the number of symptom days averted). Final outcome measures (e.g. life years gained) are preferred to intermediate measures (e.g. cholesterol level) as our interest is in the ultimate impact of a technology on health. Also, as final outcome measures are relevant to multiple health technologies and diseases, their use facilitates comparison of the efficiency of various technologies. The results of a cost-effectiveness analysis are expressed by means of an incremental cost-effectiveness ratio:

Incremental cost-effectiveness ratio $= (C_1 - C_0) / (E_1 - E_0)$ where C_1 is the cost of the health technology; C_0 is the cost of the comparator technology; E_1 and E_0 are the outcomes of the technology and the comparator, respectively.

A cost-effectiveness analysis is only possible if the health technologies affect the same outcome. However, technologies may affect multiple outcomes. In this case, a cost-consequence analysis can be carried out, which presents costs and multiple outcomes. The results can be expressed as several incremental cost-effectiveness ratios, one for each outcome. The drawback is that a cost-consequence analysis does not provide an assessment of the overall efficiency of a health technology.

The previous types of economic evaluation pose a number of challenges. In particular, health technologies may impact multiple outcomes, outcomes may differ between health technologies, and patients may attach more importance to some outcomes than others. In response to this, the two following types of economic evaluation have been developed that combine and value the various outcomes in a single generic measure of health improvement.

An economic evaluation that measures costs and outcomes by means of specific health-related quality of life measures, such as quality-adjusted life years, is referred to as a *cost-utility analysis*. The *quality-adjusted life year* takes into account the quantity and quality of life. The quality of life associated with a health state is measured through the use of health utilities. A utility reflects the preference of the general public for the health state. Utilities are elicited on a scale of 0 (reflecting death) to 1 (reflecting perfect health) using techniques such as the visual analogue scale, the standard gamble or the time trade-off (see Torrance, Furlong, & Feeny, 2002 for more information about health utility estimation). Quality of life data are then combined with estimates of the time period for which the health benefits last to generate quality-adjusted life years. The results of a cost-utility analysis using quality-adjusted life years are expressed by means of an incremental cost-utility ratio:

Incremental cost-utility ratio $= (C_1 - C_0) / (Q_1 - Q_0)$ where C_1 is the cost of the health technology; C_0 is the cost of the comparator technology; Q_1 and Q_0 are the number of quality-adjusted life years associated with the technology and the comparator, respectively.

A *cost-benefit analysis* values outcomes in monetary terms (the 'benefits') in addition to costs. A monetary value can be assigned to outcomes by means of the human capital approach, the revealed preference approach or the willingness-to-pay technique (see Ryan, Watson, & Amaya-Amaya, 2003 for more information about the monetary valuation of outcomes). However, assigning monetary values to outcomes is controversial and further work on methods to value outcomes needs to be carried out. As both costs and outcomes are expressed in monetary terms, costs can be directly compared with benefits and the net worth (benefits minus costs) of a health technology can be estimated. The results of a cost-benefit analysis may be stated in the form of the net benefit (or net loss) of one health technology over another or in the form of an incremental cost-benefit ratio:

Net benefit = $(B_1 – B_0)$ - $(C_1 – C_0)$

Incremental cost-benefit ratio = $(C_1 – C_0) / (B_1 – B_0)$ where C_1 is the cost of the health technology; C_0 is the cost of the comparator technology; B_1 and B_0 are the health benefits of the technology and the comparator, respectively.

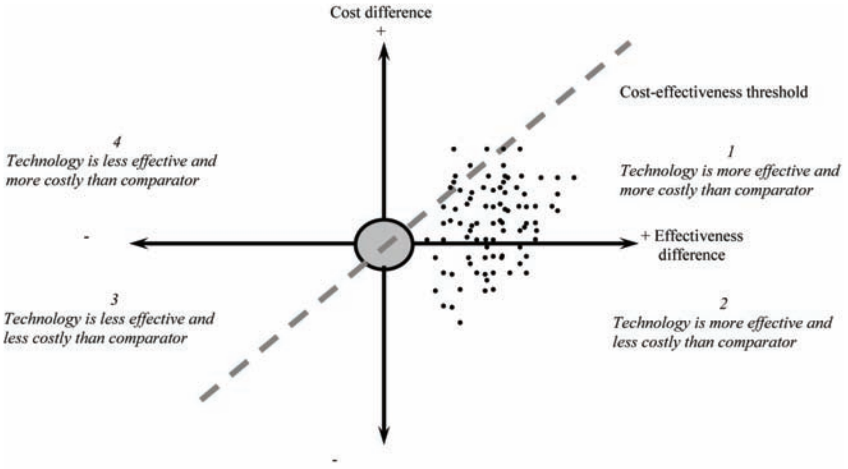
A cost-benefit analysis is not only suited to assess whether the costs of a health technology are justified by its benefits. This type of analysis can also be used to compare the benefits and costs of technologies in sectors other than healthcare. As a consequence, cost-benefit analysis answers the question of allocative efficiency and enables us to allocate resources to the most efficient technologies across sectors. This contrasts with cost-effectiveness and cost-utility analysis, which answer the question of productive efficiency by calculating the additional costs to achieve, for instance, one additional life year or one additional quality-adjusted life year. Assessment of value for money in a cost-effectiveness and cost-utility analysis necessitate a (subjective) judgement of the societal worth of one unit of outcome (e.g. one life-year gained). In response to this, so-called cost-effectiveness thresholds and cost-utility thresholds have emerged. These thresholds represent the maximum cost per (quality-adjusted) life-year gained that authorities are willing to pay for a health technology. For instance, the National Institute for Health and Clinical Excellence has stated that it does not have official thresholds to assess the value for money of health technologies in England and Wales. However, a review of their guidance issued between 1999 and 2005 concluded that technologies having an incremental cost-utility ratio exceeding £30,000 per quality-adjusted life year are likely to represent an unacceptable use of limited resources (Raftery, 2006).

The Cost-Effectiveness Plane

The question whether to conduct an economic evaluation can be answered by looking at the so-called *cost-effectiveness plane* (see Figure 3) (Black, 1990). On the horizontal axis, the difference in effectiveness (e.g. life years) between the health technology and the comparator is portrayed. The vertical axis represents the cost difference between the technology and the comparator. The technology may have higher or lower costs, and higher or lower effectiveness than the comparator, so that its point may fall into one of the four quadrants.

If the point falls into quadrant 2, the technology is more effective and less costly than the comparator. In other words, the technology dominates the comparator. This indicates that the technology needs to be adopted and that there is no need to conduct an economic evaluation. Conversely, if the point falls into quadrant 4, the comparator dominates the technology and the comparator should be adopted. In quadrants 1 and 3, one option is more effective, but also more costly than the other option. In these cases, an economic evaluation needs to be carried out. The efficiency of the technology depends on the cost-effectiveness threshold adopted by the authorities. The gradient of the dashed line represents one cost-effectiveness threshold. The technology is efficient if its point falls to the south-east of this dashed line.

Figure 3. The cost-effectiveness plane



Trial- and Model-Based Economic Evaluation

There are two ways to carry out an economic evaluation: a *trial-based economic evaluation* or a *model-based economic evaluation* (Briggs, Claxton, & Sculpher, 2006).

An economic evaluation can be carried out alongside a clinical trial. Such evaluations are called trial-based economic evaluations or piggy-back studies. In the case of a piggy-back study of a new drug, the economic evaluation can be carried out alongside a Phase III clinical trial, which examines the efficacy and adverse reactions during the drug development process. Such economic evaluations provide timely information with high internal validity that can be used by manufacturers, policy makers, healthcare professionals and patients to assess the value of a new drug. The economic evaluation can also be conducted alongside a Phase IV clinical trial, which examines long-term effectiveness following regulatory approval of the drug. Such economic evaluations explore the efficiency of a new drug under conditions of day-to-day practice and benefit from greater external validity.

There is a wide diversity in the design, conduct and analysis of trial-based economic evaluations. However, a number of good research practices have emerged (Ramsey et al., 2005). A gold standard trial-based economic evaluation should have adequate power with a view to testing hypotheses about expected differences in costs and outcomes. An adequate time horizon needs to capture the long-term impact of the health technology. The choice of clinical outcomes in the trial must be suited for use in the economic evaluation. For instance, quality-of-life values derived from the trial can be used to calculate quality-adjusted life years in a cost-utility analysis. The identification, collection and management of economic data should be fully integrated into the clinical trial. Data analysis should follow an intention-to-treat approach, assess uncertainty, take account of time preference for costs and outcomes, and account for missing or censored data. Appropriate summary measures need to be used to calculate the relative value of the technology vis-à-vis the comparator.

Nevertheless, there are some drawbacks to using piggy-back studies for the purpose of economic evaluation. These include:

- Inadequate sample size
- Restrictive patient selection (patient characteristics, co-morbidities, disease severity)
- Inappropriate comparator
- Short time horizon
- Occurrence of protocol-driven resource use (which leads to over-estimation of costs)
- Artificially enhanced compliance
- Inappropriate outcome measures

Even if a trial-based economic evaluation exists, some *decision-analytic modeling* is likely to be needed. For instance, to examine the full impact of a health technology, modeling beyond the time horizon of the trial may be required. In general, decision-analytic modeling addresses some shortcomings of trial-based economic evaluations by allowing us to compare all relevant options; to incorporate all appropriate evidence; to translate intermediate endpoints into final outcomes; to extrapolate over the appropriate time horizon of the evaluation; and to generalize to other settings or populations (Buxton et al., 1997).

Decision-analytic modeling is a quantitative approach to decision making under conditions of uncertainty. A model can be defined as an analytic methodology that accounts for events over time with a view to estimating the impact of a health technology on costs and outcomes (Weinstein et al., 2003). Decision-analytic modeling can take the form of a decision tree or a Markov model. A decision tree is a graphic representation of the various diagnosis and treatment pathways of a specific disease in combination with the probabilities, costs and outcomes associated with each pathway. A Markov model structures a disease and its treatment process by means of mutually exclusive and exhaustive health states, with patients moving from one health state to another based on transition probabilities. Typically, states have a uniform time period. The time spent in a health state generates costs and outcomes. Estimates of probabilities, costs and outcomes used in decision trees and Markov models are usually derived from the literature or from expert opinion.

With respect to modeling, concerns have been raised about the inappropriate use of clinical data, about biases in observational data, about the difficulties of extrapolation, and about the transparency or validity of models (Buxton et al., 1997). Therefore, it is important to adhere to principles of good practice for decision-analytic modeling in economic evaluation by keeping the model as simple as possible; by presenting the results in a transparent way; by respecting the quality of the data used in the model; and by exploring uncertainty. Attention also needs to be paid to validating the model by comparing the results with those of similar studies and by updating the model when more data become available. Finally, the reader should note that a decision analytic model is only as good (or bad) as the quality of its data and its specification. Thus, model-based economic evaluations need to clearly state the caveat that the results are conditional on the data and assumptions incorporated in the model.

Discounting

The costs and outcomes of a health technology generally do not take place in the same year, but may be spread out over multiple years. For instance, current costs of a vaccination programme need to be compared by future benefits of prevented disease and reduced healthcare costs. An economic evaluation needs to take account of the timing of costs and outcomes because individuals have a positive rate of time preference. This means that individuals attach greater importance to current than to future costs and outcomes. This positive rate of time preference mainly derives from three reasons: a) individuals consider the short run only; b) individuals are uncertain about the future; and c) individuals can invest a Euro now and expect to receive more than a Euro in the future.

Time preference is taken into account in an economic evaluation by the process of *discounting*.

Discounting calculates the present value of costs and outcomes occurring in the future (Brouwer, Niessen, Postma, & Rutten, 2005). By calculating present values, alternative health technologies with differential timing of costs and outcomes can be compared from the same baseline. Although there has been a debate about whether outcomes should be discounted at a different rate than costs, a consensus has emerged that outcomes should be discounted at the same rate as costs. Some countries provide advice on the discount rate to be used. In the absence of such advice, analysts tend to set the discount rate equal to the interest rate on long-term, risk-free investment such as government bonds.

Sensitivity Analysis

Any variable used in an economic evaluation is subject to some uncertainty (Briggs, Sculpher, & Buxton, 1994). This uncertainty can originate from methodological disagreements, researchers' assumptions in the absence of data, imprecise data, need to extrapolate results over time, and the need to generalize results to other settings or other countries. A *sensitivity analysis* determines the direction and the extent to which the results of the economic evaluation vary when estimates of input variables change. There are two approaches to carrying out a sensitivity analysis: deterministic and probabilistic sensitivity analysis.

A deterministic sensitivity analysis explores the impact on results of changes in one input variable (one-way analysis) or of simultaneous changes in multiple variables (multi-way analysis). One application of a multi-way analysis is a scenario analysis. Such an analysis typically includes a best case scenario, where all input variables are changed in the most optimistic way, and a worst case scenario, where input variables take on the most pessimistic values. A scenario analysis provides insight into the efficiency of the health technology in the best case and in the worst case. Finally, a threshold analysis identifies the combination of variable estimates that ensures that the incremental cost-effectiveness or cost-utility ratio of the technology does not exceed the threshold adopted by authorities.

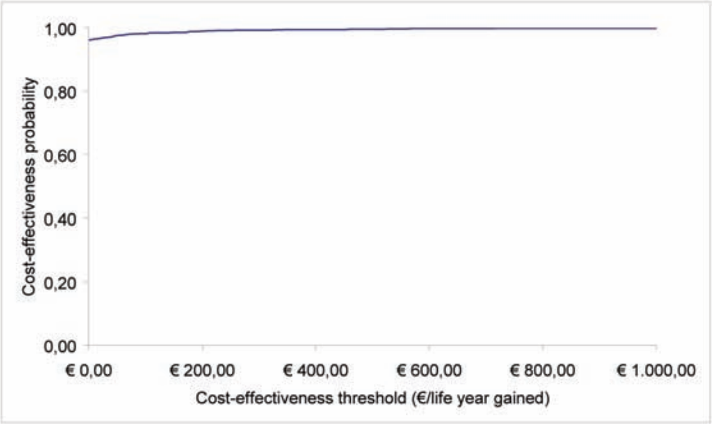
A probabilistic sensitivity analysis is based on a Monte Carlo simulation. The principle is to run the analysis a large number of times (e.g. 10,000 times) with different sets of variable estimates drawn from distributions. This requires that a probability distribution is assigned to each input variable. For each iteration, the simulation draws input parameters at random from their statistical distributions and calculates cost and effectiveness pairs. At the end of the 10,000 iterations, the joint statistical distribution for costs and effectiveness is represented as a cloud of points on the cost-effectiveness plane (see Figure 3).

The gradient of the dashed line in Figure 3 indicates one cost-effectiveness threshold. Typically, this line cuts through the cloud of cost and effectiveness pairs generated by the probabilistic sensitivity analysis. Simulations falling to the south-east of the line support the cost-effectiveness of the health technology. The probability that the technology is cost-effective is estimated as the proportion of points to the south-east of this line. As the cost-effectiveness threshold increases, the dashed line rotates anti-clockwise around the origin, increasing the proportion of points to the right of the line. This allows us to draw cost-effectiveness *acceptability curves* representing the probability that the health technology is efficient for a range of cost-effectiveness thresholds (see Figure 4).

Use of Economic Evaluation by Decision Makers

Is economic evaluation useful? The strength of economic evaluation is corroborated by the dramatic increase in the number of published economic evaluations in recent years. Also, evidence of economic evaluations is taken into account in pricing and reimbursement decisions of health

Figure 4. Cost-effectiveness acceptability curve



technologies in an increasing number of countries. Efficient technologies are rewarded by means of a more favourable price and/or reimbursement. As decision makers appreciate the need to evaluate projects in terms of costs and benefits, economic evaluation offers a framework that presents information about technologies in a format that is familiar and useful to them.

Nevertheless, certain aspects of the decision making process restrict the usefulness of economic evaluations in informing resource allocation decisions. A first aspect relates to institutional features of the healthcare system. For instance, in most European countries, health expenditure is divided across several budgets, with a tendency for decision makers to adopt a silo mentality. This means that decision makers consider each budget separately, but do not take account of the full impact of a technology across budgets. This silo mentality poses challenges for economic evaluation because health technologies are likely to have an impact on multiple budgets. For instance, although the introduction of a new drug may add to the pharmaceutical budget, this may be accompanied by reduced expenditure on other health services utilization. Therefore, there is a need to overcome this silo mentality in order to enhance the value of economic evaluation.

Economic evaluations need to report findings that have practical relevance. For instance, savings arising from fewer hospitalizations are accounted for as a financial benefit in an economic evaluation. However, the benefit does not necessarily materialize in a real setting as vacated beds may be used in the treatment of other patients. If this is the case, researchers are essentially taking into account freed resources, whereas decision makers have an interest in actual financial savings. It is therefore important for researchers to understand the perspective of decision makers, to ascertain for what purpose decision makers wish to use the information derived from the economic evaluation, and to present the results accordingly.

Although decision makers embrace the principle of weighing costs and benefits in making decisions, their actual knowledge of economic evaluation techniques is generally limited and they have doubts about the methodological quality of studies (Drummond et al., 2003). To overcome this barrier, there is a need for better education and training of decision makers in economic evaluation techniques. Moreover, a higher degree of standardization and consensus surrounding methodological principles of economic evaluation is required.

BUDGET IMPACT ANALYSIS

In addition to information about the efficiency of a new health technology, regulatory agencies in an increasing number of countries now require data about the budgetary impact of the technology on national, regional or local budgets. Whereas an economic evaluation allows decision makers to assess the value for money of a health technology, a *budget impact analysis* examines the financial impact of the adoption and diffusion of the technology within a particular setting. Thus, a budget impact analysis considers the affordability of a technology. Specifically, a budget impact analysis explores how a change in the current mix of treatment strategies by the introduction of a new technology will impact spending on a disease. The review by Mauskopf, Earnshaw, & Mullins (2005) presents a number of published examples of budget impact analyses.

Budget impact analysis in combination with cost study and economic evaluation play a crucial part in the comprehensive assessment of a health technology and may inform reimbursement decisions (Cohen, Stolk, & Niezen, 2007). Reimbursement may be withheld from a cost-effective health technology if it has a high budgetary impact. Conversely, a cost-ineffective technology may receive reimbursement if its budgetary impact is limited. The reimbursement of orphan drugs, for instance, shows that decision makers may attach more importance to budget impact and equity considerations than to efficiency.

The methodology of budget impact analysis is still developing, although principles of good practice for budget impact analysis have recently been proposed (Mauskopf et al., 2007). A budget impact analysis starts with providing all relevant epidemiological, clinical and economic information of the disease. Then, the current mix of treatment strategies is described. This may cover no active therapy as well as therapies that may or may not be replaced by the new health technology. The introduction of the technology may lead to technology substitution and market expansion. Therefore, a budget impact analysis considers all patients who might be treated with the new technology, including previously untreated patients who may now seek treatment. Finally, the analysis considers the budgetary impact of various scenarios of how the current mix of treatment strategies changes when the new technology becomes available.

CONCLUSION

Health technology assessment and health economics are suitable tools to evaluate health technologies. Indeed, these instruments present information about the safety, efficacy, effectiveness; organizational, social, ethical and legal implications; and value for money of a technology to decision makers with a view to optimising health policy.

In order to fully exploit the value of health technology assessment and health economics, researchers need to take care to conduct such exercises according to methodologically sound principles. As health technology assessment and health economics are relatively ‘young’ scientific disciplines, further research is needed to refine the methodologies used. Such work will not only enhance the quality of health technology assessment and health economics, but also increase the confidence of decision makers in such exercises and contribute to better health policy.

Additionally, researchers need to take into account the decision making context. Health technology assessment and health economics allow decision makers to maximize health gain subject to the constraint of limited resources. However, one needs to appreciate that such exercises represent only one of the criteria on the basis of which policy makers make decisions, and that they are not necessarily the most important criterion. In addition to health technology assessment and health economics, decision making by policy makers may be guided by the need to achieve certain performance targets imposed on the healthcare system. For instance, a survey of Australian healthcare decision makers found that political factors, the history of existing policies, administrative feasibility, and equity considerations also carried weight in influencing resource allocation decisions (Ross, 1995). Therefore, researchers need to identify the various goals that decision makers pursue and discuss how decision makers can use findings of health technology assessment and health economics to attain these objectives.

More and more countries are using information derived from health technology assessment and health economics to inform decisions to register and reimburse health technologies, particularly drugs. If such studies are well-conducted and have practical relevance to decision makers, health technology assessment and health economics will lead to better decisions about the allocation of scarce resources in healthcare.

KEY TERMS AND DEFINITIONS

Budget Impact Analysis: Analysis of the financial impact of the adoption and diffusion of a health technology within a particular setting.

Cost Analysis: Comparison of the costs of two or more approaches to diagnosis and treatment of a disease (for instance, medical versus surgical therapy).

Cost-Benefit Analysis: An economic evaluation that values outcomes in monetary terms (the 'benefits') in addition to costs.

Cost-Effectiveness Analysis: An economic evaluation that measures costs in a monetary unit and quantifies a single outcome in a physical or natural unit (e.g. the number of successfully treated patients, the number of life years gained, the number of symptom days averted).

Cost-of-Illness Analysis: Analysis of the economic burden of a disease to society by measuring the costs of diagnosing and treating a disease as well as the costs arising as a result of the disease (for instance, productivity loss due to time taken off work).

Cost-Utility Analysis: An economic evaluation that measures costs and outcomes by means of specific health-related quality of life measures, such as quality-adjusted life years.

Economic Evaluation: A comparative analysis of at least two health technologies in terms of both their costs and outcomes.

Health Technology Assessment: Type of policy research that explores the safety; efficacy and effectiveness; organizational implications; social and ethical consequences; legal considerations; and health economic aspects of the application of a health technology.

Sensitivity Analysis: Analysis of the direction and the extent to which the results of the economic evaluation vary when estimates of input variables change.

Chapter 1.21

Telemedicine Barriers

María José Crisóstomo-Acevedo
Jerez Hospital, Spain

José Aurelio Medina-Garrido
University of Cadiz, Spain

INTRODUCTION

Telemedicine implies that there is an exchange of information, without personal contact, between two physicians or between a physician and a patient. Thanks to telecommunications technologies telemedicine enables the provision of healthcare services or the exchange of healthcare information across geographic, temporal, social, and cultural barriers (Chau & Hu, 2004).

Through telemedicine, healthcare centers can offer diverse specialty services to other centers, to other physicians, or directly to the patient, such as for example telecardiology, teledermatology, teleendoscopy, telemedicine, telemonitoring, telenursing, telepathology, teleradiology, or telesurgery (Tachakra, 2003).

Telemedicine should not be confused with e-health (or teleHealth). Telemedicine only refers to the provision of medical services (Chau & Hu, 2004). E-health, on the other hand, refers both to medical services and to any other type of service, as long as it has something to do with health and employs information technology (Eysenbach, 2001; Rodger & Pendharkar, 2000). In this respect, e-health would also include healthcare educational activities, research in the health sciences, the handling of electronic files in the healthcare system, and any other use of information technologies in the healthcare system.

Telemedicine requires a new type of worker: the healthcare teleworker. But unlike in other types of telework, the human factor is much more important for the success of projects in telemedicine. Nevertheless, physicians remain wary of adopting

DOI: 10.4018/978-1-59904-883-3.ch122

telemedicine. This work examines the sources of the resistance to incorporate telemedicine. It adopts a focus centering on the difficulties that human factors have in accepting the practice of telemedicine.

It would be useful, for their design, to analyze telemedicine project acceptance among the human factor involved. This would allow managers to make management decisions concerning the design of the project, its implementation, and the subsequent resolution of problems with the personnel involved.

The rest of this article is organized as follows. The second section discusses the relationship between telemedicine and human resource management. The third section tries to identify the obstacles in the way of an adequate acceptance and development of telemedicine. Section four suggests some future research opportunities within the domain of the telemedicine topic.

BACKGROUND

The various barriers to the implementation and development of telemedicine projects include patient acceptance (Eikelboom & Atlas, 2005; Hofmann-Wellenhof, Salmhofer, Binder, Okcu, et al., 2006; Turner, Thomas, & Gailiun, 2001; Wyman, 1994), government regulation (McGee, 2004; Schindler, 2005), the cost of the technology (Guy, 1997; McGee, 2004; Schindler, 2005), the absence of insurance coverage (Guy, 1997), technological barriers (Paul, Pearlson, & McDaniel, 1999), and social and cultural obstacles (Bangert & Doktor, 2002; Jarudi, 2000; Spil, Schuring, & Michel-Verkerke, 2004) among others. Nevertheless, there is consensus that the most important source of resistance comes from the failure to accept such systems by the healthcare workers, precisely the ones who will have to use them (Chau & Hu, 2002; Hu & Chau, 1999; Hu, Chau, Sheng, & Tam, 1999; Qavi, Corley, & Kay, 2001).

Nevertheless, few studies analyze the impact of telemedicine projects on the management of the human resources participating in such projects. Some studies that do so analyze the psychological determinants of the physicians in telemedicine adoption (Croteau & Vieru, 2002; Hu et al., 1999). Of particular note is the hierarchical telemedicine acceptance model proposed by Hu and Chau (1999), which includes human and technological dimensions and organizational levels. At the organizational level they analyze the relation between the decision to adopt telemedicine and the compatibility of the technology to be used with the physicians' previous work routines.

The consideration of a close relationship between technological and human resources is not a new concept. The sociotechnical approach (Emery & Trist, 1965; Miller & Rice, 1967; Rice, 1958; Trist & Bamforth, 1951) was a clear expression of the notion that companies should unite both their human and technological dimensions. The human relations (McGregor, 1960; Roethlisberger & Dickson, 1939) and contingency schools (Lawrence & Lorsch, 1967) also noted this relationship.

This lack of attention given to the human factor in the adoption and implementation of telemedicine projects is surprising, since the healthcare staff's reluctance to accept the new technology or collaborate in it is one of the main causes of the failure of such projects, these professionals being the proposed end-users of the system (Gagnon, Lamothe, Fortin, Cloutier, et al., 2005). This concept is well known in the literature on the adoption of information technologies in organizations (Bruque-Cámara, Vargas-Sánchez, & Hernández-Ortiz, 2004; Khatri, 2006; Melville, Kraemer, & Gurbaxani, 2004; Powell & Dent-Micallef, 1997), but the question has received too little attention in the specific case of telemedicine projects.

The rejection of telemedicine by the healthcare workers involved is often a result of the resistance to change generated by inertias in the existing organizational routines (Pardo & Martinez, 2003;

Rumelt, 1995). These routines are threatened by the need to redefine traditional professional roles and by the professionals' loss of status, since IT blurs the functional and hierarchical boundaries in healthcare organizations (Aas, 2001, May, Gask, Atkinson, Ellis, Mair, & Esmail, 2001).

Technology cannot transform a company by its mere presence. The necessary transformation requires a fundamental change in habits, attitudes, values, expectations, and incentives relating to information management. Thus, attention should focus not on the technology but rather on healthcare itself, as equipment, whether low- or high-tech, does not in itself necessarily help either patients or healthcare professionals; it depends on how such equipment is used by people (Loane & Wootton, 2002).

Telemedicine will not work simply by making certain information technologies available to healthcare specialists. If IT is not integrated with complementary resources then it is not efficient in its own right. Some authors ask why some companies encounter difficulties and yet others prosper when using the same IT, and why IT-based advantages dissipate so quickly. Their response is that integration should be produced between the IT, complementary human resources, and business capabilities (Bruque-Cámara et al., 2004; Khatri, 2006; Melville et al., 2004; Powell & Dent-Micallef, 1997). The integrated management of IT and complementary resources and capabilities can be regarded as the most feasible path towards attaining IT advantages.

TELEMEDICINE BARRIERS

This section analyzes the main factors that may explain practitioners' resistance to accept telemedicine. The most important obstacles to the development of telemedicine are as follows: inertias in the existing organizational routines and employees' resistance to change, lack of time, limitations of the technologies, patients' incompetence, difficulty in using the technologies and understanding their utility, lack of training, and lack of trust.

The inertias in the existing organizational routines are one of the most important obstacles to the adoption of projects, whatever their nature (Pardo & Martinez, 2003; Rumelt, 1995). Among the organizational routines that are typical in the healthcare sector are procedures and medical protocols. Some procedures and medical protocols in healthcare services prevent medicine from being conducted at a distance. Some of these protocols and procedures are inefficient and obsolete (Kirsch, 2002). They also prevent healthcare professionals from accessing more advanced clinical practices or using the available information to improve their diagnoses and treatments.

Employees' resistance to change may be a result of their lack of participation in the project, the failure to consider their interests or needs, the fear that their jobs or status are under threat, lack of training and information, fear of uncertainty of what will happen when the new system is launched, the perception that change is unnecessary, the tendency to concentrate on short-run problems, the refusal to believe that past successes may end unless things change, group pressure on the individual to continue with what has been normal up to now, the risk of failure, the effort required when adopting something new, a lack of strategic vision throwing doubt on whether the right path has been taken, a lack of consensus with regard to the decisions taken, the difficulty in breaking with the established routines, and waiting for others to act so as not to run the risk of changing unilaterally.

Physicians often argue that they do not have time to attend to patients remotely, as they are too busy with the consultations and medical services they provide to the patients who see them in person. This is a shortsighted view from the strategic perspective, since they would be able to attend to more patients if they saved time on traveling and if they automated medical services wherever possible. By using technology to automate existing routine tasks, performance can be optimized (Kirsch, 2002). Better efficiency is driven by better use of information, and this is where telemedicine can be utilized.

One of the most reasonable concerns of telemedicine professionals is the doubt about whether telemedicine can really substitute properly for face-to-face care. Clearly, telemedicine cannot be used as successfully in all circumstances as direct, face-to-face contact with the patient. Using telemedicine to care for patients requires a thorough understanding of its technical limitations. But despite these limitations, telemedicine is still very useful when distance or an emergency situation prevents healthcare professionals from attending a patient in person.

One of the most common misconceptions among healthcare professionals, which leads them to reject telemedicine, is to assume that patients are not able to take decisions, and so they do not need to be given all the information. But telemedicine can provide patients—who are consumers of healthcare services, and consequently the "customers"—with the information they need to participate in their own care and take informed decisions in the choice of hospitals, physicians, and treatments (Thames, 2003). The Internet allows patients to participate from a distance as partners in taking medical decisions during the course of their treatments (Miller & Derse, 2002).

On the other hand, physicians' acceptance of telemedicine is strongly influenced by psychological and perceptual factors. Thus, physicians' acceptance of telemedicine depends on their attitude towards the use of technologies in general, their previous experience in using technologies (Qavi et al., 2001), and their perception that the technologies are easy to use, and that they will prove useful in their work (Hu et al., 1999).

The need for training and preparation in the use of the technologies supporting telemedicine is not reflected in the syllabuses of university medical departments (Ferrer-Roca, 2001). This is why many healthcare professionals fail to see the connection between their work and the technical issues (i.e., use of applications and databases, electronic interchange of data and image files, standards to use, etc.) or legal issues (e.g., IT security, data protection and privacy, international practice of telemedicine, etc.) that concern telemedicine.

Telemedicine often brings physicians who do not know each other into contact so they can share information or work together in virtual healthcare teams. Trust plays a key role in all collaboration relationships (Gefen, 2000), and this is particularly true in virtual relationships. Telemedicine projects that do not inspire trust among the physicians do not tend to encourage team working (Paul & McDaniel, 2004). Nevertheless telemedicine brings its own additional problems in creating and maintaining trust. This is because telemedicine involves the participation of multidisciplinary teams, and in virtual processes that are different from the ones healthcare professionals are used to. Launching a telemedicine project can also be seen as a threat as the first step in the replacement of the healthcare professionals by other professionals delocated geographically, even in other countries.

FUTURE TRENDS

Telemedicine will not work simply by making certain information technologies are available to healthcare specialists. If IT is not integrated with complementary resources then it is not efficient in its own right. Integration should be produced between the IT, complementary human resources, and business capabilities (Bruque-Cámara et al., 2004; Khatri, 2006; Melville et al., 2004; Powell & Dent-Micallef, 1997).

This work has focused on a general analysis of the motives leading healthcare professionals to reject telemedicine. An interesting future line of research would be to analyze acceptance segmented in function of the medical specialty involved, or of whether the objective is to reduce the disparities in the population in access to the healthcare system or not (Ahern, Kreslake & Phalen, 2006; Cashen, Dykes, & Gerber, 2004; Gibbons, 2005).

Future research should also examine whether human resource practices have the same positive impact on the performance of IT-based projects in the healthcare sector as in other industries.

CONCLUSION

The participation of the human resources involved in telemedicine projects is vital for the successful implementation and operation of these projects, since they are the ones who will have to use the telemedicine system when it is put in place (Gagnon et al., 2005).

This work analyzed various factors leading healthcare staff to reject telemedicine. Chief among these have been the obstacles to change generated by inertias in the current organizational routines, the irrational excuse of lack of time, the impossibility of these technologies substituting for personal contact with the patient, the perception of an assumed inability of patients to take decisions, the perception of the ease of use and utility of the technologies to be applied, the lack of training and preparation in the use of the technologies, and problems of trust for working in virtual teams.

Understanding why the human factor involved resists implementation of telemedicine projects should be useful for managers when they make their decisions about the design of the project, its implementation, and the subsequent resolution of problems with the personnel involved.

Some practical recommendations for managers of telemedicine projects follow. These managers would be recommended to develop human resource management practices centering on: (1) the existence of a fluid communication between healthcare staff and the management; (2) flexibility in the procedures; (3) participative decision making; (4) interdepartmental working groups; (5) training for the new technologies; and (6) the fit between the technology used and the human resources' interests (Bruque-Cámara et al., 2004).

KEY TERMS AND DEFINITIONS

E-Health: The provision of any healthcare service that is supported by electronic processes and communications.

Electronic Medical Records: Computer-based patient medical records. Patient medical records are a systematic documentation of a patient's medical history and care.

Telemedicine: The use of information and communications technologies to exchange information between practitioners, or to deliver medical services to a patient remotely

Telemonitoring: The remote monitoring of patients' state of health. It is fundamentally used to control and treat chronic patients.

Telenursing: Healthcare services provided by nurses remotely, such as monitoring patients in their homes, or referring patients to the appropriate medical services through the processing of patient data

Telepathology: The digital transmission between healthcare professionals of high-resolution images of, for example, microscope slides, photographs of injuries or smears, among others

Virtual Healthcare Teams: Teams made up of healthcare professionals that share information about patients electronically in order to improve their knowledge and decision making.

ABSTRACT

Nurses play a pivotal role in the provision of healthcare. Home telehealth, the use of information and communication technologies to deliver and support healthcare directly to the home, is emerging as an important application for nurses. This chapter provides an overview of home telehealth and how it may be applied to the practical challenges nurses face everyday. We provide a summary of the evidence available to support its use in specific areas and a guide for those thinking of implementing telehealth in their own practice. The future of home telehealth lies in carefully considered and designed research, ongoing education and training and a multidisciplinary approach. This chapter aims to stimulate the consideration of home telehealth as an application that may improve nursing care and ultimately patient outcomes.

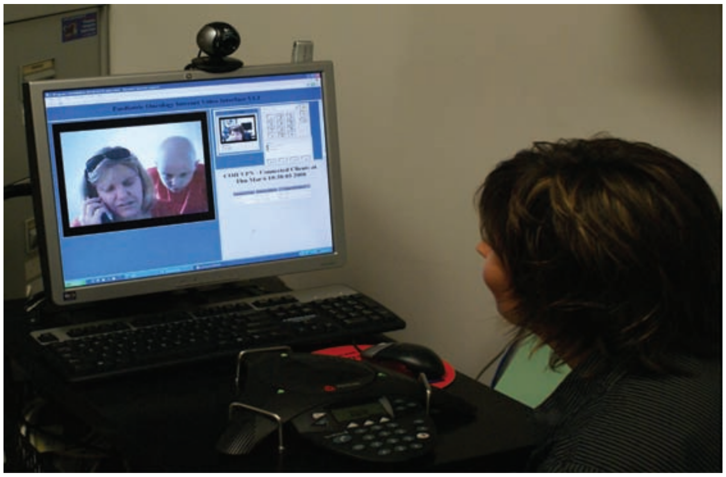
INTRODUCTION

The increasing incidence of chronic diseases (such as cancer, coronary heart disease, diabetes and dementia) and the growing aged population have added to the pressure on health care systems worldwide. The World Health Organization (WHO) predicts that chronic disease will be the leading cause of disability by 2020 and will be the most expensive

Figure 1. Real-time home telehealth using web cams and the Internet. Mother and child at home discussing care with an oncology clinical nurse consultant



problem facing health care systems (Belfield & Colin-Thome, 2004). For example, type II diabetes mellitus is becoming the most common chronic disease in the United States, affecting 7% of the adult population. Congestive heart failure affects about 5 million Americans each year and accounts for around 20% of hospitalised patients over 65 years (ATA, 2007). Studies show that caring for people with chronic diseases consumes approximately 78% of all health care spending in the United States – more than $1 trillion annually (ITAA e-Health Committee, 2004). The Centres for Medicare and Medicare Services estimated that total national health expenditure for home care was $40 billion in 2003, an increase of almost ten percent over the previous year. An additional $111 billion was spent on nursing home care (National Health Expenditures). With the ageing of the population, this rate of growth will increase.

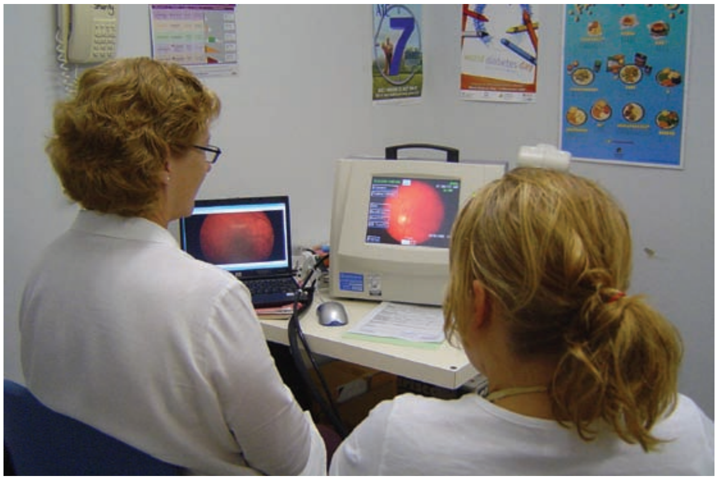
Undoubtedly, these tendencies have put additional pressure on the already overburdened nursing community around the world. Nurses form the largest professional health care group and their role as a care provider has changed significantly since the last century. The lack of nursing professionals is a global phenomenon (Kingma, 2006). Producing more nurses is one answer that requires long term investment and policy implementation. Finding other complementary mechanisms to address these urgent needs is also required.

THE ROLE OF NURSES IN HEALTH CARE

Nurses play an important role in almost every sphere of health care from primary to tertiary care. Nurses have rapidly evolving roles and responsibilities. Terms such as district nurse, health visitor, school nurse, GP practice nurse, nurse consultant, clinical nurse specialist and nurse practitioner reflect just some of the diversity of nursing practice.

Among other roles, nurses are also responsible for delivering care to patients at home, especially elderly patients. There is a continuing demand for such a role. However, statistics show that the lack of nursing professionals and the growing aged population is a prime concern for health systems around the world (Flesner, 2004). Despite these challenges nurses have shown remarkable flexibility and adaptability. The nursing profession has been an early group to embrace home telehealth

Figure 2. Store and forward home telehealth. A nurse screening children with diabetes for eye problems sending clinical information and images to a specialist ophthalmologist via email



which offers an alternative to providing face-to-face care.

WHAT IS HOME TELEHEALTH?

Home telehealth is the use of information and communication technologies to deliver and support health care in a non-institutional setting – that is, at home or in an assisted-living facility (Wootton, Kvedar & Dimmick, 2006). Home telehealth applications may include real time techniques, for example videoconferencing (Figure 1) as well as store and forward techniques, for example email or web-based applications (Figure 2).

In addition, various devices such as alarms, sensors and monitoring equipment are being used in home telehealth applications (Darkins, et al, 1996). Telehealth gives an opportunity to contact patients remotely augmenting and extending conventional care.

There are signs that interest in home telehealth is developing. Recent data shows that 20% of American based home health agencies employ some kind of telehealth in their day to day operations and another 20% plan to offer telehealth services in the next 12 months (Wootton, Kvedar & Dimmick, 2006). An increase has also occurred in the number of home health episodes. During 2001-2003 the number of Medicare home health users increased to 2.6 million and the number of episodes rose to 36 million. At the same time, the average number of visits per episode fell slightly to 17.3 (Wootton, Kvedar & Dimmick, 2006). The last few years have also seen an increase in the number of manufacturers of home telehealth equipment in the USA (mainly) and elsewhere.

HOW CAN TELEHEALTH ASSIST NURSES?

The role of the nurse practitioner, a registered nurse educated to function in an advanced clinical role, (Darkins et al, 1996) has major implications for health services. Experienced nurses have more responsibility in managing patients, particularly where access to medical and health services is inadequate. Telehealth has been reported as a useful tool for nurse practitioners.

To Support Remote Nurses

For example in the United Kingdom (UK) nurse practitioner units have been established to provide care to patients with minor injuries. Telehealth is used in these units as a support for nurses (Darkins et al, 1996). They can use videoconferencing to contact emergency medicine specialists for advice and support. This has effectively reduced the need to refer patients to the tertiary emergency medicine department and to the local general practitioner, saving time and reducing costs. Home telehealth can assist nurses to expand their role, to access direct clinical support for this expansion, and to reach more patients and provide more services (Jenkins & White, 2001).

One nurse practitioner in the USA uses home telehealth to support other nurses in a remote medical facility by conducting patient consultations online (Reed, 2005). This allows the nurse practitioner, working with the remote nurse, to complete patient histories, assess patients using peripherals such as a stethoscope, a camera for viewing eardrums, nasal mucosa, mouths and throats as well as a dermascope used to view and magnify skin lesions. The nurse practitioner can remotely print prescriptions for the patient, order additional investigations or refer the patient to specialist care.

To Support the Patient in the Home

Another benefit of home telehealth is the ability to make more frequent visits to patients. Home telehealth provides a unique opportunity to maintain frequent interpersonal contact using information and communication technologies like videoconferencing. Nurses can ‘visit’ their patients more often, prioritising in-person visits and avoiding unnecessary travel (Ryan, Kobb & Hilsen, 2003; Kobb, Hilsen & Ryan, 2003).

One example of supporting patients in the home using telehealth is wound care. A pilot investigation used a combination of real-time consultation and the capture of digital wound images to provide specialist wound care (Moore, Britton & Chetney, 2003). Outcomes included earlier assessment of patients by a specialist wound care nurse, a reduction in healing time, fewer in-person home visits and an increase in productivity. Additional benefits included improved education of patients and improved education and professional development in the use of wound care protocols for generalist home care nurses. Home telehealth is an alternative means of delivering the knowledge and expertise of a wound care nurse to underserved patients.

Another development in patient in-home support is the smart-home concept. This idea focuses on autonomy and independence with the aim to give people (and those caring for them) added security, safety, quality of life and access to medical care without an in-patient admission (Rialle, et al, 2007). In some cases it may delay or avoid institutionalisation.

In the mid 1990’s, smart-homes were equipped with sensors that turned on lights at night when movement was detected, turned off stoves if overheating or left on, unlocked doors and turned on lights if smoke was detected, alerted staff if residents were out of bed for prolonged periods and, for wandering people, alerted staff if external doors were opened (Bjorneby, 2000).

Newer developments in smart-home sensors include detectors worn by the resident to alert staff if a fall occurs (Gibson, 2003) or if a resident at risk of falling, sits-up in bed (Gelhaus, 2002) and to monitor the mobility and subsequent health status of residents (Prado, 2002).

To Promote and Support Self-Care

The role of home telehealth in helping patients to mange their own health is another growing area. Many elderly people live with at least one chronic disease or condition, such as diabetes or heart disease. On discharge from hospitals (particularly if the patient is newly diagnosed) patients need extensive support to manage their condition successfully. Traditionally this has been done with routine home nursing visits. However, home telehealth provides an opportunity to interact with and instruct patients at home. This may improve self-care, reduce subsequent readmissions and allow people to stay in their own familiar environment.

Telehealth units are available with the ability to add peripheral monitoring devices for tracking a patient's physiological status and providing this information to them as part of an ongoing education and self-management program. Peripherals can include a blood glucose meter, blood pressure cuff, pulse oximeter and other measuring/monitoring devices. Multimedia materials can also be integrated into home telehealth units. These materials may be used to remind patients to track their weight daily, to alter their fluid intake or increase their activity levels. Of course all of these activities require the support of an experienced and qualified health care provider. The use of this type of home telehealth requires frequent communication with patients to reiterate directions, educate and coach.

To Improve Medication Management and Compliance

There is also a growing body of literature on the value of home telehealth in medication management. Medication-related complications are a contributing factor in accidents and illnesses that lead to hospitalization (Joanna Briggs Institute, 2006). Research has shown that patients with greater than nine medications have at least a 22 percent incidence of medication errors which in turn contribute to adverse reactions and hospitalisation (Ahrens, Feldman & Frey, 2002). Home telehealth in medication management has proven effective. For example, a study by the Veteran's Administration in the USA demonstrated a 30 percent improvement in medication compliance after telehealth implementation (Kobb, Hilsen & Ryan, 2003). Medication reminders, interactive voice response (IVR) systems and telemonitoring solutions can improve medication management and enable nurses to improve the quality of care provided.

Given all of these benefits, what evidence is there to support the use of home telehealth?

The Evidence-Base for Home Telehealth

There is much hype surrounding home telehealth; a lot has been written about its potential and promise but little clinical research has been undertaken. A recent review of home telehealth (Bensink, Hailey & Wootton, 2006a) used a comprehensive search of electronic databases including Medline, PsychINFO, CINAHL, EBSCOhost and EMBASE to identify research in the area. These searches identified 769 references to home telehealth. Only 18% of these were controlled studies comparing a home telehealth alternative to a usual care control group. Despite the hype, there are still good to high quality studies in the area (Bensink, Hailey & Wootton, 2007a).

An Emerging Area of Research

The first reports of controlled investigations into the use of home telehealth began emerging in the early 1980s and there has been progressive interest in the area ever since. Not surprisingly, these early investigations used the ordinary home telephone to support patients. Topics of investigation included support after heart surgery; counselling hypertensive patients; and educating, counselling and monitoring patients after a heart attack. Since these early reports the number of published studies has steadily increased. Our review in 2006 identified 138 papers reporting on 130 home telehealth research projects.

The Technologies Used

Given its widespread operation in most areas of industrialised countries, the public switched telephone network (PSTN) continues to provide a readily available, affordable and reliable link to the home for home telehealth. The home telephone can itself be used or alternatively a variety of devices can interface with the telephone network. These devices can connect directly to computers or computer servers in a hospital or provide data over the Internet. Specifically designed devices are also available to provide transmission of vital signs data such as oxygen saturation, blood pressure and blood glucose level. Broadband Internet connectivity over home telephone lines is also emerging as a technology of interest to home telehealth providing higher bandwidth connections than the PSTN network. This is opening new areas of research allowing improved quality video-telephony amongst other applications.

Diseases/Conditions Studied

The majority of the published evidence (over two-thirds) has been from the United States with countries like the UK, Japan, Italy and France contributing a further 19%. The areas with the most supporting evidence are chronic conditions such as diabetes, heart failure, mental health problems and cardiac disorders although evidence exists in other areas such as high risk pregnancy monitoring.

Although the majority of studies have been completed in these areas, telephone counselling targeted at people trying to quit smoking, represents an interesting exception. In this area only six randomised controlled trials supporting the use of different technologies were identified. What set these studies apart was the sample size; over 10,000 people participated in these six trials. Results showed there is evidence that telephone counselling is an effective strategy for assisting self-quitters over and above self-quitting guides alone (Orleans et al, 1991).

Home Telehealth Evidence and Nurses

The primary care providers in over half of the studies identified in our review were nurses, most commonly providing a combination of remote patient monitoring, health counselling and education. One example of this is the use of a “dialogue box” for diabetes related patient monitoring in the home (Chumbler et al, 2005). This device attached to the home telephone line and allowed patients to answer basic questions on diabetes care and metabolic control using a simple key pad. Entered information was then relayed via the Internet and presented to a nurse who determined if any intervention was required for example, either health counselling over the telephone, a home visit or a clinic visit.

Neglected Areas

Some areas of health care are only emerging as topics of home telehealth research; these include paediatrics, neonatal care and obstetrics. Our own investigations in paediatric oncology are some of the first to appear in the literature (Bensink et al, 2004, 2005, 2006, 2007, 2007b) Here the use of videotelephony allows nurses to provide support to the patient and family at home, themselves or to coordinate support from other members of the specialist paediatric oncology team.

Economics

Another, more general area of neglect is the evaluation of the economic benefit of home telehealth. It is perhaps the economics of home telehealth that will encourage health care authorities to support projects as well as acting as a catalyst to the widespread adoption of home telehealth. In our review, only 17% of the 138 studies identified contained economic evaluations.

The care of patients with heart failure is one area where economic evidence does exist. Advanced practice nurses working with a cardiologist, were able to use data collected by the patient and relayed via the Internet, to provide treatment advice over the telephone (Benatar, Bondmass & Ghitelman, 2003). This study identified a reduction in readmissions to hospital and the overall cost of care for these patients. In another study, nurses provided telephone follow-up and received transmissions of one-lead ECG recordings from chronic heart failure patients at home (Scalvini et al, 2005). Again, a reduction in hospital admissions and a reduction in the corresponding cost of care were identified. There is an excellent overview of the main features of economic evaluation methodologies as applied to home telehealth in Scuffham et al, 2006.

Research Quality

Study design is an important point to consider in home telehealth, whether you are assessing the evidence available in a given area, or designing a study into a home telehealth intervention. As in any area of health research, large randomised controlled studies are the gold standard (Egger, Smith & Altman, 2001). Other non-randomised designs provide less reliable estimates of the relative effects of interventions (Clarke, 2004). Other study designs include case-controlled studies, matched cohort studies, time series studies and retrospective studies. Each provides a different level of evidence.

In the home telehealth studies we evaluated, 80% were randomised controlled trials. This, along with assessment of the quality of these studies, (Bensink et al, 2007) provides some reassurance on the level of evidence available for home telehealth in the areas identified. Some problems with the quality of published home telehealth research are still apparent. Patient selection, patient disposal and outcomes reported were areas where studies lacked sufficient information. The use of recognised guidelines, such as the CONSORT statement, (Moher, Schulz & Altman, 2001) can provide guidance not only when preparing trial results for publication, but also much earlier in the planning process when designing studies.

Research Challenges

One problem identified in some areas is the clear identification of exactly what the home telehealth alternative is and what usual care control group it is being compared against.

An example of where confusion can occur is the use of the Internet to provide support for a variety of mental health problems. A number of these studies compared two or more home telehealth interventions. For example, assessing home monitoring of lung transplant patients via the telephone versus an electronic diary (Mullan et al, 2003). Other studies compared a home telehealth alternative to a wait-list control rather than a usual care control group (Devineni & Blanchard, 2005; Andersson, Stromgren & Strom, 2002; Lange et al, 2003). These studies, although they provide interesting information, do not provide clear evidence to support the use of a home telehealth alternative over the care usually provided to patients as part of standard health care services (e.g. in-patient stays, out-patient visits or face-to-face home visits).

Even with a usual care control group, the comparisons are not always straight forward. An example of this is in the area of home uterine activity monitoring (HUAM). Despite the promise identified in early studies, one study found no difference in preterm birth rate, preterm labour incidence, average birth weight or the gestational age of infants with home monitoring (Iam, Johnson & O'Shaughnessy, 1988). The authors of this study concluded that the favourable outcomes credited to HUAM in earlier studies were related not to the home telehealth intervention, but instead to the increased contact with nurses, a focus on symptoms of preterm labour and perceived contractions. This sparked widespread debate in the field. A recent review identified that the use of control groups whose care was, in some studies, more similar to HUAM than the usual care available at the time, was an issue (Morrison & Chauhan, 2003). This set an artificially high standard to compare HUAM against.

What was the final conclusion? When HUAM is used correctly by patients at high risk for preterm birth, with suitable alarm rates and precise monitors, early diagnosis of preterm labour, prolongation of pregnancy, reduced incidence of preterm birth and reduced neonatal morbidity is always demonstrated when compared to a standard care control group. Specifically, for these studies, the authors noted that standard care was the care routinely available to obstetricians in the USA (Morrison & Chauhan, 2003).

Future Research

For health services to embrace home telehealth as a viable and sustainable method of health service delivery more evidence is required. A scientifically sound case requires more randomized controlled trials to be undertaken with appropriate methodological rigour and quality. In any particular area, for example care of patients with diabetes or depression, these trials will need to investigate the use of the same intervention in comparable populations. Ideally, studies will also provide information on the economic, as well as the clinical effectiveness of the intervention. Finally, subsequent meta-analysis of results will provide a clearer view of the evidence available for a particular intervention in a population with specific characteristics.

This process is beginning to occur. A recent review and meta-analysis of home telehealth for patients with chronic heart failure concluded that programmes which include remote monitoring have a positive effect on clinical outcomes (Clark, Inglis & McAlister, 2007).

IMPLEMENTATION

Given the above examples, home telehealth has some benefits. These may be interpreted from a range of perspectives including that of the patient, the health service provider – or society as a whole. It is also important to appreciate the underlying reason(s) for using telehealth in general, whether to the home or for other applications. According to Wootton (2006), there are two broad reasons which may influence the use of telehealth:

The first is that there may be no alternative. An obvious example is if the patient is on a ship at sea or on a space expedition. In these circumstances, it is not logistically possible to visit a medical facility in person, and therefore the patient will depend on information delivered from a distance. A more common example is if the patient lives in a very remote country location with no local health services within close proximity. If the patient is unable to travel it may be reasonable to consider the opportunities for delivering services using telehealth.

The second main reason to develop a telehealth service is that there may be evidence which shows that telehealth is 'better' in some way than the conventional services available. That is, telehealth may be more clinically effective, may provide patients with more regular contact with a specialist, may be cheaper and more sustainable than the alternative, and may be more useful for early intervention and preventative health care services.

In brief, there are a number of practical aspects to consider when starting a new telehealth service.

Getting Started

- Identify the need for telehealth. Why telehealth? What is the clinical problem to be solved?
- What is the best method – real-time; store-and-forward, or a hybrid? This will also

depend on the type of information to be transmitted, i.e. live video, digital photographs, text only, audio etc.

- What equipment will be required for the telehealth service?
- Telecommunications – what will be required?
- Obtain funding? The amount of funding available will influence choice of application.
- What incentive is there for clinicians to do telehealth?
- What support will be provided to clinicians – technical, administrative, executive?
- Identify clinical coordinators at both ends. Who will be responsible?
- Give consideration to change management.
- Have an evaluation plan in place – i.e. evaluate the service – investigate feasibility, cost-effectiveness, satisfaction, clinical effectiveness etc.
- Start small – feasibility testing first and develop service incrementally.

Be Aware

- Identify previous successes and failures and learn from others experiences and mistakes.
- Don't duplicate known failures.

Logistical Factors

Telehealth should not automatically be viewed as a new service. Instead, telehealth may provide an alternative method of delivering services which already exist. It is very important when establishing a telehealth service, to understand the underlying requirements of the service. That is, what are the factors which support the need for telehealth (distance, limited access to specialist services); what telehealth methods are most suitable for the needs identified (real-time, store-and-forward); what is the service going to achieve (perhaps reduced travel for patients, improved recruitment of medical staff to rural areas or improved emergency responses from regional areas).

It is also important to consider how the telehealth service respects and integrates with established working practices (e.g. existing referral mechanisms, patient flows, and dischare support services).

Telehealth requirements in different areas should be judged on individual merit. What works well in one area, does not necessarily guarantee that it will work well in another. Review the literature first and learn from the experiences (positive and negative) reported by others.

The decision to use telehealth instead of conventional methods of service delivery may be directly related to the alternative services available. For instance, if the conventional referral process is easy to use, as is the case in many states in Australia (patients are reimbursed for travel costs), an even more convenient process (incentive) would have to be developed, before clinicians were likely to consider alternatives, such as telehealth. Even today, telehealth is often perceived as being more complex and time consuming for clinicians to set up than the conventional method of sending the patients to see the specialist in person. This may explain why very few clinical telehealth services have emerged as mainstream services in Australia and throughout the world.

Economics

Like any new service, if one is considering establishing a new telehealth service they ought to have a good understanding of the likely establishment and daily operating costs. In addition, one should investigate whether there are economic advantages in doing telehealth, instead of using conventional methods of service delivery, i.e. how do the costs of home telehealth compare to conventional methods of health service delivery such as nurse visits to the patient homes and appointments in specialist hospitals.

Table 1. Types of economic evaluations (Drummond 1996)

Type of analysis	Definition
Cost-benefit	measures costs and benefits in monetary units and computes a cost-benefit ratio
Cost-effectiveness	compares interventions or programmes having a common measurement of health outcome in a situation where, for a given level of resources, the decision maker wishes to maximise the health benefits conferred to the population of concern
Cost-utility	measures benefits in utility-weighted life-years (QALYs) and which computes a cost per utility-measure ratio for comparison between programmes
Cost-minimisation	measures and compares the costs for each service whereby the health outcomes for both services are assumed to be equivalent

There are a various types of economic evaluation methods which may be selected subject to specific factors which need to be assessed. Common examples include cost-benefit; cost-effectiveness, cost-utility and cost-minimisation analysis (see Table 1) (Drummond, 1996).

Perhaps the most common type of economic analysis reported in telehealth studies is the cost-minimisation analysis in which the total costs of two or more services (with comparable health outcomes) are compared to determine the most economical choice of service at a given workload. This type of analysis is also useful to determine what workload (i.e. number of consultations) must be achieved in order for one service to cost the same as another. This point is often referred to as the threshold.

In order to do a cost-minimisation analysis, you will need to identify all of the costs associated with operating your telehealth service and the costs of operating the alternative service. These costs are usually categorised as fixed and variable costs. Fixed costs include equipment, installation and rental of telecommunications, managing staff salaries and facility costs. Variable costs are related to the volume of activity and include telecommunication (call) costs, clinician salaries, travel and accommodation costs. Once these costs are determined, you are then able to calculate the total costs of each service based on a selected workload. It will be possible to calculate the average cost per consultation by dividing the total cost of operating the service by the number of consultations. More importantly, you will be able to determine the cost of providing one additional consultation, assuming all establishment costs are in place. This is referred to as the marginal cost.

Case Example

Although not a home telehealth application, instead providing links between a tertiary paediatric referral centre and regional hospitals, the experiences of the telepaediatric service in Queensland, provides a valuable insight into telehealth implementation.

As an incentive to use telehealth, clinicians at selected regional sites throughout Queensland were given exclusive access to a centralised referral centre - contactable by a single toll-free telephone number. By calling this number, clinicians had a direct link to a telehealth coordinator based in Brisbane. Once a referral was made to the telepaediatric service, the telehealth coordinator took full responsibility for the case, liaised with the appropriate specialists and guaranteed a response within 24 hours. The single point of contact model has been a critical factor leading to the uptake and integration of telehealth services into the routine component of outreach service delivery.

A cost-minimisation analysis was conducted to compare the cost of providing telepaediatric services to two hospitals during a five year period. These costs were compared to the potential cost

Table 2. Telepaediatric service costs and potential costs had all patients travelled to Brisbane

Expenditure	Telepaediatrics ($)	Outpatients ($)
FIXED COSTS		
Equipment (5-year total annuatized cost)	128,191	0
ISDN Installation	2655	0
ISDN Line rental	32,400	0
Coordinators salaries	475,000	0
Sub total (fixed costs)	***638,246***	***0***
VARIABLE COSTS		
Telecommunications *ISDN Line charges*	65,400	0
Staff salaries:		
RCH Consultants ($200 per h)	109,000	109,000
RCH Nursing / Allied Health ($50 per h)	27,250	27,250
RCH Admin Support ($30 per h)	0	16,350
Regional presenter ($150 per h)	81,750	0
Regional admin support ($30 per h)	16,350	0
Patient travel subsidy scheme: *Travel Accommodation*	0 0	1,391,670 8,994
Project costs	18,000	0
Sub total (variable costs)	***317,750***	***1,553,264***
TOTAL COST	**955,996**	**1,553,264**
Average cost per consultation (Divide total cost by the number of consultations)	637.76	1036.20
Marginal cost (Divide the total variable cost by the number of consultations)	211.97	1036.20

of transporting patients to the nearest hospital to see their specialist in person. During this period a total of 1499 consultations were conducted. In this analysis, we assumed that all patients would have had to travel to see the specialist in person, had the telepaediatric service not been available.

All costs are reported in Table 2.

In the above example (at the reported workload actually experienced) telepaediatrics was a much cheaper method of delivering the specialist service, mainly due to the high costs associated with potential travel. Had the workload (number of consultations) been significantly lower, the overall economics of doing telehealth would have been less attractive. Similarly, had the workload been higher, the economics would have been even more favourable.

BARRIERS

Given that home telehealth has the potential to assist health service provision in a number of ways, that evidence exists to support its use in a number of areas and the success demonstrated by a number of telehealth projects, what other factors may be impeding the uptake of home telehealth?

Education and Training

In line with other developments in health care, education and training is a key factor in uptake. Like advances in medical imaging, ongoing education and training are critical for patient safety and for staff to use these systems efficiently and effectively. Advances in telehealth should be no different.

Very little attention has been paid to education and training in telehealth. Research has shown that despite the fact that health practitioners are familiar with computers and other electronic devices the practice of telehealth requires systematic education and training (Edirippulige, Smith & Young, 2006). The lack of knowledge of telehealth, its basic concepts and application is a result of the absence of systematic education (Edirippulige, Smith, Beattie, Davies & Wootton, 2007). Unless students are given education in basic concepts, principles and the variety of applications possible, then it is unlikely that telehealth will become a part of their practice. The potential benefits of telehealth can only be realised if students are provided with formal education as part of their curriculum.

In addition, integrating telehealth into ongoing professional development and support is also important. Health and medical professionals must be supported to acquire (until telehealth is integrated into curricula) and maintain their knowledge and practical skills in telehealth via continuing professional development (CPD) programmes. For this to occur, these courses will need to be recognised by relevant professional bodies through formal accreditation and support provided by employers for staff to attend.

A Multidisciplinary Approach

Another barrier to ongoing development in telehealth is the lack of interdisciplinary collaboration. Successful home telehealth implementation depends fundamentally on the ability to form, and lead, a multidisciplinary team through a lifecycle from initial analysis to the eventual day-to-day routine delivery of the service. It is important to remember that, whilst home telehealth uses technology as the vehicle for delivery of clinical services, there are other important non-technical aspects that must be given equal attention to ensure uptake and successful operation. This of course includes clinical aspects as mentioned previously, but also includes administrative aspects associated with coordination and ongoing operation.

Although the composition of a telehealth team will change over time, the underlying membership of the team must consist of skilled individuals in three key areas:

1. Clinical (e.g. nurses, doctors, social workers)
2. Technical (e.g. application developers, networkers)
3. Administrative (e.g. telehealth service coordinators, medical records staff).

Because these areas are closely interlinked, all members of the team need to be involved from initial inception of the project. The team, and its leader, must posses an uncommonly wide range of skills and experience in both project management and operational service management.

In common with general technology projects, a successful telehealth implementation will result from a delicate balancing act of both project-oriented and operational tasks carried out by a skilled team. In contrast with most general technology projects, the telehealth project requires a multidisciplinary approach and the necessity for each of the disciplines to be represented at all stages of the project. In addition, the project manager must have a broad understanding of all of the issues across clinical, technical and administrative boundaries and be able to manage various demands of the team to successful implementation.

CONCLUSION

Home telehealth is the use of information and communication technologies to deliver and support health care directly to the home. For nurses, home telehealth provides an opportunity, amongst other applications, to support other nurses at a distance, to support patients in the home through direct communication or via passive monitoring techniques, to promote and support self-care and to help patients with medication management and compliance.

Despite the hype, home telehealth is still an emerging application. As in all areas of health service, evidence is required to establish the worth of investing in home telealth examining both the clinical and cost-effectiveness of interventions.

Nurses have an opportunity to place themselves at the forefront of these developments. To achieve this, nurses will need to identify, in their own practice and area of expertise, how telehealth may play a role and why it might be of benefit, which methods are most appropriate and what outcomes might be achieved.

Nurses are also well placed (clinically, practically and historically) to play a key role in multidisciplinary telehealth teams. This collaborative approach is required to bridge the gap between patients and the clinical, administrative and technical aspects inherent in care delivery via telehealth techniques.

Finally, as a catalyst for this type of development, nurses need to know more about telehealth through systematic education as an integral part of undergraduate and graduate nursing curricula.

KEY TERMS AND DEFINITIONS

Telehealth: The delivery of health-related services and information over distance via telecommunications technologies.

Home Telehealth: The use of telehealth techniques in a non-institutinal setting such as the home or residential care facility.

Evidence: The collection of data through observation and experimentation used to determine or demonstrate the truth of an assertion.

Telepaediatrics: Telehealth applications relevant to the health and wellbeing of children, young people and families.

Real-Time Mode: The use of telecommunications allowing instantaneous two-way interaction between participants e.g. videoconferencing.

Store-and-Forward Mode: The delayed exchange of data requiring first capture using for example a digital camera, voice recorder, X-ray machine or video camera, sub sequent storage and latter transmission.

Health Economics: A specialist field of economics related to the demand and supply of health and health care.

Multidisciplinary: The collaboration of individuals and groups with specialised education and expertise in distinct and different areas.

Telehealth Education and Training: The formal and systematic imparting of the knowledge and skill required to apply best practice principles to the application of telehealth in practice.

Process-Based Evaluation of Hospital Information Systems:

Application of an Information Systems Success Model (PRISE) in the Healthcare Domain

Sevgi Ozkan
Brunel University Business School, UK

Nazife Baykal
Informatics Institute Metu, Turkey

Murat Sincan
Informatics Institute Metu, Turkey

ABSTRACT

Although there is limited research and evidence base, it is reasonable to expect that high quality information technology is an integral factor in the success of today's healthcare sector. However, the healthcare sector is considered to be low level investor in information technology (IT) when compared to other sectors. There are studies that look at the sums spent on health IT as a basis for determining how effective the IT systems are. We support the idea that the effectiveness of IT systems is not an exact measure and a more systematic approach needs to be taken when evaluating success of an IT system. In this study, we have evaluated an assessment method, process based information systems effectiveness (PRISE), which is based on a novel model of information systems effectiveness in the healthcare domain. The results of our case series provide specific implications concerning the applicability of a general "information systems assessment" approach, in the medical context.

DOI: 10.4018/978-1-60566-030-1.ch005

INTRODUCTION

Health care organizations and patients can benefit greatly from the appropriate and effective use of information systems (hereafter IS) (Kaushal, Barker and Bates, 2001). Effective implementation of IT in health care has the potential to save billions of dollars while reducing morbidity and mortality (Chaudhry, Wang, Wu, Maglione, Mojica, Roth, Morton, and Shekelle, 2006). As Burke and Menachemi (2004) stated in the paper, in the recent years, health care investment in IT has experienced a significant increase, which in parallel results with an increase in IT capabilities. Empirical research has shown that effective information systems in healthcare organizations are associated with reduced costs and with better care and organizational performance (Chang and King, 2005; Li and Ye, 1999), which suggests a connection between IS process improvement and organizational effectiveness. However the impact of IS implementations are hard to measure and identify (Jayasuriya, 1997). Researchers also suggest that the impact of IS is usually accidental rather than planned (Borum and Christiansen, 2006).

While the effectiveness of information systems is recognized as an important issue, the definition of IS effectiveness in the information systems literature is not yet mature and consistent (Ozkan, Hackney and Bilgen, 2007). Various models such as Capability Maturity Model (CMM/CMMI) (SEI, 2007), Control Objectives for Information Technology (COBIT) (ISACA, 2007) and Information Technology Infrastructure Library (ITIL) (OGC, 2007), have been proposed and used by the IT industry (Ozkan et al, 2007). IS management and evaluation frameworks are not limited to the above mentioned and the list includes approaches that range from the generic ISO 9001 (Braa and Ogrim, 1995), Six Sigma (Schroeder, 2007), and EFQM (EFQM, 2006; Donahue and Vanostenberg, 2000) models through IT specific models such as SPICE (SEI, 2007), ISO 9126, ISO 20000 (ISO,2007), to healthcare-IT specific models such as Q-Rec (Q-Rec,2007), Joint Commission International Information Management Standard (Donahue and Vanostenberg, 2000) and HIS-Monitor (Ammenwerth et al, 2007). Each of these approaches has a distinct focus, and its own strengths and weaknesses.

In their seminal review paper, DeLone and McLean defined IS success in terms of success in six categories. These categories were system quality, information quality, user and user satisfaction, individual impact and organizational impact (DeLone and McLean, 2003). In 2003, they revised their model to include service quality as another quality category and they united individual and organizational impact into one "net benefits" category (DeLone and McLean, 2003).

Proper evaluation and assessment is essential for the ongoing improvement of information systems. Yet, a great number of studies that evaluate the organizational aspects of hospital information systems (hereafter HIS) are based on exploratory methods (i.e. do not test a pre-defined hypothesis) (Ammenwerth and Keizer, 2005). Objective and explanatory measurement methods are needed to better evaluate organizational aspects of IS, both in general IS and in HIS context. Another deficiency of the IS evaluation studies is that the evaluated system usually has a limited focus (Ammenwerth and Keizer, 2005), either in functionality or localization (i.e. departmental systems). Among the explanatory studies that utilize formal assessment and/or measurement data rather than user feedback or satisfaction, there are very few studies that have a wider focus and evaluate enterprise-wide systems (Ammenwerth and Keizer, 2005)

It is logical to think that there must be a strong relationship between "improvement in managing IS" and "overall performance of the organization" as measured by effectiveness. Systematic measurements are needed to test this hypothesis. The first step in attracting attention to this area is to review the current level and status of information systems management practices. As Eccles (1991) says, "What gets measured gets attention". To improve the current status we need to measure IS management and IS effectiveness, although effectiveness is extremely hard to measure (Borum and Christiansen, 2006) because of the highly complex "sociotechnical systems" that make up an information system.

DeLone and McLean emphasize the need for a validated measuring instrument which could provide a standardized evaluation of information systems effectiveness; this would permit comparisons across departments, systems, users and organizations (DeLone and McLean, 2003). Such a measurement would help to build a cumulative research tradition which could clarify effectiveness measures.

IS evaluation is an active and organization-dependent undertaking. Organizations need a comprehensive framework for assessment to help and guide them, in developing an IS evaluation methodology.

This study takes a method used previously in non-medical settings and applies it to the health care domain. We also aim to show how organizational factors are related to the management of IS processes.

RATIONALE FOR THE STUDY

Several studies have looked at the effects of information systems on health care organizations (Jayasuriya, 1997). Electronic health records is the single most important type of system evaluated, followed by clinical physician order entry (CPOE), clinical decision support systems (CDSS), telemedicine, radiology information systems (RIS) and picture archiving and communication systems (PACS) (Keizer and Ammenwerth, 2005). Numerous health care-specific information systems are used in a modern health care facility; their effect on both organizational performance and health care quality is important. The combined effect is also more than the sum of their individual impacts on the organization.

Before we delve more into information systems evaluation, we need to clarify the difference between IT and IS. Information Systems is a wider concept than information technology and is closely related to organizational functions and information requirements (Wilcocks and Lester, 1993; Ozkan, 2004, 2005; Ozkan and Bilgen 2003). IS are both affected by organizational practices and in return have an effect on the organization. Methods are needed to make these relationships between organizational factors (i.e. size, effectiveness, human resources, and financial health) and information systems, visible and measurable. IS projects are more likely to fail than succeed but a correlation between organizational factors and IS success, could guide decision makers in planning and implementing systems.

OBJECTIVES OF THE STUDY

Our objective is to use the PRISE evaluation tool to measure the level of process maturity of hospital information systems. Although the acronym HIS is generally used for “hospital information systems” and “health information systems” interchangeably, our focus in this study is limited to ”hospital information systems” and does not include other information systems used in health care settings. We use the following definition for a Hospital Information System: “Computer system designed to support the comprehensive information requirements of hospitals and medical centers, including patient, clinical, ancillary and financial management” (Shortcliffe and Cimino, 2006).

Information systems are composed of elements; some are easier to measure than others. An assessment framework that only focuses on discrete “easy to measure” elements cannot show the whole picture or provide an exclusive assessment of the success of a system (Perera et al, 2007). Central processor unit utilization time and network load are easily measured, but the usability of a new graphical user interface or the usefulness of a decision support advice might be harder to measure.

The goal of an HIS evaluation framework is to provide a set of measures and performance indicators that can be used to predict the quality of processes that ultimately result in better outcomes at either a user/patient or cost saving level(Perera et al, 2007). Development of a universal set of indicators and measures require best practice data and established validity pertaining to the individual indicators (Perera et al, 2007). This scope of evidence is only possible through many studies that provide this kind of scientific proof from numerous different systems and implementation settings. One of our goals is to provide methodology and data that contributes to this body of knowledge.

PRISE is a novel, comprehensive and innovative approach to assessing the effectiveness of IS processes; it was developed by one of the authors of this paper as part of a PhD thesis (Ozkan et al, 2007) and to help organizations evaluate their IS management with a strong process focus. The PRISE questions can be asked by an external assessor or reviewed internally for self evaluation. PRISE has 10 process areas, all of which are all related to IS. Each area includes more detailed questions which are scored on a scale that has six levels. Each score level from 0 to 5 represents a different level of maturity in IS processes.

PRISE has successfully evaluated IS process maturity in non-health care technology organizations as applied in the original PhD thesis (Ozkan, 2006; Ozkan et al, 2007). Since there is a lack of specific health IS assessment frameworks, we believe that the application of general IS assessment frameworks such as PRISE might suggest how health IS assessment methods should be developed and applied.

We hypothesize that there are correlations between PRISE scores and organizational factors within a health care organization. Identifying these correlations will guide future research in determining causal relationships between these organizational factors and IS success. Our research question is: "*Is there a relationship between certain organizational factors and PRISE scores?*"

RESEARCH METHODOLOGY

Organizational Setting

The assessment was carried out in Turkish health care provider organizations with inpatient capabilities: state hospitals, private hospitals and academic medical centers (university hospitals). The Hospital Information Systems (HIS) were assessed using the information systems success assessment tool: PRISE (Process Research for Information Systems Evaluation). All of the hospitals used commercial software systems with little or no internal development of support or maintenance. The research did not involve any general and administrative systems (i.e. accounting information systems) nor any departmental information system confined to that department.

Study Design

819 hospitals were initially contacted via e-mail. A total of 4 e-mail reminders were sent to all the target hospitals. Total number of institutions which agreed to participate in our study is 17. Each health care organization was sent an e-mail message with an attached copy of the assessment tool (see appendix) and instructions on how to use it. The institutions were asked to assign a senior IS officer to complete the self-assessment process.

Prise Evaluation Tool

The Hospital Information Systems (HIS) were assessed using the information systems success assessment tool: PRISE (Process Research for Information Systems Evaluation). PRISE (Ozkan, 2006; Ozkan, Hackney and Bilgen, 2007) was developed to provide a comprehensive and integrative information systems assessment framework. Jayasuriya et al, note that most other approaches to evaluate IS effectiveness lack an integrated approach; they may yield convenient solutions within their specific contexts, but they do not

Table 1. PRISE process areas

	P9	Change management
	P10	Monitoring services

comply with all of the guidelines in the literature (Borum and Christiansen, 2006). PRISE aims to provide an integrated approach to IS evaluation by complying with the guidelines.

The PRISE model consists of three main components: People, Resources, Services and Benefits, with a total of 10 process areas within those components (Table 1). The model consists of 92 questions in 10 process groups, which are assesses on a 6 level scale as shown in Table 2.

Participants

10 of the participants were State hospitals, owned by the government and run by the Ministry of Health. Some of these state hospitals are third level research hospitals but most are secondary level care hospitals. The University hospitals that participated in our study are also owned by the government. Only 2 of the participating hospitals were privately owned. Table 3 shows a detailed distribution of the participants.

We had participants from thirteen different provinces of a total of 81 provinces in Turkey. 13 health care providers were from provincial centers and 4 of them were from smaller towns. The number of beds ranged from 19 to 1200 with a mean of 411. The number of physicians ranged between 10 and 1390 with a mean of 276. 13 of the institutions had an internal IT or IS department independent of an outsource company. Not surprisingly, the hospitals that were located in provincial centers (urban centers) had IT/IS departments and the hospitals in small towns (rural centers) did not; 12 of the hospitals had 2 or fewer people employed in the IT/IS departments. One

Table 2. PRISE scale

Level	Explanation
0	Non existent
1	Initial /Ad Hoc
2	Repeatable but intuitive
3	Defined process
4	Managed and measurable
5	Optimized

Hospital Type	Number
State hospital	10
University Hospital	4
Private Hospital	1
Medical Center	1
Mouth and dental health center	1
Total	17

institution employed 31 people in IT/IS services. This large variation in the number of IT/IS services personnel (standard deviation SD=7.9) reflects organizational differences in the approach to IT/IS management.

Our participants had a mean of 4.2 years of experience (SD=3.1) with their enterprise-wide information systems and they had been using their most recent installation for a mean of 3 years (SD=2.9). We found that 10 hospitals had not changed vendors and used only the information system currently in use. The average number of different IS used was 1.6 (SD=0.8). We found that 13 hospitals used only one enterprise-wide information system for their information processing needs.

None of the participating institutions had a model of its enterprise workflow and business processes prior to the last installation. Nor did they have any previous experience with a formal IT/IS assessment or evaluation framework such as COBIT (ISACA, 2007), CMMI (SEI,2007) or ITIL (OGC,2007).

All of our participants utilized an outside company to provide IT services although some health care providers in Turkey use software developed in-house.

Application of the Tool and the Conduct of the Study

Each self assessor was asked to report according to the above scale. The assessment form that was e-mailed to hospitals included instructions about PRISE and information about the logistics of the study; there was a link to a web site that had textual and video training about PRISE and additional questions regarding organizational factors. The respondents had to give a numerical value for each item on the scale based on the level definitions according to a pre-defined scale. Each participant was asked to fill in the assessment forms and return the results to the researchers. There are two main reasons for choosing the self assessment method. First, PRISE is neither a legal nor an industry standard, but rather a publicly available free guideline. For a framework that is not formally endorsed the only viable dissemination method is adoption and self assessment .Second, although self assessment of IS processes is a major undertaking requiring a lot of preparation and effort, we believe this self assessment model can help organizations become aware of weaknesses in their IS processes and practices as they get some practice in IS evaluation. Since there is currently no economic or legal incentive for PRISE adoption, we believe that self assessment and improving the assessment methodology to better support this approach, is the most viable approach at the present time.

FINDINGS

In order to examine the data, statistical and qualitative analysis methods have been used. Descriptive statistics were run to analyze the collected data. The responses to the questionnaire were analyzed using the SPSS (Statistical Package for the Social Sciences) 15.0 Windows software program. Charts and tables were created from the data using SPSS features.

Table 4 shows that PRISE scores ranged between 0.4 – 3.54 (SD=0.86). The mean for all cases was 2.18 and the median was 2.11. The scores for individual process areas varied; the minimum scores for each process area ranged from 0.0-0.7 and the maximums ranged from 3.33-4.7.

13 health care providers (76.5%) received scores of 3 or lower. Level 3 signifies a documented process and a standard way of carrying out IS related management activities. We checked whether there were any statistically significant relationships between process scores and such organizational factors as location (being in a provincial center rather than a smaller town) or size of the target population. Mann-Whitney U tests showed significant differences in P5-Configura-

Table 4. PRISE scores

PRISEProcess	P1	P2	P3	P4	P5	P6	P7	P8	P9	P10	Total
Mean	2.47	2.31	2.28	1.53	2.21	2.19	2.35	2.56	1.87	2.02	2.18
Median	2.22	2.44	2.00	1.40	2.09	2.00	2.42	2.56	1.80	2.00	2.11
Std. Deviation	0.97	1.06	1.07	1.20	1.03	1.00	0.76	1.11	0.88	1.10	0.86
Minimum	0.67	0.22	0.70	0.00	0.55	0.33	0.58	0.44	0.18	0.10	0.40
Maximum	4.11	3.75	3.80	3.80	4.09	3.50	3.33	4.78	4.00	4.10	3.54

The process areas, P4 – IS interactions, and P9 – Change management received the lowest mean scores. Process areas, P1- Definition of the IS organization and relationships, and P8 – Continuous service received the highest mean scores.

tion management and in P8-Continuous service process areas for health care institutions with different target populations. We used Spearman's bivariate correlation analysis to see if there were any significant correlations in these differences. Our data shows a strong positive correlation between the target population of the institution and P5-Configuration management scores with a correlation coefficient of 0.573 ($P = 0.02$).

We also explored whether the providers' own size (number of beds and/or number of physicians) were associated with any difference in the PRISE scores. We analyzed the results with Mann-Whitney U test and found that none of the process areas showed any significant differences.

We expected to find a correlation between the number of IT staff and certain process area scores. We found that the higher the number of IT personnel, the higher an institution scored on P8-Continuous service process area; organizations which give importance to maintaining a continuous level of service must have sufficient resources to perform such tasks. The number of IT personnel was also positively correlated with the overall PRISE score (see Table 5). The overall PRISE Score was calculated by taking the mean of all 92 PRISE questions.

DISCUSSION AND LESSONS LEARNED

It is imperative to provide quality care while reducing soaring health care costs. To accomplish, we must know if the models we apply in other industries will also result in efficiency and effectiveness in health care information systems. The only way we can achieve this is through evidence-based health care informatics.

Table 5. Correlation between the number of IT personnel and certain PRISE scores

			P8	PRISE Score	IT personnel
Spearman's rho	P8	Correlation Coefficient	1.000	0.896(**)	0.632(**)
		Sig. (2-tailed)	.	0.000	0.006
	PRISE Score	Correlation Coefficient	0.896(**)	1.000	0.534(*)
		Sig. (2-tailed)	0.000	.	0.027
	IT personnel	Correlation Coefficient	**0.632(**)**	**0.534(*)**	1.000
		Sig. (2-tailed)	**0.006**	**0.027**	.

** Correlation is significant at the 0.01 level (2-tailed).

* Correlation is significant at the 0.05 level (2-tailed).

-- N=17

More research should identify factors that result in effective health care information systems. We also need to prove that IT actually reduces costs instead of being a cost center for the enterprise. Information systems assessment and health informatics evaluation are aspects of evidence-based health informatics that can provide answers to these important questions. We believe our study is a contribution and a step forward in showing that health care information systems can benefit from the IS assessment models used in other industries.

PRISE contained some questions that were not really suited to a hospital setting. Despite their many differences, all our participant hospitals had consistently higher or lower scores on certain process areas, indicating that regardless of size, location, ownership model or focus, they shared certain characteristics.

This situation is illustrated by the "P5-Configuration management process" area which contains 11 questions, some of which did not apply closely in health care settings. Although there is a certain amount of software development activity, none of our health care institutions primarily developed software; they all bought or outsourced their IT services. In this situation, contract management and service management activities become more important than management of development activities. Yet, our data showed a strong positive correlation between the target population of the institution and P5-Configuration Management area scores. We believe this is due to the fact that software development, hence configuration-management related activities were only carried out in larger hospitals that were generally located in large urban areas. Our analysis also reflect a similar relationship between IT personnel number and P5- Configuration management process area; these hospitals could afford tailored software (developed either by their own personnel or by contractors) to increase the functionality of their systems, and they reported higher level management practices in the area of configuration-management process. This result suggests that small rural hospitals should be supported in terms of IT personnel and software development since every institution has specific information needs that can be satisfied with appropriate development.

All of the participating institutions had some form of management support and initiatives to implement better IS/IT management practices. Some hospitals were required to plan and document IS management activities for external reasons such as quality improvement and accreditation (i.e. ISO 9001 and/or JCI Accreditation); others had people at the top management level with IT/IS know-how. Both of these resulted in relatively higher scores in P1- Definition of the IS organization and relationships. We believe that these relatively higher scores did not translate into higher scores in other process areas, because of a lack of organizational culture and effective communication in terms of IT/IS management.

We found that despite their differences, all organizations share common strong and weak process areas. It is not surprising that process area "1-Definition of the IS organization and relationships" and process area "8-Continuous services" have higher scores than other process areas. All organizations were aware that good IS management and the provision of continuous service is crucial to the continuity of their business operations and a failure to maintain business continuity could result not just in catastrophic financial losses but even in the loss of patient lives.

Organizations received generally lower scores for the process areas "4-IS interactions" and "9-Change management"; given the current nature of medical services in Turkey, this result is quite normal. Hospitals operate within their own defined domains; they are not concerned about data sharing and interoperability. Process area "9-Change management and monitoring services" is another weak side of these organizations. These results may be partially due to a lack of understanding of general change management and monitoring services, which in turn, affects IS as well. Organizations did not have a clear understanding of either of these concepts; we found that most if not all the items in this section, were implemented only at a very basic level.

Probably our most important finding was the correlation between the Total PRISE score and number of IT personnel in a hospital. IT personnel number was the only organizational factor correlated with total PRISE scores; other factors were found to be correlated with scores for sub process areas. This finding indicates that the human factor is very important in IS processes' success and that appropriate staffing of IT departments is closely related to the quality of information systems.

Although the PRISE model, is very thorough in assessing the IS processes of a general organization, we believe it can be more effectively applied in health care domain if it is modified for the specific needs and attributes of health care organizations.

Some things were not evaluated thoroughly by PRISE. These included the outsourcing model (which was very common in the IS sourcing of our participating organizations) and some other very important health-IS related issues such as privacy and confidentiality, workflow management issues and outcomes management, PRISE covers the breadth of IS assessment, but lacks specific questions or the depth necessary to effectively evaluate issues regarding clinical aspects of hospital information systems. A new model that can address such issues must be developed to improve assessment in the health care IS domain. Such a model can be a promising future research topic.

It is important to note that the findings from this research study are useful for the following IS stakeholders: (1) IS managers, (2) IS users, (3) IS developers. The evaluation of IS processes of an IS organization, i.e. in this study "hospitals", by means of using PRISE model are primarily valuable for the managers of hospitals.

LIMITATIONS

Our study assumed that every health care organization had a functional organization-wide HIS and was capable of using a questionnaire-based self assessment tool to evaluate its own effectiveness in managing IS. We observed that both the motivation and the capability to conduct such a self assessment were less than expected resulting in a low participation rate in our study. More participation could have allowed us to generalize the results of our case study country-wide. A future project that receives financial support may be able to reach more hospitals and perform a more thorough analysis of IS management.

Application of PRISE may yield different results, if a trained assessor carries out the assessment. An increase in the number of hospitals participating in our study would produce a better statistical analysis and might show different relationships between PRISE scores and organizational characteristics. We believe that organizational effectiveness should also be measured and compared with the results of PRISE measurements. It would be very important for future research to study whether higher PRISE scores, meaning a better information system, are related to better financial and medical outcomes. We believe our study is an important attempt to objectively measure management practices related to the information systems in the health care environment. Hopefully our findings will pave the way for improvement in health care information systems, perhaps leading to better health care.

ACKNOWLEDGMENT

We would like to thank Prof. Elske Ammenwerth and Dr. Aysu Betin-Can for their valuable comments on the drafts of our manuscript. This paper is supported by an JMIR Institutional Membership grant form Birim Bilgi Islem Teknolojileri AS . This grant had no support or any requirements that might have had any affect on the scientific quality or content of this research paper. The sponsor had no role in the conduct of our study, in the reporting of our findings or in reviewing our paper.

CONFLICT OF INTEREST

PRISE is a freely available tool. One of the authors is a faculty member at the university that governs one of the participating hospitals; however this fact had no affect on the conduct of our study, nor did it affect our reporting in any way. The authors did not receive any financial support.

KEY TERMS AND DEFINITIONS

Information systems effectiveness: Refers to the systematic approach needs to be taken when evaluating success of an information system.

Information systems evaluation: It is the process that contains several criteria through which key areas of the proposed information systems will be evaluated.

Information systems resources: The resources of the information systems refer to people hardware software and data.

Information technology management: According to Michael K. Badawy Information Technology Management is concerned with exploring and understanding **IT** as a corporate resource that determines both the strategic and operational capabilities of the firm in designing and developing products and services for maximum customer satisfaction, corporate productivity, profitability and competitiveness

APPENDIX

Process: P1 Definition of the IS organisation and relationships

Component of PRISE: People

Questions:

1. Does the IS organisation communicate its goals and results at all levels?
2. Is the IS organised to be involved in all decision processes, respond to key organisation initiatives and focus on all corporate automation needs?
3. Is the IS organisational model aligned with the organisation functions and does is adapt rapidly to changes in the organisation environment?
4. Through encouraging and promoting the taking of responsibility, does the IS organisation develop and grow individuals and heightens collaboration?
5. Are there clear command and control processes, with segregation where needed, specialisation where required and empowerment where beneficial?
6. Does the IS organisation properly position security, internal control and quality functions, and adequately balances supervision and empowerment?
7. Is the IS organisation flexible to adapt to risk and crisis situations and moves from a hierarchical model, when all is well, to a team-based model when pressure mounts, empowering individuals in times of crisis?
8. Can a strong management control be established over the outsourcing of IS services, with a clear policy, and awareness of the total cost of outsourcing?
9. Are essential IS functions explicitly identified in the organisation model, with clearly specified roles and responsibilities?

Process: P2 Education and training of users

Component of PRISE: People

Questions:

1. Is there a comprehensive education and training program, focused on individual and corporate needs in place?
2. Are these education and training programs supported by budgets, resources, facilities and trainers?
3. Are training and education critical components of the employee career paths?
4. Do employees and managers identify and document training needs?
5. Is the needed training provided in a timely manner?
6. Is there senior management support to ensure that employees perform their duties in an ethical and secure manner?
7. Do employees receive system security practices training in protecting against harm from failures affecting availability, confidentiality and integrity?

8. Does the corporate policy require that all employees receive a basic training program covering ethical conducts, system security practices and permitted use of IS resources?
9. Is there management acceptance that training costs are investments in lowering the total costs of technology ownership?

Process: P3 Provision of assistance and advice to IS users

Component of PRISE: People

Questions:

1. Are there up-to-date and easily accessible Frequently Asked Questions (FAQs) and their answers available?
2. Do knowledgeable and customer-oriented support staff resolve problems in close co-operation with the problem management staff?
3. Are all user inquiries consistently and thoroughly registered by the help desk?
4. Are the user inquiries that cannot be resolved in a timely manner appropriately escalated?
5. Is the clearance of user inquiries monitored?
6. Are user questions resolved in a timely manner?
7. Are those user inquiries that cannot be resolved in a timely manner investigated and acted upon?
8. Does the management monitor trends to identify root causes in a proactive manner and follow up with analysis and the development of sustainable solutions?
9. Are there corporate policies and programs defined for training users in technology use and security practices?
10. Is there management awareness of the cost of support services and user downtime and of the need to take action on root-cause issues?
11. Are support costs charged back to the business using simple tools and clear policies?

Process: P4 IS Interactions

Component of PRISE: Resources

Questions:

1. Are communication with the customers done via the Internet medium ?
2. Is there an extensive use of the other information systems web pages?
3. Is there an extensive interaction with the customer via the Internet?
4. Is the use of other information systems documented?
5. Is there an extensive use of similar information systems for improvement?

Process: P5 Configuration Management

Component of PRISE: Resources

Questions:

1. Are there owners established for all configuration elements who responsible for maintaining the inventory and controlling change?
2. Is the configuration information maintained and accessible, based on up-to-date inventories and a comprehensive naming convention?
3. Is there an appropriate software library structure in place, addressing the needs of development, testing and production environments?
4. Is there a release management policy and a system to enforce it?
5. Are record keeping and physical custody duties kept segregated?
6. Is there an integration with procurement and change management processes?
7. Are vendor catalogues and configuration aligned?
8. Do configuration baselines exist, identifying the minimum standard components and integration requirements, consistency and integration criteria?
9. Is there an automatic configuration detection and checking mechanism available?
10. Is there an automatic distribution and upgrade process implemented?
11. Is there zero tolerance for illegal software?

Process: P6 Performance and capacity management

Component of PRISE: Resources

Questions:

1. Are the performance and capacity implications of IS service requirements for all critical business processes clearly understood?
2. Are the performance requirements included in all IS development and maintenance projects?
3. Are the capacity and performance issues dealt with at all appropriate stages in the system acquisition and deployment methodology?
4. Is the technology infrastructure regularly reviewed to take advantage of cost/performance ratios and enable the acquisition of resources providing maximum performance capability at the lowest price?
5. Are skills and tools available to analyse current and forecasted capacity?
6. Is the current and projected capacity and usage information made available to users and management in an understandable and usable form?

Process: P7 Operations management

Component of PRISE: Resources

Questions:

1. Are operations instructions well defined, according to standards, and with provision of clear cut-off and restart points?

2. Is there a high degree of standardisation of operations?
3. Is there close co-ordination with related processes, including problem and change management functions, and availability and continuity management?
4. Is there a high degree of automation of operations tasks?
5. Are operational processes re-engineered to work effectively with automated tools?
6. Is rationalisation and standardisation of systems management tools implemented?
7. Is the input and output handling, as much as possible, confined to the users?
8. Are changes to job schedules strictly controlled?
9. Are there strict acceptance procedures for new job schedules, including documentation delivered?
10. Are there preventive maintenance schemes in place?
11. Are the service support agreements with vendors defined and enforced?
12. Are there clear and concise detection, inspection and escalation procedures established?

Process: P8 Continuous Service

Component of PRISE: Services and Benefits

Questions:

1. Is there a no-break power system installed and regularly tested?
2. Are potential availability risks proactively detected and addressed?
3. Are the critical infrastructure components identified and continuously monitored?
4. Is the continuous service provision a continuum of advance capacity planning, acquisition of high-availability components, needed redundancy, existence of tested contingency plans and the removal of single points of failure?
5. Is there a procedural action taken on the lessons learned from actual downtime incidents and test executions of contingency plans?
6. Is the availability requirements analysis performed regularly?
7. Are the agreements used to raise awareness and increase cooperation with suppliers for continuity needs?
8. Is the escalation process clearly understood and based on a classification of availability incidents?
9. Are the costs of interrupted service specified and quantified where possible, providing the motivation to develop appropriate plans and arrange for contingency facilities?

Process: P9 Change Management

Component of PRISE: Services and Benefits

Questions:

1. Are change policies clear and known and are they rigorously and systematically implemented?
2. Is the change management strongly integrated with release management and is it an integral part of configuration management?
3. Is there a rapid and efficient planning, approval and initiation process covering identification, categorisation, impact assessment and prioritisation of changes?
4. Are there automated process tools available to support workflow definition, pro-forma workplans, approval templates, testing, configuration and distribution?
5. Are there expedient and comprehensive acceptance test procedures applied prior to making the change?
6. Is there a system for tracking and following individual changes, as well as change process parameters, in place?
7. Is there a formal process for hand-over from development to operations defined?
8. Do the changes take the impact on capacity and performance requirements into account?
9. Is there a complete and up-to-date application and configuration documentation available?
10. Is there a process in place to manage co-ordination between changes, recognising interdependencies?
11. Is there an independent process for verification of the success or failure of change implemented?
12. Is there segregation of duties between development and production?

Process: P10 Monitoring services

Component of PRISE: Services and Benefits

Questions:

1. Are there useful, accurate and timely management reports available?
2. Have the processes been defined and understood what the targets are and how to achieve them?
3. Do the measurements of IS performance include financial, operational, customer and organisational learning criteria that ensure alignment with organisation-wide goals?
4. Are there clearly understood and communicated process objectives?
5. Is there a framework established for defining and implementing IS management reporting requirements?
6. Is there a knowledge base of historical performance established?
7. Is there a consistent application of the right limited number of performance indicators?
8. Is there an increased number of process improvement opportunities detected and acted upon?
9. Is the management satisfied with performance reporting?
10. Is there reduced number of outstanding process deficiencies observed?

Raman Paranjape
University of Regina, and TRLabs Regina, Canada

ABSTRACT

This chapter reviews and summarizes eight selected paper in the area of agent-based healthcare systems. The objective of the summaries is to provide an overview of recent research work in the area and to examine the characteristics of agent-based healthcare applications. The chapter also briefly discusses reasons for adopting agent-based simulation and modeling over traditional modeling techniques.

INTRODUCTION

Agent-based modeling and simulation is a modern approach to model complex systems. Agent-based simulation systems are comprised of autonomous agents that interact with each other to create a working dynamic model of a real world system. Today, applications of this new paradigm of modeling and simulation can be found in variety of domains ranging from modeling the stock market and supply chains behaviours to modeling the complexities of the human immune system and predicting the spread of epidemics (Macal & North, 2006). Traditional modeling techniques are no longer sufficient in dealing with the complexities of real world systems as they are becoming increasingly more sophisticated. Software agents can break a large problem or task to smaller tasks and distributes the work over number of agents to provide an optimal solution. The operation of healthcare is complex as it involves large numbers of staff and other resources that work together to deliver healthcare services to patients. The agent-based modeling and simulation approach is increasingly attracting researchers who exploit the capability of agent system in order to explain the complex behaviour of healthcare systems.

Software agents can be defined in numerous ways. Each definition varies depending on the

DOI: 10.4018/978-1-60566-772-0.ch003

context and the application. However the main attributes are common to all the definitions. The common attributes of software agents are: autonomy, pro-activity/re-activity, communicativity, collaborative problem solving and mobility. The mobility attribute refers to the ability of an agent to travel across different platforms to achieve its goal. Autonomy pertains to the ability of an agent to act autonomously with limited or no user interaction and to completely represent an object or entity. Pro-activity/re-activity implies the ability to react to the environment and adapt its behaviour accordingly. Communicativity refers to the capability of agents to exchange messages between each other and with the external users and systems. The collaborative problem solving attribute pertains to the ability of agent to collaborate and work together to accomplish a common goal which no single agent is able to attain on its own.

Software agents should only be used to develop applications for systems which require some or all of the above attributes of agents. Most of these attributes are required in order to create effective and accurate simulations and models of healthcare systems. In this chapter, we review and summarize eight recent papers to provide an overview of the state of research in agent-based healthcare modeling system. Agent-based modeling and simulation is a relatively new approach in healthcare modeling. We observe three common themes in the work presented in this chapter - these are: (i) support for patients and medical professionals; (ii) effective and efficient communication between health professionals; and (iii) optimization of healthcare delivery services.

We provide a brief introduction on each selected paper to give a high level picture of the content of the summaries before proceeding to the actual summaries.

A Multi-Agent Approach to the Design of an E-Medicine System

This paper proposes a multi-agent based framework for the development of an e-medicine system. E-medicine integrates information communication technology with medical technology to deliver healthcare to geographically distributed areas. The paper presents a case study on telemedicine for diabetes to illustrate the development of an e-medicine system.

Building Agent Based Corporate Information Systems: An Application to Medicine

In this paper, author proposes an agent-based framework for supporting collaborative work among human and software agents. The proposed framework is applied in the field of telemedicine to build complex and cooperative decision support systems (DSS) within the context.

A Framework for Building Cooperative Software Agents in Medical Applications

This paper focuses on improving the cooperation and interoperability among different health care professionals engaged in the process of delivering health care services with the aid of software agent technology. This paper experiments the management of patients affected by acute myeloid leukemia (AML) with the help of developed prototype.

HealthSim: An Agent-Based Model for Simulating Health Care Delivery

This paper introduces an agent-based simulation model, called HealthSim, which facilitates users understand various health care delivery issues in a hospital environment through simulations. The system is primarily designed for managers and planners of hospitals who want to identify the effectiveness and efficiency of health care services that are being provided to patients. HealthSim has a potential to address several aspects of health care operations that deals with procurement, distribution, maintenance, and replacement of medical equipment and personnel. It also helps in the management of the details of medical operation.

Mobile Software Agents for the Support of Chronic Illness: A Case Study in Diabetes Management for Rural Areas

This paper presents a framework for managing diabetes particularly in rural areas using mobile agents. This paper presents a framework which has a potential to manage and control diabetes in remote areas that lacks diabetic specialists.

Nature-Inspired Planner Agent for Health Care

This paper presents an agent-based human thinking reasoning model based on past experience. The main purpose of the development of this model is to facilitate elderly people with disabilities, in particular with Alzheimer.

Mobile Agent-Based Framework for Healthcare Knowledge Management System

This paper presents a framework for effective management of information and knowledge in healthcare sector using mobile agents. Authors sense the necessity of transposing stored healthcare data and information into knowledge so that it can serve as a facilitator for making critical decisions during healthcare operations. This paper presents various components that can work together to create an effective knowledge management system (KMS).

A Multi-Agent Security Framework for e-Health Services

This paper presents a multi-agent security framework for e-health services. It describes and categorizes various type of communication into different levels that takes place among health care professionals. Subsequently, the paper identifies security requirements associated to each level of communication and introduces a multi-agent based security approach for e-health services.

REVIEW

Title: A Multi-agent Approach to the Design of an E-medicine System

Authors: Jiang Tian, Huaglory Tianfield

Source: Multiagent system technologies. German conference, Erfurt, ALLEMAGNE (22/09/2003) 2003, vol. 2831, pp. 85-94

Publisher: Springer-Verlag Berlin Heidelberg

This paper proposes a multi-agent based framework for the development of an e-medicine system. E-medicine integrates information communication technology with medical technology to deliver healthcare to geographically distributed areas. The paper first explores the functional and non-functional requirements of e-medicine system and then presents a structural design of agent-based e-medicine system. In the end, the paper presents a case study on telemedicine for diabetes to illustrate the development of e-medicine system.

The four basic functions of medicine presented in the paper are disease prevention, disease diagnosis, disease treatment, and health consultation. According to these functions, authors have divided requirements of an e-medicine system into functional and non-functional requirements. Distant medical services such as telemedicine, e-healthcare, teleconsultation; distant clinical practices such as telesurgery, telementoring, and training patient; establishing medical databases and exchanging medical information are included in the functional requirements of e-medicine systems. On the other hand, security and privacy, efficiency, convenience and reusability are considered as non-functional requirements.

This paper adopts a multi-agent approach to align the complex requirements with the design of an e-medicine system. Design itself is broken into two parts: design of agents and design of multi-agent society. Designing an agent includes the proper identification of roles and responsibilities of each agent in e-medicine systems. And, design of multi-agent society focuses on the architectural design of multi-agent system and interactions between the agents. Authors believe that the general set of requirements provided in the paper can serve as a reference guide to build any kind of e-medicine system.

The proposed framework of an e-medicine system involves a large number of agents. Each agent carries out specific task and may interact with other agents to complete the assigned task. Agents in the e-medicine systems are categorized into three groups: the Control group, the Implementation group, and the Interface group. The interface group consists of agents responsible for providing the user with graphical user interface, initiating a search, or showing the results of a query to the user. The interface group may contain interface agent, search agent, or any other agent responsible for keeping the link between patient and other e-medicine systems. The second group, which is the control group, contains the controller agent, administration agent and department agent. The controller agent controls the whole e-medicine system and resolves the conflict among agents. The administration agent assigns tasks and helps cooperate between departments and agents. The department agent has knowledge of certain medical department and manages the internal department affairs. The third group is the implementation group. The implementation group implements the monitoring, diagnosis, therapy, consultation, and archival function to achieve the goals. The implementation group contains most number of agents namely the monitoring agent, data processing agent, diagnosis agent, therapy agent, archival agent, education agent, decision support agent, training agent, consultation agent, surgery agent, and database wrapper agent.

The interaction in e-medicine systems is divided into the internal model and external model. The internal model is responsible for internal communication while external for external communication. Control group, implementation group, and interface group carry out internal communication. External communication takes place when agents belonging to the implementation group and interface group interact with an external environment.

To illustrate the framework proposed for e-medicine systems, the paper present a case study of telemedicine for diabetes. The Telemedicine system provides diabetic patients with real-time health monitoring and can also provide immediate therapy. After a complete requirement analysis of telemedicine for diabetes, the paper listed down several services that a telemedicine system must provide on a daily basis. These services are visiting the patient and providing individual therapy, monitoring the patients in real time and processing the monitored data immediately, diagnosing the patients in term of monitored data and making a proper therapy for the diabetic patients, training the diabetic patients to monitor themselves and educating the physicians to update their skills, maintaining patients record/database, providing consultations to patients and the system must have a functionality to interact with other systems in e-medicine systems.

The diabetic telemedicine system makes use of several agents in order to fulfill the identified requirements. Agents in the implementation group are monitoring agent, data processing agent, diagnosis agent, therapy agent, consultation agent, decision support agent, training agent, archival agent, department agent, and interface agent. Each of them is responsible for certain task and interacts with other agents. The monitoring agent is responsible for real time monitoring of diabetic patient and transmits the data to the data Processing agent. The data processing agent integrate the data and process it for diagnosis agent. The diagnosis agent plays an important role in implementation group as diagnosis is a complex process. It examines the situation and makes and accurate judgement for the patient. The diagnosis agent not only interacts with other agents in implementation group but also communicate with decision support agent, clinic agent, education agent, and consultation agent. Depending on the decision made by the diagnosis agent, the therapy agent determines a proper therapy method for the diabetic patient. The consultation agent provides consultation to the enquiry of patients. The decision support agent, as name implies, provide decision support. Both consultation agent and decision support agent interacts with diagnosis agent. The Training agent trains patient by giving instructions on the proper intake of medicine and self care. The Archival agent maintains the patient record and used therapy methods. It encrypts the information and links it to the medical database. Control group and Interface group, contains department agent and interface agent respectively. Department agent is responsible for the control of the telemedicine system while interface agent provides the interface with search services and information services.

This paper presents a multi-agent approach to the design of an e-medicine system. The paper examines various functional and non-functional requirements that must be considered in e-medicine system. Based on that, it presents a general structural design of an e-medicine system composed of many software agents. To illustrate the application of the system in the real world scenario, the paper adapts a general design of an e-medicine system to a more specific diabetic telemedicine system.

Title: Building Agent Based Corporate Information Systems: An Application to Medicine

Author: Tung Bui

Source: European Journal of Operational Research 122 (2000) 243-257

Publisher: Elsevier

In this paper, author proposes an agent-based framework for supporting collaborative work among human and software agents. Bui's (2000) framework enables geographically dispersed organizations to distribute the task across the internet and work collaboratively. The system is embedded with the intelligent software agents that are capable of making decisions facilitating the implementation of complex and distributed decision making process. The proposed framework is applied in the field of telemedicine to build complex and cooperative decision support systems (DSS) within the context. Telemedicine is an application of clinical medicine where medical information is transferred via telephone, the internet or other networks for the purpose of consulting, and sometimes remote medical procedures or examinations (AbsoluteAstronomy, 2009).

The paper presented taxonomy of an agent characteristics and the proposed taxonomy can facilitate in identifying different types of agents to support different type of decision tasks. Furthermore, this paper proposed a development lifecycle for building agent-based systems. Author sensed the need of adopting a new approach for the development of an agent-based system. The new methodology supports a two-tier approach to design a given system. The first tier functions as an assignment model which is primarily responsible for searching, identifying and selecting the agent(s) that are believed to be most appropriate to perform required tasks. It covers the first three phases of the lifecycle. The second tier manages a coordination and collaboration strategy for all the participating agents to work together and makes the last two phases of the lifecycle.

The first phase of a software-agent development lifecycle begins with analyzing the problem task. It consists of all the elements necessary for examining the problem task such as decision support requirements and detailed breakdown of all decision processes. The decision processes are collections of partially ordered steps that are required to reach a particular goal. The next phase involves searching of eligible agents in an iterative manner or creation of new agents that meets the requirements determined in the preceding phase. Agents are selected on the basis of their competence, reliability, and cost to perform the given task. The third phase specifies agent's behaviour. Instructions are pre-set for showing identifications, following protocols and utilizing web-resources in a cost effective fashion. The last phase involves assigning appropriate tasks to selected agents. The execution plan to solve the entire problem is sketched in this phase.

The proposed framework is adopted to build a web-enabled telemedicine. Referring to the first phase of software-agent development life cycle where the problem task is analyzed, problem solving associated to the healthcare is categorized into four processes. The processes are (i) medical examination, (ii) diagonosis, (iii) treatment recommendation (Dx), and (iv) treatment plan/prognosis (Tx). In the real world scenario, people involved in the telemedicine are patients, advice nurse, doctors on duty, and other specialists. And in the proposed agent-based web-enabled telemedicine, duties of above people are supported by software agents named as (i) the Exam Manager, (ii) Dx/Tx Manager, (iii) Session Manager, (iv) Speciality Problem Solver, and (v) Negotiation Manager.

In this experimental set up, the Exam Manager gathers the subjective data such as patient's description of symptoms, feelings and other biographical data through web form via internet at the patient site. The data may also be collected through sensors/health monitoring equipments as well. The data is then passed down to the Dx/Tx Manager. The Dx/Tx Manager examines the received patient data and decides which Speciality Problem Solver should take part in generating treatment recommendations. Once all Speciality Problem Solvers are identified and selected, the Session Manager initiates the communication and administers it throughout the session. Problem can be executed, independently or interactively with a human specialist, by the Speciality Problem Solvers to come up with recommendations. Recommendations made by various Solvers are then received by the Negotiation Manager and the Negotiation Manager facilitates in reaching a single consensual solution. Subsequently, the solution is transmitted back to the Dx/Tx Manager and then presented to the field provider through a human interface.

The next phase of the software agent development lifecycle decides whether or not a software agent should be developed to implement that process and if so then selects which would be the most appropriate profile of that agent. The selection of agents is based on the cost-benefit analyzes. Profile of each agent is created through examining each of the agents attributes and gives the most suitable value for it. Intelligence, Mobility, Lifetime, Interaction, Task-specificity, and Initiative are the attributes of agents. Once agent profile is determined, agents are ready to be embedded into workflow.

According to Bui (2000), there are lot of benefits of the proposed system. The biggest benefit is that the data can be collected seamlessly and cost effectively with relatively low investment of the internet infrastructure. Internet provides adequate communication support to carry out the task of medical information system connectivity. Other benefits include that the system has a potential to provide anytime anywhere healthcare as the patient is always in touch with his/her primary care provider no matter where in the world he/she is.

Title: A Framework for Building Cooperative Software Agents in medical applications

Authors: Lanzola G.; Gatti L.; Falasconi S.; Stefanelli M.

Source: Artificial Intelligence in Medicine, Vol. 16, Number 3, July 1999, pp. 223-249(27)

Publisher: Elsevier

This paper focuses on improving the cooperation and interoperability among different health care professionals engaged in the process of delivering health care services with the aid of software agent technology. It is evident that during the course of medical process, a variety of information and knowledge traverses among number of health care staff. This information may range from a simple biographical data of a patient to sensitive contagious disease information. Although there might be different communication channels available to heath care workers, the primary medium of conveying information is typically through phone calls or face-to-face talks. Frequent interruption is very common in this sort of interactions. The interruption may occur in any form such as if a doctor is attending a patient and nurse calls him and asks him to urgently attend another patient which is in a serious condition, the doctor may pass the health related information of the current patient to a nurse and advices her to take necessary steps for the betterment of the patient. Since, it is an emergency situation, a nurse may not be able to comprehend all the information bombarded by the doctor at her and there is a very good chance that a nurse may make wrong assumptions. Authors believe that this may cause serious consequences if some sensitive information is lost or misinterpreted. Such situations arises primarily because of the intrinsic nature of hospitals which are highly event driven environments where professionals are required to regularly move across several departments and sometimes even off campus.

As described in the paper, the process of delivering health care services involves large number of people like clinicians, nurses, laboratorists, etc. and features a high distribution of expertise, knowledge and physical resources. Thus the effectiveness and proficiency strictly depend both on the skills of the professionals involved as well as on the level of cooperation and coordination reached by them within the clinical context. As such authors insist that there is a need of improvement in the clinical communication infrastructure. A careful deployment of the information technology will have a great impact on improving the interoperability among people working together in the health care settings and minimizes the problems associated to it. In this paper, an information technology tool called Software Agent has been proposed to achieve effective and efficient flow of information among health care professionals.

Software Agents have the tendency to act on behalf of some entities and make intelligent decisions based on the working environment. They may also interact with each other to achieve their goal. This paper tends to simulate the real world interaction of different health care professionals through Cooperative Software Agents. These Agents are equipped with the Task Specific Knowledge and Cooperation Knowledge. The Task Specific Knowledge handles information required to achieve a certain task. For instance, if it is an optometrist agent then it is responsible for providing instructions pertaining to eye related illness. The Cooperation Knowledge, on the other hand, tells an agent how to cooperate with other agents to perform a specific task. It also constitutes Agent Communication Language module which implements communication protocol and administers agent-interaction over the network. Each Agent is linked to the Knowledge-Based System. The Knowledge-Based System is an information repository which has a reference to a database of knowledge of any particular subject. Thus, in the given computational model one section is concerned with the interconnection among Software Agents and enabling of the exchange of information and knowledge among them through a suitable Agent Communication Language (ACL), while other one addresses the problem of effectively modelling and representing cooperation knowledge within each Agent. Authors have followed KQML specifications to develop a tool that has a tendency to achieve a high-level communication between Software Agents. KQML is declarative, syntactically simple, extensible and easily readable by humans. This framework facilitates in developing a generic communication model which could be coupled with pre-existing legacy systems or other available applications, thereby helping them converting into Software Agents while preserving much of their internal coding and functionality.

The paper also states that even though ACL is powerful tool that has a capacity to provide a solid foundation for exchanging information and knowledge among agents, the ability to interoperate with other agents and to exploit some kind of social behaviour demonstrated by each agent in the environment cannot be accomplished by the language alone. Authors sensed the need of enhancing task specific knowledge already available within agents with a set of suitable primitives that should be able to contour their behaviour to be adopted while interoperating with others.

This paper experiments the management of patients affected by acute myeloid leukemia (AML) with the help of developed prototype. Several Software Agents were implemented tailoring the specific need of a particular health care professional and enforcing his/her cooperation with others involved in the treatment of a patient suffering from AML. Participating agents in this experimental set up are the General Practioner, Hospital Administration, Hematologist, Nurse, Donor Bank, BMT Unit, and Oncologist. These agents interact with each other and may get multiple task requests from different agents at a given point of time. Agent allocates resources to different task on the basis of its importance and priority. The information collected by these agents in the course of this process is stored in the database and can be fetched for a later use.

This paper provides a framework that has a potential to achieve an effective and efficient communication among agents. Old legacy systems and other standard applications utilized by Hospitals may be converted to agents following the given framework. Moreover, it also opens the door for many other researchers to exercise the idea and develop agent based information system for hospitals for their specific needs.

Title: HealthSim: An Agent-Based Model for Simulating Health Care Delivery

Authors: John H. Christiansen and A. Peter Campbell

Source: Argonne National Laboratory, Chicago, Illinois

This paper introduces an agent-based simulation model, called HealthSim, which facilitates users understand various health care delivery issues in a hospital environment through simulations. The system is primarily designed for managers and planners of hospitals who want to identify the effectiveness and efficiency of health care services that are being provided to patients. HealthSim is flexible enough to be deployed in a small to large scaled organizations. It can be used in a small department in a hospital, for a single-practioner surgery, or in a major medical centre with hundreds of thousands of patient each year.

HealthSim has a potential to address several aspects of health care operations that deals with procurement, distribution, maintenance, and replacement of medical equipment and personnel. It also helps in the management of the details of medical operation.

HealthSim runs various models with thousands of agents in a single simulation to understand the relation of different dynamic behaviours associated to health care. These behaviours may include human physiological processes such as beginning and progression of disease, development of signs and symptoms, and effects of interventions; human cognitive behaviour such as response to symptoms and making and keeping appointments; clinical/logistical processes such as clinical practice guidelines, office procedures and personnel policies; and medical monitoring equipment response.

The system has a potential to address various health care management issues depending on type of simulation performed. For instance, the response to various perturbations in health care delivery service can be investigated by simulating the inpatient and outpatient loads for a hospital unit within a health care system. Inpatient is a patient who is admitted to the hospital and stays overnight in hospital for quite some time depending on the illness. Outpatient on the other hand is not hospitalized overnight but regularly visits a doctor for diagnosis or treatment. In this simulation, the main inputs are service provider's schedules, outpatient visit rates for each type of visit, inpatient visit rates for each diagnostic related group (DRG), and call center operator schedules. The main outputs are appointment wait times, average phone waits, costs, revenues and many more. These outputs help the management in making critical decisions. The system can also be used to examine the effects of new technology or equipment, efficiency of new treatment paths, cost effectiveness of new drugs, and consequences of changes to management procedures or policies.

HealthSim accepts number of adjustable inputs from the user to perform the simulation providing a great deal of flexibility. The input and output items of the system can be easily replaced, added or deleted with no or minimal effect on the overall simulation structure. The paper has listed down several results that can be obtained from the simulation. Few of them are average appointment length (in minutes) by department, average appointment wait (in days) by department, admittance trends report, average length of stay by DRG, average phone waits (in seconds), inpatient bed-days per month by DRG, hospital financial report by month and year, daily number of beds occupied, and number of appointment by department.

HealthSim is an agent-based framework that is based on the Dynamic Information Architecture System (DIAS) and the Framework for Addressing Cooperative Extended Transactions (FACET). Both DIAS and FACET are developed at Argonne National Laboratory (ANL). HealthSim is largely implemented in SmallTalk with some of key functionalities coded in C++. The system runs on Unix or Windows platform and may be configured to run in a distributed environment.

DIAS executes time-ordered event simulations where event objects and associated data structures are distributed to the appropriate objects. All event posting are managed by the DIAS global even manager. Each object response to the even posted by itself or by another object. DIAS object class definition supports abstraction where abstraction description of object behaviour is given with no implementation details. As it is indicated in the paper, DIAS is a general framework for building simulation systems which consists of many models. In DIAS, objects are interlinked to other objects appropriately in the system during their activation depending on the state of the simulation. These factors make DIAS ideal for simulating the complex operations involved in health care delivery.

In HealthSim, models of social behaviour patterns are constructed with the aid of FACET. It is composed of several software objects that can be used to build and run complicated and cooperative behaviour models of agents. In FACET, complex operations are broken into several courses of actions (COA's), and these courses of actions are further sub-divided into COA steps. Each step of COA represents an action or series of actions which are tied to some constraints and negotiate with participating entities for their cooperation. In case the condition does not meet, COA step is broken down further until all the conditions are met.

Both DIAS and FACET are incorporated into HealthSim. There are various Objects and Processes that are modeled in HealthSim. The general classes of the objects include Persons such as patients, doctors, nurses, administrators etc; Organizations such as different medical departments, Infrastructure such as rooms, utilities etc; any equipments either medical, safety or administrative; medicines and supplies; and financial and usage records. The classes of the processes that are modelled in the system are normal physiological processes in each patient, disease processes in each patient, diagnostic equipment response and behaviour pattern models for patients, staff, and organizations. Models of normal physiological processes and pathophysiology behaviour are embedded in Person objects. Pathophysiology is the study of the disturbance of normal mechanical, physical, and biochemical functions normally caused by a disease (NationMaster, 2009). Sofware Agents in HealthSim represent patients, healthcare workers of all type, administrative/management personnel and hospital departments. Each patient agent has a detailed physiological model and a set of disease model. Disease model is heavily based on the differential-equation-solver model that simulates the beginning and progression of the disease, development of signs and symptoms of the disease, and physiological response to interventions. Furthermore, the progression of any existing disease will alter the physiological state for other disease as the disease models are linked through common risk factors.

HealthSim is a flexible event simulation tool which contains numerous models and agents to represent different entities involved in the health care delivery mechanism. Authors believes that the system can be used for various kinds of applications ranging from small work flow involved in a single surgery to the management of complex operations in large hospitals. The tool can be very useful to executives and administrator of medical centres in various decision-making processes.

Title: Mobile Software Agents for the Support of Chronic Illness: A Case Study in Diabetes Management for Rural Areas

Authors: Tarapornsin, V.; Ray, P.; Chowdhury, A.

Source: e-Health Networking, Applications and Services, 2006. HEALTHCOM 2006. 8th International Conference on Volume, Issue, 17-19 Aug. 2006 Page(s): 72 – 77

This paper presents a framework for managing diabetes particularly in rural areas using mobile agents. As stated in the paper, diabetes is one of the serious and most widely spread diseases. Approximately 150 million people are affected with this chronic illness and their numbers are growing rapidly. Diabetes can result in a variety of complications if it is not properly managed or left untreated. These complications include heart disease, kidney disease, eye disease, impotence and nerve damage. Diabetes can be managed by doing exercise, eating healthy food, measuring blood glucose levels on a regular basis, and having a regular consultation with the doctor. According to authors, most patients in rural areas do not have the advantage of having their blood test regularly due to lack of facilities and diabetic specialists. This factor lowers the treatment of diabetes in rural areas. This paper explores the possibility of mobile agents to address this problem assuming the availability of internet in rural side.

The paper points out several efforts in the past to control diabetes by designing tools and models for monitoring and managing diabetic patients. Among them are “Fit for Life” programme by Ministry of Health in Singapore, “Check Your Health” programme of Alexandra Hospital, An Ontology-driven Multi-agent approach for Diabetes Management (Ganendran G. et al, 2002), A multi-agent Healthcare System- An Example for Diabetes Management (Vivian, A., Venky, S., & Y.Y.Zhu., 2001), and 3G Network Oriented Mobile Agents for Intelligent Diabetes Management: A conceptual Model (Li, M., & Istepanian, R.S.H., 2003). This research focuses on the improvement of diabetes in rural areas where most of the diabetic care is provided by generalists. The paper addresses the challenge of creating a system where a patient, generalist and a diabetic specialist coordinate and work together to improve the care of diabetic condition. The authors implements mobile agents to improve the quality of diabetic care in rural areas. They also affirm that with the aid of mobile agents, patients can receive better consultation on time no matter where a diabetic specialist is physically located.

The paper deploys the mobile agent system to address this problem as the mobile agent technology has a capacity to travel across network which may help health care professionals such as diabetic specialists, general practitioner, clinicians, and patients locate one another and transact diagnose electronically. Furthermore, authors have specified that the implementation of mobile agents in health care to control diabetes will allow the interconnection and interoperation of multiple existing systems such as legacy patient health information, patients decision support systems, or other e-health systems; improve scalability of the system as agents have the capability to deal with dynamic environments; and provide solutions withdrawn from distributed information sources.

According to the architecture presented in the paper, each village (node) is connected to a city hospital (speciality hub) with adequate number of diabetic specialist. Village generalist registers the patient details to the diabetic support system by entering the medical data and history such as blood glucose measurements and other symptoms of his/her patient in it. The data is carried to the speciality hub, which in this case is a city hospital, where diabetic specialists can access the medical data. In this way, diabetic specialists may view medical record of all the patients suffering from diabetes from various villages on a single site and coordinate the intervention of all available diabetic specialists to response to symptoms of rural patients throughout the year. To make the system more effective, villages located within the region are connected to their Regional Hub. There can be number of regional hubs such as northern hub, southern hub etc. Each Regional Hub is further connected to various diabetic specialists through several Central Agencies. Each central agency contains adequate number of diabetic specialist agents. Each central agency containing diabetic specialist agents are linked to the database wrapper which first retrieves internal medical information from the diabetic departmental database and then stores in its database. Central Agencies are also connected to each other to provide coordination. Village patient and central agencies connects to the Regional Hub, which serves as a centralized information repository, at each state to provide and receive medical treatments and follow -ups.

Mobile agents involved in the system are the Village Agent and Diabetic Specialist Agent. When a patient is registered in the system by a local generalist, the Village Agent is created which hold medical information of the patient. Patient's medical information contains the name of the patient, patient identification number, address, date of birth, allergies, medical history which contains information about medical examination, date of visit, problem description, medical centre ID, generalist ID, and Specialist ID. Specialist ID is not available until the completion of the first cycle of the diabetic support system. Once the village agent is created and loaded with the required information, it travels across the network from a village health care centre to the regional hub and wait for the central agency to provide list of available diabetic specialists. The regional hub holds general information of each central agency such as list of diabetic specialists in each centre in the area. It also checks the availability of each diabetic specialist in that area and directs the village agent to available specialist in a timely fashion. The diabetic specialist agent is responsible for maintaining the schedule of the specialist and holding his appointment times. Once the diabetic specialist is chosen, the regional hub directs the village agent to meet the diabetic specialist agent at the central agency. After the completion of interaction between the village agent and diabetic specialist agent, the village agent goes back to the village health centre and provides the obtained recommendations and consultations to the village generalist.

According to authors, the idea of keeping a centralized database in each region brings numerous advantages such as huge amount of data of patients can be compacted for easy storage, data processing becomes faster, easier maintenance of patient data, and better availability of information. This paper presents a framework which has a potential to manage and control diabetes in remote areas that lacks diabetic specialists.

Title: Nature-Inspired Planner Agent for Health Care

Authors: Javier Bajo, Dante I. Tapia[2], Sara Rodríguez, Ana de Luis and Juan M. Corchado

This paper presents an agent-based human thinking reasoning model based on past experience. The main purpose of the development of this model is to facilitate elderly people with disabilities, in particular with Alzheimer. Alzheimer is a progressive and fatal brain disease in the form of dementia (loss of memory and other intellectual abilities serious enough to interfere with daily life) with no current cure (Alzheimer's Association, 2009). The paper presents an autonomous deliberative Case-based Planner agent named AGALZ or Autonomous Agent for Monitoring Alzheimer Patients. AGALZ integrates with an environment aware multi-agent system called ALZ-MAS to improve health care of aged people. ALZ-MAS exploit RFID technology which is mounted on bracelets worn on the patient's wrist or ankle to learn about the environment. The RFID technology uses radio waves to automatically identify people or objects (Webopedia, 2009).

Authors incorporates the Case-Based Planning (CBP) mechanism (a derivative of Case-Based Reasoning architecture) together with the BDI (Believe, Desire, Intention) architecture to develop nature inspired deliberative agents, AGALZ, which have a capability to respond to events, take the initiative according to their goals, communicate with other agents, interact with users, and make use of past experience to identify best plans to achieve goals. The CBP helps AGALZ generate plans using past experiences and planning strategies. CBP cycles through four stages. The function of each stage is as follows: the retrieve stage to recover the most similar past experience to the current one; the reuse stage to combine the retrieved solutions in order to obtain a new optimal solution; the revise stage to evaluate the obtained solution; and the retain stage to learn from the new experience. Each cycle of CBP is implemented through goals and plans. AGALZ implements multi-agent system to work coordinately with other agents to solve problems in a distributed fashion.

AGALZ formulate plans in such a way that each plan is composed of a sequence of tasks. These tasks have to be carried out by a nurse to execute a plan. A task creates a problem description for a nurse to carry out, resources available, and times assigned for their shift. Similar problem descriptions with an original problem are recovered during the retrieve stage of AGALZ. To achieve this, AGALZ applies various similarity algorithms and upon the selection of most similar problem description, it recovers the solutions associated to these problems. A solution contains all the plans and these plans are combined later in the reuse stage to determine available resources that are needed to fulfill the global plan. The resources that are required to complete some of tasks can be food, equipments, rooms and some other. Availability of time of nurse can be a problem restriction.

In this paper, the model is tested in the Alzheimer Santisima Trinidad (ST) Residence of Salamanca to improve the current services being offered to its patients. This residence is build for elderly people, specifically over 65 years old. The residence offers variety of services and facilities such as TV, room, geriatric bathroom, hairdressing, salon, medical service, religious attention, occupational therapy, technical assistance, terrace, garden, laundry service, clothes adjustment, infirmary, reading room, living room, visitors' room, cafeteria, social worker, chapel, elevator, customized diet, and multipurpose room. Authors selected 30 patients from the residence to test the system. They also installed 42 ID door readers, one on each door and elevator, 4 controllers, one at each exit, and 36 bracelets mounted with RFID one for each patient and nurses. The ID door readers get the ID number from the bracelets and send the data to the controllers which send a notification to the Manager Agent. Manager agent is located in a central computer. For the purpose of testing, authors instantiated 30 Patient agents, 10 AGALZ agents, 2 Doctor agents, and 1 Manager agent. Together these agents make a framework called ALZ-MAS Each one of these agents is explained below.

The Patient Agent runs on a central computer and manages the personal data of patient and its behaviour such as monitoring location, daily tasks, and anomalies. According to authors every hour a patient agent validates the patient location, monitors the patient state and sends a copy of its memory base, which is patient state, goals and plans, to the manager agent for the backup purposes. At the time of execution, the patient state is created as a set of beliefs. These beliefs are controlled through goals that must be achieved or maintained. These beliefs define the general state of the patient at residence. The beliefs are in the form of weight, temperature, blood pressure, feeding (diet characteristics and next time to eat), oral medication, parenteral medication, posture change, toileting, personal hygiene, and exercise. The paper also states that the beliefs and goals set for every patient depend on the treatment plan or plans that the doctors prescribe. The state of the patient is known by the patient agent by means of accomplished or failed goals. To track whether the goal has been accomplished or has failed, the patient agent maintains continuous communication with the rest of the ALZ-MAS agents especially with AGALZ. AGALZ can send the result of nurse agent's assigned tasks to the patient agent. Authors also state that the communication between the patient agent and the nurse agent must take place at least once per day depending on the corresponding treatment.

The second agent involved in ALZ-MAS framework is the Manager Agent. It also runs on a central computer. The paper lists down two roles of the Manager Agent: the security role and the manager role. In security role, the manager agent controls the patients' location and manages locks and alarms and during the manager role, it manages the medical record database and the doctor-patient and nurse-patient assignment.

The Doctor agent is the third agent of ALZ-MAS. In simple words, Doctor agent treats patients. The doctor agent interacts with all the agents of ALZ-MAS. It sends treatment to the patient agent and receives periodic reports. It communicates with the manager agent to consult medical records and assigned patients and it transact with AGALZ agent to determine patients' evolution.

The fourth and the last agent of the proposed framework is the AGALZ. As it is discussed above the main responsibilities of the AGALZ include scheduling the working day of nurse, managing nurse's profile, tasks, available time and resources. The AGALZ agent runs on a mobile device so that each nurse can see her plans task by task. System has placed a limit of 8 hour working time for any nurse.

Upon the implementation of the system, authors have derived some useful results. According to authors, the workers have reduced the time spent on routine tasks. Activities of the patient and staff are also monitored and the monitored data can be used for the purpose of analysis to further improve the quality of health care to patients. Authors further affirms that the system also improves the security of the residence as it monitors the location of the patients which guarantees that there are in the right place and secondly, only authorised personnel can gain access to the residence protected areas.

Title: Mobile Agent-Based Framework for Healthcare Knowledge Management System

Authors: LEE Sang-Young, LEE Yun-Hyeon

Source: Mobile ad-hoc and sensor networks, International conference, Wuhan, China, December 13-15, 2005, vol. 3794, pp. 1103-1109

Publisher: Springer Berlin / Heidelberg

This paper presents a framework for effective management of information and knowledge in healthcare sector using mobile agents. Authors sense the necessity of transposing stored healthcare data and information into knowledge so that it can serve as a facilitator for making critical decisions during healthcare operations. The architecture has a number of components which are further divided into sub-components. Each component is responsible for carrying out specific task. The Knowledge Identification Agent and the Knowledge Interchange Agent are the two main agents that are implemented in the proposed healthcare knowledge management system. The system is further supported by the knowledge organization agent, knowledge reusability agent, knowledge query agent, knowledge visualize agent, new knowledge discovery agent and mobile dynamic planning agent.

Proposed healthcare knowledge management framework is primarily divided into two areas: the application area and the service area. The application area is responsible for tasks such as acquisition, identification, organization and reusability of knowledge. It consists of the knowledge acquisition tool which facilitates healthcare experts to insert basic information into the system. It is also equipped with the identification and interchange tool which is useful in sharing knowledge, provided by healthcare professional, with others or for personal use with the aid of mobile agents. Another tool that is a part of application area of the system is the organization and reusability tool. This tool provides systematization and reformatting of information for special purposes.

The second area of the proposed healthcare knowledge management system is the service area. This area is in charge of making strategic plan and assessment, and consists of three tools. The first tool is the dynamic healthcare knowledge visualize tool. As the name implies, the main functionality of this component is to visualize healthcare knowledge acquired from repository for better understanding. The second tool is the dynamic healthcare planning tool with customization feature which is intended for personal use. The third and the last tool which is a part of service area is the healthcare coalition information tool. This tool exercises plans, schedules, and resources to formulate the optimal team to execute work in healthcare administration.

The application area of the framework is based on mobile agents and, as discussed above, is composed of three tools: the knowledge acquisition tool, the identification and interchange tool and the organization and reusability tool. Basic functionalities of these tools are summarized above however the paper further breaks down each of these tools into its sub-components.

The first tool which is the knowledge acquisition tool is composed of three components: the mail server, the application server, and the mail repository. The mail server is responsible for handling email transactions, email forwarding and formulation of an auditor group (specialized for health issues) controlled by intellectual email administrator, and the re-formatting of emails before they are stored into the database or forwarded to a receiver. The application server component is in control of receiving services required by users and evaluation of emails in the form of usage, accuracy and pertinence. The last component of knowledge acquisition tool is the mail repository which is the main mechanism for saving mails into database.

The knowledge management framework of mobile agent base, the knowledge identification agent and the knowledge interchange agent are part of the knowledge identification and interchange tool. The knowledge management framework of mobile agent base provides basic and general architecture to mobile agent sub-components. The knowledge identification agent implements a search protocol which facilitates the non-professional healthcare people to perform their queries effectively and fetches the most proximate healthcare related results. The Multi-query acquisition, query optimization, knowledge delivery and knowledge matching are the sub-components of the knowledge identification agent. These components are linked together to provide the most efficient results to the user. The last element of the knowledge identification and interchange tool is the knowledge interchange agent. This agent is equipped with three components: the interchange knowledge detection, knowledge formatting, and knowledge interchange delivery component. The knowledge interchange agent carries out various tasks such as detecting knowledge through searching documents and emails, providing formatting, and sharing knowledge by transmitting it to other platforms.

The third tool is the knowledge organization and reusability tool. It consists of two agents: the knowledge organization agent and the knowledge reusability agent. The knowledge organization agent organizes the stored knowledge autonomously and keeps the database up-to date and removes unnecessary data from the repository. The second agent is the knowledge reusability agent and it is responsible for the effective re-use of healthcare knowledge. It has an ability to apply the existing healthcare knowledge for solving new problem. It also personalizes the solutions based on the user of the system.

The service area of the proposed healthcare knowledge management framework is in charge of providing tools for knowledge visualization, healthcare planning, and healthcare coalition. The knowledge visualization tool includes knowledge discovery engine, knowledge query agent, knowledge structure engine, knowledge structure DB, graphic rendering engine, knowledge visualize agent, knowledge delete engine and new knowledge discovery agent. All of these components work together to provide efficient knowledge visualization services.

Another tool in the service area of the proposed system is dynamic healthcare planning tool which provides support for healthcare planning. The subcomponents of this tool are: the general planning repository, resource and schedule repository and mobile dynamic planning agent which are responsible for healthcare plan storage, individual health condition and information resource storage, and dynamic planning with the help cooperation with other two components respectively.

This paper presents various components that can work together to create an effective knowledge management system (KMS). Authors believe that this framework has a potential to address issues with regards to the management of knowledge in healthcare.

This paper presents a multi-agent security framework for e-health services. It describes and categorizes various type of communication into different levels that takes place among health care professionals. Subsequently, the paper identifies security requirements associated to each level of communication and introduces a multi-agent based security approach for e-health services.

The paper begins with the thought that the internet is not a secure place to communicate and share sensitive information. Computer systems are often compromised for illegitimate purposes and organizations that transact business through internet must make sure that their systems are secured. For example, e-health exercises information technology to deliver its services to people. During this process, sensitive information is communicated among users in e-health either through wired or wireless media. Thus, it is necessary to safeguard the communication mediums between medical professionals and patients to ensure the confidentiality and integrity of the transmitted information. To address this, the paper presents a security framework for e-health services based on the multi-agent system.

Communication occurs among various actors or users over network in e-health settings. To demonstrate this, authors present a scenario in e-health where a doctor in a hospital communicates with another doctor from another hospital through internet and a paramedic at an accident spot communicate with a system coordinator at the hospital to update current status of a patient using his personal data assistance (PDA). Authors identify seven actors which may participate in the given scenario. These are the Doctor, Patient, Nurse, Social Worker, Paramedic, System Coordinator, and System Administrator. In addition to that the type of communication among these actors are identified as (1) Doctor <=> Doctor, (2) Doctor <=> Patient, (3) Doctor <=> Nurse, (4) Nurse <=> Patient, (5) Paramedic <=> Social Worker, (6) Social Worker <=> Doctor, (7) System Administrator <=> (Doctor, Nurse, Patient, Social Worker, System Coordinator, and Paramedic).

Each of the above communication paths requires different level of protection depending on the sensitivity of information involved in the communication process. For instance Doctor <=> Doctor and Doctor <=> Patient communication exchange more sensitive information compared to Doctor <=> Social Worker interaction since social worker does not have to know all the details of the patient illness. Taking this into account, the paper categorises these communications into five levels on the basis of the sensitivity of information transmitted. Level 1 is classified as Extremely Sensitive Communication and requires highest protection which includes Doctor <=> Doctor, Doctor <=> Patient, Doctor <=> Nurse, Nurse <=> Patient communications. Level 2 is classified as Highly Sensitive Communication that involves System Coordinator <=> paramedic communication as information on patient's current condition is exchanged which is considered highly sensitive as well. Level 3 being a Medium Sensitive Communication only involves general information which does not require a great deal of protection but a medium security protection would suffice. Social Worker <=> Doctor can be considered a level 3 communication. Then comes the level 4, also referred as Low Sensitive Communication, which engages low sensitive information but high in confidentiality such as communication regarding user accounts or passwords. Interaction between the System Administrator and all other users falls under level 4 communication. The last type of communication is Level 5, named Public, and is open for public. Broadcasted announcements and seminars is an example of level 5 communication.

From this point, the paper identifies distinct security requirements associated to each communication level in order to design a secure system environment. Authentication to enter the system, confidentiality to prevent disclosure of sensitive information, and anonymity are the general requirements listed in the paper for a system used in health care. It further states that, these requirements can be met by securing the communication processes among users, analyzing and monitoring the network to protect against security breaches, and organization security policies. These policies include but are not limited to access control policy, site policy, hardened host policy, incident and disaster response, and auditing policy. Furthermore, authors concerns about the client and server communication and urge that the messages must be encrypted or digitally signed before transmission. Web servers can be compromised easily if they are physically accessible therefore all authorized users must follow the access control policy to access data and all the actions of users must be logged for auditing purposes. Authors also recommend that the email client must support digital certificate technology and signs and encrypts the message before sending it. With that, all activities from the firewall, intrusion detection system, and software patches and updates should be logged in to analyze any irregularity in the system. At last but not the least, authors insist that all the security policies of organization must be enforced for suitable results.

Taking all the security requirements into account, the paper presents a multi-agent based security framework for e-health. The framework is structured into three main components which are the Organizational Policies, Communication Manager Agent (CMA), and Network Analysis and Monitoring Agent (NAMA). The framework also has an Interface Agent and Authentication Agent. The Interface Agent gets information from the user such as ID and password and passes down to the Authentication Agent which is responsible for authentication process. The Communication Manager Agent manages other agents such as

Multi-level communications agent, Message Encryption/Detection Agent, and Email Agent based on services needed. Multi-level communication agent determines the level of communication for a user based on the user's role such as doctor, nurse, patient, etc. The Communication Manager Agent makes sure that all the types of communications adhere to the standard security processes as encryption algorithm required in level 1 is stronger than level 3. The Email Agent also plays an important role in the proposed framework as it assures that there is certificate installed at the user's machine to encrypt the message before sending it out to the network. The Network Analysis and Monitoring Agent monitors and track agents such as Intrusion Detection System Agent, Firewall Agent, Patch Server updates Agent, and Anti-virus Agent. These Agents communicates with Network Analysis and Monitoring Agent to provide on-going state of the system to analyze the network traffic for any malicious activity.

This paper presents a multi-agent based security framework for e-health at a superficial level. It introduces a multi-level communication approach to provide more effective and efficient security to the network. Authors believes that this framework will be implemented in future to study the capability of agents to coordinate and cooperate together to improve the performance of the security processes.

ABSTRACT

A fundamental requirement for achieving continuity of care is commonly accepted to be the integration and interoperability of different clinical oriented systems towards the realization of a "longitudinal" Electronic Healthcare Record. To enable seamless integration of various kinds of IT applications into a healthcare network, a commonly accepted framework based on international relevant standards has become an urgent need. However, there is much marketplace confusion today in the healthcare domain, due to the variety of overlapping or complementary interoperability standards and initiatives, which have evolved over the years addressing integration of applications at different levels. This chapter provides a brief overview of the most relevant Electronic Healthcare Record standards, by examining the level of interoperability and functionality they provide, in terms of context, structure, access services, multimedia support, and security, to provide healthcare decision-makers and system integrators with a clear perspective regarding the capabilities and limitations of each standard.

INTRODUCTION

In order to manage the safe and effective delivery of complex and knowledge intensive healthcare, clinical practitioners increasingly require timely access to detailed, accurate, and complete patient healthcare records, along with efficient communication methods to share segments of a patient's record within and between care teams (Smith, 1996). Also,

DOI:

as the focus of healthcare delivery, over the years, has shifted progressively from medical centres of excellence to primary care, community settings, and to the patient's personal environment (e.g., home care), patients nowadays require as well access to their own healthcare records to an extend that allows them to play an active role in their health management (Lewis et al., 2005). The development of a longitudinal, patient-centred electronic healthcare record (EHR), which has been a key research field in the health informatics domain for many years, is a much anticipated solution to these issues.

According to Tang and McDonald (2006), "an EHR is a repository of electronically maintained information about an individual's lifetime health status and health care, stored such that it can serve the multiple legitimate users of the record". Iakovidis (1998) also argues that the purpose of an EHR should be toward the support of continuity of care, education and research. On the other hand, an EHR system is defined as a set of interoperable information system components establishing appropriate mechanisms to generate, use, store and retrieve an EHR, while ensuring confidentiality at all times (Blobel, 2002). Ideally, an EHR shall include information such as patient identification, observations, vital signs, physical examinations, treatments, therapy interventions, administered drugs, allergies, diagnostic and laboratory tests, as well as imaging reports.

Yet, much of these fine-grained clinical information on which quality care depends is usually stored in distributed, isolated clinical systems and databases in different kinds of proprietary formats within healthcare organizations. Typical formats may include mixtures of narrative, structured, coded, and multimedia entries, unstructured or structured document-based storage, relational database tables, as well as digitized hardcopies maintained in a document management system. One of the major impediments towards the realization of an EHR is the fact that healthcare organizations, all too frequently, consist of a large number of disparate and heterogeneous information systems, which have been deployed to support specific departmental needs Most of these information systems today are proprietary and have been designed autonomously by different vendors, in order to optimize specific processes within various departmental units. Therefore, each system, required to participate in the co-operative healthcare process and facilitation of an EHR, usually differs in technological and architectural aspects (e.g., user interface, functionality, presentation, terminology, data representation and semantics), preserving the problem of system integration prevalent and of significant complexity (Xu et al., 2000; Lenz and Kuhn, 2002). This has constituted a severe interoperability problem in the healthcare informatics domain, allowing healthcare organizations to be left with islands of heterogeneous systems and technologies that are difficult to integrate. Thus, the requirements to provide clinical professionals of any speciality with an integrated, and relevant to their profession, view of the complete health care history of each patient under their care has so far proved to be a significant challenge. Nevertheless, this need is now widely recognised to be a major obstacle to the safe and effective delivery of healthcare services, by clinical professions, by health service organisations and by governments internationally.

There are many perceived benefits of making EHR systems interoperable. EHRs can contribute to more effective and efficient patient care by facilitating the retrieval, acquirement, organization, processing, communication, and view of patient health record data from different sites (Tang and McDonald 2006). Duplicate data entry and prescribing can be avoided, while real-time transferring of patient data between care sites can be improved, if information is captured, maintained, and communicated securely and consistently, in line with clinical needs. Moreover, EHR systems complimented by clinical decision support tools are capable of reducing errors, improve productivity and decision-making choices, benefit patient care by providing automatic reminders, alerts to possible drug interactions, flag of abnormal values and lists of possible explanations for those abnormalities, along with other possible functions too numerous and constantly evolving to mention (Garg et al., 2005). Nevertheless, meeting these potential requirements and benefits necessitates the interoperability among various clinical oriented information systems that support the seamless communication of health record data, while preserving faithfully the clinical meaning of the individual authored contributions within it.

Generally speaking, interoperability is the ability of different information technology systems and software applications to communicate by exchanging data accurately, effectively, and consistently, and to use the information that has been exchanged. More specifically, according to Brown and Reynolds (2000), the term interoperability is defined as follows:

Interoperability with regard to a specific task is said to exist between two applications when one application can accept data (including data in the form of a service request) from the other and perform the task in an appropriate and satisfactory manner (as judged by the user of the receiving system) without the need for extra operator intervention.

The above definition implies the following

- The ability to communicate data (connectivity).
- The data received by the receiving system is sufficient to perform the task and the meaning attached to each data item is the same as the understood by the creators and users of the sending and receiving systems.
- The task is performed to the satisfaction of the user of the receiving system

Given the continuous evolution of technological innovation and the important need for EHR interoperability, over the years a number of interoperability standards have been developed and continuously refined, in order to improve the compatibility among a variety of healthcare applications and systems. Standards such as the Health Level 7 (HL7) Clinical Document Architecture (CDA), CEN EN 13606 EHRcom, and the OpenEHR initiative, aiming to structure the clinical content of an EHR with the purpose to facilitate the exchange of meaningful clinical data, as well as industry initiatives and de facto standards such as integrating the healthcare enterprise (IHE), and digital imaging communications in medicine (DICOM), have played so far a significant role towards the development of interoperable EHR systems. However, given the plethora of international standards and industry initiatives, and also the fact that different types of integration requirements, all too frequent, can not be satisfied by one standard or integration approach only, selecting the most appropriate solution can be a complex task both for system and service providers (Mykkanen, et al., 2003).

This chapter aims to provide an analysis of the aforementioned prominent EHR standards, in order to provide healthcare decision-makers and system integrators with a clear perspective regarding the capabilities and limitations of each standard by examining the level of interoperability and functionality they provide, in terms of context, structure, access services, multimedia support, and security.

The GEHR/OpenEHR Initiative

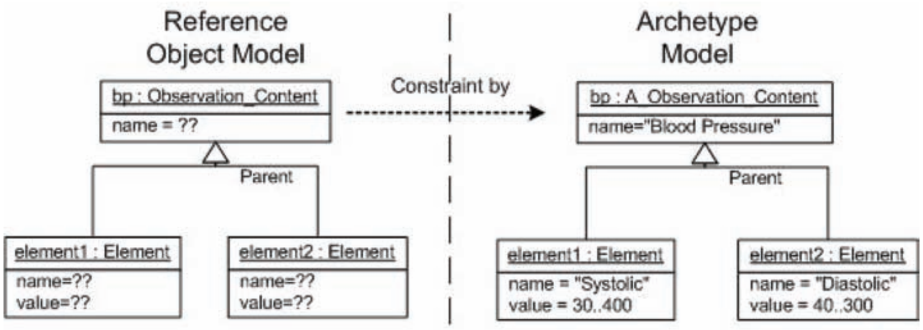
Realising the electronic health record has been at the heart of the EU health telematics programmes for the past fifteen years (Iakovidis, 1998). Considerable research has been undertaken, in order to explore the user requirements for adopting EHRs, as well as proposed architecture formalisms to capture healthcare data comprehensively and in a manner which is medico-legally rigorous and preserves the clinical meaning intended by the original author.

One of the most well known Research and Development Projects, funded by the EU Health Telematics research programme in 1991, is the Good European Health Record (GEHR) initiative (Ingram 1995; Griffith et al., 1995). From 1991-1995, the GEHR Project, who's consortium involved 21 participating organisations in seven European countries, and included clinicians from different professions and disciplines, computer scientists in commercial and academic institutions, and major multi-national companies, explored a wide range of clinical requirements for the wide-scale adoption of electronic health records (EHRs), in place of paper records within primary and secondary care and across different specialities. The outcome of this effort was the development and evaluation of different EHR prototypes, which were based on a set of architecture models, exchange formats, specifications of access and integration tools and a standard architecture, all made available and placed in the public domain. This initiative was later continued under the name Good Electronic Health Record with strong participation from Australia. Currently, this initiative is maintained by an international online, non-profit organization, called the OpenEHR Foundation[1], whose aim is to promote and facilitate progress towards the development of high-quality and interoperable EHRs to support the needs of patients and clinicians.

The most noteworthy concept of these initiatives, proposed and defined independently by the Australian GEHR team, is a knowledge-based model, also known as the archetype modelling technique, which facilitates on one hand the specification of a generic clinical record structure, and on the other hand the specific semantic definitions of clinical contents that need to be standardized (Beale, 2002). This model utilizes a dual-level methodology to define the EHR structure. More specifically, the first level is used to define a small, but constant in time, Reference Object Model (ROM) for an EHR, which typically contains only a few generic, non-volatile, concepts/classes (e.g., role, act, entity, participation, observation, etc). In addition, at this level (the level of the ROM), additional methods on how to organize and group clinical information, capture contextual information, query and update the health record, and use of versioning to safely manage clinical information from a medico-legal point of view, are specified (Beale, 2005; Beale and Heard, 2005). Although the ROM has rich capabilities, it is generic enough to store any type of clinical information. Subsequently, in order to overcome the problem of modelling and specifying the concepts and semantic definitions of clinical contents (e.g. blood pressure, lab results, etc.), the proposed methodology utilizes a second level, in which the constraint rules and mechanisms, called archetypes, specialize the generic data structures that have been implemented using the ROM. Figure 1, illustrates a simple example of the dual-methodology concept. A generic class called "Observation_Content" (implemented in the ROM) can be constraint and restricted by an archetype model class called "A_Observation_Content". This later class is further defined and constraint by an instance archetype called "Blood Pressure". The "Blood Pressure" archetype in turn specifies to the Archetype Model and subsequently to the ROM that the first element in the blood pressure group of elements, will have the name "systolic", and its value must be an integer between 40 and 300 mm[Hg], while the second element will have the name "diastolic" with the same constraints on its value. Of course it has to be noted that in real clinical practice much richer and complicated models usually exist.

A formal language called Archetype Definition Language (ADL) (Beale and Heard, 2003) has been introduced by the OpenEHR initiative in order to describe for each archetype three basic parts: descriptive data, constraint rules, and

Figure 1. Blood pressure instance in the dual-methodology approach



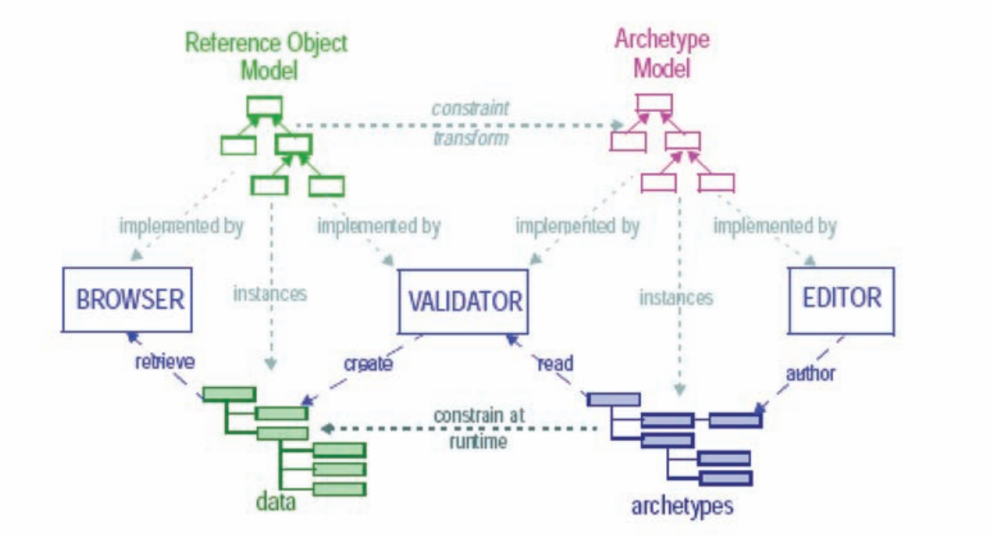
ontological definitions. Descriptive data usually contain a unique identifier for the archetype, a machine readable code describing the clinical concepts modelled by the archetype, as well as various metadata such as author, version, and purpose. Also, due to the fact that an archetype may be a specialization of another archetype, the ADL language also states probable specializations. In turn, the constraint rules are the core aspects of each archetype, defining the potential restrictions on the valid structure, cardinality, and content of the EHR component models. In addition, the ontological part defines the controlled vocabulary that can be used in specific places within an instance archetype.

The main advantage of the dual-level methodology and the archetypes approach is that clinical concepts (represented by the archetypes) are modelled externally and separately from the reference information model of the EHR system. In other words, instead of following the traditional "single-level" development method of a clinical information system, where the domain concepts and semantics which the system has to process are hard-coded directly into its software and database models, the archetype methodology allows domain concepts to be defined separately by domain specialist (e.g., doctors, nurses, clinical bodies, etc.) without worrying about the internal mechanics of the static application software model (the ROM). Derived from this perspective, a basic requirement of an EHR system, illustrated in Figure 2, is to provide three building blocks that are specific to the archetype approach:

- An editor for creating and maintaining the archetypes
- A validator that enforces the constraints are runtime, and
- A browser component who will allow an optimized display of specific archetypes, such as the example archetype illustrated in Figure 1.

Based on the above building blocks, user data entries that need to be stored into an EHR system are guided and validated at runtime against the constraints which are defined in the archetypes for each specific concept. The dual-methodology also allows for the development of "OpenEHR templates". Templates aim to describe the organization and order of models and entries into a record or document (e.g. discharge summaries, antenatal examination, etc.) by using a set (a specified number) of archetypes that can be used for a particular data collection. The OpenEHR foundation maintains libraries of validated templates and archetypes, which can be re-used as a starting point towards the easier and faster development of an EHR system as opposed to a development from scratch approach.

Figure 2. Meta-architecture of the OpenEHR methodology approach (Beale 2002)



Overall, the framework of the OpenEHR foundation includes a Reference Information Model, the ADL language specification for expressing archetypes, an archetype library, implementation technology specifications such as XML schemas, IDL specifications, and a collection of open source implementations for OpenEHR specifications, all published in the OpenEHR web site (www.openehr.org).

The CEN/TC 251 AND ENV/ EN13606 EHRcom

Much of the work and experience of the GEHR project and the OpenEHR foundation, along with other European research and development projects such as the EHCR Support Action (Dixon et al, 2001), and the Synapses project (Grimson et al, 1998), have provided significant input and opportunities for progress on the CEN and ISO standardization organizations.

The CEN/TC 251 (CEN/TC 251), supported by the European Commission DGIII (industry), healthcare organizations, suppliers of ICT-solutions and users, is the technical committee on Health Informatics for the European Committee for Standardization. Its mission is to achieve compatibility and interoperability between independent health information systems and to enable modularity by means of standardization. The TC 251 team comprises of four working groups, which cover: information models, systems of concepts and terminology, security, and technologies for interoperable communications. In particular, the overall scope of the CEN Working Group I (WPI) focuses on standards for the representation of the electronic healthcare record and standards for messages to meet the specific business needs for the communication of healthcare information. In the framework of this working group two work items in the 1990s were intended to be studied and further defines. The first work item, developed as the pre-standard ENV 12265 was the Electronic Healthcare Record Architecture (EHCRA). The ENV 12265 was a foundation standard defining the basic principles upon which electronic healthcare records should be based (CEN ENV 12265). The majority of the requirements for this work item were mainly derived from the GEHR mentioned in the previous section. The second work item, called Electronic Healthcare Record Extended

Architecture, published in 1999, was a four-part EHCR successor standard called ENV 13606.

The CEN standard ENV 13606 Electronic Healthcare Record Communication, is predominantly a message-based standard for the exchange of electronic healthcare records. This is mainly due to the fact that the ENV 13606 does not attempt to specify a complete EHR system, but instead, it focuses on the following main parts:

- The Domain Termlist, which provides a set of measures to be used in order to structure the EHR content.
- The Distribution rules, which specify a set of data objects that represent the rules under which certain EHR content may be shared with other systems, and finally.
- The Messaging, which defines a set of request and response messages enabling the partial or entire communication and also the updating of a patient's EHR.

Several EHR demonstrator projects and few suppliers in the UK (Booth et al., 1999; Markwell et al., 1999), Spain, the Netherlands, Denmark (Bredegaard, 2000), and Greece (Deftereos et al., 2001) have selected to use the ENV 13606, however, implementation efforts and experiences were not successful due to the fact that the standard suffered many weaknessess. The single-level modeling approach made the information model extremely complex with lots of optionatiality and levels of abstraction. These weaknesses unfortunately enforced the implementor parties to pursue several adaptations to the ENV 13606, made in an ad hoc approach, defeating therefore the main objective of the standard.

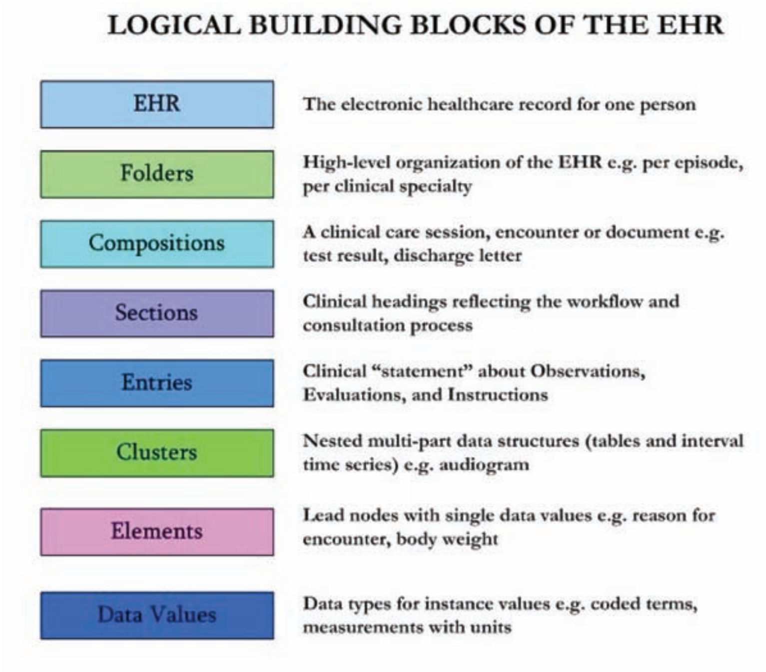
In December 2001, the Health Informatics Technical Committee of the European standards organisation CEN appointed a Task Force, known as EHRcom, to review and revise its 1999 four-part pre-standard ENV 13606 relating to EHR Communications, to produce a definitive European Standard. The mission of the EHRcom Task Force is to produce a rigorous and durable information architecture for representing the EHR, in order to support the interoperability of systems and components that need to interact with EHR services (Kalra, 2006):

- As discrete systems or as middleware components;
- To access, transfer, add or modify health record entries;
- Via electronic messages or distributed objects;
- Preserving the original clinical meaning intended by the author;
- Reflecting the confidentiality of that data as intended by the author and patient.

The revised ENV 13606 (CEN ENV 13606:2000), also called EHRcom, is a five-part standard consisting of the following parts:

- **Part 1—The Reference Model:** A comprehensive, generic EHR model drawing on 14 years of R&D and 2 previous CEN standards. The Reference Model will also be mapped to the HL7 RIM and Clinical Document Architecture (see next section about HL7 and CDA).
- **Part 2—The Archetype Interchange Specification:** An information model and exchange syntax for communicating archetypes; this specification is an adoption of the OpenEHR archetype approach, and will also be compatible with the emerging HL7 Template specification.
- **Part 3—The Reference Archetypes and Term Lists*:*** Contain a set of vocabularies and term lists to support the Reference Model. It also contains guidelines on how to use the Reference Model classes and attributes, and how to design archetypes.
- **Part 4—The Security Features:** Defines measures to support access control, consent and audit of EHR communications.

Figure 3. Main hierarchy of classes of the EHR in the EHRcom (Kalra 2006)



LOGICAL BUILDING BLOCKS OF THE EHR

EHR	The electronic healthcare record for one person
Folders	High-level organization of the EHR e.g. per episode, per clinical specialty
Compositions	A clinical care session, encounter or document e.g. test result, discharge letter
Sections	Clinical headings reflecting the workflow and consultation process
Entries	Clinical "statement" about Observations, Evaluations, and Instructions
Clusters	Nested multi-part data structures (tables and interval time series) e.g. audiogram
Elements	Lead nodes with single data values e.g. reason for encounter, body weight
Data Values	Data types for instance values e.g. coded terms, measurements with units

- **Part 5—The Exchange Models:** Define messages and service interfaces to enable EHR and archetype communication.

Currently, parts 1 and 4 are officially approved and published as European Standards, while parts 2,3, and 5 are still in work progress and are expected to be approved in 2008. It should also be noted that there is a wide international interest in this CEN work, and the Reference Model (Part 1) has been adopted by the International Organisation for Standardisation (ISO) as a draft standard for consultation and subsequent voting. In general, the CEN Reference Model for EHR communication is a generic model capable of representing the structure and context of part or all of the electronic health record of one subject of care, to support interoperable communications between systems and services that might request or provide EHR data. It is not intended to specify the internal architecture or database design of such systems. Figure 3, shows the logical hierarchy of building blocks which allows EHR content to be mapped.

On the highest level, folders may contain compositions by reference. A composition, ideally corresponds to a clinical document, and usually contains various sections defined by section headers and different entries, which in turn consists of specific elements or in some cases consist of clusters of elements. Each element contains values, and each value is based on a specific data type.

Similarly, with the GEHR/OpenEHR initiative, the most important approach that the EHRcom establishes, as opposed to the 1999 version, is dual-methodology based on archetypes. As described in the previous section, archetypes are used to specify clinical concepts (e.g. blood pressure, heart rate, ECG measurements, etc.) that work as constraint rules to restrict possible values or even relationships of the record components in an EHR composition. An Archetype Definition Language, similar to the one utilized by the OpenEHR will be defined by the EHRcom. Efforts are also made by the EHRcom group to harmonize the concept of archetypes with other standards, such as that of the HL7 and the Clinical Document Architecture, which is further described in the next section.

Overall, the completion of the EHRcom standard, which have drawn important lessons from the previous ENV 13606 standard as well as the experiences from several R&D projects, is very much anticipated by the European health informatics industry, since it will provide a revolutionary solution to the EHR interoperability issues. However, at this point there is no evidence neither for implementation outcomes or market acceptance, since the standard is not fully completed.

The HL7 and Clinical Document Architecture

Health Level 7 (HL7) is an ad hoc standards group organization that was formed in 1987, as a result of efforts to develop an integrated Hospital Information System by interconnecting function specific systems that deal with several aspects of patient's care in a hospital (e.g., patient admission, transfer or discharge, orders for drugs, procedures or tests and their results, finance and billing information, etc). The number "7" in its name refers to the application layer in the OSI reference model (Tanenbaum, 1988). HL7 is now an American National Standards Institute (ANSI) approved Standards Developing Organization (SDO) operating in the healthcare area. HL7 is presently being used in the United States, Australia, Canada, Germany, the Netherlands, Greece, Israel, Japan, and New Zealand, while additional countries are joining each year[2].

HL7 provides a collection of communication standard formats specifying syntactically and semantically standardized messages as well as interfaces for the electronic interchange, management, and integration of data between computer applications from different vendors within a healthcare network. It does not assume or make any assumption of data storage within applications; neither comprises an architectural framework for health information systems. For this reason, it doesn't tackle any aspects of functional integration between different software components, but only integration at the data level. Moreover, the HL7 standard does not focus on the requirements of a particular department within a healthcare organization. It simply supports various healthcare systems by specifying the precise messaging syntax to be used, including definitions of segments and internal code strings. In general, it can be viewed as a message oriented standard designed to support communication among distributed systems by utilizing a trigger event model that causes the sending system to transmit a standard pre-defined message to the receiving unit with a subsequent response by the receiving unit. For example, when an event occurs, such as the admission of a patient in a healthcare facility, in an HL7 compliant system (e.g., and admission discharge transfer (ADT) system), an HL7 message is prepared by collecting the necessary data (e.g. demographics data) from the underlying application system and it passes them on to a number of other requestor systems (e.g. a Billing Information System), usually as an Electronic Data Interchange message.

Currently, HL7 supports two message protocols, Version 2 and Version 3. The HL7 Version 2 messaging standard is the most widely, internationally implemented standard within a hospital information system (HL7 2.5: 2000). It has been developed and refined over the years to reflect standardised reporting data sets for several aspects of a patient's care in hospital. However, despite its wide uptake, being an HL7 Version 2 compliant does not necessarily guarantees full scale interoperability between healthcare applications and systems. This is mainly due to the fact that Version 2 does not rely on an underlying reference information model. The definitions for many data are rather vague, and there are also multiple optional fields that can be used or excluded from the implementation. Although, these optional fields provide a degree of flexibility, any implementation effort towards the interoperability between healthcare systems requires primarily a detailed bilateral agreement, also known as a "conformant statement". However, this solution is not scalable and requires a great effort of analysis work. In many cases, the use of HL7 Version 2 standard has created the problem of inconsistent implementations due an enormous and unsystematic growth of message segment definitions that have limited the realization of interoperability.

In order to remedy this problem, the HL7 has created a Version 3 standard (HL7 V3). The key feature of Version 3 is an object-oriented model, called the Reference Information Model (RIM) (HL7 RIM). The RIM is a formal information model representing the core classes and attributes, which specify and ensure the validity of content for any Version 3 messages that need to be exchanged between healthcare systems. In general, the RIM defines four major classes of information:

- Entities, (e.g., for persons, organisations, places and devices)
- Roles (e.g. a patient or an employee;
- Participation relationships (e.g. a patient and a clinician relationship), and
- Acts, (e.g. for the recording of appointments, patient encounters, procedures, etc).

In addition, the HL7 organization in Version 3 has introduced the Clinical Document Architecture (CDA), previously known as Patient Record Architecture (PRA), in order to facilitate the exchange of messages between medical information systems. CDA is currently on its second release and was approved as an ANSI standard in May 2005 (HL7 CDA Release 2:2005). The CDA is a document markup standard that defines a generic structure of messages and semantics for the communication and exchange of clinical documents (e.g. discharge summaries, progress notes, etc.), encoded in Extensible Markup Language (XML). By leveraging the use of XML, the CDA makes documents both machine-readable for XML-aware Web browses, so they are easily parsed and processed electronically, and also human-readable so that they can be easily retrieved and used by the people who need them. CDA documents derive their meaning (coded vocabulary) and data types from the HL7 Reference Information Model. More specifically the CDA, based on its letter "A", which stands for Architecture, can be thought of as a set of hierarchically related XML Document Type Definitions (DTDs) or schemas. In the current CDA standard three levels of hierarchy are defined:

- **Level One — Document Header and Body:** The document header, which is derived from the RIM, is consisted of four parts: the document information, encountered data, service actors and service targets (Dolin et al., 2001). It defines the semantics of each entry in the document and conveys the context in which the document was created. Its primary purposes are to make clinical document exchange possible across and within institutions and also facilitate the compilation of an individual patient's clinical documents into an EHR. The Body contains the clinical document context and can comprise either an unstructured text or nested containers such as sections, paragraphs, lists and tables through structured markup.
- **Level Two—Section Level Templates:** In this level the fine-grained observations and instructions within each heading are defined, through a set of RIM Act classes. In level two a set of Templates that can be layered on top of the CDA Level One specification specify or else constraint both the structure and the content of a document, supporting in this way the interoperability since the receiver knows what to expect. A Template may specify a document type (e.g. physical examination) and

further define its sections (e.g. Vital signs, or Cardiovascular examination, etc.), however the specific semantics of each entity are defined in Level Three.

- **Level Three—Entry Level Templates:** This label enables clinical content and semantics to be formally specified to the extend that they can be expressed in an HL7 Version 3 message based on the RIM model. For instance, this level can allow messages to be extracted from a clinical document for a laboratory order or a representation of symptoms findings.

Many national and international implementation projects, as well as commercial products, use the HL7 CDA as a formal format for defining clinical documents, particularly those who have used the HL7 standards for clinical information systems. However, it has to be pointed out that the HL7 clinical document architecture (CDA) is not an EHR standard per say, since it only defines parts of an EHR architecture. Nevertheless, it can form an important component of an EHR, and for this reason, efforts are made to harmonize the release two with the equivalent components of the EN 13606 Reference Model as well as the OpenEHR initiatives.

Digital Imaging and Communications in Medicine

The digital imaging and communications in medicine (DICOM) (DICOM, 2004) is a de facto standard published in 1993 jointly by the American College of Radiology (ACR) and the National Electrical Manufacturers Association (NEMA), building on two previous ACR-NEMA specifications originating from 1985. It addresses the issue of vendor-independent data formats and data transfers for digital medical images, in order to achieve compatibility and to improve workflow efficiency between imaging systems and other clinical information systems within the healthcare environment. Both CEN and ANSI have adopted DICOM by reference in their imaging standards. Nevertheless, given the fact that the DICOM standard was published in 1993, it precedes the development of Web Technologies, such as XML and Web services. Thus, it utilizes a binary encoding, as opposed to the aforementioned standards, with lists of hierarchy for data elements that are identified by numerical tags. In order to remedy this problem, DICOM issued two additional supplementary standards, called Web Access to DICOM Persistent Objects (WADO), and DICOM Structured Reporting (SR).

Web Access to DICOM Persistent Objects (WADO)

Web Access to DICOM Persistent Objects (WADO) standard was published in 2004, as an extension to the initial DICOM standard, and was a collaboration effort among DICOM and ISO (DICOM Supplument 85, 2004; ISO 17432, 2004). Generally speaking, WADO defines a Web-service that can be utilized by web clients who do not speak DICOM, in order to access particular DICOM objects (e.g. radiology images) via HTTP or HTTPS from a Web server. Although, this may sound a straight forward and simple process, it has to be pointed out that DICOM does not support any query mechanisms, and for this purpose every time a client wants to retrieve an object, it has to specify that object by its unique identifiers. In order perform this task the standard provides a method to harmonize the HTTP query syntax with pre-existing DICOM-enabled servers. In addition, there are a number of other options that can be passed on to the web server. The first and most common option, used for teaching purposes and clinical trials, is a request by the client to the server to hide during the transition any fields containing names or other unique identification data from that specific object. Other options include the conversion of the image presentation (e.g. from

DICOM to JPEG), the selection of the size transformation for the requested image, the quality, the selection of a specific region of that image, and so on.

The WADO standard provides a good approach to be utilized by EHR web-based system that need to gain access to DICOM objects, and make them available to other systems (e.g. via email) within and between healthcare organizations. A number of commercial implementations of the standard are already available.

DICOM Structured Reporting (DICOM-SR)

Another extension to the initial DICOM standard is the DICOM structuring reports (SR) specification, which was published in 2000 (Hussein, 2004a, 2004b). The SR specification provides primarily a standard information model for the electronic representation of medical image structured reports in DICOM's tag-based format for inclusion within an EHR. Based on this model, the actual content of a structured report is represented by a document tree, which specifies the structure (nesting level), the depth, and in a hierarchical way, the relationships among contents. Every content works as a node and comprises its own information (semantics), which are described based on machine-readable codes. In addition, the standard, just like other standards, specifies a range of different templates (e.g. template for diagnostic imaging report) in order to facilitate improved document structuring and harmonization among implementations. Although, its information model provides a high degree of flexibility to store different kinds of data, ranging from text reports to completely structured documents, it is not sufficiently rich in medico-legal and revision attributes to satisfy the requirements of an EHR. Thus, it is highly unlikely that the standard will be accepted in the near future by commercial implementers away from the imaging field.

ISO/TC 215 Health Informatics and the EHR Architecture (ISO TS 18308)

The ISO Technical Committee 215 (Health Informatics) was formed in 1999 to support the compatibility and interoperability of independent information and communication technology (ICT) systems in healthcare. This scope includes also the development of EHR standards. However, the ISO committee is still somewhat in a phase of trying to define its role, since relatively few work items have been formally approved, although a number of projects have been initiated. Regarding the focus on the development of an EHR architecture the ISO committee has only provided individual building blocks but not yet a complete comprehensive standard that defines the architecture itself. One of these standardization building blocks has been the Web Access to DICOM persistent object, mentioned in the previous section, which was a joint-effort with the DICOM.

In addition, the technical committee 215 published in 2004 another important specification the TS 18308 – Requirements for an electronic health record Architecture (ISO/TS 18308). This specification lists and collates a set of clinical and technical requirements for the implementation of an electronic health record architecture that shall support the use and communication of EHRs across different health sectors, countries, and models of healthcare delivery. However, the TS 18308 provides only requirements and not the actual technical architecture itself. Thus, the primary target groups of this specification document are developers of EHR reference architecture standards such as the CEN EN 13606 and other the OpenEHR. In fact the OpenEHR has harmonized its own requirements for the development of the EHR architecture with the TS 18308. In addition, the TS 18308 is complemented by a technical recommendation draft (ISO/TR 20514), published by the ISO Committee in 2005. This draft describes "a pragmatic classification of electronic health records" and furthermore provides "simple definitions for the main categories of EHR and supporting descriptions of the characteristics of electronic health records and EHR systems." These definitions also support legislative and access control requirements that are applicable to all kinds of EHRs.

Integrating the Healthcare Enterprise (IHE)

Integrating the healthcare environment (IHE)[3] is a recently-formed industry sponsored organization, founded in 1998, in the USA by the Radiological Society of North America and the Healthcare Information and Management Systems Society (HIMSS). Overall, the IHE is seeking to promote interoperability between systems within specialist departments such as radiology, and the conventional hospital systems used to order such investigations and to receive imaging study reports. It is working closely with standards organisations such as CEN and HL7. The IHE initiative does not develop standards, however, it selects and promotes appropriate standards from other organizations for specific cases, while also develops application profiles that work as restrictions for these standards. Among these integration profiles, describe in the next subsections, are the "retrieve information for display (RID)" and the "cross-enterprise document sharing (XDS)". Both address methods on how to access EHRs in various formats (IHE, 2005a).

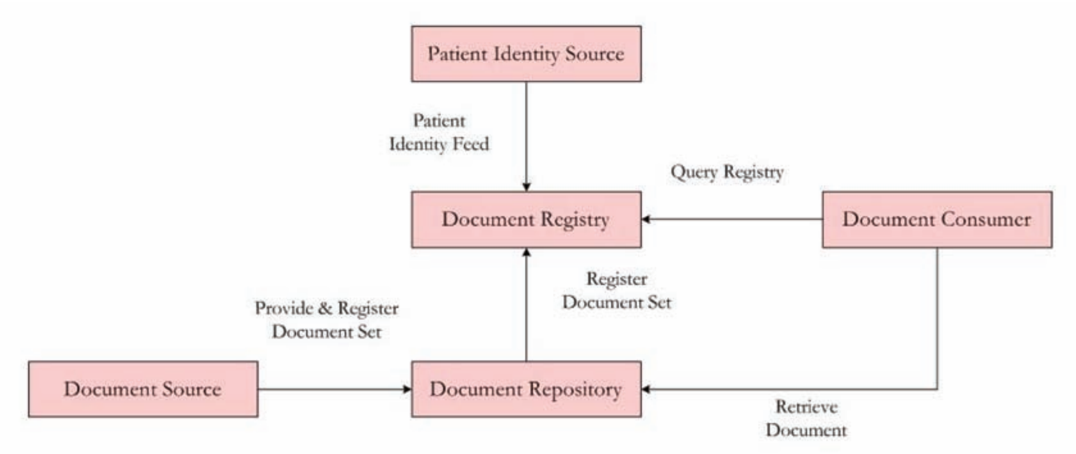
Retrieve Information for Display (RID)

The RID is best described as a Web service and provides through its WSDL (Web Service Description Language) a simple and rapid read-only access to patient-centric clinical information located outside a user's application. It supports access to existing persistent documents in well-known presentation formats such as HL7 CDA Level One, PDF or JPEG, as well as access to specific key patient-centric information for presentation to clinicians. Overall, the main focus of the RID integration profile is visual presentation and not a complete integration of structured databases. It is the responsibility of the information source to convert the healthcare specific semantics into a suitable presentation format. The display, on the other hand, may process and render this presentation format with only generic healthcare semantics knowledge, but will in general not be able to provide any processing of the healthcare information beyond document display. In addition to the above, the RID integration profile does not address access control or security measures for the transmitted information. Other integration profiles offered by the IHE, such as the enterprise user authentication (EUA) and audit trail and node authentication (ATNA) can be used to facilitate these tasks. The RID profile was initially published in August 2003 and has seen a rather quick market uptake. Several prototype implementations from different vendors have been successfully tested for their interoperability at the IHE cross-vendor testing events, and several commercial products are already available on the market.

Cross-Enterprise Document Sharing (XDS)

Another IHE specification aiming to provide means for EHR document archiving is the cross-enterprise document charing (XDS). XDS is a rather new since the final implementation documentation was released in 2005 (IHE 2005b). It defines registry and repository services, by using an ebXML registry with one or more attached repository systems, and can function as a centralised or distributed warehouse for clinical documents. However, XDS is document centric and "content agnostic" in the sense that any kind of document can be stored in an XDS archive, provided that the metadata for the document, for which XDS has a detailed specification, are available. Figure 1, offers a simple view of the systems (actors) and transactions (interfaces) that are defined by the

Figure 4. Actors and transactions of the IHE XDS integration profile (IHE 2005b)



XDS integration profile. A *Document Source* represents a healthcare information system that acts as a point of service where care is provided and clinical information is collected. Subsequently, a document source provides clinical documents (along with metadata) to one or more *Document Repositories* which store the document and then forward the metadata to the central *Document Registry,* in order to register the document. In other words, the document registry does not actually store any document per say, it simply stores the related to the document meta information along with reference regarding the repository from which a document can later be retrieved. A *Document Consumer* is a service application system where care is provided and access to clinical documents is needed. The document consumer queries the central registry for certain documents and receives as a response a list of corresponding to the query documents. Access to the documents and retrieval is then possible through direct access to the document repositories where the documents are stored. The *Patient Identity Source*, finally, is the central system that assigns and manages patient identifiers for one XDS installation.

Based on this simple description it becomes evident that the XDS integration profile mainly provides a storage, indexing and distribution mechanism. However, through specific collaborations between the involved parties, it will be capable of supporting and complementing HL7 CDA documents and EHRcom (13606) equivalent structures, but not a full EHR system.

DISCUSSION

Based on the above overview of the standardization efforts toward the realization of interoperable and compatible EHRs, it becomes evident that the related standards vary widely with regard to their scope and content. Some of them offer a specific content and structured format while others do not. Moreover, some standards define access services, and security features for retrieving and submitting EHR content. For this reason, it is necessary to provide the readers with a simple yet comprehensive guide, presenting all the standards described earlier along with their most important capabilities (Table 1).

Table 1, initially assesses the EHR scope of each standard in terms of content structure and access services. Afterwards, it investigates each standard by utilizing specific EHR aspects (e.g. for content structure, access services, and security features). Features that are not supported

Table 1. Overview of features and service of EHR standards (Adapted by Eichelberg et al., 2005)

	CEN EHRcom	HL7 CDA	DICOM WADO	DICOM SR	IHE RID	IHE XDS
EHR Scope						
EHR content structure	Yes	Yes	No	Yes	No	No
EHR access services	Yes	No	Yes	No	Yes	No
EHR content structure						
EHR contains persistent documents	Yes	Yes	**N/A**	Yes	**N/A**	**N/A**
EHR can contain multimedia data	Yes	Yes	**N/A**	Yes	**N/A**	**N/A**
EHR can contain references to multimedia data	Yes	Yes	**N/A**	Yes		
EHR structured content suitable for processing	Yes	Yes	**N/A**	Yes	**N/A**	**N/A**
EHR supports archetypes /templates	Yes	Yes	**N/A**	Yes	**N/A**	**N/A**
EHR specifies library of archetypes/ templates	Yes	Yes	**N/A**	Yes	**N/A**	**N/A**
EHR specifies distribution rules	Yes	No	**N/A**	No	**N/A**	**N/A**
EHR standard covers visualization	No	Yes	**N/A**	No	**N/A**	**N/A**
EHR supports digital signatures on persistent documents	No	No	**N/A**	Yes	**N/A**	**N/A**
EHR access services						
Service for querying EHR content	Yes	**N/A**	No	Yes	Yes	Yes
Service for retrieving EHR content	Yes	**N/A**	Yes	Yes	Yes	Yes
Service for submitting EHR content	Yes	**N/A**	No	Yes	No	Yes
Document-Centric storage/retrieval	No	**N/A**	Yes	Yes	Yes	Yes
Content format agnostic	No	**N/A**	No	No	Yes	Yes
EHR security features						
Supports transport level encryption	Yes	**N/A**	Yes	Yes	Yes	Yes
Protocol allows to transmit user credentials	Yes	**N/A**	Yes	Yes	Yes	Yes
Protocol enforces access rules	Yes	**N/A**	No	No	No	Yes

by specific standards are characterized with the initials N/A, meaning “Not Applicable”. In addition, bearing in mind that some EHR standards have overlapping areas, it makes an absolute sence to consider the combination of different aspects of EHR standard functions and services. However, this is a complicated task with many hidden risks, since implementation project needs, scope and targeted areas may vary. Nevertheless, an important initiative that can work as a source for finding a plethora of important information regarding not only the technical specifications and capabilities of each standard, but also the possibility of standard’s combination, is the RIDE Project[4] (Funded by the European Union). RIDE is “a roadmap project for interoperability of eHealth systems leading to recommendations for actions and to preparatory actions at the European level”. This roadmap will “prepare the ground for future actions as envisioned in the action plan of the eHealth Communication COM 356, by coordinating various efforts on eHealth interoperability in member states and the associated states".

CONCLUSION

The ever increasing demand for cost containments and provision of quality patient care has led to making healthcare organizations heavily dependent on Information and Communication Technology (ICT). However, the rapid evolution of software applications and healthcare information systems has created an urgent demand for standardization in the healthcare IT market. This demand for standards has also become an urgent need, in order to enable EHR information to be shared between different healthcare facilities. Standards to support EHR communication are at an advanced stage of development, however, further research and implementation work to refine and improve these standards is a must. Overall, standards can support affordable and scalable systems that can be upgraded, as opposed to risky investments in proprietary solutions. Communication standards can allow products from multiple vendors to easily exchange clinical information and contribute to the improved compatibility and interoperability among a variety of applications and systems. Moreover, by utilizing standardized products, healthcare organizations can start with low-entry systems for single departmental solutions and gradually build up larger scale systems up to a comprehensive Electronic Health Record spanning across healthcare enterprises.

KEY TERMS AND DEFINITIONS

E-Health: It is a relatively recent term for healthcare practice which is supported by electronic processes and communication. The term is inconsistently used: some would argue it is interchangeable with health care informatics and a sub set of Health informatics, while others use it in the narrower sense of healthcare practice using the Internet. The term can encompass a range of services that are at the edge of medicine/healthcare and information technology like electronic health records, telemedicine, evidence-based medicine, virtual healthcare teams etc.

Electronic Health Record: An electronic health record (EHR) refers to an individual patient's medical record in digital format. Electronic health record systems co-ordinate the storage and retrieval of individual records with the aid of computers. EHRs are usually accessed on a computer, often over a network. It may be made up of electronic medical records (EMRs) from many locations and/or sources. A variety of types of healthcare-related information may be stored and accessed in this way.

Health Level Seven (HL7): It is an all-volunteer, not-for-profit organization involved in development of international healthcare standards. HL7 is also used to refer to some of the specific standards created by the organization (i.e. HL7 v2.x, v3.0, HL7 RIM etc.).

Electronic Health Record (EHR) Standards: Standards are documented agreements containing technical specifications or other precise criteria to be used consistently as rules, guidelines, or definitions of characteristics, to ensure that materials, products, processes and services are fit for their purpose. There are three main organizations that create standards related to EHR- HL7, CEN TC 215 and ASTM E31. HL7, operating in the United States, develops the most widely used healthcare-related electronic data exchange standards in North America, while CEN TC 215, operating in 19 European member states, is the preeminent healthcare information technology standards developing organization in Europe.

Interoperability: Interoperability is the ability of information and communication systems and business processes to support data flow and to enable the exchange of information and knowledge. Interoperability must be secured at the technical (norms and standards for linking computer systems and services), semantic (meaning of data) and process levels (defining business aims, modelling business processes and actualizing cooperation between various management units). Interoperability can be achieved by adopting national and international technical norms.

INTRODUCTION

The challenges faced by U.S. health care system are vividly explained in the U.S. Government's health information technology plan,

> The U.S. health care system faces major challenges. Health care spending and health insurance premiums continue to rise at rates much higher than the rate of inflation. Despite spending over $1.6 trillion on health care, there are still serious concerns about preventable errors, uneven health care quality, and poor communication among doctors, hospitals, and many other health care providers involved in the care of any one person. The Institute of Medicine estimates that between 44,000 and 98,000 Americans die each year from medical errors. Many more die or have permanent disability because of inappropriate treatments, mistreatments, or missed treatments in ambulatory settings. It has been found that as much as $300 billion is spent each year on health care that does not improve patient outcomes – treatment that is unnecessary, inappropriate, inefficient, or ineffective. All these problems – high costs, uncertain value, medical errors, variable quality, administrative inefficiencies, and poor coordination – are closely connected to inadequate use of health care information technology. (U.S. Federal Government Health Information Technology Plan, 2004).

These challenges have resulted in formidable and compelling pressures on the U.S. Federal Government, professional bodies, and accreditation authorities to undertake measures to bring about significant improvements in the quality of health

DOI: 10.4018/978-1-59904-889-5.ch136

care in both inpatient and outpatients settings. Quality is defined by the Institute of Medicine as having three overlapping domains: safety of patients and practitioners, practice consistent with current domain knowledge, and patient centered care (Kohn, Corrigan, & Donaldson, 2000). In the current environment, one of the important measures undertaken to improve quality of health care is adoption and use of computers and information technology such as electronic medical records system (EMR) by health care providers and medical institutions.

Introduction of EMR has received considerable attention because of its potential effectiveness in (a) implementation of decision support, (b) reducing practice expenses, (c) increasing revenues by improving office efficiency, and (d) making health records more up to date, accessible, legible, and modifiable (Gill, Ewen, & Nsereko, 2001; Hippisley-Cox, Pringle, Carter, Wynn, Hammersley, & Coupland, 2003; Singh, Servoss, Kalsman, Fox, & Singh, 2004).

Even though a few studies in the literature have tried to examine the usefulness of EMR at organizational level (Gill et al., 2001; Hippisley-Cox et al., 2003; Miller & Sim, 2004; Singh et al., 2004), very little research has been done on examining the various components of EMR systems and the process level benefits of these systems. As Barua, Kriebel, and Makhopadyay (1995) point out, by attempting to relate IT implementation directly to output variables at the organizational level, the intermediate processes through which IT impacts are felt are totally ignored. When information technologies such as EMR systems are deployed effectively, they interact with intermediate organizational processes, and deliver value by building unique process level benefits, which finally result in organizational level outcomes. Therefore, there is a need for more granular studies that explicate the underlying linking mechanism (process) between IT implementation and organizational level impacts (Radhakrishnan, Zu, & Grover, 2007).

In this article, we pursue this line of thought and examine the various components of EMR and the potential process level benefits of EMR systems by presenting case summaries. This article contributes to the literature and practice in two ways: First, it provides insights into various modules of EMR system and how they interact with each other to bring out value to users. Second, we present six case summaries (based on qualitative case analysis and content analysis of Web sites) to illustrate the potential process level benefits of EMR systems. The remainder of this article is organized as follows. The next section provides an overview of EMR and its components. In the following section, we present six case summaries to illustrate the potential process level benefits of EMR systems.

OVERVIEW OF EMR

What is EMR?

Electronic medical records system (EMR) is defined as an interorganizational information system that captures the essential components of a patient's medical encounter with the medical provider, including storage and retrieval of subjective, objective patient information, and assessment and plans for patient care (Lenhart, Honess, Covington, & Johnson, 2000). EMR systems facilitate physicians and other health care professionals to:

- Monitor the health status of their patients with electronic medical charts.
- Support health care decisions with evidence-based guidelines.
- Expedite referrals to specialists and other health care providers.
- Computerize ordering of prescription drugs, laboratory tests, and radiology results.
- Store and retrieve patients' medical records from different locations.

Why EMR?

While conducting a field study involving hospitals in countries such as UK and USA, Lederman (2005) found that there are several problems faced by health care professionals while handling patients' medical records. These problems are listed below:

First, in many hospitals, only paper-based records are maintained. Management of paper-based records becomes a significant problem due to the possibilities of losing or misplacing records.

Second, data inconsistency and data integrity are other problems related to paper-based records. Patient files can be changed with no assurance that changes made would be incorporated into a central repository or vice versa. This could lead to a possibility of different, conflicting records being held for the same patient. This increases the probability of incorrect information being accessed.

Third, nonintegrated databases across hospitals pose a significant problem, providing a major impediment to collection, access, and ability to view patient records. The medical staff in each hospital manually enters patients' records into the system. This may cause potential problems like inefficient use of time, loss of productivity, and data entry errors.

EMR can help in overcoming these problems (Bria, 2006; Doyle, 2006; Simon & Simon, 2006). In a survey of 703 practicing family physicians in the U.S., Karsh, Beasley, and Hagenauer (2004) found that the physicians preferred electronic medical records to paper based records as they were up to date, modifiable to meet individual needs, accessible when needed that resulted in better record quality. These studies highlight the value of EMR systems.

Components of EMR

An EMR system has several different modules. Organizations can implement specific modules or all the modules depending upon their needs.

Patient Registration Module (PRM)

This module helps with patient's registration. It helps track and maintain relevant details on the patient (such as name, date of birth, address, contact number, financial class), health insurance plans (insurance company, type of insurance policy, and level of copay), and historical as well as scheduled appointments.

Appointment Scheduling Module (ASM)

This module helps with scheduling appointments. Appointment reservations are scheduled for specialists, general practitioners, and for other resources such as medical labs, emergency rooms, operation theaters, and so forth. It provides flexible appointment schedules where one can request convenient time slots. Patients and support staff can search and view availability of resources within various departments, specialties, and locations.

Medical Billing and Receivables Module (MBRM)

This module helps with "super-bill" (i.e., comprehensive bill) creation and collection of receivables. This module helps track charges associated with diagnosis, medical check-ups, medical procedures, surgical procedures, lab tests, and medical prescriptions. Then super-bills are created by bundling all the charges for a variety of services provided by different departments. The co-pay amounts from patients are recorded. This module retrieves patients' insurance details and sends medical claims to insurance clearance agencies. This module tracks all the accounts receivables from insurance agencies. If payments are not received from insurance agencies within the stipulated period, it rebills the customers for outstanding dues.

Ambulatory Care Module (ACM)

This module maintains patient's medical records. It maintains patients' family and social history, statistics on vital parameters, immunization records, allergies, surgical procedures, physical examination reports, diagnosis results, lab reports, radiology reports, EKG charts, MRI, CT scan reports, medication reports, and any other remarks from other physicians in a central repository. This module permits users to record and retrieve digital photos, transcriptions, drawings, radiology images, MRI, CT scan charts, texts, graphs, and voice. Physicians can have their dictated progress notes transcribed and imported into the EMR, or record handwritten progress notes using a tablet PC.

E-Prescription Module (EPM)

This module generates and tracks electronic prescriptions. Physicians can write prescriptions electronically, which are then transmitted to the associated formularies and retail drug stores. Physicians can even electronically order referrals and laboratory and radiology tests. Users can track test-order status and extent to which a particular prescription is filled by a drug store.

Workflow Management Module (WMM)

This module manages the workflow within a health care organization. This module creates work lists for various professionals such as Specialists, General Practitioners, Nurses, and Lab Staff. This module interacts with the Appointment Scheduling Module and creates work lists for various professionals who are working in a health care organization.

Knowledge Base Module (KBM)

EMR system maintains a repository of clinical references for various disorders, medical complications and tracks information on latest drug dosages and delivery systems. Medical professionals can search this repository for any reference information.

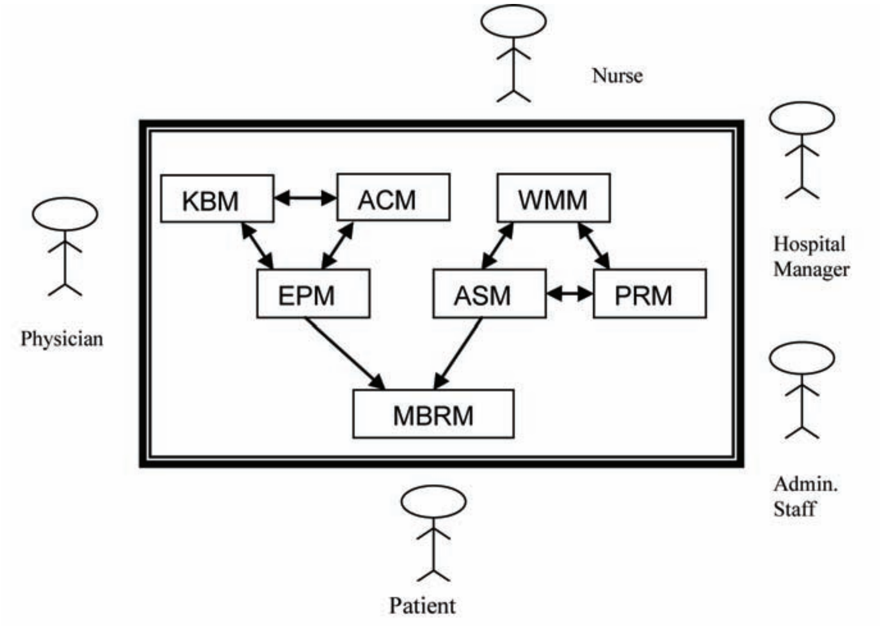
Figure 1 shows the different modules and their interaction. The appointment scheduling module (ASM), patient registration module (PRM) and workflow management module (WMM) frequently interact with each other while knowledge base module (KBM), ambulatory care module (ACM) and e-prescription module (EPM) frequently interact with each other. ASM and EPM feed into medical billing and receivables module (MBRM). As shown in Figure 1, physicians, nurses, hospital managers, administrative staff, and patients use EMR system.

RESEARCH METHODOLOGY

We conducted an exploratory case study on process level benefits of EMR systems. A case study is appropriate for an exploratory investigation like this (Yin, 2002). We employed a case study design using six organizations. We conducted interviews with EMR managers, physician champions, nurses, radiologists, and EMR vendors associated with a few hospitals and physician organizations that had adopted an EMR. We conducted the interviews during the period 2005-06. Using six different organizations allowed comparisons between them for more general research results (Benbasat, Goldstein, & Mead, 1987; Yin, 2002).

We triangulated qualitative data from multiple sources. As mentioned earlier, we conducted telephonic interviews with EMR managers, physician champions, nurses, radiologists, and EMR vendors. We relied heavily on the support of these experts. We used a structured interview guide for our interviews. This interview guide had both closed ended questions and open ended probing questions. Findings from closed ended responses were compared with answers to the open-ended questions. We verified answers by having interviewees review our notes on their responses. We also conducted several face-to-face meetings with

Figure 1. Modules of EMR system and their inter-relationship



representatives from one hospital who were willing to participate in our project.

We also reviewed reports from secondary sources such as trade journals. We also conducted content analysis of Web sites of organizations. We considered data associated with the period 2001-2006. Krippendorf (1980) defines content analysis as a technique wherein a researcher searches for structures and regularities in the content and draws inferences on the basis of these regularities. Here content refers to process level benefits. For consistency, the same researcher did content analysis of the various Web sites.

We conducted cross-case analysis and identified consistent patterns regarding process level benefits of EMR systems.

ANALYSIS AND DISCUSSION OF PROCESS LEVEL BENEFITS

We present six case summaries to highlight the process level benefits of EMR systems.

Case Summaries

Case #1: Oconee Memorial Hospital (http://www.oconeememorial.org/index.cfm?PageID=72)

Oconee Memorial Hospital operates in South Carolina, USA, and is considered progressive in the use of health care IT systems. In late 2003, they got interested in implementing an EMR system known as Practice Management Plus and Horizon Ambulatory Care. It is a part of a larger information network known as Foothills Health Information Network. They initially implemented the system in the radiology section in early 2004 before using it hospital wide. Radiologists used EMR to create and interpret images derived from a variety of modalities: radiography, ultrasound, magnetic resonance imaging (MRI), positron emission tomography (PET), and computed tomography (CT). EMR captures both analog and digital images. EMR also captures metadata concerning who viewed, annotated, printed, and sent specific data and when those activities occurred. This ability of EMR to capture and replay aspects of invisible work resulted in information richness as well as new accountabilities. The search and retrieval processes were enhanced in a digital environment. Now this hospital uses many modules such as appointment scheduling, billing and receivables, patient registration, ambulatory care, and workflow management. Based on the post-implementation evaluation, they have identified the following process level benefits: improved coordination among departments within the hospital, improved access to the patients' medical records from remote locations, improved throughput of diagnosis, treatment and consultation, reduced time taken for delivery of services, improved speed and accuracy of medical insurance claims registration, improved data integrity of patient's medical records, better control of employee work schedule and the institution's overall responsiveness.

Case # 2: Ogden Clinic (http://www.nextgen.com/images/pdfs/Ogden-FCG.pdf)

Ogden Clinic is a multispecialty group practice in Utah, USA. They implemented Next Gen EMR and enterprise practice management systems in 2005. Ogden Clinic began experiencing the following process level improvements: Patient check-in process gets completed in half the time and several reporting tasks associated with the receptionist function have been reduced by half. Using point-of-care documentation templates have allowed Ogden Clinic to eliminate 95% of its transcription use. Scanning and electronic storage of documents have reduced the volume of paper work by 75%. Electronic ordering and results management have been greatly streamlined—with an electronic interface to the laboratory information system, an EKG interface, and e-prescribing capabilities saving valuable physician and support staff time. With health maintenance reminders linked to its disease management programs and a robust set of online patient education materials, Ogden Clinic automatically generates patient recall reminders on a weekly basis, alert physicians when patient interventions are overdue, and provide comprehensive clinical information tailored to each patient's condition. As a result, the organization has recorded an annual increase in revenue of $72,000 attributable to the additional health maintenance visits. Whenever a national drug is recalled, Ogden Clinic generates a list of all its patients on that medication and sends them personalized letters with instructions, providing timely care and saving staff time.

Case # 3: Northwest Diagnostic (www.healthmgttech.com)

Northwest Diagnostic is a family practice clinic in Texas, USA. They implemented the clinical charting, ambulatory care, billing, and scheduling modules of the e-MD EMR system in 2005. Viewing capabilities of EMR system resulted in an up to date availability of data and charts, better data organization and legibility. Support staff reported that they spend less time finding, pulling and filing charts. Physicians reported that they spend less time in locating information. They were able to access and modify the records as and when needed. They reported that they are able to spend more time on assessment and patient care. Coding documentation (different medical procedures have different codes) also improved. Quality of preventive care and disease management improved because of use of electronic alerts on symptoms and allergy lists. Billing procedures also dramatically improved. All these resulted in a saving of a quarter of million dollars in the very first year after implementation.

Case # 4: Cayuga Family Medicine (http://www.healthmgttech.com/archives/1106/1106bridging_gap.htm)

Cayuga Family Medicine is a New York-based low volume practice that focuses on pediatrics and obstetrics. They implemented the patient registration, appointment scheduling and medical billing modules of EMR system in 2000. Cayuga realized the following process level improvements: reduction in the transcription and billing errors, improvement in the speed and accuracy of medical insurance claims registration, data consistency of the patient's medical records and overall productivity of the physicians and front office staff.

Case # 5: Newport Heart (http://www.alteer.com)

Newport Heart is a California based cardiology unit. It implemented the medical billing, clinical charting, and patient registration modules of the EMR system. They experienced the following benefits after implementation of the EMR system: improvement in cash flows, reduction in accounts receivables by 25%, reduction in the time taken for delivery of services to patients, improved ability to inform patients about their up to date financial account status, accurate patients' records, and reduction in the paper work by 90%.

Case # 6: Public Hospitals and Polyclinics under National Health Care Group and Singapore Health Services, Singapore (http://www.zdnetasia.com/news/business/0,39047112,39189253,00.htm)

Seven public hospitals under National Health Care Group and 17 polyclinics under the Singapore Health Services share in-patient discharge summarizes including prescriptions, treatments, and allergies and out-patient records, x ray and lab reports through a centralized platform of EMR system. The hospitals and polyclinics have realized the following benefits: better coordinated care for patients moving across different providers, reduction in transcription errors, better clinical decisions with access to complete and legible clinical histories, cost savings through the avoidance of unnecessary repeat tests and investigations, 24-hour access to real time data for up-to-date results reporting, and improved data security with provision for audit trails.

In summary, we were able to identify several process level benefits from EMR adoption and use such as:

a. Improved coordination between departments in the hospital,
b. Better access to legible medical records from remote locations,
c. Increased throughput for diagnosis, treatment and consultation,
d. Increased speed and accuracy of medical insurance claims registration,
e. Improved data integrity of patient medical records,
f. Better work schedule management,
g. Improved data security and audit trails,
h. Better disease management and preventive care, and
i. Increased costs savings.

CONCLUSION

Electronic Medical Records system (EMR) is an enabling interorganizational information system for overall improvement in health care quality. In this article, various modules of EMR and the relationships between them were presented. There are several modules such as patient registration, appointment scheduling, ambulatory care, e-prescription, knowledge base management, work flow management, billing and receivables management modules. They all work synergistically to increase the value and benefits to all stakeholders.

The process level benefits of EMR systems were then examined by conducting qualitative case analysis of six organizations that had implemented EMR systems and content analysis of their Web sites. Assessment of benefits (at the process level) helps to explicate the underlying linking mechanism between EMR implementation and organizational level impacts. We were able to identify several process level benefits from EMR adoption.

While a few studies in the literature tried to examine the usefulness of EMR at organizational level, very little research has been done to examine the various components of EMR and process level benefits of EMR systems. We have set a stage for examining process level benefits of EMR systems to organizations. Researchers should further this line of research by conducting a longitudinal study involving several health care organizations and examine the process level benefits of EMR systems. Researchers could use theoretical lenses of Transaction Cost Economics, Resource Based View, and Digital Options theory to explain the process level benefits of EMR systems.

KEY TERMS AND DEFINITIONS

Electronic Medical Records System: An interorganizational information system that captures the essential components of a patient's medical encounter with the medical provider, including storage and retrieval of subjective, objective patient information, assessment, and plans for patient care (Lenhart et al., 2000).

EMR Process Level Benefit: A benefit measured at the process level after 2 years of adoption and use of Electronic Medical Records System in medical institutions (adapted from Radhakrishnan et al., 2007).

Health Care Information System: An arrangement of information technology, people, data, and processes that interact to gather, process, store, and disseminate health care information (adapted from Whitten & Bentley, 2007).

This work was previously published in Encyclopedia of Healthcare Information Systems, edited by N. Wickramasinghe; E. Geisler, pp. 1085-1092, copyright 2008 by Medical Information Science Reference (an imprint of IGI Global).

Chapter 1.27

A Comparison of How Canada, England, and Denmark are Managing their Electronic Health Record Journeys

Denis Protti
University of Victoria, Canada

ABSTRACT

Healthcare is one of the world's most information-intensive industries. Every day, volumes of data are produced which, properly used, can improve clinical practice and outcomes, guide planning and resource allocation, and enhance accountability. Electronic health information is fundamental to better healthcare. There will be no significant increase in healthcare quality and efficiency without high quality, user-friendly health information compiled and delivered electronically. The growing use of information and communication technology (ICT) in the healthcare sector has introduced numerous opportunities and benefits to patients, providers and governments alike. Patients are being provided with tools to help them manage and monitor their healthcare, providers are able to seamlessly access up-to-date patient information, and governments are showing transparency to the public by reporting health data and information on their websites. There is mounting evidence that national, regional, and organizational e-health strategies are being developed and implemented worldwide. This chapter provides an overview of three different national e-health strategies, and identifies the lessons learned from the e-health strategies of Canada, England and Denmark.

INTRODUCTION

Due to the ever increasing pressures and demands for healthcare services and the strain those services put on the economy, many nations have realized that they must develop a more sustainable, efficient and effective healthcare system. In doing this, there has been much investment in ICT. Information systems play a significant role in helping improve health outcomes and decision-making at the point of care, and the benefits don't stop there. There are a number of global themes that emerge regarding

Table 1. Global themes in health information systems

Theme	Deliverables and Challenges
Electronic Health Records (EHRs)	• Conveys clinical information • Coordinates care for particular diseases or services • "Virtual concept" reliant on the network approach • Pulls data from multiple stores
Decision Support Tools	• Supports clinician decision making at the service (planning, peer reviews) and care level (care plans, individual clinical actions) • Uses include: o Computerized Physician Order Entry (CPOE) o Computerized Nurse Order Entry (CNOE) o E-Prescribing o Formularies
Unique Patient Identifiers	• Enable EHRs to span across the continuum of care • Manages patient visits and person data
Connectivity	• Online access demands create a need for greater bandwidth • Addressing security demands in order to ensure patient information is secure
Common Standards and Minimum Data Sets	• Detailed data sets lack consensus within and across countries • Consistent and standardized reporting is lacking, worldwide
Coordination of Care in General Practice	• Growing use of more sophisticated practice management systems • Opportunities for greater functionality including clinical uses • Individual care plans are supported • Increasing number of electronic interactions • Supports the global trend to focus on primary care as the main focus of health service delivery • IT vendors are focusing more research and development budgets in this area
Telehealth	• Delivers community and home-based services remotely • Potential to provide specialist services to rural and disadvantaged communities, from a distance • Opportunity to deliver care, monitor and manage chronic conditions remotely via the internet • Devices available for home use to capture vital signs and transmit to the care provider
Consumer Involvement	• Consumers are making informed decisions • Demand for health information and knowledge • Available information should be integrated into service delivery to better involve consumers • Demand for individually tailored care
Access	• Demands on the healthcare system has resulted in various initiatives which allows consumers access to the most appropriate care provider o Call centers, knowledge bases, nurse-based telephone triage

the use of health information systems (Table 1). These themes include establishing electronic health records, developing clinical decision support tools and introducing Telehealth services to those in remote and rural areas often with a high incidence of chronic disease. Orchestrating the change from the paper-based world, to one with seamless and fluid information systems requires a great amount of coordination, time and funding and most importantly a comprehensive strategy.

The impact of the electronic health record (EHR) on patient care can be quite substantial (Infoway, 2006). Some of the potential benefits include:

- Improved communication between providers, and between providers and patients. In many countries, the flow of information has grown exponentially.
- In a number of countries, the implementation of the EHR among various professions has created momentum for working in teams. The EHR has been a catalyst for accelerating this key element of healthcare

innovation widely supported at the policy level throughout the world.

- Patient empowerment. In Denmark, people have access to their EHR. They can review information such as laboratory results and prescriptions to improve self-care—particularly important for chronic disease management. They can see which providers have viewed their records, which allows them to monitor privacy.
- Improved adherence to preventive measures. The literature suggests that electronically generated reminders for screening and follow-up increases adherence by 10% to 15%.
- Improved delivery of recommended care for various conditions. The Vanguard group, in Boston, delivered recommended care about 60% of the time in a baseline study. It improved to over 90% by combining team-based practice with the EHR.
- Nation-wide implementation of the EHR in the USA, including e-prescribing with decision support tools built in, could reduce adverse drug events by two million annually, preventing 190,000 hospitalizations.
- According to the literature, introducing the EHR into the ICU reduces ICU mortality by 46% to 68%; complications by 44% to 50%; and overall hospital mortality by 30% to 33%.
- The use of e-prescribing in Denmark has reduced the medication problem rate from 33% to 14%, and laboratory systems have reduced tube labeling errors from 18% to 2%.
- A major touted benefit of the EHR is chronic disease management (CDM). Some believe the benefits have already been demonstrated and there is consensus that the EHR is a necessary, but perhaps not sufficient, tool to improve CDM.

CANADA'S JOURNEY

Canada has an e-health strategy that is committed to accelerating the implementation of electronic health information systems in Canada. Canada Health Infoway Inc., an independent, not-for-profit organization, created in 2000, is governed by Canada's 14 federal, provincial and territorial Deputy Ministers of Health. Infoway provides leadership by establishing a strategic direction for EHR implementation in Canada in collaboration with the provinces and territories.

Canada Health Infoway recently released an updated electronic health record Solution blueprint for Canada. This blueprint is meant to be a business and technical framework defining how health information is shared "between health services providers (physicians, specialists, nurses and pharmacists) across care settings (hospitals, emergency rooms, clinics and homecare settings) and across geographical distances."

Currently, a key focus in Canada is to develop a network of interoperable electronic health record solutions across Canada, through linking clinics, hospitals, pharmacies and other points of care, in order to help increase access to healthcare services, enhance the quality of care and make the healthcare system more productive. Canada is planning on accomplishing the goals of achieving a comprehensive integrated electronic health records solution, through nine investment programs.

The main areas of interest of Canada Health Infoway are interoperable EHRs and related telehealth and applications. Priority activities are defined and funded from an allocation of $1.2 billion from the federal government. Infoway acts as a "strategic investor"and aims to build on existing work in Canadian Provinces or explore new initiatives in collaboration with other partners, whether healthcare organizations or commercial IT suppliers.

There are nine Infoway programs:

- Interoperable EHR (including privacy and security architecture and standards)
- Infostructure— (architecture, standards to ensure interoperability of systems and support reuse)
- Registries—to provide electronic identification of patients and providers and provide basis of health record system
- Telehealth Diagnostic Imaging
- Drug Information Systems—medication profiles and eventually e-prescribing
- Lab Information Systems—to view lab results
- Telehealth—particularly for rural and remote settings
- Health Surveillance
- Innovation/Adoption

The main objective is to make interoperable electronic health records available for 50% of the population by 2009. However, Canada's healthcare system still manages information with old technologies and practices, some of which literally originated in the 19th century (94% of physician visits in Canada involve paper records; most prescriptions are handwritten). The production of information has grown exponentially, but the capacity to process, analyze, and deploy it to good effect has not kept pace.

Though there has been some progress towards the EHR, it was recently reported that Canada lags significantly on use of electronic medical records in physician's offices (Schoen, 2006). An international survey of more than 6,000 doctors in seven countries found that only 23% of Canadian physicians use electronic medical records, which is the lowest percentage and far behind the 98% level in The Netherlands. Primary care doctors in Australia, the Netherlands, New Zealand and the United Kingdom have the most widespread and multifunctional systems. The majority of doctors in these countries also reported routine use of electronic prescribing and electronic access to test results. Overall, fewer than one-in-five Canadian and U.S. primary-care doctors have access to robust information systems that provide a foundation to guarantee high-quality care.

In the four countries that report widespread EMR use, about 50 to as much as 90% of doctors routinely use computerized alerts to notify themselves of possible prescribing problems, reminder systems to notify patients about preventive or follow-up care, and prompt to advise patients of test results. In contrast, less than a quarter of Canadian and U.S. doctors have computerized systems for these tasks.

Canada has five priorities in healthcare (Infoway, 2006):

1. Reduced wait times, not only in high profile areas such as hip and knee replacements and cancer care, but also in access to primary and specialty care, and underserved areas such as mental health;
2. Primary healthcare, with interdisciplinary teams providing comprehensive, convenient care with an increased emphasis on health promotion and prevention.
3. Enhanced patient safety in the community and institutions.
4. Improved quality of care, particularly for people with chronic conditions.
5. Improved efficiency and better value for money.

The EHR could contribute to addressing them provided there is full-fledged implementation across the country. As the EHR becomes richer, with more elements and connectivity, the potential impact grows. In some areas, there is already solid evidence that the benefits can be realized. In others, the logical case appears persuasive, but there is a need for stronger empirical evidence.

ENGLAND'S JOURNEY

England journey is based on building on its success in the primary care computing arena. There are currently approximately 8,900 general practices (GP) in England, of which 97% have a GP clinical computer system. All practices use their systems for NHS acute prescribing (once only) and for repeat prescribing. Exceptions to this rule are those prescriptions generated during home visits or when prescribing controlled drugs which at present by law these must be hand written. Many practices are using electronic appointment systems and an increasing number of practices scan all hospital letters, reports etc which are then attached to the individual patient record. There are estimates of up to 30% of practices running 'paper-light' systems today.

All health systems such as England's NHS depend on successful handling of vast quantities of information to function safely and effectively. The National Programme for Information Technology in the NHS (NPfIT—now referred to as Connecting for Health—CfH) is a 10-year program which presents an unprecedented opportunity to use information technology (IT) to reform the way the NHS in England uses information, and hence to improve services and the quality of patient care. The core of CfH will be the NHS Care Records Service, which will make relevant parts of a patient's clinical record available to whoever needs it to care for the patient. The national program also includes many other elements, including medical images accessible by computer, electronic transmission of prescriptions, and electronic booking of first outpatient appointments.

According to a recent National Audit Office report, in the past, individual NHS organizations procuring and maintaining their own IT systems and the procurement and development of IT within the NHS was haphazard. The Department of Health did not consider this approach to have been successful, and one of the aims of the national program has been to provide strong central direction of IT development, and increase the rate of take up of advanced IT. CfH is being delivered mainly through contracts negotiated by NHS Connecting for Health with IT service suppliers. Once systems have been developed by the suppliers, further action is needed to bring them into use, such as integrating with existing IT systems and configuring them to meet local circumstances, training staff to use them, and adapting ways of working to make the best of the solutions. Four local service providers are primarily responsible for organizing this work, but much work is needed by local NHS organizations—strategic health authorities, NHS Trusts and other providers working for the NHS, such as GPs and pharmacists.

The scope, vision and complexity of CfH is wider and more extensive than any ongoing or planned healthcare IT program in the world, and it represents the largest single IT investment in the UK to date. If successful, it will deliver important financial, patient safety and service benefits. The main implementation phase of CfH and the realization of benefits is mainly a matter for the future and it will therefore be some time before it is possible fully to assess the value for money, as this will depend on the progress made in developing and using the systems it is intended to provide.

CfH has not been without significant growing pains. An April 2006 open letter by 23 English academics to the Health Select Committee argued that the committee should be aware of the concerns of health professionals, technologists and professional organizations about the £6bn NHS National Programme for Information Technology (NPfIT). It pointed out that the NHS Confederation has said "the IT changes being proposed are individually technically feasible but they have not been integrated, so as to provide comprehensive solutions, anywhere else in the world."

The letter went on to point out that two of NPfIT's largest suppliers had issued warnings about profits in relation to their work and a third has been fined for inadequate performance.

Various independent surveys show that support from healthcare staff is not assured. Concern was expressed that concrete, objective information about NPfIT's progress is not available to external observers. Reliable sources within NPfIT have raised concerns about the technology itself. Questions which the academics felt had not been answered included: Have realistic assessments been carried out about the volumes of data and traffic that a fully functioning NPfIT will have to support across the 1000's of healthcare organizations in England; need for responsiveness, reliability, resilience and recovery under routine and full system load?

As a result of the letter and a series of other documents and accounts—particularly about privacy and confidentiality of the national care record—a shift of responsibility for NHS IM&T in England from the center to local organizations was signaled in the service's new plan for 2007-2008 which was published on December 11, 2006.

The NHS in England: the operating framework for 2007-8 was launched by the NHS chief executive, who says in his foreword: "We are devolving power from the centre to the service in many ways, not least in how we allocate money, such as the unbundling of central budgets. Some of the key enablers of service transformation, such as the delivery of information technology, will also increasingly need to be driven and owned by the service rather than from the centre so that patients can get the full benefits as quickly as possible."

Plans will be required from NHS organizations showing not only how local but national priorities will be achieved including: implementation of GP Systems of Choice; preparing for the National Summary Care Record; the completion of picture archiving and communications rollout; implementation and benefits realization for the Electronic Prescriptions Service and further exploitation of e-booking. The framework also says plans should show how organizations will carry out the deployment and benefits realization for patient administration systems and order communications and results functionality, in line with existing commitments and targets set by each SHA, in the context of existing commercial arrangements.

The broad planning local NHS organizations will be required to do is set out, though the framework says more detailed guidance will be issued shortly. All NHS providers will have to have a forward looking IM&T plan which is "core to their business, exploits fully the NPfIT opportunity and thereby demonstrates migration to the NHS Care Record Service." Primary care trusts, as commissioners, will have their own comprehensive IM&T plan and work with all providers in their local health communities to align IM&T plans and enable patient-centered service transformation. Strategic health authorities will be charged with assuring that the local NHS has the capability and resources to deliver their plans.

From 2007/08 onwards, IM&T investment and exploitation will form part of mainstream NHS planning in support of health and service priorities and reform. With the shift to a self-improving system, the new accent is on local ownership and leadership—away from the centralized approach used by CfH—driving a local IM&T agenda which also meets a defined set of national expectations and exploits the National Programme for IT (NPfIT). Some have suggested that the direction of travel is reminiscent of the 1998 national health information strategy.

DENMARK'S JOURNEY

Denmark is perhaps the most advanced nation in the world when it comes to the use of information technology in healthcare (Protti & Johansen, 2003). Virtually all Danish GPs, and as of January, 2007 (all specialists as well), use their computers to electronically send and receive clinical messages such as prescriptions, lab results, lab requests, discharge summaries, referrals, and so forth. Sixty standardized messages (up from 32 in 2002), including their "One letter solution," have been implemented in approximately 100 computer systems, including physician office systems, hospital systems, laboratory systems and pharmacy systems. The national network is used by over three quarters of the healthcare sector, altogether more than 5,000 different organisations. All hospitals, all pharmacies, all laboratories and general practices take part. As of January, 2006, all private physiotherapists (1,750 in 550 clinics) and all private dentists (2,800 in 1,600 clinics) were also connected to the network. By the end of 2006, all 240 private chiropractor clinics and all 675 private psychologists will also be part of the electronic network. The majority of specialists and all of the local authority health visitor services now participate in the electronic communication via the healthcare data network. Over 90% of the country's clinical communications in the primary sector are exchanged over Denmark's national network. This high level of connectivity means that most Danish physicians run paper-light offices.

GPs enter all medications themselves. They access a drug database that is maintained centrally by the national Danish Drug Agency. The Agency automatically updates the physician office systems every 14 days. Physicians are required to use the lowest cost drug unless a "no substitution" order is given. Most systems provide some decision support in terms of drug-drug interaction, warnings concerning pregnant patients, etc. After the physician selects the patient's pharmacy from a pull down menu, the prescription is sent electronically to the specific pharmacy. At this time, over 85% of prescriptions are sent electronically to pharmacies. All 332 pharmacies with four different IT systems are able to receive electronic prescriptions. As of 2006, all dispensed medications are in a central database which is accessible via the health portal to both physicians and patients who have a digital signature (Johansen, 2006).

Thirty-five percent of Danish hospitals have electronic patient record (EPR) systems, a figure higher than most of Western Europe. EPR penetration in Denmark is expected to rise to 100% during the next two years. Ninety-eight percent of general practitioners (GPs) and a large percentage of specialists use electronic medical record (EMR) systems—a level similar to the UK, The Netherlands, and the other Nordic countries.

MedCom, Denmark's coordinating organization for healthcare IT was founded in 1994 to address these problems. By 2002, it had developed national standards for electronic data interchange (EDI) communication and ensured their widespread adoption in primary care. MedCom is funded 50% by the Ministry of Health, 35% by the Association of County Councils, with the remainder of the funding coming from municipalities, the Danish Pharmacy Association, and other organizations. MedCom has a staff of approximately 15 and a budget of three million euros per year.

MedCom created standard EDI forms for the six principal information flows in primary care for which paper forms were used: lab orders and results; prescriptions ordered by GPs; referrals from GPs to specialists; radiology orders and results; community (home care) messages; and insurance claims submissions and reimbursements. It disseminated these standards through local projects funded by the counties. To encourage adoption, MedCom published on its Web site the number of messages sent in each county, and the progress of vendors in modifying their applications to become compliant with the standards. The main problem was that the standards were too ambiguous. Focus groups involving clinicians, IT professionals and vendors resulted in more-precise versions of the standards.

Since 2002, MedCom has:

- Formed a health data network by linking existing local and regional secure healthcare networks and the value-added network services of counties, hospitals, vendors and other organizations to a central hub via a virtual private network (VPN). The VPN is used for transferring messages, as well as for videoconferencing, conducting teledermatology, accessing digital images, and accessing the standardized extracts of patient data (SUP) system and the national portal.

- Developed a tool to convert EDI messages to XML. One of the goals is to facilitate the transition from existing administrative and clinical applications to applications based on the new EPR data model.
- Developed standards for hospital-to-hospital discharge letters, patient referrals, correspondence messages and clinical biochemistry laboratory results. MedCom paid vendors to modify their applications to incorporate these standards.
- Developed messages for GPs and hospitals to communicate with local authorities and home care providers. This is particularly important in the care of senior citizens, who are frequently transferred between hospital and home care.
- Has been certifying all supplier systems since 2000. Currently suppliers do not have to pay for certification, which entails not only messaging standards but also presentation formats, functionality, ability to change, etc. Suppliers are certified for life unless they introduce major changes (e.g., convert their operating system from DOS to Windows). There are currently 11 suppliers who support 16 different physician office systems, with the major products being either local install or through an Internet service provision. Three suppliers have 57% of the market. Overall, there are some 60 vendors with over 100 software systems using the MedCom network.

The Danish central government contributes to healthcare IT through the National Board of Health (Edwards, 2006).

The board has created a EPR data model known as the basic structure for electronic health records. The board plans to bring the data model into compliance with the health level seven (HL7) version 3 reference information model (RIM) during the next few years. The data model specifies the functionality that every EPR system in Denmark should contain. It is being used as the basis for the tenders that counties are issuing for EPR systems. The board is also completing the development of a national terminology server, including a translation of systematized nomenclature of human medicine (SNOMED) into Danish.

The purpose of the SUP project, which was designed by two counties and three vendors and was implemented by MedCom, is to make data held by Danish hospitals available to clinicians and patients across the country. SUP is currently supplied with data on 16% of the population. Three counties are contributing data. The SUP metadata model contains the data common to the main administrative and clinical applications used in Danish hospitals. Every 24 hours, the data from local applications is copied into an XML file, which is transferred to the SUP database. Clinicians can only view the data; they cannot download it into their own applications.

Once vendors adopt the EPR data model and hospitals implement upgraded EPR applications, the SUP metadata model will be updated, which is expected to enable data extracts every one to two hours. It is likely that SUP will become an EHR covering the entire country.

Since year-end 2003, Denmark has had a healthcare portal, Sundhed.dk, which is funded by the same organizations as MedCom. The portal was developed by IBM Acure and runs on an IBM WebSphere portal server, WebSphere application server and DB2 database. The portal cost 15 million euros to set up. Its annual cost is 4.5 million euros: 3 million euros for IT operations and 1.5 million euros for administration. The content is contributed by the stakeholders (principally the counties and local authorities).

The portal enables patients to:

- View their data from the SUP database (to go into effect in August 2006).
- View their medicine profiles.
- Renew prescriptions.
- View summaries of their medical histories (as of September 2005).
- View a shared care pregnancy record.
- Purchase prescription drugs from pharmacies.
- View information on medical conditions, preventive medicine, and health laws and regulations.
- Specify their organ donation preferences.
- Book appointments with GPs, view a calendar containing their appointments and set up appointment reminders.
- Have electronic consultations with GPs, which are reimbursed according to nationally agreed fees. The Danish GP association has agreed that, by year-end 2007, all GPs will offer electronic consultations.
- View a directory of healthcare organizations, with information on waiting times, quality and accessibility.

Clinicians can view the same information as patients. In addition, they can view clinical knowledge (the Cochrane Library), job listings, laboratory test results (a pilot project) and guidelines for referring patients to hospitals. The portal uses a public-key infrastructure (PKI) for security. Access by patients requires a digital signature; 650,000 have been issued to date. Patients store the digital signatures on their personal PCs and can also transfer them onto thumb drives if they wish to access the portal from another PC. There are approximately 175,000 unique patient visits to the portal per month.

Access by clinicians or pharmacies requires special security certificates. Patients can view the name of the person viewing their data, the date and time of the access, and the action taken. In theory, Danish patients have to give explicit consent each time data is shared, they are allowed to choose which clinicians can access their medical records, and they are allowed to restrict access to data on mental and sexual health. In reality, patients are encouraged not to exercise these powers. Consent to share data is requested only when the patient changes physicians or hospitals.

Studies have concluded that MedCom has produced financial benefits (Gartner). A cost-benefit analysis conducted in 2006 by the market research firm Empirica estimated that the cumulative present value cost of MedCom prior to year-end 2005 was 536 million euros, and the benefit was 872 million euros. Empirica estimated that a typical GP, serving 1,300 patients, saves 30 hours per week of secretarial work by using the MedCom standards.

Higher quality and higher throughput by individual GPs due to the use of EMRs and electronic communication have been shown. On average, GPs have experienced a 20% increase in number of consultations after beginning use of EMRs and electronic communications. Other outcomes include reduced cost of medications and a lower mortality rate due cervical cancer. There are less smear samples and a reduction in cervical cancer (62 in 1988 down to 18 in 2004) and in deaths (29 in 1988 down to 12 in 2001).

Though there is little hard evidence of clinical benefits, soft evidence includes more effective communications (clear, accurate, complete and consistent), more-efficient communications (rapid and lower-cost), and more widespread communications. GPs and hospitals spend less on administrative processing and get reimbursed faster. Local authorities spend less on handling transfers of patients between hospital and home care. Patients benefit from more-efficient delivery of health services, better and more rapid communication of patient data, and access to information about their health.

LESSONS LEARNED

Canada embarked on its particular EHR journey for a number of reasons. One was because at the time when Canada started with EHRs there was not a proliferation of EMRs in doctors' offices. Since healthcare is a provincial responsibility, moving that agenda forward is based on the provinces negotiating with their doctors to install computers in their offices. Secondly, national statistics suggested that the system errors, the adverse effects occur in hospitals, in emergency departments. Infoway wanted to make medication history, lab results and diagnostic imaging data available at that front line.

Lesson learned from the Canadian journey include:

- Secured funding from the federal government
- Facilitated unprecedented federal/ provincial/territorial cooperation
- Enabled a broad language of acceptance around the need for and expected benefits of EHRs
- Established standards
- Secured some early implementation successes (e.g., registries)
- Achieved savings from national procurement initiatives

Despite the investments of funding, planning, goodwill and achievements to date, some feel that the current process for building an electronic infrastructure for the Canadian healthcare system faces a very real danger of delivering a fragmented system that may provide less value to patients in terms of providing better care, and alienates the majority of physicians expected to embrace these new tools (Pascal, 2006). Pascal argues that without serious re-evaluation of our investment priorities and the timing of those investments, as well as how best to involve and support frontline healthcare workers—especially physicians—in meaningful ways throughout this process, Canada is at risk falling far short of our goal of improving healthcare outcomes through the effective application of ICT. He argues that the current approach is seriously impairing the achievement of an adequate return on value (ROV—return on value is the assessment of quantitative and qualitative costs and benefits from IT investments in the healthcare sector; ROV is richer than ROI which only deals with the quantification side of the equation).

According to Pascal (2006), as Canada Health Infoway, provincial and regional jurisdictions go about their work concentrating on the acute sector; there is growing concern within the medical community about how the process is unfolding without their involvement. The greatest gains in healthcare outcomes occur in the community care as over 80% of care originates and is delivered in community settings. Pascal questions why the concentration on the construction of large data bases when physicians and other healthcare workers have little or no connectivity to neither this information, nor the electronic capabilities in their offices to capture or display it? One of the goals of the Canada Infoway e-health strategy is was to have the right information, at the right place, with the right provider, at the right time to provide the best care possible. To do this there has to be connectivity between points of care and the necessary technologies available at them when the encounter occurs. The majority of health information that will make up an EHR or that will be shared among providers to support the care of a patient will be generated at the community level and captured in physician's EMRs.

The lessons learned from England were recently addressed by the British Computer Society who suggested that in order for the national program to succeed the following changes are required:

- Provide a business context for CfH owned at national and local level

- Focus on local implementations at Trust and provider unit level, for example, hospitals, diagnostic and treatment centers, community and mental health trusts, and practices. Providing specialty, service-specific and niche systems will encourage clinical involvement and give quicker benefits
- Persuade local NHS management that informatics is an essential part of business solutions and service transformation. Provide explicit additional funds for business change and service transformation. Embed informatics in trust business targets with realistic target dates.
- Adopt a truly patient-centered approach at the local health community level.
- The strategy should be evolutionary, building on what presently works and encouraging convergence to standards over time, rather than revolutionary.
- Given a heterogeneous set of systems, there needs to be a greater emphasis on standards to enable systems to interoperate effectively, rather than focusing on relatively few monolithic systems.
- Establish basic informatics elements that are standard across the UK to enable coherent treatment of patients irrespective of their movement across home country borders. Ensure that other facets of the English strategy support this coherence.
- Fully implement GP system choice at practice level.
- There needs to be an accreditation process for all new and existing systems, both against the chosen standards and functionality requirements that does not stifle innovation.
- Revisit and reallocate roles and responsibilities of the NHS at each level, NHS CFH nationally and locally, and system suppliers.
- Transform NHS CFH into an open partnership with NHS management, users, the informatics community, suppliers, patients and their careers that is based on trust and respect.
- There are major issues about the sharing of electronic patient data which need to be resolved whatever the shape of future informatics in the NHS. These must not be hijacked by technical issues, and informed patient consent should be paramount.
- Information sharing between care professionals should initially be by messaging using the Spine TMS service pending further work on information governance and the National Care Record Service.
- Clearly define what the NHS Care Record Service (NHS CRS) is. A virtual service offering views of the distributed records available for a patient would seem appropriate.
- Put implementation of the personal spine information system (PSIS) on hold.
- Consider developing the equivalent of the Scottish Emergency Care Summary. General practice systems could provide this on demand.
- The clinical professions, NHS management and informaticians should collaborate to provide clear and comprehensive guidance for all sectors on good informatics practices, such as record keeping and information management—clinical and other—and embed this in undergraduate and post-graduate training. The NHS should facilitate the take-up of this guidance.
- More appropriately skilled/qualified staff is likely to be needed. The approximate volumes need to be agreed, and their supply enabled. The process of professionalizing informatics staff should continue.
- Data quality is critical to reaping the benefits of the raised investment in IT. The improvement of general practice patient data across England has been the subject of work for some years. The same needs

happen in all care sectors, including private and voluntary care providers, and to be extended to data other than patient data.

The lessons learned from Denmark are many and include:

- Support to adopt MedCom standards is paid for by counties. Project coordinators at hospitals involve staff in determining the data to be communicated electronically and develop new procedures for handling electronic messages. Data consultants, paid for by the counties, train physicians and their staff on how to use electronic communications. Physicians are paid to help hospitals communicate better with physician practices.
- Precise standards. MedCom did not just create standards; it worked with clinicians to define the precise content of the standards. This process, though time-consuming, resulted in more-accurate communications and was critical in educating clinicians about the value of IT. Vendors are actively involved as well in setting standards.
- Peer pressure through public monitoring of participation. The MedCom Web site displayed a running total of electronic messages sent, participating counties and compliant vendors.
- Gradual approach with realistic time frames. There is an acceptance by all parties that the adoption of electronic communication takes many years and should not be rushed. Danes start simple and keep it as simple as possible. It is tempting to take on many projects at once, but increasing the level of complexity does not bring a corresponding increase in benefits.
- Financial incentives to physicians to adopt EMR systems. Physicians in Denmark are independent contractors who make independent decisions about IT. Physicians who adopted EMR systems and used the MedCom standards received faster reimbursement.
- Incentives to vendors. No one requires healthcare organizations to use a particular vendor. Counties encourage vendors to upgrade their applications to the MedCom standards by committing to purchase the upgraded applications.
- Culture of consensus. MedCom is funded by many different stakeholders and is viewed as an impartial organization. There is an appropriate balance between central coordination and local leadership
- Project-based approach. Approximately half of MedCom's budget is spent on permanent employees and overhead. The rest is devoted to projects. MedCom believes that this approach has given it more flexibility.
- The Danish Act on Processing of Personal Data (July 2000) was amended in 2004 to permit physicians to have access to medication data. Prior to the change, it was against the law to have access to medication profiles without patients' consent. In terms of patient consent, the current legislation is based on an 'opt-in' model which means that the patient has to give his or her verbally or written consent to let a health professional have access to this/her data. Danish law forbids the interconnection of IT systems across sectors (e.g., health and taxation).

CONCLUSION

No healthcare jurisdiction, other than perhaps the Veteran's Administration in the United States, has achieved a fully automated, comprehensive EHR for its entire population. Hence there are no definitively proven strategies for problem-free implementation. However, a number of insights are beginning to emerge from the countries leading the way, including:

- The transition period is invariably difficult. The initial preferences of users (e.g., text-based rather than structured data entry) may change over time. Flexibility is therefore essential.
- Moving to an EHR in its fullest form is not just a technical innovation; it is a cultural transformation. Change management is vital, and failure to build in processes for effecting the transformation will reduce both uptake and impact. Providers and managers need to complete the transition from resistance to electronic information (historical position) to acceptance (current position) to addiction (cannot function without it).
- Implementation takes time, but can be accelerated once adoption and proven successes have reached a critical mass, or tipping point. At these stages, policy can drive faster change, for example, by making certain resources available only through electronic portals.
- The data elements are the core of any system, and spending time and resources on standardizing definitions and usage will go a long way toward creating information systems that yield valid and reliable measures of quality and performance.
- There will be far greater acceptance of provider-level information technology (IT) if workflow is modified accordingly to gain improvements.
- Creating secure networks for communicating information in any form has proven to be hugely appealing to providers in almost every country. E-mail use grows very rapidly and is an effective vehicle for introducing providers to the world of electronic information.
- It is very important to structure contracts so that risks are appropriately shared, and purchasers do not pay for systems that do not work. The National Health Service (NHS) in England has taken a firm stance, and while it incurred delays because it changed a principal vendor, it did not take a huge financial hit.
- Leadership at all levels—including the very top—is crucial. Clinician leadership is essential but cannot be effective in isolation.
- Helping family doctors use the data generated by the EHR to analyze and improve their own practices will increase uptake. In Denmark, the counties fund data consultants who visit each practice 1-2 times per year to troubleshoot and help produce usable quality-oriented information on treatment patterns, and so forth.
- If providers perceive “early wins” in the process, they will be more likely to invest their own money and agree to standards.
- Some strategies to enhance adoption among providers include clinical stories, peer-to-peer training, demonstration clinics, mentorship, and protected time.

As stated in the Infoway findings at Montebello, the EHR by itself cannot guarantee improved performance. The culture must also change, and all health system stakeholders, including users of services, must be inclined and trained to convert the potential of health information into concrete improvements in quality and efficiency. The benefits of the EHR grow over time as providers in particular exploit its potential to enhance communications, improve safety and quality by using decision support tools, expand the network of trusted colleagues, and generate valid performance measures and comparisons. In other words, however indifferent the initial reaction and despite the inevitable pain of the transition phase, over time the human and capital investment generates a high rate of return. No one ever goes back to paper world once exposed to an EHR.

FUTURE RESEARCH

A common frustration in all nations is determining the true cost of information technology in healthcare. One of the problems is that there is little consistency across healthcare organizations as to what is to be included in the IT domain—let alone the information management (IM) domain. As part of a course taught at the University of Victoria, 28 Canadian healthcare CIOs were interviewed and asked to describe the departments they were responsible for. The survey found that the CIOs were heading divisions that had 17 different names, with 'information management' leading the way—used in four sites. To say that our Canadian healthcare CIOs are responsible for a diverse set of departments would be an understatement. The areas of responsibility range from the usual IM&T areas to others areas such as networks, health records, decision support, telecommunications, biomedical engineering services, switchboard and information desk, library services, privacy, and so forth. The areas that the CIOs were responsible for generated a list that was two pages long! Little wonder it is difficult to find a common set of measurements as what the IT investment really is.

The conundrum of measuring the IT function is that:

- Efficiency (doing things right) is easier to measure than effectiveness (doing the right things)
- Since effectiveness ("doing the right things") and innovation ("doing new things") can not be readily quantified in terms of traditional outputs, improvements are not usually reflected in economic efficiency statistics
- New systems are intended to change difficult to measure actions
- Strategic systems elude measurement
- Infrastructure investments cannot be cost justified on a ROI basis

As with any infrastructure, IT infrastructure does not provide direct business performance. Rather it enables other systems that do yield business benefits. ICT infrastructure is strikingly similar to other public infrastructures such as roads, hospitals, sewers, schools, etc. They are all long term and require large investments. They enable business activity by users that would otherwise not be economically feasible. They are difficult to cost-justify in advance as well as to show benefits in hindsight. They require a delicate investment balance—too little investment leads to duplication, incompatibility, and suboptimal use; while too much discourages user investment and involvement and may result in unused capacity.

Further research is required to determine whether or not ICT in healthcare, i.e. the EHR, is very much about infrastructure. If so, a new way of thinking of the investment and the return on investment is needed.

Oscar Arevalo
University of Kentucky, USA

ABSTRACT

Electronic Oral Health Records (EOHRs) contains all personal health information belonging to an individual and is entered and accessed electronically by healthcare providers over the person's lifetime. This chapter presents a systematic review about EOHRs, describes the current status of availability of EOHR systems, benefits and barriers for implementation and EOHR usage in clinical, public health and research settings to pave the way for their rapid deployment. The chapter draws the scenario of how a fully integrated EOHR system would work and discuss the requirements for computer resources, connectivity issues, data security, legal framework within which a fully integrated EOHR may be accessed for real time data retrieval in service of good patient care practices. This chapter also describes the need for defining required criteria to establish research and routine clinical EOHR and how their differences may impact utilization and research opportunities to establish practice-based research networks.

INTRODUCTION

In 2003, Sittig, Kirshner and Maupomé (Sittig et al.2003) described an informatics-oriented, future-patient care scenario and identified key functions, applications, or technologies in the field of dental informatics. The scenario envisioned a completely paper-less series of interaction between a patient, his/her dentist, and several specialists starting from her initial presentation to completion of a series of procedures and scheduling periodic recall leading to an "ideal" treatment experience. It would be naive to think that such a system will not happen – its fundamentals are already in place. Such a system

DOI: 10.4018/978-1-60566-292-3.ch013

does not require technological marvels, but only needs proper integration of technologies that are in existence for some time. Central to this variety of tasks and sub-tasks in the oral health care system is the patient's health record.

Traditionally, patient information ranging from clinical history to research results has been stored in hard copy format all around the world. Such a storage system demands ever increasing space and is prone to easy destruction requiring great security systems for its physical existence and control of privacy of the information. Such a system also poses difficulty in duplication of data when needed, availability of real-time updated patient information over space and time, and poses even greater difficulty in organizing and aggregating the data for analyses. With the advent of computerized information processing and ever increasing cheap computer disk space and memory, it has become imperative to use this easily available resource to organize health records of patients in an easily retrievable manner in digitized format called electronic health records (EHRs).

EHRs digitize the contained information becoming a database that allows easy access to the information from individual EHRs, or in an aggregated manner. Development of electronic records for oral health requires substantial departures from standard EHRs because several specialty-specific nuances need to be incorporated to appropriately address the needs and maximize the benefits for patients, researchers, practitioners and academicians. Although EHRs have come into existence in routine medical care facilities, their adoption has been slow for a variety of reasons. Similarly, although development and incorporation of electronic oral health records (EOHRs) in day to day clinical practice has been anticipated, forecast and urged for long (Green 1996, Greenwood 1997, Miller 1995, Rada 1995, Schleyer 1995, Schleyer et al. 2001, 2003, Snyder 1995, Walther 1998), their adoption has been still slower. To respond proactively to the digital transformation of oral health care, dentists must become familiar with technologies and concepts (Umar 2002a, 2002b). They must learn what new information technology can do for them and their patients and then develop creative applications that promote the profession and their approaches to care (Bauer & Brown 2001).

WHAT IS EOHR?

Terminology of EHRs have undergone several changes and currently several terms are still used to represent EHRs. Terms such as: automated medical record (AMR), clinical data repository (CDR), computerized medical record (CMR), computerized patient record (CPR), computer-based patient record system (CPRS), electronic health record (EHR), electronic medical record (EMR), electronic patient record (EPR), lifetime data repository (LDR), virtual health record (VHR), virtual patient record (VPR) are some of the terms that have used interchangeably for EHRs. In dentistry, these systems have been variously referred to as: "electronic dental records", "dental electronic records", "electronic dental patient records", "electronic patient record system", "computer-based patient record", and "dental EHR". However, the term EOHR is more comprehensive compared to and is frequently being used universally – therefore, we resolved to use this term.

In general, EOHR is an electronic repository of patients oral health related information in form of a database at the back-end. Therefore EOHR contains a wide array of information (Heid et al.2002) including:

- Patient demographics
- Practitioner characterization
- Immunizations
- Health history
- Health conditions/ problems
- Examinations and findings

- Treatment plans/ clinical orders
- Diagnostic observations
- Radiographs, laboratory data and other investigation reports
- Prescribed medications
- All therapeutic interventions
- Hospital admissions and attendances
- Scheduled events
- Patient encounters

EOHR, therefore "contains all personal health information belonging to an individual and is entered and accessed electronically by healthcare providers over the person's lifetime. EOHR extends beyond acute inpatient situations including all ambulatory care settings at which the patient receives care. Ideally it should reflect the entire health history of an individual across his or her lifetime including data from multiple providers from a variety of healthcare settings, primarily to support continuing, efficient, and quality healthcare." (WHO, 2006) EOHRs must also continue to meet legal, confidentiality, and retention requirements of the patient, the attending health professional and the healthcare institution/ country

The Status of EOHRs

Currently, the use of EHRs and EOHRs and their outcomes are still considered as scientifically reportable events and clear quality assurance guidelines are derived from the HIPAA in the US.

EOHRs are slowly being recognized as the cornerstone of data storing and management on clinical, public health and research settings all over the world although the main thrust of evolving workable EOHRs has remained in the developing world, especially Canada, the United States, United Kingdom, Germany, Australia and New Zealand. EOHR development and adoption are also being reported from the developing countries such as Argentina, Brazil, China, Hong Kong, India, Indonesia, Korea, Malaysia, Singapore, Taiwan, and Thailand. In general, the world over, the introduction of EHR "seems overwhelming and almost out of reach to many healthcare providers and administrators as well as medical record/health information managers" (WHO, 2006).

The US Department of Health and Human Services (DHHS) took the lead in developing a National Health Information Infrastructure (NHII) which is a voluntary initiative aiming at improving "the effectiveness, efficiency and overall quality of health and health care in the United States". This infrastructure has been conceived as "a comprehensive knowledge-based network of interoperable systems of clinical, public health, and personal health information that would improve decision-making by making health information available when and where it is needed" (DHHS 2004) NHII integrates various aspects of individual health, health care, and public health such as: technologies, standards, applications, systems, values, and laws. The central focus of NHII is to implement computer-based patient records for most Americans, connect personal health information with other clinical and public health information, and enable different types of care providers to access computer-based patient records.

USDHHS pointed out categorically that the NHII is not a centralized database of medical records or a government regulation. The NHII integrates the "'lessons-learned' from other National systems (Canada, United Kingdom, and Australia) and ongoing projects". The NHII has three defined stages with outlined timelines: 1) development of leadership (2-years); 2) building collaboration between stake holders (5-years); and 3) Developing and implementing the infrastructure in all relevant public and private sectors (10-years – final target year: 2014) (USDHHS 2004).

Development of the NHII begot the question: Should dentistry be part of the National Health Information Infrastructure? (Schleyer et al. 2004b). The authors pointed out that the advantages of NNHII including "transparency of health information across health care providers, potentially increased involvement of patients in their care, better clinical decision making through connecting patient-specific information with the best clinical evidence, increased efficiency, enhanced bioterrorism defense and potential cost savings" and argued for integration of Dentistry into the NHII (Schleyer et al. 2004b).

EOHR: BENEFITS

EOHRs provide immense benefits in storage, retrieval, and utilization of data and are a key component of establishing efficient and effective evidence based clinical practices. EOHR help to save time and money by reducing paper work, duplicate laboratory and radiologic testing and eliminating the need for dictating services, reducing transcribing errors. In general, EOHRs:

- Improve the accuracy, precision and quality of data recorded in a health record and reduce errors in data recording
- Enhance access to patients' healthcare information by clinicians, researchers and public health authorities and increasing the ability to share data and facilitating continuity of care.
- Improve the quality of care as a result of having health information immediately available at all times facilitating inter-consulting among health care providers.
- Improve the efficiency of the health care delivery system.
- Contain healthcare costs

Access to Clinical Data, Medical Information and Population Data

Without an up-to-date record, it often becomes difficult to provide time high-quality care. Clinical dentistry has a need for complete current data on patients including medical history, radiological, laboratory, patient's drug sensitivity, resistances and allergies. Often such data may be present in different physical locations across clinics and centers which make difficult to procure and may lead to repeated procedures and testing. EOHRs allow available data to be accessed easily, even from distant locations in a comprehensive manner at any time of the day. This increases the efficiency of medical care and also allows speedy resolution to several issues by bypassing logistic problems related to manual chart retrieval and storage problems. Because EOHRs can be easily duplicated, it is also possible for more than one clinician to access the records at different places simultaneously. At the same time, integrating technological advances such as tele-dentistry into the system allows for quick conferences between multiple clinicians, laboratory staff, administrators and healthcare/ insurance managers.

Evidence based practice demands ready knowledge about recent advances. EOHRs address this issue by allowing the presentation of current medical findings which can be incorporated both actively and passively. Using EOHRs, practitioners can easily integrate references and cross-checks by incorporating guidelines, protocols, recommendations, clinical notes, directions at the point of care efficiently and effectively. EOHRs may also incorporate "built-in rules, alerts, or reminders that act to remind clinicians about care that is due for patients, both for preventive care and for chronic disease management. In more advanced systems, these reminders may allow for resolution of the issue at the point of care, allowing a clinician to resolve the issue from within the alert itself." (Cusack, 2008)

EOHRs can add functionality to track population data and parameters, incorporate flags to schedule and recall patients for preventive care, follow-up patients with a set of risk factors. The clinician can easily not just track laboratory, pathology, radiologic tests, but can also incorporate automatic flagging and alerts for abnormal results. Use of EOHRs eliminates the need for dictation and use of transcribing services. This eliminates a source of errors resulting from medical transcription errors.

Improvement in Patient Safety and Quality of Care

The Institute of Medicine's (IOM) report *To Err is Human* (IOM 2000) estimated that up to 98,000 patients were dying each year in the United States because of medical errors. A subsequent report suggested that the IOM's figure be an underestimate and the true number may be as high as 225,000 a year (Healthgrades 2004). Medical errors have been reported in dentistry resulting from procedural, diagnostic, dispensing, prescription and other processes (Pontes et al.2008, Ogunbodede et al.2005, Kim 2004, Bergenholtz et al.2004, Kim 2004, Krol et al.2002, Vaubert et al.1999, Oakley & Brunette 2002).

EOHRs with inbuilt rules, alerts, stops, range checks can go a long way in preventing a large proportion of these errors and maximize patient safety. It has been reported that even achieving a 10% improvement in quality care measures for the population served by small offices could have a substantial effect on public health (Baron, 2007) and EHRs contribute substantially to this improvement.

For example, in a pilot study at the University of Washington, a diabetes care module was developed, and the feasibility of allowing patients with type 2 diabetes to co-manage their disease from home using institutional EHR and web access by the patients in which one newly diagnosed patient was started on an oral hypoglycemic, underwent two upward dose adjustments, and achieved control by reducing HbA1c from 8.0% to 6.1% (Goldberg et al.2003). Similarly, several recent studies have reported the use of EOHRs to successfully assess health risk and improve oral health care quality and dental education. (Atkinson 2002, Delany 2004, Delrose 2000, Finkeissen et al.2002, Fouad & Burleson 2003, Freydberg 2001, Reis-Schmidt 2000)

Clinical Quality Assurance and Education Improvement

EOHRs play a major role in dental educational institutions in terms of improving student and patient experience, quality assurance, improving quality of education, and inculcating principles of evidence based practices among dental students and residents.

The international development and deployment of an electronic modularized dental curriculum is central to the development of an electronic engine to be used for the effective management of dental education. This will ensure continuity in high quality of care across all boundaries, through the continuous updating of its content and linkages to contemporary resources and databases. An electronic engine to be used for the effective management of dental education in a comprehensive dental school/hospital setting is at the core of an international 'virtual' dental education institution. The issue of policy development necessary to ensure consistency, quality and management for an electronic engine is at the very centre of: a) systems management and system databases; b) records of students, patients and personnel; and c) financial records.(Eplee et al.2002)

For example, in a recent study, Shelly et al.(2007) evaluated the use of an EOHR system to assess quality of care in an academic dental institution. Their primary outcome of interest was the timeliness and completeness of restorative care following completion of nonsurgical root canal therapy. They were quickly able to query the system and develop a report assessing permanent restoration, teeth build-ups, complete coverage restorations and were able to assess if patients were receiving recommended treatment. They were able to use EOHR "to objectively and efficiently assess one aspect of quality of care in a dental school environment" and found the use of EOHR to help in clinical assessment and quality assurance.

Minimizing Medication Errors

The Agency for Healthcare Research and Quality (AHRQ) in the United States has defined error as an act of commission (doing something wrong) or omission (failing to do the right thing) that leads to an undesirable outcome or significant potential for such an outcome. Medication errors may or may not cause harm to the patient. Such errors include any errors in dose, route, frequency, and drug choice (IOM 2000, Cusack 2008) that may due to prescribing multiple drugs of similar class, or due to drug-drug, and other possible interactions. Adverse drug events (ADE) may or may not involve medication errors, but may be avoidable if a patient has previous history of similar or related events. ADEs need to be tracked irrespective of whether they occur due to medication error or not.

EOHRs, when linked to electronic prescription systems and drug checking software, can reduce ADE and medication errors by alerting the clinician of such possibilities (for example through a pop-up message about ADE's and drug interactions, related to medications being prescribed, and by cross checking prescriptions against patient history, laboratory test results and other prescribed medications). One study found that some 21% of the prescriptions had errors (Shaughnessy & Nickel 1989). EOHRs also minimize errors resulting from legibility of prescriptions and prevent difficulties resulting from lost/ mutilated/ forgotten prescriptions and fraudulently prepared prescriptions. Drug dosing calculations based on patient's age and weight linked with updated information on liver, renal and other patho-physiological conditions can reduce dosing errors by calculating correct dosages, and modifying those in real-time on an as per need basis.

ADOPTION OF EOHRS IN CLINICAL SETTINGS

The fact that electronic systems, especially computers in dental clinical offices could revolutionize clinical management and practice was recognized very early. The earliest article we found that dealt with electronic data processing in the storage and retrieval of dental patient file information was published in 1967. (MacGregor & Halabisky 1967) With the advent of personal computers, their role in clinical dentistry was envisioned quickly and several articles predicted various scenarios of automated clinical practice. (Green 1996, Greenwood et al. 1997. Miller 1995)

A British study noted that despite the advantages of using computerized systems, many dental practices were only using them to a limited extent. (John et al. 2003) In a study about the adoption, utilization and attitudes toward clinical computing Schleyer et al.(2006) surveyed 256 randomly selected general dentists in the US using a 39-item interview questionnaire. These dentists were selected from among 1159 because they met the eligibility criteria of having computers at chairside. Among these, only 102 (39.8%) could be interviewed. The authors found that 1.8% of the dentists were working in a completely paperless environment. "Auxiliary personnel, such as dental assistants and hygienists, entered most data. Respondents adopted clinical computing to improve office efficiency and operations, support diagnosis and treatment, and enhance patient communication and perception. Barriers included insufficient operational reliability, program limitations, a steep learning curve, cost, and infection control issues." (Schleyer et al.2006)

... general dentistry has become increasingly computerized in the past 20 years ... the proportion of all dental offices (generalists and specialists) with computers has increased from 11% in 1984 to over 85% in 2000. According to data from the Dental Products Report (DPR), a dental trade

publication, the adoption of computers in treatment rooms follows a similar curve with a time lag of approximately 13 to 15 years. The 2004 Survey on computer/ internet usage by the DPR found that 30% of all general dentists used computers in the operatory [an operatory is a treatment room or bay equipped with a dental chair] (Goff 2004). Respondents' primary uses for computers at chairside included scheduling (77.9%), treatment planning (63.9%), patient education (60.7%), hard tissue charting (58.2%), and periodontal charting (54.1%). (Schleyer et al.2006)

Implementing clinical computing in a dental office is a difficult undertaking for a number of reasons. Most dental offices are small (75.3% of all dentists work in a solo practice) (ADA 2003) and thus cannot spend large amounts of capital on information technology (IT). Limited personnel resources require that most dentists outsource the installation and maintenance of the IT infrastructure to a vendor or consultant. Dental computer applications are complex because they must integrate and maintain structured data (such as intraoral findings, treatment plans, and the medical/dental history), free text (such as progress notes), images (such as radiographs and photographs), and three-dimensional models. (Eisner et al.1993) On a small scale, these systems integrate the functions that are typically found in medical software applications for registration, admission, discharge, and transfer; laboratory results; picture archiving and communications; computer-based patient records (CPRs); and billing and insurance processing. Currently, different companies supply the necessary software and hardware components, which makes integration a significant challenge for end users (Schleyler 2004a) … future research must address usefulness and ease of use, workflow support, infection control, integration, and implementation issues." (Schleyer et al.2006)

A study conducted by Flores-Mir reported on the perceptions of Canadian dentists. Using an anonymous self-administered survey by mail to a stratified random sample of 1,096 Canadian dentists (283 were finally available for analysis), the study found: the "usefulness of digital technologies in improving dental practice and resolving practice issues; to determine dentists' willingness to use digital and electronic technologies; to determine perceived obstacles to the use of digital and electronic technologies in dental offices; and to determine dentists' attitudes toward Internet privacy issues." (Flores-Mir et al. 2006)

Diffusion of innovation is the process by which an innovation is communicated through certain channels over time among the members of a social system (Rogers 2003). Depending upon whether people innovate or adopt innovation, they can be divided into: innovators, early adopters, secondary adopters, tertiary adopters, quaternary adopters, and laggards. Innovators are very few and only a small number of people are early adopters. Most people fall under "secondary, tertiary and quaternary adopters" depending upon how quickly they adopt the innovation. Laggards are the most skeptical people who are the last to adopt the innovation. In relation to EOHRs, at this time, it seems that in the US, early adopters have appeared and are incorporating EOHRs in their dental clinical environment.

EOHRs have started to make inroads into dental clinics and institutions slowly – though EOHRs are being increasingly adopted by dental professionals, the adoption rate is slow as is evident from the findings of the studies described above. EOHRs may be viewed as innovations and adoption of innovations takes time because adoption of EOHRs requires behavioral modification on part of dental professionals. Behavior changes are slow and acceptance and adoption of innovations occur through processes known as "diffusion of innovation". In relation to EOHRs, at this time, it seems that in the US, early adopters have appeared and are incorporating EOHRs in their dental clinical environment.

Commercial EOHR systems are critical to universal adoption of EOHRs across the world because the development of these systems represent good business opportunities for private investors. Larger scale adoption of EOHRs will require settling of the commercial EOHR offerings. Currently there are several major technical problems facing the developers of EOHR programs which may prevent quick adoption of EOHR by most of the dental community.

EOHR: PROBLEMS, PITFALLS AND BARRIERS

The interest in implementing EHR is similar in developing and developed countries as are the key issues, challenges and barriers (WHO 2006). Different countries and Institutions within countries are at different stages of implementation of EOHRs. While some countries are in the planning stage, others have implemented pilot projects, and some have implemented functional systems and are progressing to large-scale deployment and development of nationally integrated systems. Slow adoption of EOHRs has been attributed to several factors such as: clinician resistance, high costs, skepticism about return on investment, misaligned incentives, and technical issues related to their compatibility with query systems and larger back-end database systems. Anecdotal evidence suggests that EOHRs do not represent clinical information with the same degree of completeness and fidelity as paper records. These issues, challenges and barriers may be summarized into the following points.

- Resistance to change on part of healthcare providers
- Lack of standard terminology
- Issues related to clinical data entry
- Data coding issues and lack of skill in using disease classification systems
- Concerns about the correct software choice
- Issues related to integration of EOHR software with existing database systems
- High costs of hardware and software
- Data security, privacy and confidentiality issues
- Resistance to computer technology
- Lack of computer literacy and need for relearning and updating skills
- Concern about availability/ retrieval and accuracy of information in a timely manner
- Quality of electronic healthcare information and accuracy of data entries
- Issues related to space requirement and other associated logistics
- Involvement of clinicians and hospital administrators

Dealing barriers in implementing EOHRs require deft management of all or some of the points mentioned above. We approached a clinic manager of an academic institution in the US who described his experience in implementing EOHRs in an academic institution. He responded:

The initial function of the clinical management system (CMS) was for keeping accurate track of patients, procedures and billing. The CMS had 7 or 8 components, one of which was the EOHR. To make use of the EOHR it was necessary to implement the major pieces of the CMS which feed into the EOHR. A major concern for implementation was the significant dollar investment. The initial investment can be hundreds of thousands of dollars and then the yearly maintenance fees in addition to licensing for users although some software is based on having blocks like 1-25, 25-50, 100+, etc. Although there is basic software that works well in private practice, in that particular academic institution we were charged to implement an enterprise CMS for the network offices that would eventually go into the dental school. (Sullivan 2008).

Data Related Barriers

Lack of uniform standard data format and record content across clinical facilities is a major limitation for implementation of EOHR. Practitioners use different record formats, and even those using the same format may not collect data uniformly. This factor limits the integration of data among clinical facilities and health care organizations. This issue is compounded because different commercial EOHR systems use different formats and different technical specifications for the data. Technical data related barriers include:

- Different data formats and specifications used by different EOHRs.
- Lack of diagnostic codes impedes linking of diagnostic, treatment and claims data sets
- Adoption of ICD systems or procedure codes is not uniform and a variety of terminology exists to describe diagnoses, treatment and procedures
- Lack of universal identifiers (in several settings).

The dental profession should develop a more common record with standard diagnostic codes and clinical outcome measures to make the EOHR more useful for clinical research and improve the quality of care (Atkinson et al.2002). Bailit (2003) has pointed out the problem of inaccurate and non-specific diagnoses found in dental charts:

... the nomenclature used to describe dental diseases and treatments. For example, stating that the patient has periodontal disease means little, since this is a very broad term and does not describe the location, severity, or type of periodontal disease. Further, there is considerable subjectivity in how different dentists use this term. This means that periodontal disease may mean one thing in one practice but something different in another practice. Of course, this problem is not unique to dentistry, but it is a problem for researchers trying to use record data to understand why some patients are receiving certain services.

Data charting: Charting of dental data is a tedious and time consuming process. Therefore for those who are used to manual charting, the transition to electronic format involves re-learning the entire process and re-orienting to a new process. Flipping through paper is different from clicking through tabs. Similarly, the orientation of data fields in paper formats and EOHR are substantially different in structure.

A typical scenario leading to frustration out of technical issues not easily resolvable by the data entry operator or similar end user that occurs with EHR was recently reported by Baron (2007):

Unfortunately, our electronic signature did not transfer the contents of that document to the chart as data that a computer could conveniently manipulate. For that to happen, data must be entered into the chart in a structured format… An EHR is a large, highly structured database. Because patients do not usually present themselves or their histories in a structured data format, EHR users must translate what they hear or read into a format that the computer can use... Although much information can be readily translated (for example, medication data), some of it cannot (for example, recording for preserving the patient's voice). Electronic interfaces can automatically import certain data, such as quantitative laboratory results, into the chart in a structured format. However, interfaces may not be reliably available for many clinical data."

However, data retrieved from EOHRs although present in electronic form, give rise to several issues. Most EOHRs export data elements in Excel format. This limits the analytical functionality of the data to those functions that may be easily performed in Excel. However to maximize analytical yield, specialized statistical software need to be used. Transferring data from Excel to formats suitable for statistical software requires thorough checking of the Excel spreadsheets for appropriate marking of missing data, correct formatting of date and data fields etc., a process generally called as "data cleanup". Data clean up preparation of data elements and formats for proper use in statistical analytical software consumes a large amount of data analyst's time, apart from being a tedious process. Most of the times, analysts involved in cleaning of such data annotate their data clean-up outputs with a "the best that I could do". Anecdotal data suggests that in a study, some 90-95% of the total time is taken up in data cleaning whereas the actual analysis takes only 5% of the time. Our experience at the University of Kentucky has also been along similar lines. Furthermore, the data cleanup process cannot be automated because of non-standard terminology, data fields, varying formats and filters and variables across different EOHR programs. If multiple formats are to be accommodated in an analysis of data aggregated from different sources, the enormous data cleanup time required may even prohibit the conduct of the analysis.

In order to obtain greater harmony across EOHRs and make these systems better than paper records, the question to be asked is: what information should be contained in EOHRs, and in what format should those be inputted, retained and exported? A recent qualitative study reported an attempt to develop a basic content model for clinical information in paper-based records and examine its degree of coverage by commercially available EOHRs. (Schleyer et al.2007) The general conclusions from the study were revealing:

- Although dental records contain a relatively large number of fields, there is little agreement on what those fields should be.
- A complied list of dental record elements aggregated across different paper record formats contained more data elements than any EOHR system (70% of the elements were present in EOHR).
- Dental schools' records covered slightly more categories dentists' and vendors' records.
- Dental schools use more comprehensive medical history forms.
- There was a relatively high level of agreement on categories among paper-based and computer-based record formats.
- This agreement did not extend to data fields – only 57% of the data fields occurring in five or more paper records were contained in more than two EOHRs.
- Limitations in information representation in EOHRs were evident in charting hard tissue and periodontal findings, and procedures.
- Dedicated fields associated with developing problem lists or making diagnoses were absent in EOHRs
- Information coverage in EOHRs were more limited that paper formats

EOHRs contain lesser information and provide limited scope for covering clinical information that clinicians' may wish to add. Furthermore, data fields/ elements in EOHRs are grouped differently than paper formats which may lead to clinician's resistance in using EOHRs. Extensive navigation requirements in EOHRs through routines that may be perceived as counterintuitive may also be a limiting factor in clinician's resistance in using EOHRs. This suggests that the front-end interface of EOHR may need major modifications and redesigning to improve clinician compliance with using EOHRs on regular basis.

Data Entry Issues

Anecdotal data suggests some uneasiness in using a chair side computer for clinical data entry as it leads to breaks in the "rhythm" of clinical work. Infection control issues have also been raised by some clinicians. One alternative could be to record the data in paper and then input it into the EOHR.

However, such a mechanism leads to repetitive work, increases costs and is time consuming. An alternative to have dedicated personnel for direct data entry as the clinician dictates is expensive and has the potential for transcription entry errors. As an alternative to these methods, voice activated direct data entry systems have drawn considerable attention as an ideal mechanism for data entry. Therefore, the possibility of a voice activated data entry system integrated with an EOHR system could be a perfect solution to popularize adoption of EOHRs.

Speech recognition in voice activated systems allows clinicians a hands-free option for interacting with computers, which is important for dentists who have difficulty using a keyboard and a mouse while working with patients. While roughly 13% of all general dentists with computers at chairside use speech recognition for data entry, 16% have tried and discontinued using this technology. (Yuhaniak et al.2007) Voice-activated modules are available for most leading EOHRs. “Improvements in speech recognition and microphone technology have helped voice-activated charting and clinical note dictation become more accurate, faster and easier to carry out than previously possible.” (Drevenstedt et al.2005).

It has been suggested that with improvement of technology, voice activation will become a mainstream part of dental computer technology. Currently speech functionality faces several hurdles. It has been suggested that instead of being intuitive, speech functionality is directly comparable to using a mouse and the available systems require memorizing an enormous amount of specific terminology opposed to using natural language. “Overall, limited speech functionality reduces the ability of clinicians to interact directly with the computer during clinical care. This can hinder the benefits of electronic patient records and clinical decision support systems.” (Yuhaniak et al.2007)

In an attempt to solve these issues, a recent study reported the analysis of structured data entry for dentistry using an interactive dental cross (DentCross component). This component is a graphic part of dental documentation connected to an EOHR. In conjunction with an automatic speech recognition system, based on a statistical approach, the speaker-independent (DentVoice component) made the data entry easier and faster. The study showed the practical ability of the DentCross component to deliver a real service to dental care and the ability to support the identification of a person in forensic dentistry. (Zvarova 2008)

Another recent study from the European Center for Medical Informatics, Statistics and Epidemiology at Prague in the Czech Republic (EuroMISE Centre) also reported encouraging results in voice activated EOHR technology using DentCross and DentVoice components (Nagy 2008). This study reported that “the junction of voice control and graphical representation of dental arch makes hand-busy activities in dental praxis easier, quicker and more comfortable.” It is anticipated that these advancements will lead to better quality of the data stored in a structured form in dental EOHRs.

Security Issues and Health Information Protection

Security of data, when in storage or when transported/ transmitted via electronic medium, has been a major concern with patients, administrators, and governments. Personal information privacy issues have been regulated strongly in developed countries. The European Commission (1995) through the Directive 95/46/EC protected right to privacy of individuals with regard to the processing of personal data and transfer of data. Protection of electronic storage of clinical records was mandated in Japan through the directive number HPB No. 517 (Director-General HPB Japan 1999). Although the HPB No. 57 regulated data storage, these directives fell short of complete privacy of data:

These criteria must be followed when storing clinical records in electronic form, but do not need to be followed when using the information from the clinical records. However, an individual medical facility must pay attention to ensure the proper utilization of information from clinical records stored in various systems (i.e. source-input system, new and old systems). (Director-General HPB Japan 1999)

Because EOHRs deal with personally identifiable information and the nature of information is personal and private for the patient, the importance of maintaining privacy, security and confidentiality is paramount. To protect personal health information (PHI), measures are being taken at different level of social organization dealing with PHI – policy, judicial-legal, administrative, personnel and software levels. This issue has become more important due to the potential security breaches in databases that are reported in the media regularly and frequently. Data security is a major concern because of the potential for great harm that stolen data may cause in the hands of unscrupulous elements.

Computer-based, electronic dental record keeping involves complex issues of patient privacy and the dental practitioner's ethical duty of confidentiality… Authenticating the electronic record in terms of ensuring its reliability and accuracy is essential in order to protect its admissibility as evidence in legal actions. Security systems must be carefully planned to limit access and provide for back-up and storage of dental records. Carefully planned security systems protect the patient from disclosure without the patient's consent and also protect the practitioner from the liability that would arise from such disclosure. Human errors account for the majority of data security problems. Personnel security is assured through pre-employment screening, employment contracts, policies, and staff education. Contracts for health information systems should include provisions for indemnification and ensure the confidentiality of the system by the vendor. (Szekely 1996)

The lead in assuring security of PHI was taken by the US with the enactment of the Health Insurance Portability and Accountability Act (HIPAA) that was enacted by the U.S. Congress in 1996 under the Clinton Administration. It is also known as the Kennedy-Kassebaum Act. Title I of HIPAA protects health insurance coverage for workers and their families when they change or lose their jobs. Title II of HIPAA, known as the Administrative Simplification provisions, requires the establishment of national standards for electronic health care transactions and national identifiers for providers, health insurance plans, and employers. (USDHHS 2008, ADA 2005) HIPAA requires PHI to have administrative, physical and technical safeguards. A primary goal of HIPAA is to maintain confidentiality of an individual's identifiable health information if it is transmitted by electronic means for administrative purposes. (USDHHS 2001, Pai & Zimmerman 2002) The phrase, "identifiable health information," means the information itself can be directly or indirectly linked to a person. Another goal of HIPAA is the establishment of commonality of the format used for administrative "transactions."(Chasteen et al.2003a, 2003b)

The HIPAA privacy rule is designed to protect a patient's personal health information from being accessed by an unauthorized person. It mandates the creation of a format to be used by healthcare entities such as a dental clinic/ office/ hospital which transmit health information electronically to protect the confidentiality and security of health information by setting and enforcing standards. (Walker 2002) "The security regulations contain standards with both 'required' implementation specifications and 'addressable' implementation specifications. The security regulations require covered entities to adopt administrative, physical and technical safeguards to protect electronic protected health information." (Sfikas 2003) Some functions covered under HIPAA include: enrolment, claims (encounters, status, payments, and attachments), referrals, eligibility verification, premium billing, and first report of injury or compensation. All EOHR systems therefore are required to confirm to HIPAA mandates, and to modifications of regulations specific to the countries where those are used. (Day 2000, 2001) It is expected that other countries will develop their own regulations by adapting existing regulations from European Union, Japan and USA.

Impact on Workflow

Impact of EHR on workflow in terms of slowing down clinical work has been known to contribute to clinician resistance in using EHRs (Dansky et al.1999). Clinicians were concerned that a negative impact on workflow would reduce productivity. However, EHRs require re-learning and adapting to a new paradigm of data entry, and the learning-curve integrated in this need to re-learn may be the bottleneck for the workflow impact. It has been shown that once clinicians learn the EHR processes, their workflow and productivity return to normal in 30 days (Krall 1995).

It has been suggested that the possible slowdown in workflow with an EHR may be mitigated by using templates and forms. However, prior to implementing an EHR, paper templates should be created around all commonly seen diagnoses follow-up (Cusack 2008) and electronic templates should be adequately tested against those as has been reported by Schleyer et al.(2007). Thereafter, the electronic templates should be modified for comprehensive coverage, smooth navigation and ease of use in a busy clinical facility.

ESTABLISHING EOHR AND TRANSFORMING FROM PAPER RECORDS TO ELECTRONIC RECORDS

With the massive growth in computer technology and exponentially reducing digital storage space costs, implementing EOHRs is not really a choice anymore, but a necessity. An EOHR has become a priority in many countries, including the UK (Reynolds et al. 2008).

> *In the last several years, dentistry has crossed over into the new frontier of electronic dentistry. It has embraced such developments as computer programs for producing digital radiographs and photographs, as well as digital programs that enhance these images, store and organize them into a retrievable "chart-like" fashion, and transmit them via the Internet. In Europe, I saw patients with an electronic "health card." This credit card-sized CD can carry all the information on a patient's written charts, results of laboratory tests, radiographic/imaging information and more. It is expected that the mobile phone will be an alternate vehicle for patient records, and that these records will be accessed with a password security system. This will allow patients to carry their records from location to location. Certainly, the dental implications of such seemingly advanced processes are evident. The expression, 'The future is now,' was never truer. (Schutze 2001)*

One of the key problems faced by any institution or clinical facility when converting from a paper-based/ manual health record system to EOHR is the planning of such a transition because the change reflects a paradigm shift in the way daily work is done. When instituting any major large-scale change, it is generally necessary to establish an Executive committee or hire a consultant knowledgeable in EOHR. These individuals must be integrated from the first day of planning and retained until the transition is completed.

WHO has developed a step-by-step manual to guide implementation of EHRs in developing countries (WHO 2006). The WHO guide reviews current health record systems and policies related to medical records practice. Thereafter it provides a sequential guidance to every aspect of setting up EHRs: planning for the introduction of an EHR; developing an implementation plan; factors to be considered when developing an EHR implementation plan; and finally points out the issues and challenges, providing reasonable solutions. This document is downloadable freely from WHO web site [http://www.wpro.who.int/publications/PUB_9290612177.htm] and is a very useful guide to anyone anywhere wanting to set up an EOHR system.

In order to implement electronic technology dependent methods, some key safeguards are necessary to ensure proper functioning. The basic general needed safeguards for EOHRs include existence of:

- Regular, reliable and efficient back-up system and protocol
- Electrical system emergency preparedness protocol and disaster-recovery protocol for EOHR
- Efficient, practical and easy to use security for work stations and servers and data
- Control over who is able to access the data and a system for data de-identification of data when accessed by individuals who do not need to know the patients' identity
- Mechanism to identify who accesses and/or modifies the data.

In the early 1990's the American Dental Association (ADA) published the monograph "The Computer-based Oral Health Record," to describe a specific EOHR that complements the EHR used for general healthcare. Subsequently, the ADA established a Standards Committee for Dental Informatics (SCDI) that promoted the application of information and various computerized technology. (Heid et al.2002) In 2001, the SCDI developed American National Standards Institute/ADA Specification 1000: Standard Clinical Data Architecture (ADA 2006) outlining the Structure and Content of an Electronic Health Record and is the first ANSI standard that defines the fundamental data structures used to create patient health records. The standard promotes the sharing of like data between dentists, physicians, and hospitals (Harrell et al. 2005). "This is a blueprint from which commercial vendors are encouraged to build uniform health records in interoperable practice management systems to prevent incompatibility problems between vendor systems. The SCDI is preparing an informational report called "Practitioner's Guide to Electronic Dental Records" to specify the capabilities of computer-based dental record systems." (Hamilton 2005) The ADA Technical Report No. 1004 provides a checklist of features and functions helps the dentist determine specific requirements and their priorities. "Characteristics of specific systems are then compared to these specific needs to rank the available choices. The report has also been updated to reflect increasing sophistication in the industry such as the charting interface of the clinical workstation. This specification will also be updated to reflect the growth of web-based systems and dental specialty requirements." (ADA 2004)

Supported by the ADA, orthodontic oriented solutions are being developed to send patient information to colleagues allowing practitioners to share the same patient record across different software programs by solving technical incompatibilities. (Magni et al. 2007) These orthodontic EOHRs aim to establish a seamless interchange of data between software programs and to create a standard for electronic orthodontic patient records.

EOHR SYSTEMS IN THE MARKET

Several EOHR systems are available in the market around the world, but most developers are in the US – most systems are commercial although few are freeware. Several notable systems are being developed by firms based in Canada, France, Germany, New Zealand, and elsewhere. Table 1 provides a list of commercially available and freeware EOHR systems along with the web addresses of the firms that are involved in developing those programs. Different EOHR programs work differently and comparative studies are rare. Only one comparative analysis has been published so far which found that commonly mentioned strengths of the software applications included easy to use/learn, scheduling, integration and flexibility, whereas common weaknesses included complexity, and integration issues. (Schleyer et al.2006)

The market-share of different programs varies. A study published in the United States found that the top five systems in terms of market share were Dentrix (26.2%) and Easy Dental (9.8%) (both from Dentrix Dental Systems, American Fork, UT), SoftDent (15.0%) and PracticeWorks (7.9%) (both from Kodak Corp., Rochester, NY), and EagleSoft (11.0%) (Patterson Dental, St. Paul, MN). (Clinical Research Associates, 2003 cited in Schleyer et al.2006) Anecdotal data suggests that in the US dental schools, AxiUm is commonly used system with EOHR software.

The main features included in the EOHR systems available in the market are: (a) appointment management, (b) clinical charting, (c) employees management, (d) financial management,(e) generation of presentations, (f) image interface, (g) insurance management, (h) laboratory tracking, (i) marketing management, (j) patient & family information, k) practice paperless, (l) prescription writing, m) reports tool, n) software integration, (o) touch screen, (p) treatment plan, and (q) 3D feature. Pricing of different commercial software vary substantially. Some have no up-front cost where one does not have to purchase the software *per se* but has to pay a monthly or annual fee for use the product (license). Others use a more traditional mechanism which one purchases at a one-time cost. Still others ask for payments of different services, such as support, maintenance or updates.

EOHRS IN RESEARCH AND PUBLIC HEALTH

EOHRs in Practice Based Research

Practice Based Research Networks (PBRNs) are teams of practicing dentists who investigate "everyday" issues in the delivery of oral healthcare with greater scientific rigor (NIDCR 2008).

In March of 2005, the US National Institute of Dental and Craniofacial Research (NIDCR) announced it has awarded three grants, totaling $75 million that establish regional "practice-based" research networks (PBRN) to investigate with greater scientific rigor "everyday" issues in the delivery of oral healthcare. (NIDCR 2008) The goal of PBRNs is to encourage practicing dentists and hygienists to propose and conduct each clinical study in close collaboration with their network colleagues. The general idea of developing the PBRNs is to address practical, real-world issues and generate data that will be of immediate interest to practitioners and their patients. (NIDCR 2008) Recently, a group of dental practitioners participating in the PBRN effort wrote about their perspective calling the effort to be a "win-win for private-practice dentists and the future of dentistry". (Veitz-Keenan 2007) Although not enough data is available at this moment about success or utility of PBRNs in dentistry, such networks have been in existence in medical research for over two decades; they have generally been successful (Moskowitz 2007) and have resulted in significant clinical protocol changes. (Chattopadhyay et al. 2008)

Successful PBRN activity requires that the PBRNs are linked group of clinical practices that can pool their data and resources to conduct research. Such data sharing will be possible only through coordinated use of compatible and standardized EOHR systems that allow data sharing and analyses. Similarly, administrative databases are also reservoirs of wealth of information that contribute greatly to develop workable health improvement policies. Several studies demonstrated the benefit of linking the service data to patient or provider characteristic through EOHRs. (Leake, Werneck 2005) The success of PBRNs depends upon active participation of dental practitioners who must use computers and EOHRs. As noted earlier, adoption of computerization among dentists have been slow. Training and follow-up support may encourage dental practice teams to develop more positive attitudes towards computerization and encourage them to use computers more extensively in clinical practice. (John et al. 2003)

EOHRs in Dental Public Health

Public health policies are usually based on analyses of data collected over a long period of time which also requires time for analyses. This creates a large time lag between the origin of the data and development and enactment of policies by when the nature of oral health realities may have changed. Use of EOHRs in PBRNs, public health settings and in other relevant clinical examination based surveys can help speed up the process and reduce the time between data collection and publication of analytical results from the survey thereby making policy making in "real time" possible - use of EOHRs can help

A recent report discussed and identified important design, implementation, and methodological issues with current EHR systems and their role in public health (Kukafka et al.2007). The authors suggested that "in order to support public health's traditional focus on preventive health and socio-behavioral factors, EHR data models would need to be expanded to incorporate environmental, psychosocial, and other non-medical data elements, and workflow would have to be examined to determine the optimal way of collecting these data." They also argue that redesigning EHR systems to support public health offers benefits not only to the public health system but also to consumers, health-care institutions, and individual providers. Although the need of immediate real time data in oral health surveillance is not as urgent as in surveillance for bioterrorism (biosurveillance), the characteristics and issues involved in data transmission from EOHRs in remote areas are the same as for biosurveillance.

Biosurveillance requires near-real-time event monitoring to enable early event detection and rapid response (Ventres et al.2000). The US Healthcare Information Technology Standards Panel's Biosurveillance Technical Committee has

> *done extensive work on standards and interoperability issues for biosurveillance, employing a use case that involves transmitting ambulatory care, emergency department visit, utilization, and lab results data in standardized and anonymized format to public health agencies within one day. Steps in biosurveillance data transfer will include identifying relevant information, aggregating data, and anonymizing it, formatting it to public health specifications, identifying the relevant public health agencies, transmitting the data to them, and logging all transactions. Data could be sent data directly from individual health-care organizations, through some intermediary networked organization, or through a combination of models. Importantly, this standards project is being harmonized with that of the EHR. The Biosurveillance Technical Committee has published extensive reports (BTC 2006a, 2006b) on standards needed to support this goal, as well as on remaining interoperability issues. (Kukafka et al.2007).*

It has been suggested that guidance on what data elements to include may be gleaned from the Chronic Care Model (Wagner 1998) developed to reformulate healthcare from an acute care model in managing chronic diseases into a public health model.

One idea for use of EOHRs in public health setting is to use them in mobile devices so that data collection and transfer can be speeded up from remote areas. “No ideal customisable mobile digital solution currently exists but evidence from general healthcare use suggests that there are valuable features that can aid the general dental practitioners such as personal management and point of source assistance” (Reynolds et al.2008). Wireless personal digital assistants (PDA) together with data secure transmission of digital clinical information could be used in order to assist in disaster victim identification in areas where GSM cellular networks are available (Salo et al.2007). An experiment in the state of New York used PDAs for data collection in remote areas, but the program witnessed several transmission and integration problems inhibiting effective use of PDAs for such activities in oral health surveillance (Kumar 2008).

However, wireless transmission of records has recently been successfully adopted in orthodontic clinics.

> *Wireless cellular broadband technology currently transmits data at speeds that only wired broadband connections were capable of until now. By using high-speed data access protocols such as evolution data optimized (EV-DO) or enhanced data rate for global system for mobile communications evolution (EDGE), gaining access to patient data in an orthodontic office remotely has become a relatively simple task. Affordable and convenient cellular broadband networks allow the orthodontist to remotely access schedules, and update, review, add, or modify data virtually from anywhere. Newer generation wireless broadband technologies have made the virtual office a reality. (Mupparapu 2007)*

Further enhancement of use of technological advancements will make it possible to use remote area data collection and their real time availability in analytical centers possible through the use of EOHRs that are adaptable to mobile data collection instruments such as PDAs and other hand held devices.

EOHR Input in Research Data

Data needs for oral health related clinical and public health research, especially when integrated with etiological research and basic science information are special. For example, the scientific methods require minimizing within- and between-examiner variability, highly accurate, and precise, regular periodic unbiased measurements and a battery of biologic measurements along with detailed disease and exposure measurements that may be out of scope of routine clinical EOHRs. However, clinicians involved in PBRNs would need to have access to such detailed parts of EOHRs for the purpose of research.

A general understanding of the measurement of dental diseases can help practitioners in the process of assessing the patient's future risk of disease. More importantly, as clinical studies shift from the traditional academic setting to practice-based networks, practitioners might play a more significant role in research. An important issue in oral health disease management in the future will be the standardization of clinical criteria and the development of alternative mechanisms of data collection for epidemiologic purposes. (Chattopadhyay et al.2008)

To incorporate such standardization requirements may need substantial expansion of EOHRs which might make them prohibitively expensive or difficult to deploy in clinical settings. "It is not possible to extend the EHR data model to capture the entire host of factors, but an EHR's data model should represent those data elements that are known to contribute to the disease process in order to provide decision support and/or data transfer" to research centers on an as-per-need basis (Kukafka et al.2007).

It is however possible to develop modular EOHRs where clinical, practice, public health and research needs could be addressed by designing separate modules that can be appended to a core EOHR leading to an integrated database that can be as comprehensive as the need be, and yet deployed in smaller modules. Such a modular system can also be integrated with a clinical decision support system. (Benn et al.2000) A modular approach would enhance the scope of using EOHR system for a variety of activities beyond routine clinical work. For example, a public health EOHR modules would allow "high-quality population-level research by improving data quality, pooling it, and making it available for analysis through traditional epidemiological or data-mining methods' (Kukafka et al.2007); allow modification and redesign large surveys; expand scope of the type and depth of data collected from individuals; improve recruitment for clinical trials.

ESTABLISHING A PAPERLESS DENTAL OFFICE

The vision of a completely paperless office has the EOHR at its center, and needs several technologies to be integrated into a seamless working whole from which all benefits of EOHR can be utilized to maximum by clinicians, researchers, academicians and public health professionals and policy makers. Apparently there is a gap in the direction of research and implementation of an obviously needed system that would be conducive for modern methods of health information storage, retrieval and usage. Furthermore, implementation of EOHR is lagging way behind the available hardware and software resources for implementing EOHR. At the same time, it seems that the need for dental research databases and routine clinical use databases will have different sets of requirements to maximize analytical outputs from EOHR.

To make paperless offices possible will require researchers and dental professionals to address multiple grand challenges… The following applications, processes, and technologies would need to be designed, developed, and implemented:

1. A system could profile patient risk for specific chronic oral disease status
2. A population-based system could assess the likelihood of successful outcomes for dental treatments such as implants, periodontal surgery, prostheses, amalgam, plastic, cast, and ceramic restorations.
3. 3-D image manipulation and simulation systems could illustrate the effect on the current patient's appearance of specific proposed procedures,

4. An automated treatment planning system for all dental diagnoses could be used by clinicians (evidence-based guidelines for dental diseases and conditions, multiple semi-edentulous conditions, and malocclusions).
5. A decision aid for patients would help them learn about all personally relevant and applicable dental treatment options. Such a support system would also help patients in a decision making process that would lead to a value-based choice among the various alternatives.
6. Procedures and processes would be needed to capture and analyze digital images progressively over time to track hard-tissue changes.
7. Nano-robots would be used intra-orally to monitor and transmit information on various markers of oral health status, such as salivary pH fluctuations and long-term trends, degree of mineralization shifts at certain index tooth surfaces, salivary enzyme and bacteriologic make-up changes over time, and information about crevicular fluid flow and composition.
8. *Computer-based simulations could incorporate haptic feedback and thus allow students to develop and enhance their fine motor skills.* (Sittig et al.2003)

To attain this scenario, the following challenges that must be addressed:

1. To develop a knowledge-based ontology of dental concepts from which one could extract a standardized controlled clinical terminology to describe dental signs, symptoms, conditions, diseases, and treatments (i.e., procedures, methods, techniques, materials, and devices).
2. To develop an evidence base of etiology, diagnosis, prevention, treatment, and treatment outcomes (including materials, methods, techniques, and usage) for a large proportion of dental patients and dental practices.
3. To develop a comprehensive electronic oral health record that is seamlessly integrated into the automated medical record. Such
4. To develop a nationwide oral health database that contains basic patient-level diagnostic, treatment, and outcome data linked to a nationwide medical database
5. To automate data capture, integration, and synthesis to create real-time, knowledge-based, clinical monitoring systems based on both continuously and intermittently available analog and digital data.
6. *To develop learner-centered educational systems that select a learning goal, evaluate the student's abilities, and determine the individual learning style* (Sittig et al.2003)

CONCLUSION

Adoption of EOHR offers multiple benefits for clinical practitioners, academicians and researchers including ready access to patients' information, decreased medical errors, ability to share information with providers and health care organizations, collection of data for research purposes, etc. EOHRs must also balance the need to be integrated with EHRs although any EOHR system cannot be subordinate to, or a subset of, an EHR. From a public perspective, EOHR could result in improved oral health outcomes and reduced health care expenditures. While much progress has been made several challenges remain to be overcome. Integration of EOHR has been slow because it represents re-engineering current practices and processes, dealing with technical difficulties and data safety issues, which many perceive outweigh the benefits. However, as government and health care systems strive for improved efficiency and quality, the refinement of EOHR and wide adoption in dentistry seems to be where the future lies.

KEY TERMS AND DEFINITIONS

Electronic Oral Health Record: An electronic repository of patients oral health related information that contains all personal health information belonging to an individual and is entered and accessed electronically by healthcare providers over the person's lifetime

HIPAA: Health Insurance Portability and Accountability Act (USA), enacted in 1996; protects health insurance coverage for workers and their families when they change or lose their jobs; Provides for maintaining confidentiality of an individual's identifiable health information if it is transmitted by electronic means.

Clinical Decision Systems: Systems representing a conglomeration of clinical knowledge management technologies that support the clinical process to help with differential diagnosis, final diagnosis, investigations, treatment selection and follow up care.

Practice Based Research Network: Teams of practicing dentists who investigate "everyday" issues in the delivery of oral healthcare with greater scientific rigor

Practice Management Software: Software that allows management of all aspects of a clinical practice including patient history, health records, billing etc.

Paperless Dental Office: A dental office where use of paper for record keeping, billing and other official work is eliminated unless absolutely necessary. Such an office keeps all records in electronic format, and also interacts with patients, insurance, specialist and other officials electronically.

This work was previously published in Dental Computing and Applications: Advanced Techniques for Clinical Dentistry, edited by A. Daskalaki, pp. 191-218, copyright 2009 by Medical Information Science Reference (an imprint of IGI Global).

Section II
Development and Design Methodologies

This section provides in-depth coverage of conceptual architectures, frameworks and methodologies related to the design and implementation of health information systems. Throughout these contributions, research fundamentals in the discipline are presented and discussed. From broad examinations to specific discussions on particular frameworks and infrastructures, the research found within this section spans the discipline while also offering detailed, specific discussions. Basic designs, as well as abstract developments, are explained within these chapters, and frameworks for designing successful e-health systems, pervasive healthcare applications, and ICTs for human services are provided.

Chapter 2.1

Patient-Centered E-Health Design

Alejandro Mauro
Hospital Italiano de Buenos Aires, Argentina

Fernán González Bernaldo de Quirós
Hospital Italiano de Buenos Aires, Argentina

ABSTRACT

This chapter introduces a series of techniques and tools useful for developing patient-centered e-health. As information technology (IT) is revolutionizing health care delivery, a wide range of personal health information management tools have become available to the patients. The variety and quality of information delivered by these tools will determine how useful consumers find them. Equally important is how the information is delivered. To create quality e-health, designers must attend to the needs and wants of users by engaging them in the design and testing processes. User-centered design (UCD) is a formal approach to ensuring that new products address the needs, wants, skills, and preferences of the user throughout the tool's development. UCD is a design and evaluation process which pays special attention to the intended users, what they will do with the product, where they will use it, and what features they consider essential. This iterative approach ensures that users' needs and wants are met and ultimately increases the likelihood users will accept the final product. This chapter focuses on UCD methods and techniques, giving examples of how to use them and when.

INTRODUCTION

E-health use by patients is steadily increasing, perhaps due to the patients being empowered by physicians and the health system itself (Andreassen, Trondsen, Kummervold, Gammon, & Hjortdahl, 2006; Baker, Wagner, Singer, & Bundorf, 2003; Coulter, 1997; Eysenbach & Kohler, 2003; Street, 2003). Personal health records, patient portals, and pathology-oriented information are just a few areas of growth in patients' use of e-health. However, to be useful these applications must be easy to use and meet patients' real needs and capabilities. This is a major challenge for the development of new interfaces and systems.

DOI: 10.4018/978-1-60566-016-5.ch002

Designing usable systems is difficult, and designers need effective and accurately-tested tools. Nowadays there are multiple user-centered design (UCD) methods which make system design more efficient and effective. Inquiring, inspection and testing methods are essential when planning a UCD, and although there is plenty of information about the importance of UCD in software development, many development programs fail to comply with key principles. When failing to comply, the software can be difficult to use, and this paves the way to failure. This failure can be observed both in software which is not completely put into use or is rejected due to user dissatisfaction.

When developing interfaces and designing software for medical patients to use, developers must thoroughly understand patients' needs and capabilities. Sometimes patient's needs are difficult to assess. Patients can become seriously frightened or anxious when diagnosed with a disease and they may hide important information. Lack of health literacy is another factor that makes it difficult to assess patients' needs. In any case, patients are known to have *unrecognized needs and capabilities* which are important to be considered when developing e-health. The concept of patient-centered design is intended to identify patients' needs and capabilities through tailored application of UCD principles to the context of e-health.

UCD is a highly structured, comprehensive software development methodology that is driven by clearly specified, task-oriented business objectives, and recognition of user needs, limitations and preferences (Mauro, 2000). Information collected using UCD analysis is scientifically applied in the design, testing, and implementation of products and services. When rigorously applied, a UCD approach meets both user needs and the business objectives of the sponsoring organization, such as managing risks (Siegel, 2003). UCD can make the difference between success and failure of software applications and can contribute to innovation by revealing unsuspected opportunities for innovative design, including aspects that would not emerge in other forms of idea generation.

APPLYING UCD TO DESIGN OF PATIENT-CENTERED E-HEALTH

UCD is a design philosophy and a process where the user is the design cornerstone, and his/her limitations, hopes and objectives are given extensive attention at each stage of the design process. UCD seeks to answer questions about users and their tasks and goals, and then uses those findings to drive development and design (Katz-Haas, 1998). The chief difference from other interface design philosophies is that user-centered design tries to optimize the user interface around what people may need and what their capabilities are in order to fulfill a task, rather than force them to adapt to designers' preferences.

There are countless methods, tools and techniques intended to help designers evaluate a target product or service (for brevity these are referred to hereafter simply as *products*) from the point of view of the user. By choosing an appropriate method, it is possible to learn in just a few hours how to improve usability of a product (Mauro, 2000). In this chapter we profile several useful tools and methods which will help an e-health design project to comply with the key principles of UCD. An exemplar set of UCD principles (UsabilityNet, 2006) is shown in Table 1.

Inquiring Research Methods

Understanding What Users Want

The proper identification of what users need and what the product should offer are essential at an early stage. Inquiring methods generally gather data in an open-ended way through interviews or observation, and these data are then progressively interpreted by the investigators.

Table 1. User-Centered Design Principles (UsabilityNet, 2006)

Designing for the users and their tasks
Being consistent
Using simple and natural dialogue
Reducing unnecessary mental effort by the user
Providing adequate feedback
Providing adequate navigation mechanisms
Letting the user drive
Presenting information clearly
Being helpful
Reducing errors

Several types of methods are typically used in combination. A general classification of these methods can be summarized as follows (Friedman & Wyatt, 2006).

- ***Observation methods***: When using these methods investigators immerse themselves in the domain under study. The investigator may act purely as a detached observer and rely on multiple "informants" as a source of information, or he/she can be a participant-observer by becoming to some degree a member of the work team, empowering him/her with a more vivid impression of the living or working environment under study.
- ***Interviewing methods***: These are conducted as *formal interviews*, where both the investigator and the interviewee are aware that the answers to questions are being recorded, or *informal interviews*, occurring as spontaneous discussions between the investigators and the observational subjects. Formal interviews vary in their degree of structure. At one extreme is the unstructured interview where there are no predetermined questions, and between the extremes is the semi-structured interview where the investigator specifies in advance a set of topics he/she would like to address, but is flexible to the order in the pre-specified list (field interview). At the other extreme is the structured interview with a set of questions which are presented to each participant using the same words and in the same order (questionnaires).
- ***Document analysis /artifact analysis***: This activity consists of analyzing documents and other artifacts produced by the organized human activity in a given place. These can include written notes and forms given to patients by their physicians or administrative personnel and accesses to the patient's Personal health record (PHR). Automatically-generated user log files are key artifacts in this analysis. Data from these records are often quantifiable, and can be important for subsequent analysis.

Specific inquiring methods are describe below.

Contextual Inquiry

The *contextual inquiry* is conducted through interviews and observation in the field and is based upon three fundamental principles: understanding the context in which the study object is used, knowing that the user is one of the most important parts of the design process, and having a precise focus or study object (Hom, 1996). Goals for the contextual inquiry should be established in advance, and include development of interview questions and observation tasks to achieve each goal. The overriding goal of contextual inquiry is to understand how and why something is done or why something is not done (Beyer & Holtzblatt, 1998). During interviews, the interviewer must create a bond with the interviewee and ask questions aimed toward creating a dialogue where the interviewee can express not only experiences or opinions, but also describe his/her involvement in the problem. When the interview is over, a careful analysis of the interview transcript should be conducted to assess if the goals have been achieved and to determine if there are further questions that need to be asked in subsequent visits.

Contextual inquiry is one of the best methods to understand issues from the patient's perspective. Many times the environment in which people use a system influences their use of a product. For example, if patients ordinarily access the Internet from a cybercafé they may prefer to have their PHR display health related information displayed in a more discreet form than if they are working at their home. Contextual inquiry is also very useful when researchers do not have a clear understanding of the domain being studied, such as in the early stages of development. Because much of the information obtained through contextual inquiry is subjective, it is important to confirm the results using other methods which are more objective in nature.

Method in practice: Let's consider that you are planning to change the procedure in which patients confirm their arrival at a large ambulatory patient practice. Contextual inquiry can be applied to initially assess the needs of people involved in the process. The patients can be requested to think about what would make their waiting time easier; and what design changes would help their waiting and would avoid the queuing. In this way they become partners in the design process and their opinion will be carefully analyzed.The researcher should stay focused on one thing at the time: in this specific case, the focus would be only on reception and waiting times. It was possible for the Hospital Italiano de Buenos Aires to improve on this process by developing a system for the patients to confirm their arrival at a kiosk, therefore avoiding the need for a hospital employee to be present and increasing the rate at which patients are checked in (Plazzotta, Otero, Campos, Pedernera, Navas, Martínez, Plazzotta, et al., 2005).

Ethnographic Study / Field Observation

Ethnography (from the Greek ethnos (εθνος), "people", and grapho (γραφω), "I write") is a method of anthropological investigation in which data is gathered in the field with the members of a given community acting as informants. Analysis of this data is used to provide a compact and detailed description of their customs, beliefs, myths, genealogies and history. Similar to the contextual inquiry, ethnographic study identifies how a product is personally experienced and used by each individual within his/her cultural and organizational contexts. Observing people in the field is often one of the best ways to determine their needs and capabilities, as observation can illuminate the concepts and premises of what people understand unconsciously but may not be able to articulate. Another aspect of field observation is informally interviewing people about the way they perform tasks and the way they use the product.

Ethnographic study of patients in a hospital has been used to evaluate the various hospital domains, including waiting rooms, blood laboratory rooms, information boards, patient's wards and consulting rooms (Schultz, Bottorff, & Johnson, 2006). As an alternative, Kaufman and colleagues have applied ethnographic study methods remotely, by video-recording patients using a diabetes management software from their homes (Kaufman, Patel, Hilliman, Morin, Pevzner, Weinstock, et al., 2003).

The idea behind ethnographic study methods is to understand how tasks are done and how products are used within actual contexts of use, including aspects which the people under study may not be aware of. It is advisable to apply this method in the early stages of development, when it is most important to understand the aspects related to the use of a product rather than other characteristics of the product.

Method in practice: Continuing with the scenario begun in the initial assessment, investigators should consider the conditions in which patients arrival is checked, whether there is a receptionist, if there is a long waiting queue to confirm their arrival, if patients have to repeat their name or last name more than once in spite of having shown their identity card, or if the queues are the result of receptionists doing other things apart from checking on patient's arrival. Every detail of the place where the patients are asked to confirm their arrival should be evaluated. It is essential not only to study the desk to which the patients come to and the number of patients standing in the queues, but also the practice room itself. Every detail should be carefully assessed, including the room's tidiness, the colors of the room and the noise levels.

Focus Groups

Focus groups are carefully planned group discussions conducted by trained moderators. A small number of questions, developed in advance, are used to generate in-depth consideration of a narrowly defined topic. By using this method a direct interaction with participants is established as they are asked to express their opinions about the topic, for example, relating to interface functionality or design (Pope & Mays, 2006).

This method involves identifying questions through which it will be possible to gather relevant information about a topic or a product. It is important to frame questions as widely as possible in order to facilitate discussion in which subsequent interaction among the participants can bring out varied and thoughtful ideas, such as identifying problems which might arise when using the product.

This method can be used at any stage of system development, as long as questions are appropriate to the context. This can begin at very early stages of development, when the product requirements are still being designed, and continue through the time following product release, where the objective may be to test customer satisfaction (Kinzie, Cohn, Julian, & Knaus, 2002).

Method in practice: Let's imagine that the manager of a medical practice notices that the patients are becoming annoyed by the delays they have encountered while waiting for an appointment. He therefore decides to interview some of the patients in the waiting room to tackle this problem. He then analyzes what steps the patients take before seeing the physician in order to understand what drawbacks there are in the system. Next he organizes a focus group that includes participants who represent those involved in the situation (patients, receptionists, physicians among others) and moderates a discussion on delays in order to assess whether his observations were correct and complete and to identify potential solutions to the problem.

Questionnaire Surveys

The two terms *questionnaire* and *survey* are often confused, and some people consider surveys as a synonym for questionnaires. However this is not so. The survey is a process of investigation across a substantial population, whereas the questionnaires is a specific tool that can be used to implement the survey. Thus, the term *questionnaire survey* indicates a survey investigation conducted through the use of a questionnaire, versus other methods, such as an interview survey.

The questionnaire survey is exceptionally useful to efficiently obtain information from large numbers of individuals. This method consists of a set of questions on the subject of study which can be administered on paper or electronically.

Surveys are inherently interactive. The function of a surveyor is to lead the respondent in such a way to bring light to all the topics or ideas the surveyor wants to learn about. Design of the questions is the most important step of the survey development process. The questions should be as open and clear as possible, but this can be difficult for novices to achieve. It is helpful to consult a focused guide to creating and evaluating survey questions, such as (Rea & Parker, 2005).

It is possible to make a quantitative analysis with the results from the questionnaire survey through interpretation of charts and graphs or use of statistical analysis software. The last part of survey analysis is interpretation of the patterns and trends that arise in the results.

Method in practice: Having improved the standards by which patients confirm their arrival through a kiosk, it might be necessary afterwards to use a questionnaire to assess level of satisfaction among a larger sample of the people involved in this process. Questionnaires are a very efficient mechanism for administering this type of assessment. One example is the QUIS, a validated questionnaire for assessing users' satisfaction with interfaces that was designed at the University of Maryland at College Park. The QUIS has been widely used and can help developers to estimate the impact the new product will have (Chin, Diehl, & Norman, 1988).

Other Inquiring Methods

Other methods of inquiry may be useful at various stages of the process. Among these are *screen snapshots,* where a prototype of a product is tested (usually at mid-stage of development) and screen snapshots are taken to document users' actions at specific points, and *journaled sessions,* where journaling software is used to record user's actions, including cursor movements, mouse clicks, and other interface interactions. Journaling software can also provide dialogue boxes in which the user types in comments or observations while performing the tasks. Both approaches can provide valuable information about the usability of the software and are relatively inexpensive to implement. Internet development offers the opportunity to expand the reach of journaling software, lowering costs further and allowing large-scale product tests.

Inspection Design Methods What the Analyst Can See

Usability inspection is the generic name for a set of methods that are based on having analysts inspect a user interface. A *usability analyst* is a trained professional specialized in applying usability methods (including UCD) to ensure the ease-of-use and positive user-experience of products. Typically, usability inspection is aimed at finding usability problems in the design, with some methods also addressing specific issues such as the severity of the usability problems and the overall usability of an entire system. Inspection methods are based on the concept of task analysis, where the evaluation takes place within information processing tasks. However, inspection methods also lend themselves to the review of user interface specifications that have not necessarily been implemented yet, meaning that inspection can be performed early in the usability engineering lifecycle (Nielsen & Mack, 1994).

There are several methods of inspection, but for practical reasons this chapter focuses on two that are particularly well-suited for evaluating interfaces for patients. These are the heuristic evaluation and cognitive walkthrough methods.

Heuristic Evaluation

Heuristic evaluation is an informal method of inspection involving usability experts who judge whether each dialogue element or task follows established usability and design heuristics, i.e., rules that are intended to be applied flexibly rather than followed rigidly (Nielsen & Mack, 1994). The analyst inspects the user interface system, often by carrying out a specific task while using the system, and notes any violations of a predefined set of heuristics. It is essential, therefore, that analysts are well trained. They must clearly understand the heuristics and also be experienced in applying them across a range of situations. Nielsen and Landauer (1993) observe that most usability problems can be identified if there are between three to five analysts working on the project.

Each analyst should check the interface at least twice, observing the function of each of its elements carefully and evaluating its design, location and implementation according to the heuristic list. Analysts independently evaluate the user interface and generate a list of heuristic violations. These are then combined into a joint list of all violations reported by all the analysts. The results of the heuristic evaluation can be summarized and presented to the design team along with recommendations for improvement.

Nielsen & Mack (1994) provide the following ten heuristics as guidelines for user interface design.

1. **Visibility of system status.** Keep users informed about what is going on, through appropriate feedback in a timely fashion.
2. **Match between system and the real world.** Speak the users' language, using words, phrases and concepts familiar to the user, rather than system-oriented terms. Follow real-world conventions.
3. **User control and freedom.** Users need a clearly marked "emergency exit" to escape from any unwanted state. Support undo and redo. A goal is for the user to feel he/she is in control of the system.
4. **Consistency and standards.** Use standard conventions for all aspects of the interaction, including navigation and carrying out basic operations. Adopt all conventions of the operating system or platform.
5. **Error prevention.** Where possible, avoid problems before they can occur. Eliminate error-prone conditions or check for them and present users with a confirmation option before they commit to the action.
6. **Recognition rather than recall.** Minimize the user's memory load by making objects, actions, and options visible. Make all information that is not visible easy to find and retrieve.
7. **Flexibility and efficiency of use.** Provide mechanisms to increase efficiency by experienced users, such as control key functions and shortcuts, and to support novice users in using the product and learning use processes.
8. **Aesthetic and minimalist design:** Remove all extraneous information from dialogs with users. Avoid distractions.
9. **Help users recognize, diagnose, and recover from errors**: Error messages should be expressed in plain language that clearly indicates what the problem is and suggests solutions where this is practical.
10. **Help and documentation**: Sources for help should be indicated clearly. Where documentation is included, it should be easy to search, be focused on the user's task, list concrete steps to be carried out, and not be excessively large.

The heuristic evaluation can be used at any stage of development, but it is especially practical at the early stages, when the product is not yet ready to be shown to non-expert users. It is also possible to provide paper models or even design details to the trained analysts and to thereby detect many usability problems before software development begins.

Method in practice: Carroll and his collaborators used heuristic evaluation to inspect a clinical decision support system (CDSS). They were able to make changes in the interfaces and develop a visual thermometer in an Electronic Health Record which allowed both patients and clinicians to readily identify absolute cardiovascular risk factors (Carroll, Marsden, Soden, Naylor, New, & Dornan, 2002).

Cognitive Walkthrough

The cognitive walkthrough is a method used to identify usability issues in software or web sites by focusing on how easy it is for new users to accomplish tasks within the system. This method is based on the fact that users typically prefer to learn a system by using it rather than studying a manual. Analysts construct task scenarios and then role-play the part of a user engaged in "walking through" the interface and note which user actions are needed to carry out the steps, what goals/subgoals the users would have and what potential problems might be encountered at each step. The objective of the cognitive walkthrough is to uncover possible errors in design that would interfere with user's ability to learn how to use the system and carry out tasks. Analysts complete a series of representative tasks from which an encompassing report of potential issues is compiled and used to guide improvements to the interface.

Cognitive walkthrough has been applied to the study of usability and learnability of several distinct medical information technologies (Carroll et al., 2002; Kushniruk, Kaufman, Patel, Levesque, & Lottin, 1996; Patel & Kaufman, 1998). For example, Kaufman and collaborators used this method to improve a home-based telemedicine system for a diabetic population (Kaufman et al., 2003). Cognitive walkthroughs identified aspects of the interface that were sub-optimal or impeded the performance of certain tasks and patient-related factors that constituted barriers to productive use, such as numeracy and psychomotor skills.

The cognitive walkthrough can be effective in identifying potential problems which then can be evaluated via usability testing methods, which involve testing with representative users in real situational contexts. These are described in a subsequent section of the chapter.

Method in practice: Cognitive walkthroughs help to identify whether a product meets the user's goals and can be used efficiently to accomplish the purpose of each task. This can be seen in a system of geographical location for patients at a hospital kiosk, where a patient can ascertain, for example, the location of the laboratory where she has to get her blood tested. The patient's goal will be to find, among other tasks, where exactly the laboratory is located, what part of the building or on which floor it is and which lift she needs to take to get there. The various tasks the patient should perform will be first to identify the correct key she must press to start looking for the place she wants to reach, and then to find the laboratory in an interactive map. When analysts "walk through" the interface, it is important to identify if the patient will have difficulties in performing the tasks, for example, because the keys are not easily seen or the labels are not clear or she is distracted by other options.

Other Inspection Methods

Other helpful inspection methods include *formal usability inspections*, developed by IBM and used, among others, to identify bugs in programming, *standard inspections* which ensure compliance with industry standards and *guideline checklists* which can help ensure that usability principles will be considered in a design.

Usability Testing Methods

Usability testing refers to the evaluation of information systems by testing with representatives of the target user population as they perform representative tasks using the product in a particular context, such as patients using an e-health application to schedule an appointment. Usability testing is a means for measuring how well people can use a product for its intended purpose(s). The aim is to observe people using the product in an as realistic a setting as possible, in order to discover errors and identify areas that need improvement. Researchers report that 80% of the usability problems can be detected through these usability testing of as few as eight to ten representative subjects (Nielsen, 1993; Rubin & Hudson, 1994).

Kushniruk & Patel (2004) have defined nine phases for applying usability testing to the evaluation of clinical information systems that must be followed in order to ensure that the intended users of a clinical system, including patients, physicians, and nurses, can carry out the tasks efficiently and effectively. These phases are summarized as follows.

The **first phase** is the identification of the evaluation objectives, which may vary considerably according to the product being tested and the target users. The **second phase** is the sample selection; the subjects should be *representative* of end users of the system under study, for example, chronic disease patients in the case of a Pathology portal. It also is important to apply criteria for classifying subjects in terms of their prior computer experience. **Phase three** is the selection of representative tasks and contexts for analysis to adequately represent real scenarios. The tasks for analysis should be carefully chosen if the testing is in a usability laboratory; use of a real life scenario (naturalistic study) increases the ecological validity of the test. For example, Kaufman used a video-analytic approach to study how patients used home-care software in their own homes (Kaufman et al., 2003). The **fourth phase** is the selection of background questionnaires that can be administered either before or after the usability testing. These questionnaires are used to obtain historical information about the participants that will help evaluators to understand their behavior and performance during the test. The **fifth phase** is the selection of the evaluation environment, which can be either a usability laboratory with controlled experimental conditions, or the place where the user works or lives or uses the system, for example, selections addressed by Kushniruk and collaborators include the waiting room for testing a scheduling kiosk system for patients, automated interviewing and automated triggering questionnaires in a web-based system (Kushniruk, Patel, Patel, & Cimino, 2001). The **sixth phase** is data collection from video and audio recording, VCR recordings of the video screens or people faces were commonly used, but now screen recording tends to be software based. There are several software systems that allow recording the screens, mouse movements and clicks, as well as audio. Video recording provides a remarkably rich and vivid reproduction of an encounter. It also provides a permanent record of an event and supports multiple viewings and re-analysis of data (Jordan & Henderson, 1995). The **seventh phase** is the analysis of the video and audio files. The transformation of data into recommendations involves qualitative and quantitative analysis of the video-based usability data. The **eighth phase** is the interpretation of the findings, where the collected data are compiled and summarized in a number of aspects of a system (task accuracy, user preference data, time to completion of task, frequency and classes of problems encountered). The **ninth phase** is the iterative input into design, where the system is improved on the basis of the problems that usability testing identifies and is then re-tested to determine how the changes affect the system's usability.

Think-Aloud Protocol

The think-aloud protocol is one of the most useful and simple evaluation methods to emerge from the study of cognitive science. Subjects are instructed to "think aloud" (i.e., verbalize their thoughts) as they perform a set of specified tasks. They are asked to verbalize whatever they are looking at, thinking, doing, and feeling, as they go about their task (Lewis & Rieman, 1994). It is useful to record user actions during this process to support detailed analysis of actions, such as mouse clicks and menu selections in conjunction with audio recording of subjects verbalizations (Kushniruk, Patel, Cimino, & Barrows, 1996).

The think-aloud protocol allows the researcher to identify how the user approaches and performs tasks using the interface (Kaplan, 2003). Analyzing this information, it is possible for the researcher to better understand the user's mental model of his/her interaction with the product. There are other benefits as well, such as the ability to repeat tasks that are problematic or to introduce changes into the terminology used, as the user typically will express clearly what exact instructions he/she would have needed to have at hand when performing the task. (Johnson, Johnson, & Zhang, 2000). The think-aloud protocol is effective at all stages of development once a prototype is available for use, however, repeated testing with this method requires availability of new users in order to be effective.

Method in practice: Let's take the case of a researcher developing an application for patients to see laboratory results from their homes. He should keep in mind that laboratory reports are often difficult for patients to understand. Performing a think-aloud protocol would be a useful tool for identifying interface problems, such as visual display of laboratory numbers and test history results, the order in which buttons are displayed, or the terminology that is used.

Question-Asking Protocol

The *question asking protocol* goes beyond the think-aloud protocol by posing questions to users (Lindgaard, 1994). As with the think-aloud protocol, in the question asking protocol the user is shown a prototype or a final version of an interface and is requested to perform certain tasks while verbalizing his/her thoughts. The observer will shadow (stay behind the user watching the user's movements) and ask direct questions at specific stages to obtain more information on a given item or action. Both the readiness (ease-of-use) or drawbacks (difficulty-of-use) the user reports can be used to identify which parts of the interface are clear and which parts need to be improved.

Method in practice: While developing a health information web page, the researcher may wish to test whether an item of information is easily found. He will ask a patient to look for information about a flu vaccine. The patient will reply according to what she can see or according to what she believes should be the right place to find this information. The patient may also answer according to her experience of other interfaces and these responses will provide insights into her mental model of the product in addition to her ongoing verbalization.

Prototyping Methods

Prototyping is the process of quickly putting together a working model (a prototype) in order to test various aspects of a design, illustrate ideas or features and gather early user feedback. It allows testing to begin early in the design process. When the prototype is sufficiently refined and meets design goals relating, for example, to functionality, robustness, and manufacturability, the product is ready for production.

There are various methods in prototyping, ranging from working with a sheet of paper and a pencil (paper prototyping), to developing working but not fully capable computer applications (high-fidelity prototyping). Prototyping can be used at any time in during product development. At the early stages it can be useful to study the needs and desires of users, at a midstage it will provide information about the development of the product and how usable it is, and at later stages it will provide the necessary information to make alterations in areas which need to be refined.

Paper Prototypes

Paper prototyping is a method that lets the designer of a project mock up, test, and refine a design on paper before writing program code. It allows informal usability tests with real users to be undertaken at early stages of product development. Users can also participate in developing paper prototypes, as is detailed in a case study presented subsequently in the chapter.

A number of benefits have been identified in using paper prototypes to develop health care applications (Marill, Miller, & Kitendaugh, 2006; Plovnick & Zeng, 2004). This include the following:

1. **Paper prototypes make the researcher focus on keeping the interface simple**. Various approaches to the design of an interface can be tested with several users to see which one is the preferred.
2. **They are time savers**. Creating paper prototypes requires relatively less effort than coding, so paper prototypes can be easily abandoned if they are not working.
3. **They allow the researcher to start at an unsure stage**. Because paper prototypes have no code, they free the designer from the necessity of building a working platform for the interface. The designer can start with the parts he/she has the most questions about, rather than those that are most stable.
4. **They allow the testing of new terminology at early stages of development**. This is an important feature of paper prototypes in health related designs as many health systems and web pages face problems in presenting terminology that patients can understand.

The aim of this section is to show how it is possible to start with a simple method such as paper prototyping and produce useful improvements in usability. The following case study reports an example of using paper prototyping in the context of designing e-health software applications from a patient-centered perspective.

Case Study: Paper Prototyping in Developing a Personal Health Record (PHR)

The Hospital Italiano de Buenos Aires Experience

Since 1998, The Hospital Italiano de Buenos Aires has gradually implemented a full scale Health Information System (HIS), including ambulatory Electronic Medical Record (EMR), inpatient discharge summaries, administrative systems, scheduling systems, inpatient tracking systems, pharmacy systems and complementary studies report and visualization. It is currently working on the development of a Personal health record (PHR) to support patients' access to various functionalities and services from HIS. For this purpose, patients of the HMO were invited to participate in the activity "Internet Use: can it improve your health care?" by means of a notice published on the hospital's website and in a newsletter sent monthly by post.

Two activities were carried out in two hours. In a brief introduction it was explained to the par-

Table 2. Characteristics of study respondents

	All (n=17)
Age in years (range)	59.88 (34-81)
Female gender	11 (64.7%)
University level of study	11 (64.7%)
Internet access	15 (88.2%)
Broadband connection	13 (86.6%)
Internet health information*	12 (70.6%)

* Used Internet in the past to access health related information

ticipants what a PHR is. Then they were divided into 4 groups so that over the next 25 minutes they could discuss and write down what services or information they thought a PHR should offer. Table 2 shows participants' characteristics, based on a survey they answered at the end of the activities.

Even though the study participants were patients and potential users of the system being developed, during the session they were not in a real context of use. For this reason, the first activity used a focus group technique rather than an inquiring method, such as ethnographic study. However, their discussion included experiences and impressions of the context and their personal relationships, which offered relevant information and generated ideas. Each focus group wrote down notes about what they believed were the most important aspects a PHR should offer. At the end of the activity each of the groups shared its results with the other groups, while one investigator wrote down the information on a whiteboard.

To carry out the second activity, each group was given a photocopied sheet of paper in the form of a monitor screen and design materials (scissors, markers, papers, cardboard, and stickers). Participants were instructed to create a paper prototype of a web portal which would provide the services and information listed in the previous activity. When they finished, each group presented its prototype, explaining each of the components chosen and the function and/or information which each component should offer. An example is shown in Figure 1.

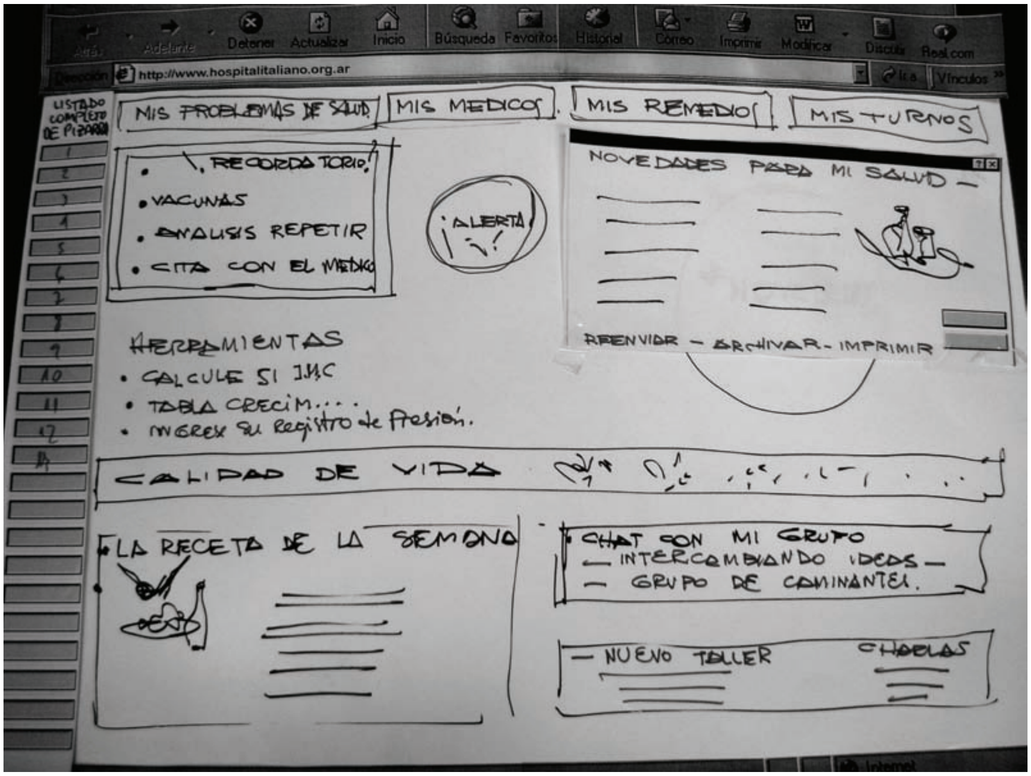
During both activities one investigator acted as moderator while another took down notes. To ensure the quality of the record, the two hours were filmed and recorded. At the end of the activities, each patient completed an anonymous questionnaire survey for us to get to know details of gender, age, educational level, access to Internet, and the perceived usefulness of the patient portal components. The information gathered through the activities was useful in:

- **Identifying users' needs and desires for a personal health record.** Focus groups, questionnaires and video-recording analysis were useful methods for gathering this information. These are some examples of participants' needs and desires that were identified:

"...we give priority to basic pathology" "we would like all the information about diabetes to be together" "in reality, what we want is that the information should be integrated" [Problem-oriented information need]

"I don't want just to know what my clinical physician thinks; I want to know what the neurologist says, the opinion of the pharmacist, the nurse's recommendations." [Integrated information]

Figure 1. Example Paper Prototype



- **Identifying user's motivations and fears.** Focus group discussion revealed several motivations and fears on the part of participants which may not be observable otherwise.

"I am afraid that with so much technology we'll lose contact with the doctor… It would be important to have access to the e-mails of the different doctors who are concerned with my health" [New ways of communication]

"I would also like to be have access to a Chat room which allowed me a more spontaneous consultation in case some drug made me feel unwell" [New ways of communication]

"We need a patients' forum, a network where we feel represented, a space where we don't feel unprotected" [New ways of communication]

"I would like to be able to access my clinical history, and that the doctors should have access to my portal, but on condition that I should be able to decide which doctor sees what, because there are things I talk about with one doctor while with another I feel embarrassed" [Access to Clinical Histories, and Data Privacy]

- **Identifying user's ideal visual display of the interface**. Paper prototyping allowed participants to contribute to PHR design.

"We would like certain criteria to be complied with for the navigation of the portal, for example that it should be easy to change the size of the letters for those who have sight difficulties" [Interface Flexibility]

"We would like a section of favorites links" "that every illness should have links to pages with information that could be useful, associations, or that would put us in contact with groups of patients who suffer from the same pathology" [Access to Information Sources]

"I would like the system to warn me in case of my forgetting to vaccinate my children by giving me an alert in red" [Warnings in red]

- Identifying user's wish and desired terminology to be seen on the screen.

"I would like to be able to understand the medical terms used. I would expect the PHR to use every day language" "Seeing my medical record from my physician's monitor screen I had to ask him what Leiomyoma was. He told me that it were the uterine fibroids I had been complaining about for a long time" [Terminology issue]

By using UCD methods the developers were able to obtain sound information about patient's needs and desires and at the same time learn about the patient's preferred methods of information display. The use of prototyping methods are highly relevant to e-health developers, as these will provide information early in design stages when it is inexpensive and quick to initiate product changes.

CONCLUSION

UCD methods can be applied effectively with patients, even to the point of allowing patients the opportunity to contribute to product design. The resulting *patient centered design* is an essential step when undertaking development of e-health that is intended to meet patients' needs and address their capabilities. However it is necessary to keep in mind that there are motives, fears, and challenges which will influence results of interaction with patients. The methods described in this chapter can be very useful in overcoming these challenges, especially when used in combination as in the case study we presented.

Chapter 2.2

Informational Priorities in Health Information System

Malgorzata Kisilowska
University of Warsaw, Poland

ABSTRACT

This chapter presents the model of a wide health information system, designed in accordance with information science theories and requirements. The model, based on modern ICT solutions, reflects the idea of information processes (collection, indexing, transfer) as seen in an information science perspective. It concentrates on optimal answering information needs of different categories of patrons, including adaptation of information-retrieval tools to their competencies. The author discusses different types of information indispensable in healthcare practice, analyzes methods of knowledge representation in health information system, proposes methodology of surveying information needs of health professionals, and describes challenges of linguistic tools used in information systems. The author hopes that such a model will emphasis the need of cooperation among ICT, health, and information professionals in designing information structures and processes.

DOI: 10.4018/978-1-60566-356-2.ch047

INTRODUCTION

Managing specialist information within one of human spheres of activity requires today very efficient procedures, structures, and qualifications. However, functionality of information management may not clearly refer to complicated networks of tools, resources, and relations. As it would be proposed below, its efficiency may depend on such factors of vital importance like simplicity and precision in searching and finding pertinent information. These can be assured not only by using modern ICT tools, but also a set of knowledge management tasks and procedures, like: architecture of information, optimizing information transfer, indexing, studying users' needs and behaviours.

Information-related research is indispensable in terms of a broad and diversified range of healthcare management issues. Information architecture and knowledge management tools and rules shall influence the architecture of health-related software. The model proposed below, if applied into ICT solutions, works for their compatibility, effectiveness, and user-friendly organisation, for the benefit of both authors and users of applications. It's specific value relies on including a user as a vital part of the health information system, especially in the light of current management surveys, indicating human factor as the most sensitive, changeable, and unpredictable element. User's participation in such a structure reflects it's role, enables system's sensitivity and learning new behaviours, information needs, and actually better management of information and knowledge.

Modelling a wide health information system (WHIS) shall refer to a few assumptions. Specifics of designing information systems in information science consists of categorizing and prioritizing information, as a main element of such a structure, holistic approach to the users, emphasizing permanent surveying of their information needs, and adapting services to the results of such a survey.

Conceptual framework includes:

- Aims and goals of a wide health information system.
- Participants of a system: units realizing information processes and the users.
- Range of their activity, categories of information they are interested in.
- Architecture – relationships among elements and participants, communication channels either among them or with the users.
- Linguistic tools for information processing.

The WHIS aims in creation of an information environment for a health domain, answering information needs of different (individual and legal) entities. Types of answers, methods of WHIS usage depend on their authorization referred to profiles of activity (medicine doctors, nurses, patients, managers, etc.). Differentiation and amount of data result in the necessity of shared responsibility and resources, for examples in distributed knowledge repositories.

Information in WHIS is indispensable for realization of specialized tasks on different levels – micro (individual both professional and private users), mezzo (primary health care units), and macro (entities responsible for resort policy, supervising national and international cooperation, like the World Health Organization's projects).

Optimal functioning of a system requires common decisions concerning shared responsibility and tasks, unified metadata, access rules, control of resources and quality-assurance tools.

WHIS USERS

Health information users can be grouped into three main categories: individual professionals, institutions, and patients. The first category consists usually of: medical doctors, dentists, pharmacists, physiotherapists, nursing, midwives, diagnosticians, and specialists in different tests, like ECG, x-ray, etc. Their representatives can work in direct care, administration, education and/or research, nevertheless their tasks stay always linked to healthcare. The users can be also seen as: potential, probable (having access to information), real/ factual (using information), and beneficiaries, getting benefits from having knowledge (Flakiewicz, 2002).

Institutions employing individual professionals can also belong to the users, as very often they either are original source of information, or answer information needs of health professionals and patients. The type and precision of required data depend on their place in a domain hierarchy, as well as a profile of activity (administrative, supervisory, research, education or practice). Differentiation of institutions' tasks and goals results also in diversified perception and usage of information for "institutional" goals. Such an information can have either narrow (medical and/or financial documentation and statistics) or broad (research, policy, national and international strategies) range. Institutional users of health information include: a ministry, national statistical office, medical academies and other education providers, health professions' chambers, research organizations and institutes, trade unions, and healthcare settings. They need and use information for organizing, ordering, and supervising execution of tasks. However, experience of information transfer is obviously related to individual decisions and practice.

The patients can be both real and potential. These first usually seek and use information concerning their health status. In general, their perception of information is often intuitional and popular, very subjective. They are quite inconsistent regarding types and forms of information given to health professionals, depending on knowledge and health status, previous experiences, reactions on therapy, attitude towards diagnosis and prognosis, health information literacy. Their information needs can also be very different: from detailed information about symptoms and therapy perspective, to very general data, for those avoiding bad news. These needs are closely related to previous experiences and knowledge, determining both range and form of data being searched. From the other side – there is also a problem of getting information from the patients, and successful interpretation of – sometimes very few and incomplete – data.

Potential patients are usually addressees of health promotion, according to international (like WHO "Health for All") and national (National Health Programmes) strategies, recommending development of public health awareness, to motivate people to improve their lifestyles and take care for their health. Such a type of information shall also be adapted to health information competencies of the users, both in contents and forms.

Analysis of the users indicates three main categories of information needed: as a unit of professional knowledge, as a tool in healthcare practice, and as a subject of relations with external environment, in particular with the patients.

Information as a unit of professional knowledge emerges firstly during education (and further lifelong learning). Updating knowledge and finding evidence are now obligatory for all health professionals, regarding their influence on life and health of the individuals. This can be either theoretical or practical information. Research information can be not only found and accepted, but also created actively, in the result of own studies and practice.

Information as a tool of professional practice in fact consists of two roles: a unit of professional knowledge, and a unit of information from and about the users/ patients. A health professional – depending on his/her position – using this information can formulate a diagnosis, present tests results, organize health services, etc. Such a "new knowledge" is then passed to a patient and/or the health team colleagues (as statements, consultations, orders, prescriptions, etc.).

Information used in research and practice is diversified, i.e. not only related to medicine, nursing, etc. Each user needs also legal, financial, organizational, or administrative information for his/her tasks. It is usually taken from adequate institutions and organizations external to a healthcare sector, in a process of communication with an environment. Health promotion is also a type of external contacts, as information for the public (or its parts, like risk groups) concerning health risks, methods of prevention, etc.

Contact with the individuals (patients) can be defined as a particular type of information exchange. In such a relation a healthcare provider tries to get knowledge about patient's health status or problems, and then a consent for therapy. In response – he/she presents a diagnosis, therapy plan, prognosis, and self-care instructions (diet, rehabilitation). It should be remembered, that information exchange between a healthcare provider and a patient is a communication process depending mostly on psychological, social, and cultural background of the participants.

Surveying and Answering Information Needs

Appropriateness of information systems' functioning depends mainly on the users satisfaction. Regarding that, surveying their information needs belongs to their basic functions, to optimize offered sources and services. Such a survey requires definition of its range, methods and techniques of data collection and processing.

The Range of Information Needs Survey

Surveying information needs shall cover all their meritorious and formal features, to get knowledge about present user's characteristic, as well as well possibilities of forecasting his/her information behaviours.

It requires collection of data concerning (Nicholas, 2000; Nicholas, Huntington, Jamali & Williams, 2007):

- Needs' range (what kind of information are being searched), according to accepted criteria.
- Quality of data (categorisation of sources, their authority, etc.)
- Scopes (chronological, geographical, language, formal)
- Goals (for what information is collected).
- Acceptable waiting time for information, as well as time for usage of a source (or: being logged to a service).
- Quantity (number of answers received vs. number of visited websites and downloaded files), also number of visits (movement in a network).
- Processing level (data forms and formats)
- A need of privacy concerning identity and range of searching
- Frequency (and/or regularity) of needs, and in consequence retrieval activity
- Methods of usage of information gained.
- Level of information indispensability
- Changes in meritorious and information competencies of the users (development of health information literacy)
- Methods of communication with information retrieval tools (accepted terminology, building retrieval instructions, etc.).

The features listed above make only a part of those characterizing information needs. Obviously, their significance differs according to a WHIS range.

For the needs of modelling a health information system, information needs of three types of the users can be surveyed: managers, providers, and patients.

Referring to specifics of the health domain, developers and administrators of WHIS have to regard particularly dependence between data quality and retrieval tools (privacy) vs. their usage for the needs of health care practice, and further maintenance and/or improvement of quality of life of persons, groups, and societies. This dependence influences also the range and tools to be used in a study itself.

Of course, individual features of information needs can be studied with different methods and techniques. (See Table 1)

Methods and Techniques of Data Collection

There are the following methods of surveying information needs:

- Inventorying, covering existing information resources and flows regarding their usefulness for the users.
- Interviews (group, individual, direct, telephone, etc.), enabling collection of subjective data, as well as new, unexpected information given by the interviewees
- Questionnaires, offering knowledge about subjective users' perceptions of their own information needs.

Table 1. Example of a survey of information needs for optimization of WHIS regarding the users' satisfaction. Source: own study.

Study subject	**Aim of study, results used for**	**Frequency of data analysis**
Number of visits	Controlling movement in portals in regard to the users of different authorization	monthly
Range and scopes of questions	Information needs according to different range criteria Modification of databases and their content Organization of access to data (verification of links, improvement of hypertext tools) Monitoring changes in information needs	weekly
Terms and structure of questions	Health information competencies of the users Courses, instructions, manuals, help Development of ontologies Optimizing retrieval tools (information-retrieval languages)	weekly, permanent actualization of a dictionary (index)
Sources visited most frequently	Trends of development of information sources Verification of resources Modification of interface (studying users' information competencies, instructions) Monitoring of changes in information needs	weekly
Individual users' portals (options, links used most frequently, etc.)	Monitoring changes in information needs and competencies	weekly
Time spent on website	Observation of changes (increase – decrease of interest, relations between time and information needs, including content)	monthly
Selected forms of communication (with service, other users individually or in groups)	Optimizing information offer, development of interactive tools	monthly
Forms of data presentation selected most frequently (text, graphics, image, multimedia, statistical data, etc.)	Modification and development of the tools of information presentation	monthly

- Preliminary offer, consulting the assumptions of a service/resource being developed with the users, also offering subjective data
- Administrative, referring to the needs coming from professional obligations (like administration tasks based on information processing).
- Modelling (case studies, system analysis, analytical modelling, methods of key factors, accepting strategic assumptions)
- Observations of tasks executed and analysis of functions (type, range, changeability, selection of sources – interviews, documents, etc.), including self-observation.
- Data mining, exploring data from databases with ICT tools (popular techniques: statistical, analysis of log registers, neuron networks, evolution methods, rough sets, fuzzy logic; data collected with these techniques require further processing to gain knowledge needed by system designers and organizers).

Table 2 presents possible application of different methods of data collection concerning information needs for the features of the latter proposed above. Application of more than one method increases reliability of data (thanks to the possibility of comparing them), and assures the synergy effect of the knowledge gained.

Diversification of the users causes the need of analyzing the features mentioned above for particular categories, with different methods. The amount of data gathered enables development of knowledge about the users, and fore-

casting trends of changes in information needs and competencies.

Building WHIS on ICT network influences also selection of surveying methods, like observation of working network, and data mining. Additional tools, like questionnaires (online and offline), interviews, etc. can be used for verification of data, also in regard of available evidence of information science, informatics, psychology, public health, etc.

Good example of a system tool both serving the users, exploring their needs, and collecting knowledge, is a “virtual librarian” – virtual customer service representative – vRep Cosmo in National Library of Medicine (Ahmed, 2006). It is a tool of communication with the users, based on natural language, available permanently, assuring better anonymity than other methods of electronic or phone contact. Cosmo answers questions concerning the way of library’s work, range of collections, as well as meritorious questions concerning health (offering information searched in MedlinePlus). It collects statistical and meritorious data concerning users’ movement and questions, which are then analysed, and conclusions implemented to the user service system (software modification, studying information behaviours, development of knowledge resources, and lexis of an information-retrieval system).

Methods of Data Processing

Data processed with traditional and/or ICT methods (interpretation, concluding, modelling, neuron networks, classification, etc.) are verified regarding both available theoretical knowledge, and results of other, similar studies. Positive result of this evaluation enables them to become a foundation of changes in functioning subsystems, modifications in those being designed, checking assumptions for quite new information services.

Awareness of a subjective character of all data gathered with sociological tools (like questionnaires or interviews) is a condition of effective surveying information needs. One shall also remember, that optimizing system regarding the users’ satisfaction cannot also assume “average needs”, resulting in resignation from services with (according to the data) quite small interest in. Controlling the needs requires further checking quality (weight) of a need, i.e. by whom and for what an information is being searched, regardless frequency of searching.

INFORMATION CATEGORIES

Information in the system can be categorized according to two main criteria: a goal (for what it is being used), and a method of creation. Then the following categories can be defined, according to the proposal of the World Health Organisation (WHO, 1999):

- Information about activity being realized within a domain (the broadest content category).
- Information about the public in regard to its information needs and qualifications.
- Research
- Education
- Management (legal, financial, human resources, logistics)
- Geographical

These categories are not separated, as their main goal is to cover all kinds of information which can emerge within a system. Below detailed description of particular categories.

Research Information

Development of one, high-quality health information service for science and research needs seems to be impossible. Numerous specializations (only among the doctors) and fields of research is difficult to be covered by only one structure. These information are being gathered mostly by libraries of medical universities and research institutes, for documentary, research and educational purposes. Serving members of a network society, these libraries have to discuss current possibilities of entering and/or creating virtual networks within a research community, functioning as so-called participatory libraries, i.e. facilitating and promoting exchange of health information and knowledge, according to their role as seen in a conversation theory (Lankes, Silverstein, Nicholson & Marshall, 2007).

Mentioning impossibility of designing such a one service, one should suggest design of a network services of cooperating databases and services managed by medical universities, clinics, primary and specialist health care units, research societies, and professional organizations representing all health professions. Each of these institutions shall manage reliable services for its specialization, regarding projects, publications, contacts, cooperation, etc.

Educational Information

Professional education is strictly regulated and accredited by specialized boards, depends also on a specifics of a discipline, and a job market. Educational health information service shall include:

- Basic information about all higher education institutions in health disciplines
- Requirements for the candidates
- Data concerning research interests
- Accreditation rules and reports
- Curricula (ECTS syllabuses)
- Courses offered
- Requirements for job candidates in healthcare
- Information about cooperation projects, students' and lecturers' exchange

The users of these types of information shall be: candidates for universities, students, health professionals searching for additional courses and qualifications, persons responsible for health education policy, supervising agents (like resort authorities), professional chambers, lecturers and teachers.

Management Information

This type gathers all data concerning realization of tasks in each and every health care unit, regarding health status of population, and costs of care. It refers also to statistical, financial, logistics, or human resources data, quality standards, and ethical codes.

Management refers also to leadership in health professions, especially those with their own authorities (chambers), like doctors, nursing, midwives, and diagnosticians. Though this type covers also information about organization of a profession, rules and consequences of belonging to the group, professional organizations and regulations.

Management information shall be accessible in services offered by health care units, supervising agents, and organizations, to be found in Internet domain portals.

This category consists also of:

- **Legal information** (all binding legal acts, regulations, both of national and local authorities, resort, chamber, trade unions, concerning all aspects of health care. Accessibility of all statutes, rules, organizational rules, ethical codes, etc. shall be regarded. It shall also include (or refer to) international regulations, those general (like convention on human rights, regulations of EU, WHO, UN, ILO), and specialist, of main health organizations, and regulations concerning current social-economic- political and health situation. Such a database of legal information in healthcare shall be managed on a national level by resort authorities, in cooperation with professional chambers, ministry responsible for higher education, and trade unions. The data shall be accessible via a health resort portal.).
- **Financial information** (like other human activities, also health care (and information services) shall have clear rules and resources of financing. Subjects of information processes of this kind are both legal entities (administration agents, health care units), and individuals (caregivers, patients). For most of them information service is of complementary or auxiliary character, i.e. is realized along with their main activity, defined as participation in health caring for a given population. Payments in health care refers mostly to primary and specialist medical and/or nursing services, and all other additional services (like laboratory tests). Either caregivers, managers, or patients participate in financial information flow. One cannot expect public accessibility of private data, however – the rules, and aggregated statistical data and reports for different categories, regions, etc. shall be available.).
- **Human resources information** (HR information includes: all general, national, legal rules concerning employment issues, as well as adequate EU and international regulations. There also should be found: data concerning employment needs in different units and professional types (both nationally and abroad); information about qualification requirements, quality of work, etc.; trade unions, and their offer. This kind of information shall be available via trade unions.).
- **Logistic information** (it consists of data concerning infrastructure and equipment in health care, accessibility of services in regard to number of places and equipment indispensable in tests and therapy. These information are collected by healthcare units, analyzed and referred by supervising organs.).

Information about Healthcare/ Public Health

Information about everyday practice and being used in caring seems to be the largest and most differentiated resource in the whole system being designed. It covers in general data concerning for example:

- Health status of a population being cared by a given unit
- Diagnostic and therapeutic needs
- Cooperation of different professionals within a health care team
- Rules, procedures, instructions obligatory in caring a patient
- Those entered in patients' records, medical and administrative reports

This differentiation comes from specifics of information needs, resulting from a type of unit (public and private healthcare, hospital or local setting, nursing home, etc.), and a position of an individual engaged in collecting and usage of data.

However, one shall also try to design information sub-systems for the needs of particular professions. This task shall belong to professional chambers, as representing interests of their members, and though offering them access to knowledge needed in an everyday work.

Laboratory Information

Laboratory information is quite specific in its form. It concerns health status of individual patients, revealed in biological and chemical indicators in numeric, graphical or image forms.

It's specific refers also to privacy requirements, as the tests' results cannot be passed to third persons. However, not just the pure results, but diagnosis become elements of information passed for the needs of health care management, for statistics of illnesses, epidemiological supervision, employment needs, costs, etc.

Information about Diseases and Epidemiological Supervision

Knowledge about diseases is built on statistical data illustrating their demographical and geographical dispersion. Monitoring life-risk diseases (like tuberculosis, malaria, AIDS, cancers, influenza, etc.) is of particular importance. Such data are collected by health care, epidemiological, and sanitary units. Long-term monitoring and information collection enable estimation of epidemiological risks in different populations and regions, developing strategies and reactions in crisis situations.

Geographical Information

This category has been named regarding horizontal scope; referring to it's range, it includes all the above mentioned categories. Geographical dispersion of such data is useful in all management processes. Each of databases and/or services shall be able to present information according to geographical limits.

Users' Participation in Development and Application of Information According to Categories

Differences in usage of information between individual (professional or not) and institutional users can be found.

The patients concentrate on direct care, its quality and costs (financial, time). Their information needs are often limited to their health problems. In general, information needs of the public may refer to information about organization of healthcare settings and services, types of diseases, epidemiological risks. However, these and other needs depend on the level of health information literacy of the public, including education status, income level, language competencies, etc.

Diversified group of health professionals works usually on information concerning prac-

Table 3. Categories of information transferred within a WHIS and in communication with an environment. Source: own study.

Type of information	Flow direction
Information FOR health care	comes from environment (international organizations, government authorities, etc. – Level 1), taken by institutions representative for a domain (resort and local authorities, supervisory bodies – Level 2) and passed to units of healthcare – Level 3
Information WITHIN health care	being created during and in the result of healthcare practice (3), passed to resort authorities and other supervisory bodies (2), and used back in healthcare services (3), partially passed to patients and/or their carers (Level 4)
Therapeutic information	concerning health status, diagnosis and therapy, passed to patients and/or their carers (4)
Information ABOUT heath care	comes from supervisory bodies (2) and healthcare units (3), passed to all interested, i.e. internal and external environment (1-4)

tice, including analytical tests' results, financial and logistic information, knowledge about health status of a given community (public health, types of diseases). In some circumstances they can also be interested in epidemiological information. They are either users of this knowledge, or it's authors or suppliers.

Institutional users, if diversified into managing healthcare, care providers, research or education institutions, are sources and authors of information in adequate subsystems. Moreover, a group of decision makers can be selected, as information receivers: about public health, management, epidemiological supervision, or geographical.

Summarising, the patients (as individuals or as the public generally) are mostly information receivers. Health professionals are both authors and users of knowledge resources. Selected subsystems are products of management procedures (financial, logistic, HRM, geographical information), created more in the result of institutions' than individual health carers' activity.

Moreover, subject and functional categories of information available in a WHIS fulfil criteria of information evaluation as used in management on different levels: operational, tactical, and statistical (Flakiewicz, 2002). (See Table 3)

Structure and Communication Channels

A wide health information system seems to be a very complicated, multilevel structure. Its complexity can be illustrated by:

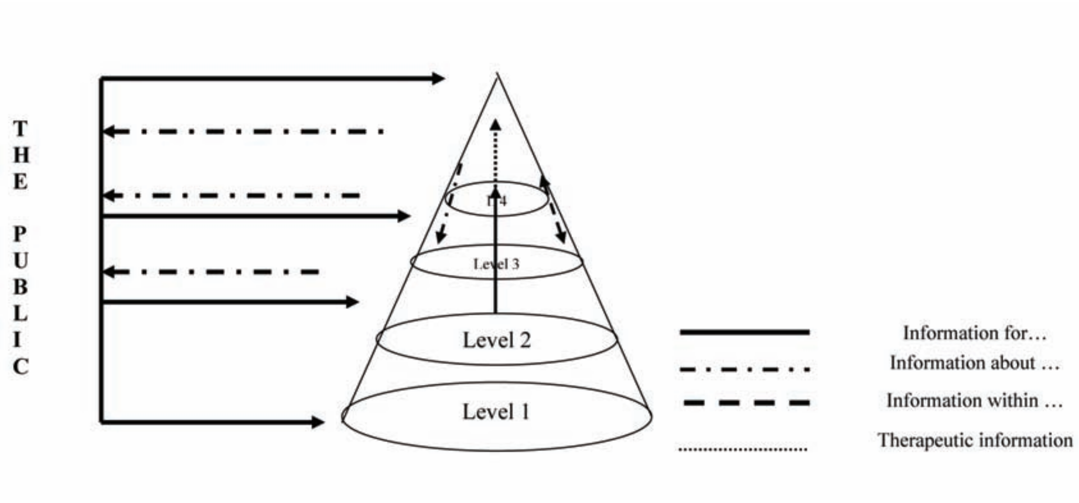
- Channels and directions of information flow
- Frequency of contacts among all interested institutions (and actualization of data)
- Rules and procedures of accessibility of different categories of information for numerous types of the users.

Design of each its unit must be preceded by surveying information needs of the users.

Several categories of information can be defined, being transferred and used both within a WHIS and between a health care sector and an external environment. They are listed and described in Table 3. Direction of their communication is presented in Figure 1.

Developing an information system requires indication of channels and directions of information transmission. It is reflected in regulations defining methods, forms, and frequency of information delivery in both horizontal and vertical communication.

Figure 1. Directions of information flow in WHIS. Source: own study.



Science communication is based on authorized, recommended channels and forms, like peer-reviewed journals and monographies (electronic and printed), conferences and seminars. Legal information is published in official journals of adequate bodies. Information about practice is obligatory kept in standard patients' and units' records, reports, regularly updated. Channels of great importance are also informal contacts among healthcare professionals. Therapeutic information is being passed in direct contact. Both its verbal and non-verbal dimensions are extremely important, as well as adequate feedback, either for effective communicating and understanding of a patient's health status and prognosis, or for showing him/her empathy and understanding. HRM information is partially enclosed in legal communication, or internal horizontal communication in organization. Popular forms enclose written communicates, direct and/or phone contacts.

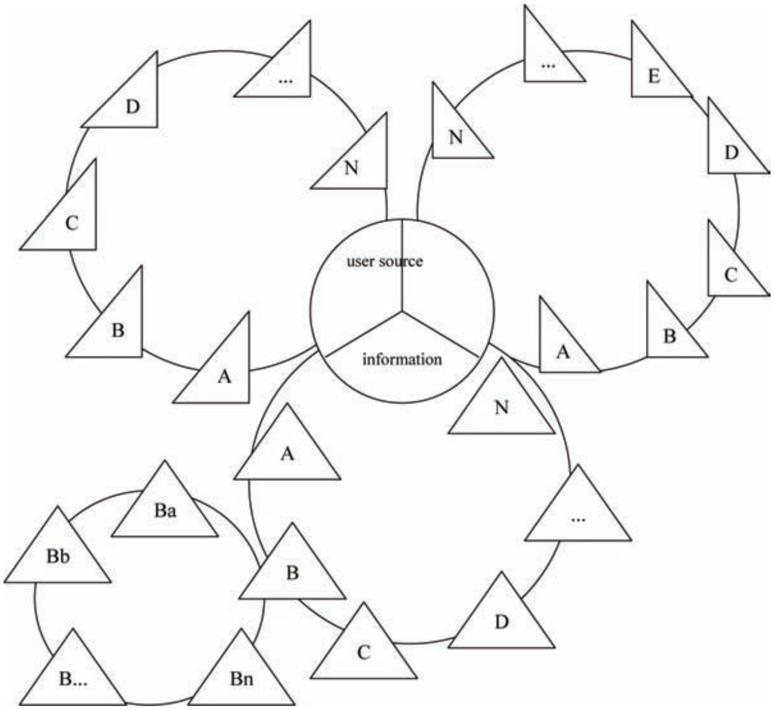
THE WHIS MODEL

Analysis of the users, their information needs, and categories of information being used within healthcare sector makes a foundation for indication of three constitutional elements of a wide health information system, a triad. These are: a user, an information, and a (information) source.

These elements need to be ordered in a structure, completing each other, as it is illustrated on the Figure 2 by a circle made from three different pieces. In other words, all of them are indispensable for proper functioning of the wide information system.

Individual units on circles represent adequately categories of: users (individual professionals, institutions, patients, the public, etc.), sources (healthcare units, administration units, education units, etc.), and information (science, educational, legal, epidemiological, etc.). General categories of each type can be further divided, like for example: information – science information – science information in medicine/ nursing/ dentistry, etc. Group of information sources shall consists of all agendas obliged to realize information processes (creation, collection, indexing, accessing). Differentiation of sources will lead to development of another "circles" on the diagram, representing more detailed information (like individual circles for hospitals, community settings, education, etc.). It is worth to emphasize, that this group consists also of people participating in information processes,

Figure 2. Model of a wide health information system as proposed by M. Kisilowska



representing interested institutions. Structure of circles enables "movement" of selected elements on central positions (creation of different "triads"), and further – free usage of different types of information by all interested parties, for optimal answering users' information needs.

The model is of morphological and process character, i.e. it includes elements indispensable for efficient realization of information processes, and a course of the latter, thanks to adequate functions of particular parts of the structure. It also refers to the system's external dependencies in the environment, like collecting external information or offering access to internal knowledge for entities from outside of the system (like supervisory institutions, media, etc.). Regarding its function, it can be perceived as a model facilitating presentation of the problem thanks to graphical representation of functional and structural connections.

The model enables presentation of 7 typical elements of an ideal system, as from an information science perspective. They are:

- A task, i.e. realization of information processes
- An entrance, i.e. data given by different participants of the systems
- An exit, i.e. knowledge produced in the result of data and information processing
- A course, i.e. direction, frequency, forms of realization of information processes
- An environment, i.e. external elements offering information
- An equipment, i.e. system's technology and architecture
- A human activity, i.e. definition of needed human actions, in particular referring to data interpretation, information processing, knowledge usage, definition of information flow, etc.

Basic three-element structure is assumed as necessary for information flow. Lack of any of these elements would made proper functioning of a WHIS impossible. For example a two-element system consisting of "information" and "sources" would in fact be a "one-element" structure consisting only of the latter, according to the communication theory statement, that "information not received and or not read cannot fulfil its fundamental function". Furthermore, resignation of "information" violates the sense of the wide *information* system, and challenge the idea of such a construction. In fact, lack of a few categories of existing health information systems was at the beginning of development of a discussed model.

A two-element structure of "information" and "user" is threatened with a significant impairment of its functionality, regarding impossibility of verification of quality of knowledge gained. A "source" belongs to the fundamental criteria of information evaluation, as well as fastens information searching – it is easier to find an answer, if known where to search.

Simple structure of this model enables its adaptation to either national, regional, or international requirements, like a subject structure of an information system as proposed by the WHO. Intentional and adequate usage of information is a condition of aiming the goals of health projects, programs and policies, like WHO's "Health for All". It enables development and usage of own, as well as participation in international health information systems, like the WHO Health and Environment Geographic Information System (HEGIS) of an European range, collecting data concerning population health and risk factors in geographical regions (WHO ROE, 1996). Access to different types and levels of information is restricted and depends on an authorisation given to institutions and individuals.

KNOWLEDGE REPRESENTATION IN WHIS

Designing knowledge organization in information systems is based mostly on empirical (statistic, historical, pragmatic) methods (Sosinska-Kalata, 2001), referring usually to disciplinary division, development of a field, and statistics of selected, representative phenomena. Specifics of health disciplines requires inclusion in a WHIS both declarative (about objects, situations, and relations among them) and procedural (about operating "declarative data") knowledge. Knowledge in WHIS is of science character, i.e. it consists of reliable information about the world. It also shall be characterised by reliability and structure (mapping world, revealing relations between elements). These information are used then either for research, or organization of health care. As Artowicz (1997) says, knowledge representation is a way of mapping pieces of a world in a given time, and types of transformations realized by a system (information searching, concluding).

Systems of concepts/terms accepted in a sphere being surveyed are reflected in terminological classifications, lists, and information-retrieval languages, like MeSH (NLM, 2007), SNOMED (SNOMED, 2007), WHO Family of Classifications (WHO, 2008), International Classification of Nursing Practice (ICN, 2007).

Information-retrieval languages adapt their structure to traditional division of medicine and related disciplines into fields and specializations, and further – subjects and methods. Their lexis often refers to original anatomical names of body parts. Differences in perception among health professionals (or even experts in the same field) are easily notified in translation processes. Structure of an original language, domination of some concept categories, shows indirectly either the way of understanding, significance of selected problems, or a policy concerning research topics and trends. Specifics of interpretation of phenomena and terminology, together with the specifics of information-retrieval lexis, as well as difficulties in optimal translation into national languages, also illustrate different methods of perceiving the world.

Each domestic system reflects unique, national approach to a profession. It reflects not only its history, the role of a discipline and its tools, but also some dominants and differences in financing research. Better developed fields have also more specified terminology in information-retrieval languages.

A few studies (Baernhodt & Lang, 2003) evidence preferential presentation of medicine against related disciplines in information-retrieval systems. Searching commonly-known databases for nursing diagnoses had positive results only in case of the US National Library of Medicine. That was possible because of UMLS (Unified Medical Language System) being developed by the team representing different health professions. Searching other databases gave positive results only if nursing terms were identical with medical ones. Meanwhile, as Baernhodt & Lang (2003) shows, a health problem is perceived differently by professionals (medical, nursing, physiotherapist) as a therapeutic "task", as they all have different professional goals. For example diagnosis concerning open fracture can result in:

- Procedure of chirurgical joining (medicine)
- Applying adequate dressing (nursing) to avoid complications (infections, scarring), and ordering painkilling drugs.
- Rehabilitation (physiotherapy)

These differences, and lack of nursing terminology in many information systems, are between the reasons of developing the International Classification of Nursing Practice, as well as other professional terminologies (like Nanda – Nursing Diagnoses).

Availability of multimedia and hypermedia enables more precious mapping of reality. They enrich linear organization of texts. Hyperinformation model of knowledge organization can be described by five features: non-linearity, flexibility, transparency, hospitality, and contextuality (Sosinska-Kalata, 1999). Hypermedia solutions enable users finding knowledge irrespective of sequence order of information. Obviously, they are very popular in education, expert, and electronic patient's record systems, in particular regarding tests' results (RTG, TK/CT, MRI, PET, CR, ECG, etc.). Sometimes these different graphic forms, and different ranges of concepts (like in case of foreign languages) enable getting unexpected results, connecting facts which would not be linked without ICT tools.

System modelling shall assume uncertainty of evaluation of information reliability, inaccuracy of mapping reality, and uncertainty of optimal knowledge representation (Sosinska-Kalata, 1999). It requires application of different retrieval criteria and tools, studying system-user interactions, and information competencies of the latter. In consequence a system of functional models of user's knowledge (5 types of knowledge) is developed:

- About user's status in problem-solving process regarding information searching.
- About subject being searched itself.
- About user's knowledge concerning the subject.
- About user's aims and goals implicated by his/her current status and forecasted actions.
- About methods of user-system cooperation, enabling getting knowledge of the previous four types listed above (Sosinska-Kalata, 1999).

System modelling assumes that users representing a given field do have adequate knowledge, and that those not related to a discipline – do not. This assumption is actually reflected in a process of translating common terms into information-retrieval language terminology, with adequate mapping of professional terminologies and classifications.

LINGUISTIC TOOLS

Development of disciplines is reflected in development of communication and specialist terminologies. Type of language selected for describing reality influences quality of data received, and level of their particularity (Flakiewicz, 2002). For example in object languages, with important share of ethnic languages, one may transmit many detailed information, but loose knowledge about relations between objects. Languages of formal models, with dominating special terminology, or formal languages (mathematic or chemical notation) transmit knowledge more synthetical, but including information about very complicated relations between objects and their features.

In medical and related sciences first classifications concerning diseases were developed in 18th century (by for example Francois de Lacroix, William Cullen, William Farr) (Kozierkiewicz, 1999). Nowadays the World Health Organization is responsible mostly for classification works in health area. It has coordinated preparation and modification in the WHO Family of International Classifications (WHO, 2008), consisting of: International Classification of Diseases (ICD-10), International Classification of Functioning, Disability and Health (ICF), and International Classification of Health Interventions (ICHI – under construction). There are also related products, like International Classification of Primary Care (ICPC), International Classification of External Causes of Injury (ICECI), The Anatomical Therapeutic Chemical Classification System, and ISO 9999 Technical Aids for Persons with Disabilities. Derived classification include field applications of ICD, for example in oncology (ICD-O-3), mental disorders, Dentistry (ICD-DA), health of children and youth (ICF-CY).

Health classifications not only organize terminology, but also facilitate realization of statistical tasks and recording health care procedures.

The SNOMED (Systemized Nomenclature in MEDicine) system is a multi-language linguistic tool used in health recording, laboratory and radiological systems, infection reporting, research coding, information searching, telemedicine, etc. around the world. It is probably the most complete classification for clinical use. Its main advantage is reference to terminologies of different health professions, facilitating communication within diversified health teams, and in searching health information.

Globalization of research and practice induces unification of terminology. Common definition of concepts are being discussed and formulated in ontologies (Gangemi, Ousanekku & Steve, 2007; Golbeck, Fragoso, Hartel, Hendler, Oberthaler & Parsia, 2007). Among different types of them, there are also authority lists, taxonomies, thesauruses (like MeSH and UMLS), data models, etc., also trying to consolidate different domains of health disciplines (Lambrix & Tan, 2006). Many authors (see: Large, 2005; Organization, 2003; Semantic Web, 2005; Summary Report, 2004; W3C, 2001) emphasise the necessity of developing ontologies facilitating knowledge management and access in health disciplines. Further works in this range shall include:

- Harmonisation of lexis, development of basic ontologies concerning sources' identification and context
- Development of common dictionaries, and following ontologies serving specific domains and research fields
- Implementation of LSI (Life Sciences Identifier) standard
- Permanent exchange of knowledge among experts in ontologies

There are also numerous examples of knowledge management in information systems supporting management of national health services, like reorganization of the US National Health Information Infrastructure (NHII) into the National Health Knowledge Infrastructure (NHKI) (Kashyap & Hongsermeier, 2005), based on the

Semantic Web. This network is going to include inter-operational systems of clinic information, information about public health, and health status of individual patients. It is assumed to improve functionality of national public health service, to fasten innovations, and to decrease costs along with increase of effectiveness. Main barriers in such a process include: linking very different information processes (in meritorious, technological, and formal aspects), realized on different data (regarding forms and formats), development of new ontologies or adaptation of existing ones and metadata standards, flexibility enabling adaptation to evolution of the Semantic Web and human knowledge.

A type of ontology is also a reference terminology model for nursing, defined in the ISO standard (ISO, 2003). A reference terminology settles number and categories of concepts to be used in describing reality – here: nursing practice – and relations among them. All professional terminologies shall be adapted regarding such a standard, if they are going to be compatible with each other, with other linguistic tools (like information-retrieval languages), and software being applied in healthcare information systems. Compatibility of professional classifications with information-retrieval languages (UMLS, MeSH) is of great importance, as it empowers success of searching for professional knowledge by health care providers, educators, managers, etc.

Development of WHO FIC, as well as structures and dictionaries used by different health professionals, reflect fast development of health disciplines, and the need of linguistic tools facilitating knowledge organization. It is also related to intensification of professional communication and documentation, based on ICT tools. Codes linked to individual terms and concepts decrease a risk of mistakes in information exchange.

Effectiveness of information processes depends directly on selection of terminology either by the users, or knowledge providers. Development of terminology is a permanent task, a condition of improvement of such a system. Construction of the International Classification of Nursing Practice and works over its structure and implementation during last 25 years can illustrate changes in awareness of indispensability of professional terminologies, for the needs of internal and external communication. Their main task is to answer optimally information needs of different categories of patrons, and to adapt information-retrieval tools to their needs and competencies.

CONCLUSION

Research on information processes within a health sector is strictly related to knowledge management. Efficient utilization of knowledge requires sufficient information skills of the users. They must be aware of the concept of professional information, and qualified in effective searching and evaluating knowledge. Proposed model of wide health information system seems to optimize realization of information processes, in regard of answering information needs of different categories of the users.

Further research trends focus on the users, communication (linguistic tools, data transmission, mobile communication), digitisation. Specifics of relation between information processes and the users' information needs comes from their dynamics, related to permanent changes in social, research, and technological circumstances. No one can assume development of one, stable information structure. It's effectiveness depends on flexibility, i.e. adaptability to current needs and potentials.

Constant development of "real virtuality" results in mediatised awareness of new generations, ICT-skilled, with new information needs in both range and form. From the other side, there are numerous surveys and projects concerning health information literacy and education for specific groups of the users, to reduce the risk of health/digital/social exclusion.

Works on health-related web ontologies indicate the direction on linguistic tools' development. Digitisation of health contents and flexibility of data transmission (also mobile), forces further works on metadata and ICT tools.

Difficulties or weaknesses of the model are connected with an unpredictable human factor. There is so far no universal method or tool to observe (and plan) human information behaviours, so there still exist not-answered questions. Also simplicity of the model is endangered with a risk of loosing too complicated or too particular objects.

The above illustrates the need of common research of health, ICT and management experts on designing more sensitive knowledge systems to be applied in organisations functioning in permanently changing environment, able to cooperate not only with information sources, but also with so-called tacit knowledge.

KEY TERMS AND DEFINITIONS

Information Need: An individual's condition when he/she wants to improve (enlarge and/or correct) his/her knowledge.

Information Processes: In library and information science there are 4 general types of such processes: collecting information, processing information, storing information, and delivering information.

Information System: A system organizing information resources and realizing information processes, equipped with information-retrieval tools (like information-retrieval languages) and procedures, with defined information providers and categories of users.

Information User: An individual who actively exercises his/her right to access different information sources (those who do not, are potential information users).

Knowledge Representation: The way of modelling and storing knowledge in information and knowledge systems and services.

Linguistic Tool: An artificial language, often an information-retrieval language or ontology, used in describing and searching information in information systems.

Wide Information System: A complicated, multispherial and multileveled information system with wide both range and scopes (geographical, formal, language, etc.), either classical information-retrieval systems in library science, or other information systems enabling access to non-documentary information.

ABSTRACT

This chapter discusses the role of open health information management in the the development of a novel, adaptable mixed-platform for supporting health care informational needs. This platform enables clients (patient users) requiring healthcare to enter an unstructured but detailed account of their day-to-day health information requirements that may be structured into a lifetime electronic health record. It illustrates the discussion with an operational model and a pilot project in order to begin to explore the potential of a collaborative network of patient and health professional users to support the provision of health care services, and helping to effectively engage patient users with their own healthcare. Such a solution has the potential to allow both patient and health professional users to produce useful materials, to contribute to improved

DOI: 10.4018/978-1-60566-246-6.ch018

social health outcomes in terms of health education and primary disease prevention, and to address both pre-treatment and post-treatment phases of illness that are often neglected in the context of overburdened support services.

INTRODUCTION

Managing chronic medical illnesses in the community is a universal challenge. The traditional patient and health professional clinical encounter has evolved into a series of fragmented exchanges of information, often between several professionals. The information exchange between professionals mostly excludes the patient and is usually limited to a synthesized 'factual' written account – often referred to as 'the clinical (integrated) medical record'. The synthesized 'factual' written account however fails to convey much of the subtlety gained through the information exchanges in the encounter (which would have built a more valuable knowledge base about a patient) (Sturmberg, 2007). The clinical encounter has the potential to actually evolve into an informational collaborative process, i.e. ongoing learning persistent in virtual space and time. A persistent clinical encounter has immense potential advantages for the patient as well as her health professionals.

Medicine is a collaborative effort in problem solving between individual patients and their health professionals. The collaborations also involve others who are directly or indirectly related to the patient and health professional (for example, the patient's relatives, the practice staff, other members of the physicians' institutions etc) who provide the necessary support to the two main actors.

We suggest viewing such an integrated approach to health care as 'User driven health care' that may be defined as, "Improved health care achieved with concerted collaborative learning between multiple users and stakeholders, primarily patients, health professionals and other actors in the care giving collaborative network across a web interface." (Biswas et al., 2008 a) It needs to be differentiated from the current ubiquitous 'Consumer driven health care' model, which is essentially a strategy for users/consumers to decide how they may pay for their own health care through multiple stakeholders like employers who provide the money and insurance companies who receive the premiums (Tan, 2005).

OPEN INFORMATION MANAGEMENT AND HEALTH 2.0

Patient user generated and suitably anonymous informational content initially confined to email boxes or web based individual health record vaults can be further invested in online web pages linked to what is loosely termed as Web 2.0 technologies. That may provide opportunities for linking common experiences in order to generate improved patient and caregiver learning

In web sites using this technology user-generated tags would allow the site to evolve, enabling individual users to conduct more precise searches, make additional associations, and explore a diverse undercurrent of themes to synthesize for learning purposes.

Health 2.0 in realtion to health care has been described to be all about Patient Empowered Healthcare whereby patients have the information they need to be able to make rational healthcare decisions (transparency of information) based on value (outcomes over price).

The Four Cornerstones (Connectivity, Price, Quality, and Incentives) of the Value Driven Healthcare movement begin to create a virtuous cycle of innovation and reform. Transparency serves as a key catalyst in this process by creating positive sum competition that can deliver better outcomes at a lower cost...

As more information becomes available as a result of increased transparency, there will be a wave of innovation at all points along the full cycle of care, which includes phases where health care professionals Educate, Prevent, Diagnose, Prepare, Intervene, Recover, Monitor, and Manage the various disease states (Health 2.0 Definition, 2007).

Each and every human has the capacity for and likelihood of performing both roles of caregiver and care seeker (patient) in their lifetimes. The illness experience posts would automatically generate related posts depending on the keyword-tags they use to represent their posts and this would enable every user posting his/her individual experience, to access similar relevant lived experiences of other individuals. This would be a tool delivered remotely, often anonymously, and yet may foster a sense of belonging and intimacy. In this way any individual user feeding input into the net can receive automatic feedback that can grow as individual users keep updating their own data in this Web-based solution. This may function purely on the power of human collaborative intelligence rather than artificial intelligence and yet may prove to be much more efficient.

Each and every individual is the author of his/her own destiny (as well as his/her own web log) that reflects their experiential life processes and decisions that can shape their future. User driven health care is an attempt to help make those decisions. It is a grassroots activity to document valuable individual experiences of patients, physicians, allied health professionals and medical students which have to-date usually gone undocumented and have been a loss to the medical literature (Biswas 2008a some text in this section has been reused with permission).

OPEN HEALTH INFORMATION MANAGEMENT AND SELF ORGANIZATION

Self-organization is the property of well functioning complex adaptive systems that allows the natural relationships among individuals and groups to shape the nature of an evolving knowledge base (Martin & Kaufman, 2007).

The organizational complexity of an individual's interactions with his/her environment defines the level of his functionality. The more the connections an individual is able to develop and the greater the diversity of his network the more it may reflect his/her vitality (Biswas 2003). This is even witnessed at a micro-level inside the human body where there is a demonstrable withering of neuronal connections and complexity with senescence and a resultant loss of neuronal functionality reflected in overall loss of functionality of aging. (Lipsitz & Goldberger, 1992). Quite a few studies demonstrate the relationship between intimacy and health, and how disease survivors who report positive family relationships or access to support groups consistently live longer than those without them. The challenge for us ahead is coupling our traditional focus on monitoring efficiencies with providing deeper human connections to promote sustainable behavior change (Darsee, 2007).

The inscrutably enduring power of the anecdote itself is what incites all our most fearsome defences. The irony in our growing intolerance of the anecdote is that storytelling is full of lessons in imagination and invention so beneficial to the creative investigator. (Campo, 2006). If only all our daily processes were documented along with the anecdotes generated from them they may yet be a valuable form of evidence. It may not be an impossible dream in this electronic information age. Web-based sharing of individual patient and health professional experiences based on individual user needs through fixed and mobile information technology interfaces, would make for better E-learning in health care. This would enable all learners to integrate information and knowledge and manage health and medicine with additional wisdom. (Sturmberg, 2007).

James Surowiecki in his book "The Wisdom of Crowds," mentions four key qualities that make for collective wisdom. It needs to be diverse, so that people are bringing different pieces of information to the table. It needs to be decentralized, so that no one at the top is dictating the crowd's answer. It needs a way of summarizing people's opinions into one collective verdict. And the people in the crowd need to be independent, so that they pay attention mostly to their own information, and not worrying about what everyone around them thinks (Surowiecki, 2004).

As a word of caution it is possible to imagine highly profitable and very destructive feedback platforms based on servers in unscrupulous jurisdictions that are driven by advertising, from personal litigation lawyers to purveyors of therapeutic snake oil. Avoiding this and achieving the best for citizens will require vision, balance and coordinated effort between all those concerned for the individual user in this new age of democratized voice (Hodgkin & Munro, 2007).

User driven health care applying multidimensional approaches of persistent clinical encounters and wisdom of crowds has the potential to be transformational in challenging the complex, high cost, institutional approach that typifies health care delivery systems today. The health care industry desperately needs ideas that offer lower costs, higher quality and greater convenience and accessibility. Also relaxing central control will make local trust and strategic health workers feel more engaged in the project (Kmietowicz, 2007). While dominant players are focused on preserving business models of expensive care and technology arsenals, user driven innovations promise cheaper and simpler access to virtual clinical encounters thus meeting learning needs of the vast majority of patients who may otherwise suffer simply due to lack of information (Biswas 2008a some text in this section has been reused with permission).

CREATING PERSISTENT CLINICAL ENCOUNTERS THROUGH OPEN HEALTH INFORMATION MANAGEMENT

At present most of our chronic disease population is managed in hospitals and clinics (both in the public and private sector). The average appointment time a patient is reviewed in the hospital may arrive at 2-3 monthly intervals. This discontinuity in patient monitoring may be due to patient related factors for example if a daily wage earner has to spend hours attending a hospital outpatient department during working hours it may mean no income for that particular day. A farmer may not be able to come for follow up during sowing and harvesting. Similarly a busy executive or business man may find it difficult to address his/her healthcare needs in terms of maintaining continuity which is vital to improve health outcomes.

In the interval between the physician visits, the patient (for example a diabetic) on his/her own is expected to continue a judicious diabetic diet, maintain an optimal exercise schedule and dutifully consume all his/her medicines on time (and presumably also have an understanding of correct dosage). Any confusion or queries on the patient's part would be solved on the next visit unless it can be prescheduled (which is not easy due to the patient related factors mentioned previously).

Apart from these usual information needs that are compromised there may be other emotional information needs that would otherwise go unexpressed.

The gap between the paucity of what is proved to be effective for selected groups of patients versus the infinitely complex clinical decisions required for individual patients has been recently recognized and termed the 'inferential gap.' The breadth of the inferential gap varies according to

Figure 1. From current limited clinical encounter to an ideal persistent clinical encounter

available knowledge, its relevance to clinical decisions, access to the knowledge (that is, what the physician actually knows at the time of a clinical decision), the variable ways in which knowledge is interpreted and translated into a decision, the patient's needs and preferences, and a host of other factors. Clinicians are required to fill in where their knowledge (or knowledge itself) falls short. (Stewart, Shah & Selna, 2007), and where their patients look for answers outside of the prevailing knowledge frameworks (Shaughnessy, Slawson & Becker, 1998).

As this need for information remains unaddressed, there may be a gradual build up of patient dissatisfaction unrelated to the worsening of the disease. Timely answering of question and concerns would have resulted in a better-educated patient and may have prevented this. Patient education has long been a recognized as a positive factor in successful management of illness and a good education may result from problem based experiential learning that begins with addressing patient's information needs

At present most patient data exist either in their own or their physician's memories as well as in very brief unstructured paper notes or records that are difficult to preserve and update. As a result there is considerable duplication as well as attrition of a single patient's data at multiple entry points as s/he shifts from one health professional to another across various healthcare facilities.

Often patients do not remember all the minute, but sometimes significant details in their illness history even on careful questioning – on each occasion we have to reconstruct our stories anew in light of our current understanding. (Greenhalgh, 2006). This may however be preserved in regular daily/weekly or even monthly inputs made by the patient her/himself that is stored and summarized into a readily retrievable electronic health record, creating a persistent clinical encounter (Figure 1) (Biswas 2008b some text and Figure 1 in this section has been reused with permission).

KEY ATTRIBUTES OF THE PROPOSED OPEN INFORMATION MANAGEMENT SOLUTION PLATFORM IN INDIA

The solution will consist of a patient information input point into a system that would produce content in the form of a dynamic electronic health record that evolves with time and is complemented by a web interface with interactive inputs from health professionals for structuring and interacting with this content in between intervals of face-to-face sessions.

The entry point for patient data would be in strategically located internet kiosks that would contain a desktop with broadband access and would be managed by a person from the same community who would type patient verbal data into the desktop portal in Hindi using English fonts or alternatively record the patient's conversation onto a voice mail.

Patient Input Data Capture and Storage

A typical case scenario would consist of a patient user who may visit the Internet kiosk at the end of a working day and pour out his/her physical/mental troubles experienced over the course of the day/week/month all of which may be recorded verbatim into an e-mail with a gmail address (for example userdrivenhealth@gmail.com). This would be done by the person managing the desktop at the rural/urban health kiosk and s/he would simultaneously mail the same unstructured data to the primary care physician project participant who would then structure the data to the best of his/her abilities and if necessary forward it to other health professionals in the collaborative online network best suited to tackle the particular patient problem.

Patient data may be recorded by the village health kiosk data entry operator simply on video or a voice mail that can be stored online inside multiple gmail boxes beginning with the internet kiosk gmail account (for example userdrivenhealth@gmail.com), the patient's own gmail account to which this data could be mailed, the gmail account of the Hindi medical transcriptionist who would convert this raw patient unstructured conversational voice data to text using Hindi and English fonts, to the gmail account of the language translator who would translate this into English and finally to the primary caregiver in charge of the patient. Other than voice and text, images (still and video) taken by patients, their relatives or caregivers with direct or indirect bearing on their disease (with due care to preserve privacy) may be easily stored in their gmail boxes (individual health record vaults).

Patient Confidentiality and Privacy

This user driven solution will encourage patient users to avoid entering any identifying information, which they may feel uncomfortable divulging or associating themselves with. The most important identifying information that would need to be omitted is patient names, addresses and names of others that may have been associated with them in the course of their illness history. Patients may only identify themselves using self assigned 10 digit numbers (one suggestion would be to use the patient's mobile phone number). There is a common assumption that a patient may not be easily identified in general through his/her mobile phone number although in reality they may still be easily identified if someone who knows their mobile number specifically looks for them. To circumvent this problem we propose giving patient's the option of using a separate Subscriber Identity Module (SIM) in a separate mobile handset solely for interacting with our healthcare network.

Patients maybe expected to have issues regarding safety of using emails (especially gmail) but as long as they utilize usernames which they can suitably make anonymous and feel comfortable with and stick to not entering any identifying information their privacy and confidentiality would be preserved.

Patient Input Data Sharing and Feedback

Patients will need regular feedback on their informational inputs particularly to address their informational requirements; their disease based queries and its myriad diagnostic and management uncertainties. This can be done by the primary physician in charge of the patient (patients may be given the option of choosing their own primary physicians). The primary physician in charge can make use of online empirical or experiential evidence to engage in persistent conversational learning with the patient all of which would be stored in the electronic health record (EHR). The physician could also ask opinion of other experts on the collaborative network (through email) again all conversations of which would be recorded on the electronic health record.

Healthcare professionals may enter their feedback onto gmail and mail it to the email addresses of the individual patient concerned as well as the gmail address where all patient electronic health records would be stored (as a central place to collate and further process the data for example userdrivenhealth@gmail.com). Putting all this patient data together on the gmail box can enable searching for similar patient experiences by simply typing a few matching keywords on to the gmail search engine and checking out matching patient records stored in the gmail box. This is one important aspect of the solution that is expected to grow with time as more and more patient data is stored in the gmail box (which also has an adaptable storage capacity to match user needs).

Other than this, patients can be transmitted limited feedback utilizing existing web-based services that allow free short messaging services (SMSes) to be sent (although limited to 80 characters as opposed to the standard 160 characters available in a basic mobile).

In rural as well as urban India there exists a large digital divide. In recent times a number of attempts have been made to bridge this gap by utilizing mobile phone technology.

These web based services could be effectively utilized by the primary physicians and other healthcare professionals in our collaborative network to provide essential informational feedback to each individual patient tailored to their informational requirements. In this manner the solution could develop a sustained conversation between patient and healthcare professional users. The best return on investment for the patient (who invests her time into this) would be in the form of health professional and other patient informational feedback that eventually helps let him/her gain favorable outcomes. For health professionals investing their time into this the biggest driver would be the insights gained into their patient's lives.

For all actors in this collaborative venture learning would be the common driver. All this learning for the health professional could be organized into health professional E-portfolios linking the health professional with his/her patient records. A patient could look up the range of cases his/her health professional has come across corroborated and validated by the network and decide if this particular health professional has handled a similar case with a similar initial illness trajectory (which could be a new approach to selecting a health professional rather than go by the not so well informed referrals from other health professionals).

FUTURE TRENDS

In the simplified solution, with the platform discussed in this chapter, a detailed Personal Health Record (PHR) shall be accessible to the patient only on the web and a very truncated version of the above may be sent through SMS on demand from the registered user. Once the present basic mobile phone version is phased out in the near future and the PDA (personal digital assistant) mobile phone becomes the basic model along with ubiquitous WiMAX (Worldwide Interoperability for Microwave Access) connectivity, larger PHRs such as these could be easily accessed by patients into their device directly from the Internet.

On completion of the test phase this web-based solution to integrate healthcare E-learning needs can be opened to the world in a simple forum model, already in use at present in various web sites using what is loosely termed as web 2.0 technology. Regular experiential informational input may be posted on to the forum along with a copy to the individual user's password protected web account that would function as an E-portfolio if s/he were posting as a caregiver and a personal health record if s/he is posting as a patient. The individual user could even do this through email and every post made by mail could easily open a new post on to the forum. Most PC users in recent times spend most of their internet time in their mailbox and integrating this solution into the mailbox would target this population (Biswas et al., 2008b).

CONCLUSION

This is an operational model of user driven health care developed in an attempt to optimally answer multidimensional needs, in individual patients and health professionals to cater to an urban-rural Indian community. It is hypothesized that this may allow them to achieve better health outcomes through inter-individual collaboration between multiple stakeholders in the care giving and care seeking collaborative network.

Overall, the project will help to explore the potential of a collaborative network of patient and health professional users to support the provision of health care services, helping to effectively engage patient users with their own healthcare. Such a solution has the potential to allow both patient and health professional users to produce useful materials, to contribute towards improved social health outcomes in terms of health education and primary disease prevention, and to address both pre-treatment and post-treatment phases of illness that are often neglected in the context of overburdened support services.

This operational prototype, which still continues to evolve, has been shared with other future stakeholders particularly in the healthcare system. We look forward to the beginning of the validation process along with a future positive collaborative venture in user driven healthcare with multiple stakeholders in the public and private sectors.

ABSTRACT

In mobile healthcare, medical information are often expressed in different formats due to the local policies and regulations and the heterogeneity of the applications, systems, and the adopted Information and communication technology. This chapter describes a framework which enables medical information, in particular clinical vital signs and professional annotations, be processed, exchanged, stored and managed modularly and flexibly in a mobile, distributed and heterogeneous environment despite the diversity of the formats used to represent the information. To deal with medical information represented in multiple formats the authors adopt techniques and constructs similar to the ones used on the Internet, in particular, the authors are inspired by the constructs used in multi-media e-mail and audio-visual data streaming standards. They additionally make a distinction of the syntax for data transfer and store from the syntax for expressing medical domain concepts. In this way, they separate the concerns of what to process, exchange and store from how the information can be encoded or transcoded for transfer over the internet. The authors use an object

DOI: 10.4018/978-1-60566-332-6.ch004

oriented information model to express the domain concepts and their relations while briefly illustrate how framework tools can be used to encode vital sign data for exchange and store in a distributed and heterogeneous environment.

INTRODUCTION

Mobile healthcare applications receive more and more attention due to the ability to reshape healthcare delivery, for example, enabling self-management of patients whilst they pursue their daily activity. Information and communication (ICT) technology and infrastructures which provide the necessary ubiquitous connectivity enable these applications. Competitive value-add ICT providers moreover facilitate these applications with alternatives to computation and communication services. Today's environment for networked applications is therefore rich in ICT services which are accessible anywhere and anytime, for example by prepaid or subscription contracts between users and ICT service providers or by collaboration contracts between these providers. Such environment enables applications to select (wireless) connections of required quality and technology which are considered best for their purpose. A mobile application may for instance seamlessly switch over between GSM, UMTS or WiFi 802.11 (Schiller, 2003) connections that are offered by competing providers. These developments enable mobile healthcare applications in choosing the appropriate situations with adequate ICT support that permit healthcare to be delivered where previously it was difficult or impossible to do so (Wootton, 2006).

Due to these ICT and business advancements, a travelling patient with a chronic disorder can be monitored continuously everywhere in the country of residence as well as abroad. If his health condition requires, he may be examined at a care centre abroad that uses equipment different than at his country of residence. This may further imply that the format of the processed healthcare data differs from the format used at his residential care centre. Local care centre's policy or local governmental health regulations may also impose the use of a different healthcare data format standard. In (near) future mobile healthcare therefore, we typically need to deal with healthcare data which are represented in multiple format standards due to the different policy or regulations and the heterogeneity of applications, systems and ICT technology.

This chapter describes a framework which enables healthcare data, in particular (digitized) continuous-time patient's vital signs and professional annotations, be processed, exchanged, stored and managed modularly and flexibly in a mobile, distributed and heterogeneous environment. A framework is often described as a basic conceptual structure to compose something from fitting parts. In the context of this chapter, a framework is an integrative (standardized) conceptual structure which brings together a set of components which themselves may be standards such as vital signs format & encoding standards (Blair & Stefani, 1998). It therefore addresses questions like:

- How to deal with healthcare data expressed in accordance with several data format standards and how to encode the data to fit to the characteristics of the provided connections to enable effective and efficient data transfers;
- How to deal with professional (textual, graphical or multimodal) annotations and derived (i.e. trend) signs in sync with the analyzed vital sign segments;
- How to manage vital sign data sets of a patient that originate from the same measurement session in a (distributed) study, which typically process data in several steps using processing tools with specific parameter settings. Similarly, how to manage vital sign data sets (of the same patient

> and the same measurement session) in different formats, e.g. if the returning traveling patient, who has been monitored and diagnosed in a care centre abroad, consults his general practitioner, who then inspects the annotations and the vital signs measured and processed using a locally certified system to confirm the annotations, the diagnosis and treatment of his colleague abroad.

The proposed framework should furthermore fit to the practices used in ICT to manage the use of multiple format and encoding standards, as discussed in the next sections.

In the next section, we discuss some of the issues of information exchange using computer networks and illustrate the need for a framework which flexibly supports exchange of healthcare data, in particular digitized continuous-time vital signs and professional annotations, in a distributed and heterogeneous environment. Thereafter, we analyze the functional requirements of mobile healthcare stakeholders on the framework. We address only those stakeholders that influence the functional aspects of a framework for multiple formatted vital signs for use in a heterogeneous distributed environment. Stakeholders addressing financial aspects like insurance companies are therefore beyond the scope of this chapter. In the section thereafter, we address the representational model, which distinguishes between the syntax for data transfer and store from the syntax for expressing medical domain concepts. Then, we discuss the information model of the framework and some ECG standards. Thereafter, we address some other syntax notations and briefly discuss tool based translations of conceptual or abstract syntax to transfer syntax. The last section presents our conclusions.

BACKGROUND

One of the issues of transferring information in an ICT environment is to preserve meaning despites the dynamic property of the data transfer characteristics of the connections and the different ways of representing information at the computer systems at the connection endpoints. A connection in this environment can be modeled by a bit or a character pipe (i.e. a model which supports the transfers of sequences of bits or characters, respectively). For example, an echocardiogram needs to be formatted as a sequence of pictures, serialized, and encoded further to suit the pipe, transferred via the pipe, and at the receiving end reconstructed (i.e. decoded). This chain of data formatting and encoding steps requires a suitable end-to-end quality to preserve the clinical interpretations of the echocardiogram. Mechanisms and techniques for data formatting and encoding have been widely investigated and developed in the area of computer networking. In this chapter, we present the data representation model of the Open Systems Interconnections (OSI) of International Organization for Standardization (ISO) (MacKinnon, 1990). This model provides clarity to and better understanding in the structures of many format and encoding standards like MPEG, JPEG, H.261, or DICOM (Le Gall, 1991; NEMA, 2007a). This is due to the distinction between abstract syntax representation, which is suitable for the entities that exchange information, and transfer syntax representation, which is suitable for the pipe that transfers the serialized and encoded data. This distinction therefore separates the concerns of exchanging concepts of the domain ontology from the concerns of serializing and transferring the encoded concepts in a meaning preserving way.

As in multimedia, several formats and encodings have been proposed or developed for vital signs, in particular for electrocardiograms (ECGs). We may identify de-jure standards developed by standardization bodies, such as the CEN/SCP-

ECG (CEN/TC251 prEN 1064, 2002), which is developed by the European Committee for Standardization CEN (CEN/TC251, 2007) and defined specifically for ECGs, or HL7 (Hinchley, 2005), which is developed by an organization cooperating with standardization bodies and accredited by the accrediting organization for US national standards, but which has a larger scope than only addressing monitored healthcare data like ECGs. Another example of a de-jure standard that can be used to represent ECGs, or vital signs in general, is VITAL (Weigand, 2005). We may also identify de-facto standards, i.e. standards that were developed by industrial or research consortia, or proprietary standards used by vendors of medical equipment or proposed by a research institute, e.g. ecgML (Wang, 2003). For our convenience, we denote ECG data format and encoding proposals found in the literature as (proprietary) standards. ECG data representation standards vary in their semantic expression levels. Some of these standards focus only on the waveform representation, some others additionally provide heart physiological or bioelectrical domain concepts like the notion of P or ST waves. These differences may imply loss of interpretation power when ECG data has to be converted from one onto another standard (lossy conversion). In this chapter, we show how the OSI data representation model (MacKinnon, 1990), in particular the abstract syntax, can be used to identify these differences in semantic expression level and how to associate equivalent ECG segments formatted in different standards. We also discuss how the abstract syntax can be used to specify professional annotations or derived (/trend) signs like heart-beats such that rendering tools are able to visualize these annotations or trend signs in sync with the associated data segment.

We apply the Unified Modeling Language (UML) (Booch, 1999) as a (graphical) abstract syntax language to express the concepts of vital signs, in particular ECGs; this results in an information model of the framework. Some of the ECG standards format ECGs as sampled time-domain bio-signals (e.g. the format described in (Browns, 2002)), others include bio-electrical or heart physiological concepts like the notion of P-waves and QRS complexes (e.g. the standard described in (CEN/TC251 prEN 1064, 2002)). The specification of ECGs using UML, addressed in (Concalves, 2007), has elaborated several ECG ontological models from different perspectives like the heart physiological, bio-electrical, including the recording session perspectives. UML is also used by other standards, for example HL7, to capture the association semantics between the healthcare domain concepts. In this chapter, however, we specify the vital signs information model from the perspective of the different format and encoding standards. This approach fits to our objective to develop a framework for processing, transferring and storing vital signs in a multiple formats environment. Our information model therefore includes multiple structures for (replicated) ECG data that are specified by the different standards and it includes structures to express their relations, for example the applied conversion tools, the settings of the tool and the actor in charge of the conversion, or the processing algorithm and settings that derive a trend sign.

To deal with the exchange of medical information represented in multiple formats we adopt similar techniques and constructs as are used on the internet. In particular, we are inspired by MIME (Multipurpose Internet Mail Extensions) (Freed, 1996) which enables users to exchange text, pictures, video clips, excel sheets, etc. independently of the computing devices, software packages or the operating systems involved. For example, the MIME construct "multipart/alternative" can be used to express the relation between two or more ECG segments of the same measurements of a patient but formatted differently, e.g. one in the CEN/SCP-ECG format and the other in the DICOM waveform format (NEMA, 2007b). The latter can be a conversion of the first to match the format of the data to the software or the equipment of the professional, for example in the earlier illustrated case of the travelling patients. As this construct specifies that the multiple parts are alternatives of one another, an ECG viewer tool can select the part that is encoded in a preferred format as indicated by a profile of preferences. Moreover, a policy that regulates tools to ignore parts that are encoded in a format unknown to the tool provides flexibility when introducing new formats without influencing existing systems (upwards compatibility and open-endedness with respect to new features or new functionality).

Furthermore, to enable synchronization of care professional's (textual or graphical) annotations with segments of analyzed vital signs, we adopt a construct similar to MIME "multipart/parallel" to inform a rendering tool that the annotations could better be visualized together with the corresponding vital sign segments.

We additionally adopt a similar technique as is applied in MPEG (Le Gall, 1991) for joining and splitting types of media, e.g. synchronized under-titles with video, to merge professional annotations, trend signs or other auxiliary data on the fly. As in MPEG, the framework includes identifiers to distinct between the data types at abstract as well as at transfer syntax level.

Besides the discussed facilities for healthcare data processing, transfer and store, this chapter also addresses the facilities to manage the dynamics experienced by mobile healthcare applications due to changes in patient's health conditions or fluctuations of the ICT infrastructural resources due to environment data traffic or roaming patients.

A framework for multiple formatted vital signs therefore needs to adopt the discussed techniques or constructs. In the next section, we justify these needs by analyzing the requirements of healthcare stakeholders that are relevant for the framework's functionality.

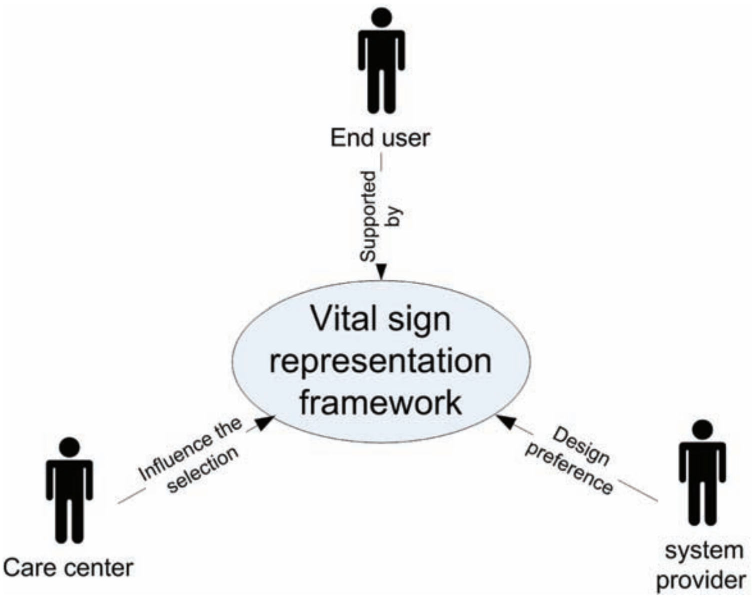
STAKEHOLDER CONSTRAINTS AND REQUIREMENTS

We analyze the needs of three mobile healthcare stakeholders to identify the functional needs that have to be accommodated by the framework. For this analysis we use our experiences collected during several mobile healthcare projects (MobiHealth, 2002; HealthService24, 2005; Myotel, 2008) and our study of several healthcare systems reported in the literature. Some of the identified needs were examined during the development of Extensible Markup Language - XML (Bray, 2004) constructs for vital signs representations. These constructs were discussed in (Mei, 2006) and several simplified scenarios were used in (Mei, 2006) to illustrate the benefits of the framework which accommodates these constructs.

We distinguish three mobile healthcare stakeholders who typically influence the vital sign representations and their use (Figure 1):

- End-users; stakeholders who use the services provided by the mobile healthcare systems. End-users include both patients and the healthcare professionals, for example the medical specialists, nurses, physiotherapists;
- Mobile healthcare system providers; stakeholders who are involved in the provisioning of mobile healthcare systems for clinical remote monitoring and treatment. In the context of this chapter, these providers are assumed to be aware of the applied information and communication technologies;
- Care centers, such as the primary care centers, healthcare call centers (also called healthcare portals), and the secondary care centre's (e.g. corporate hospitals with their departments of different specialties). For our convenience, regulatory bodies as well as medical ethical committees are categorized as this stakeholder. That is, the care centers are assumed aware of the healthcare

Figure 1. Stakeholders of vital sign representation framework



regulations that influence the way of handling patient's vital signs.

Requirements from End-Users

From the healthcare professional's point of view, the vital sign representation should be suitable for effective clinical interpretation as required by the health condition of the patient and in accordance with the working practices of these professionals:

- Healthcare professionals typically access units of interpretable segments of vital signs in a quality appropriate for the purpose of the clinical task, e.g. patient's ECG filtered from noise and movement artifacts and visualized in a resolution necessary to inspect ventricular contraction;
- Healthcare professionals may need to correlate signs that belong to a group of coherent vital signs, e.g. patient's oxygen saturation, heart beat, blood pressure, and respiration that together form an indicator of the oxygenation of the patient's brain in trauma care;
- Healthcare professionals may have priorities regarding the importance of vital signs, e.g. doctors may prefer to see trend signs and only in case of abnormalities, they need the underlying vital signs;
- Healthcare professionals may need to annotate vital sign segments;
- Healthcare professionals may need to know how vital sign data was measured and processed for evidence based treatment.

In some mobile healthcare applications, patients typically generate vital signs by attaching sensors on their body and initializing the sensing devices. These patients, especially mobile patients, may need to check and calibrate the sensors' readings from time to time to ensure accurate (local) monitoring and treatment feedback. For example, patients may need to re-attach sensors in case of bad skin contacts. For this, vital signs visualization or other feedback modality has to have a resolution suitable for patient's interpretation.

Moreover, medical and sensor technologies are evolving and new vital signs or sensors may be developed for measuring patient's health condition in mobile environments. Therefore, vital sign representations should be extensible to enable the introduction of new vital signs or the integration with new data like professional annotations.

Requirements from System Providers

Mobile healthcare system providers have the mission to facilitate the computation and communication needs of the patient's care process. In a remote monitoring and supervised treatment session, the healthcare system regularly matches the computation and communication needs of the supported care process with the resource capability and capacity of the ICT infrastructure. These systems often apply a hunting strategy to collect the available ICT resources of the contracted ICT providers. They often apply an adaptation strategy to control the vital sign data processing and transmission. For example, by down-sampling, prioritizing or discarding some of the vital sign packets, a system may improve the utility of transferring vital signs in a meaning preserving and adequate way. Therefore, a vital sign framework should enable prioritized transfers of important signs and deferred transfers of remaining signs, which may traverse other delivery routes and at cheap data communication hours. Consequently, the framework should further support aggregation and resynchronization to reconstruct the set of vital signs.

Requirements from Care Centers

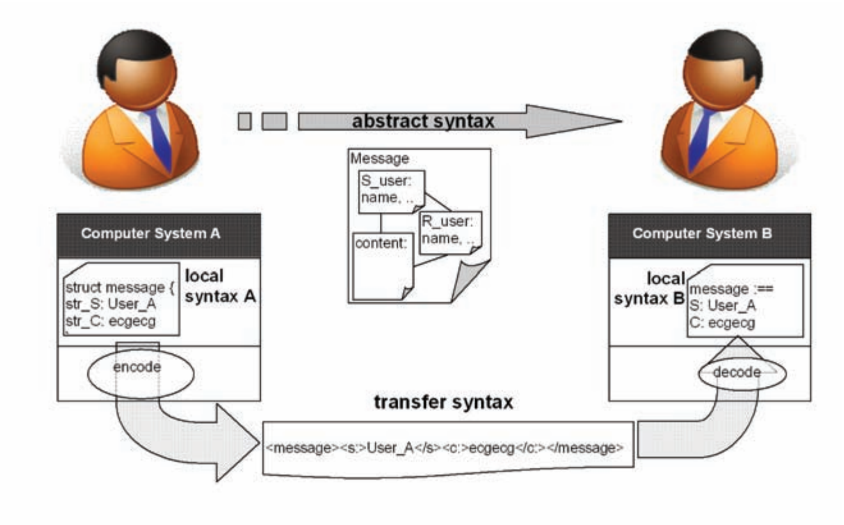
Care centers, especially corporate hospitals, often accommodate a diversity of specialized systems, each of which may apply specific vital sign formats. If furthermore, these centers also treat travelling patients, interoperability between these remote systems needs to be supported. In such cross-platform environments, vital sign representations require an open environment to facilitate multiple vital signs formats.

Healthcare data is considered private and has to be subjected to privacy rules. Monitoring and treatment protocols described in the trial designs which were proposed to the Medical Ethical Committees in the earlier mentioned healthcare projects address healthcare data privacy, such as password protected and role based access to recorded and processed data, vital signs are also made anonymous. The framework should enable transferring, processing and storing of vital signs subjected to privacy rules.

INFORMATION REPRESENTATION MODEL

A model suitable for information transfer in a heterogeneous environment, which accommodates different (wireless) communication technologies and qualities and different computer systems, is the OSI Presentation Layer model (MacKinnon, 1990) (Figure 2). This model uses three kinds of syntaxes to represent information. The earlier described *abstract syntax* represents the domain ontological structure of the information in respect of the entities exchanging the information. It is therefore the vocabulary and the structuring rules used to represent the information. This syntax is considered useful in a meaningful meaning preserving transfer, in which the sending and the receiving entities share a common universe of discourse. An abstract syntax enables these entities to interpret the exchanged information in the same way. The earlier described *transfer syntax* is the syntax used to represent data in transfer. Information expressed in a transfer syntax is therefore represented as sequential groups of bits or characters sequences. Groups, in turn, associate to terms of the abstract syntax vocabulary. The third kind is the *local syntax* which is the syntax used to represent stored data at the involved com-

Figure 2. Information representational model



puter systems. In a heterogeneous environment, the local syntaxes used by the communicating computer systems can be different, e.g. one uses a Java based local syntax and the other a C based syntax in a Unix system.

An abstract syntax is therefore not a concrete syntax as are transfer and the local syntaxes. ECGs specified from a specific perspective in an abstract syntax result in a conceptual model of the ECGs. This model can be used to reason about the elements of the ECG, for instance the bio electrical properties of the heart or the heart condition if the model is defined from those perspectives. In the perspective of interoperability in an environment that uses multiple standards, the ECG model at abstract syntax level should enable the identification of the same ECG segments which are formatted using different standards and should further enable conversion from one format to another.

An abstract syntax moreover enables the development of information exchange techniques and mechanisms for a heterogeneous environment. Information conceptually represented in an abstract syntax can be encoded to different transfer syntaxes. Information encoding from abstract syntax to a transfer syntax is virtual, because in reality the information is represented at a computer system in a local syntax. Information encoding in reality is therefore the conversion from a local syntax to a transfer syntax. The rules needed for the conversion can be derived from the encoding rules from abstract syntax to transfer syntax.

As mentioned earlier, information represented in an abstract syntax can be encoded in several transfer syntaxes, each of them binary or character sequence oriented. Moreover, some transfer syntaxes are more suitable for efficient processing rather then generating compact codes; others generate compact codes but are not processing efficient. In an e-mail application, a plain text message can be encoded amongst others as an ASCII characters sequence or a base64 character sequence (Freed, 1996). Base64 encodes 6 bits of the abstract syntax representation to one base64 transfer syntax character. Three (8 bits) characters of the plain text message will therefore be encoded to 4 base64 characters. However, binary data can be encoded using the base64 encoding to fit to a character pipe as used by internet e-mail. The benefit of binary data encoded in base64 is the availability of many internet protocols to convey the data using computer networks. On the other hand, conversions of digitized ECGs to base64 and back to a digital form at the receiving end point consume processing capacity and a lot of time, a bit oriented transfer syntax is much more efficient in such cases.

VITAL-SIGNS INFORMATION MODEL

In this section, we discuss the information model of the conceptual structure that binds together the abstract syntax level structures of vital signs, in particular ECGs, as defined in the various vital sign standards. In particular, the model specifies the different kinds of relations between the vital sign structures as identified in the stakeholder's analysis section. As discussed in that section, several kinds of relations need to be addressed:

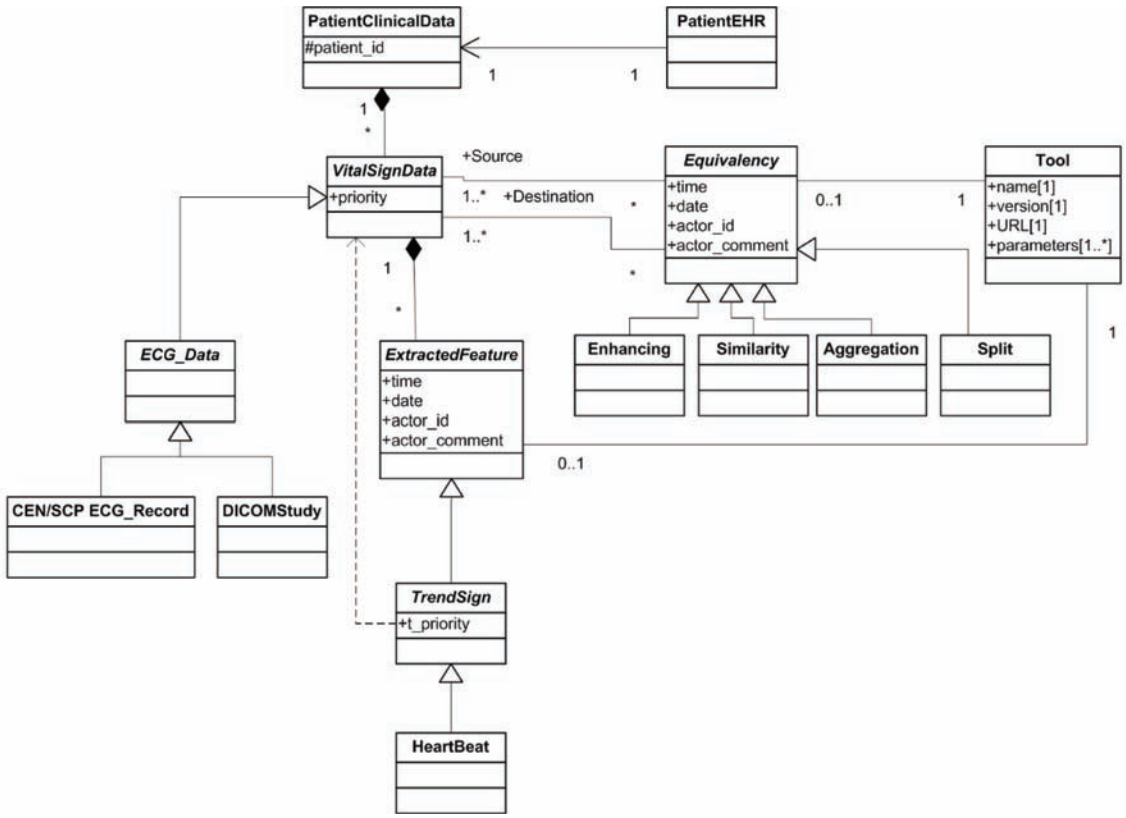
- **Similarity relation:** This relation expresses that the related segments of vital signs are similar to one another in respect of a defined context, such as the context of their use which reflects the purpose of the vital signs. Similarity is used here to associate vital signs that reflect the same (physiological) phenomena but are represented and structured in different ways in the different standards. For example, an ECG P-wave may be represented as sampled amplitude values of the wave and parameterized by a sample distant variable specified in another part of the ECG standard. This wave may similarly be represented in terms of the wave onset, duration and peak value. A converted ECG segment, which is formatted in a standard other than the original one but considered having the same interpretation and quality in the perspective of the addressed context, is defined here as being similar to the original source segment. This similarity relation therefore needs to contain the context of the similarity; it for example includes the identity of the conversion tool or algorithm, the parameter settings, the actor in charge of this conversion and the actor's comments for example to further detail the context of similarity. This similarity relation originates from the need of the care center stakeholder to enable a multi standards environment and the policies of the regulatory bodies at the different points of care.

In many cases, this relation associates one source segment to one other converted segment. In general, a many to many, many to one or a one to many association may exists, for example in the case of multiple vital signs types or in the case that the abstract syntax of the source vital sign segment standard is much richer than the abstract syntax of each of the destination standards, but together these destination abstract syntaxes span the source abstract syntax. This is for example useful in a case in which an annotated ECG segment which includes both a time based signal representation and the physiological phenomena like P-wave and QRS complexes is converted to standards that support time based signal representations, but only one of them is able to represent physiological phenomena but, on the other hand, does not support annotations. In this example, annotations but not physiological phenomena are supported by the other destination standards.

Vital sign segments which are similar are also equivalent. That is, segments which are similar also have the reflexive, symmetry and transitivity property of an equivalency relation because the related vital signs are supposed to reflect the same (physiological) phenomena. As discussed earlier, these properties are defined in the sense of the applied conversion tools and settings. That is, similar ECG segments reflect the same heart condition in respect of the resolution of the applied tool. For example, an ECG formatted in the CEN/SCP-ECG standard, which is converted to the DICOM wave form standard and the latter converted again in ecgML (Wang, 2003), is considered equivalent and even similar to the ECG representation in ecgML in the context of the applied tools and parameter settings. Remark that one of the applied tools needs only to convert the wave form of the ECG and can be unaware of the physiological phenomena expressed by the data. Therefore, the resulting ECG formatted in ecgML is not necessarily completely identical to the CEN/SCP-ECP formatted ECG, but in the context of use, which is reflected by the applied tools and settings, they are considered equally useful for the clinical purpose because at the resolution of the cascaded tools they both reflect the same heart condition. This cascade of conversions is usually called lossy if a CEN/SCP piece of data representing an abstract syntax concept is not represented in ecgML.

- **Enhancing relation:** This relation expresses that the enhanced segments of vital signs are better conditioned in respect of the context of use. For example, ECG segments filtered from undesirable noise or EMG movement artifacts are enhanced if compared against the source ECG segments. Although the enhanced segments are more appealing for use, the originating source segments essentially have the same effectiveness in respect of the context of use. This enhancing relation is meant to express vital sign segments which contain the same bio-electrical or physiological phenomena relevant for the medical purpose, but the enhanced segments are considered better conditioned for the medical purpose, for example more efficient for use. As in the case of the similarity relation, this relation needs to contain the specification of the context of use, for example it needs to include the identity of the vital sign enhancing tool or algorithm, the parameter settings, the actor in charge of this enhancement and the actor's comments, for example, to further detail the intended context. In this perspective, the enhanced and the source segments are equivalent in the specified context, that is one may replace the other without influencing the interpretation of the clinical data in the addressed monitoring and treatment context. This enhancing relation originates from the need of the professional stakeholder to provide adequate vital sign units of interpretations.
- **Priority relation:** This relation expresses the inter vital signs degree of importance. It is a means for the mobile healthcare applications to ensure continuity of processing or transfer of vital signs which are considered important for the diagnosis or treatment tasks. In case of severe bandwidth degradation, vital signs which are considered less important may for example be stalled;
- **Aggregation and splitting relations:** these relations express that the related segments of vital signs are aggregated or split, respectively, from the others. As discussed in the previous cases, especially the similarity relation, the aggregated segments are equivalent to the source segments in the sense of the aggregation tool resolution. This equivalence is therefore specified by the aggregation tool and parameter settings. We may apply the same justifications for the splitting relations. However, in the latter relation, we additionally may deal with the downscaling of vital signs, for example to fit the data onto an available transmission channel of a specific quality that otherwise is not able to transfer the vital signs. Although the quality may be reduced, the resulting vital signs are considered useful for the professional; otherwise the downscaling was meaningless, thus not executed. In this context of use, the related vital signs are also considered equivalent. As in the other cases, it is therefore necessary to

Figure 3. Vital sign information model



specify the aggregation or splitting tool, tool settings, the actor in charge of the aggregation and the splitting or the splitting strategy and the actor's comments. The tool that splits vital signs may use the priority of the vital sign discussed earlier to determine the splitting. Aggregation of vital signs, on the other hand, may also be used to concatenate (digitized continuous-time) vital signs which otherwise are located remotely; this improves availability or efficiency of the processing or the vital sign analysis by a professional. These aggregation and splitting relations come mainly from the system provider's requirements analysis and partly from the professional needs.

Concepts of vital signs at abstract syntax level can be expressed by languages like ASN.1 (ASN.1, 2008; MacKinnon, 1990), XML schemas (Malik, 2008) or UML (Booch, 1999). Figure 3 describes the information model of the framework expressed in the Unified Modeling Language (UML) class diagram. A class is symbolized by a rectangular with a class name at the top, attributes in the cell in the middle, and operations at the bottom. In this chapter, we do not detail the operations of a class and only provide those attributes that are relevant to explain the framework. The associations between the classes are represented by the lines between the related classes.

Clinical Data of Patients

Figure 3 shows that patient's clinical data (represented by the UML class PatientClinicalData) is a collection of vital signs data (represented by the abstract class *VitalSignData* explained in the next section). In Figure 3, the set of vital sign data is represented as a (genuine) part of patient's clinical data by the black diamond composition symbol. The clinical data is anonymous, because it is identified by some patient identification number. Via the patient's electronic health record PatientEHR, however, a patient's clinical data can be associated to the patient, but the other way around is not specified (in UML, this unidirectional association is symbolized by the arrow, which arrow-head denotes the navigation direction between the involved classes). The 1 to 1 multiplicity of this association indicates further that patient's clinical data represents the whole collection of measured, processed and stored vital signs of this anonymous patient. Alternatively, one may replace the left value "1" with "1 .. *", which indicates a range of one or more collections of vital signs of the patient identified by patient_id. In the context of this chapter, we assume the availability of one set of clinical data per patient.

Vital Sign Data

As mentioned earlier, the vital sign data is represented by the abstract class *VitalSignData* in Figure 3. The class is a UML abstract class, because the class is only conceptually defined, other (non-abstract) classes will refine (i.e. specialize) this class. In UML, an abstract class can be identified by the class name written in italics. For example, the abstract class *ECG_Data* is a specialization of the abstract class *VitalSignData* (specialization is an "is-a" relation and is symbolized by the open triangular symbol in UML). This abstract class *ECG-Data* may be specialized further for example by the classes DICOMStudy and SCP-ECG_Record. In this chapter, the class DICOMStudy represents ECG data formatted in accordance with the DICOM waveform standard and the class SCP-ECG_Record represents ECG segments formatted in accordance with the CEN/SCP ECG standard. The information model can be further extended with other ECG data formatted in other (de jure, de facto or proprietary) standards.

Vital Sign Relations

Via the abstract class *Equivalency*, Figure 3 also shows that some source vital sign data can be related to some other destination vital sign data. In the figure, the similarity relation discussed earlier is represented by the class Similarity, which is a specialization of the class *Equivalency*. As discussed earlier, the equivalence between vital sign data is defined in a specific contextual setting. In the model, this context for equivalence is specified by the attributes actor_id, which identifies the responsible actor for the relation between the vital sign data, actor_comment, which denotes the comments of the actor, and also the time and date information. As discussed earlier, the context is also defined by the applied tool and its settings, both are represented by the class Tool. An additional design choice is that we define the similarity relation only for vital signs that are encoded in different standardized formats. This constraint is not shown in the figure, however, it can be expressed by a UML note or specified in Object Constraint Language (OCL) (OMG, 2003).

Analogous to the similarity relation, the enhancing relation, which is expressed by the class Enhancing (Figure 3), is a specialization of the class *Equivalency*. In this model, we define an enhancing relation only for vital signs that are formatted in the same standard.

Aggregation and split relations are also specialization of the class *Equivalency*. Aggregation is a many to one relation between vital signs formatted in conformance with the same standard and the other way around, the split relation is a one to many relation.

Derived Vital Signs

Trend signs or, in general, derived vital signs are frequently used in care programs as first indicators of the condition of the patients. Instead of a plethysmogram, care programs like emergency services or COPD programs use the derived oxygen saturation O_2sat (or SpO_2) parameter as a measure for the oxygenation of blood. Heart Rate and Heart Rate Variability are other examples of trend signs, typically derived from one of the ECG leads. In contrast to the similarity and the enhancing relations, we specify derived signs as specializations of the abstract class *ExtractedFeature*, which in turn is specified as a component of the class *VitalSignData* (in UML symbolized by a black diamond (cf. Figure 3)). As the case for equivalence relations, the applied tool, tool setting, actor in charge of the trend data processing and the actor's comments refines *ExtractedFeature* even further. We model trend or derived signs as a component of the original vital signs, rather than modeling them via the equivalence relation, because it better fits to the way vital sign standards deal with derived signs and because of the complexity of the required constraints due to the transitivity of equivalency relations. For example, Heart Rate and Heart Rate Variability are derived signs but they represent different concepts; therefore they are not equivalent. Other features which can be extracted from ECG leads are for instance the high and the low frequency components, including their ratio.

Care Program Dependent Priority of Vital Signs

As discussed earlier, in mobile healthcare, data transfer bandwidth especially from wireless communication channels like GPRS may fluctuate. If available bandwidth drops below the required level, less important vital signs can be stored locally in favor of the transmission of the more important ones. The management modules of the mobile healthcare applications may (semi) automatically decide which type of vital signs to stall and which to transfer or process further if these vital signs are prioritized. Sophisticated prioritizing structures which are care program or clinical task dependent can be developed, but in this chapter we use a simple priority attribute. If necessary, this attribute can be extended with a reference to the professional actor in charge of prioritizing vital signs for the care program.

We specify the attribute priority in the abstract class *VitalSignData* to enable priority based selection at the level of the types of vital signs rather than at a more detailed level, for example at the level of digitized vital sign samples. This choice has the additional benefit that vital sign sets formatted in a specific standard can be treated as a black box; an approach which intends to preserve the structures defined in standards as atomic units. This could be necessary in case of handling vital signs formatted in proprietary standards whose internal structures are unknown to the application developers of the mobile healthcare system provider stakeholder. In this kind of cases, third party tools that have knowledge of these structures are needed to enable processing, rendering or conversion of the vital sign sets. This black-box approach is for example supported by MIME via the "-x" constructs.

In case of multi-valued or multi-channeled vital signs (e.g. the leads of ECGs) or in case of (multiple) trend signs, the earlier mentioned priority attribute can be refined further to priority of these values, channels or trends (e.g. represented by the attribute t_priority in the class *TrendSign*). Consequently, these intra vital sign priorities depend on the attribute priority of the class *VitalSignData*. This dependency is represented by the dashed arrow in Figure 3.

Table 1. CEN/SCP-ECG sections

Section No.	Title	Description
0	Pointer	the sections and their locations in the data set record
1	Header Information	patient and acquisition related information
2	Huffman tables	the Huffman compression tables
3	ECG lead definition	the leads, the sample numbers and their relativity to a reference beat (cf. Section 4)
4	QRS location and Reference beat	the location of the QRS complexes and the position of the reference beat
5	Reference beat encodings	parameters like encoding flag, sample distance, gain.
6	Rhythm data	the ECG data
7	Global measurements	info pacemaker spikes and QRS complexes like the P-, QRS-, T- on-/offsets, QT intervals
8	Interpretive statements	text based (diagnostic) annotations
9	Manufacture specific statements	manufacturer specific diagnostic annotations
10	Lead measurement	leads information and fields reserved for manufacturer data
11	Universal ECG interpretive statements	universal statement codes (cf. SCP-ECG standard) and most recent annotations which have to be consistent with annotations in other sections

ECG STANDARDS

Several de-jure, proprietary and de-facto format and encoding standards are suitable for ECGs, amongst others CEN/SCP-ECG, DICOM waveform, ecgML, FDA-ECG, HL7 and VITAL. We express some of them in UML class diagrams to illustrate the use of the information model of the framework. It is not in the scope of this chapter to provide a complete list of ECG standards neither to provide detailed UML class diagrams of all these standards.

CEN SCP-ECG STANDARD

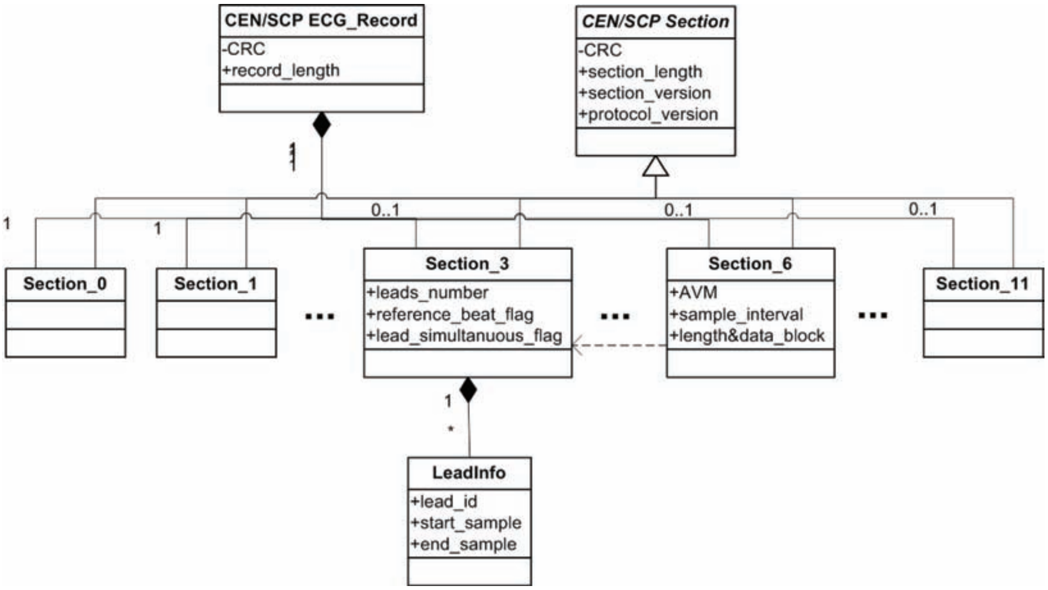
The Standard Communication Protocol for computer-assisted Electrocardiography (SCP-ECG) is a standard developed by CEN/Technical Committee (TC) 251 (CEN/TC251, 2007). Besides ECG data, SCP-ECG additionally defines ECG related data to enable the specification of patient's demographic data, the measurement settings, the performed signal processing on the ECG data, the compression and manufacturer specific information.

In SCP-ECG, the entire ECG data set is called a record. A record is further decomposed into "section" parts (indicated with section numbers from 0 to 11), each of which carrying a specific aspect like patient (demographic) information, compression tables, the ECG lead definitions, the ECG lead data, the reference ECG beat(s) of the leads, including the physiological complexes like QRS, and also interpretive annotations.

Eleven types of sections are defined in SCP-ECG. Table 1 presents the eleven sections and a brief description. Some sections are mandatory (e.g. Section 0 or Section 1), others are optional (e.g. Section 11). Sections have a common header structure, in the figure represented by the generalized class CEN/SCP Section. A high level SCP-ECG structure, expressed in a UML class diagram, is given in Figure 4.

Section_6 contains a black-box of ECG data. To render the individual ECG leads from Section_6, attributes of Section_3, which represent the metadata specifying the number of leads and

Figure 4. CEN/SCP-ECG model



the leads description, have to be accessed first. This dependency of Section_6 from Section_3 is represented in UML by the dashed arrow between these two classes.

DICOM ECG WAVEFORM SUPPLEMENT

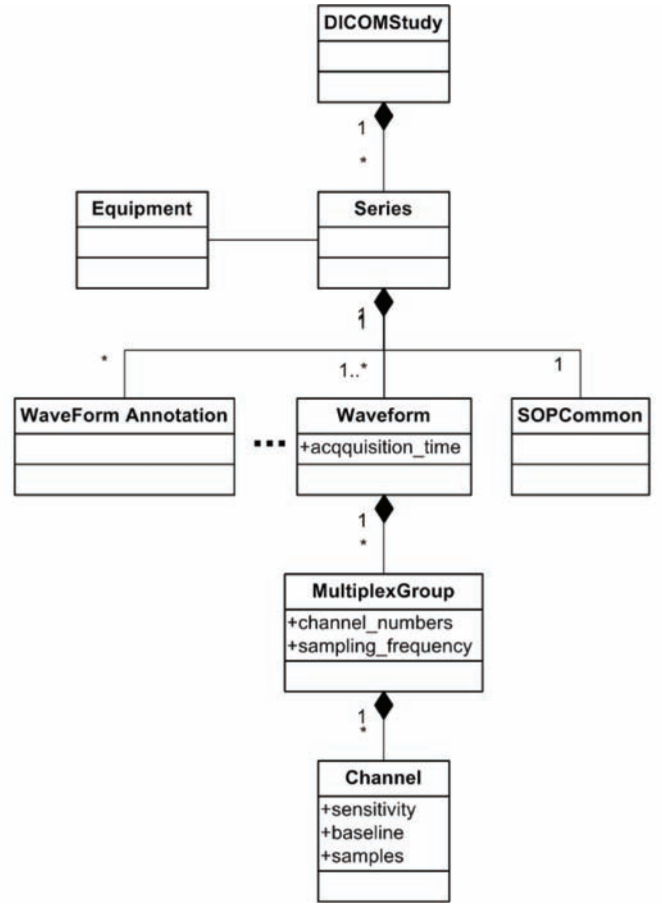
DICOM (Digital Imaging and Communications in Medicine) standards (NEMA, 2007a) are developed by a joint committee of the American College of Radiology (ACR) and the National Electrical Manufacturers Association (NEMA), often in liaison with other organisations like CEN TC251, JIRA in Japan, IEEE and the American National Standards Institute (ANSI). Although the DICOM organisation originally addresses imaging standards, it also developed a standard to exchange waveforms. This latter is therefore suitable for ECGs.

DICOM uses an object based model, therefore not only specifying the structure of the medical data content as information objects, but also the operations on the data (i.e. services). The functional units in DICOM define the classes of the information objects and the corresponding services, the so-called Service-Object Pair classes (SOP classes). One of the SOP classes is for instance meant for a waveform store.

In DICOM, a waveform information object is decomposed into information entities, each of which stored in data modules. Examples of information entities are patient, (clinical or patient) study, clinical data series within a study, equipment which creates the series, and waveforms as part of the series.

Figure 5 presents a simplified UML model of DICOM's waveform related information entities. The figure reflects the clinical procedure by using terms like studies (class DICOMStudy) and series of clinical data (class Series). Although not shown in the figure, these terms include the specification of the responsible professional, the clinical protocols, the waveform identifications (incl. the acquisition time), the annotations, the waveform data (which may be multiplexed bio signals, therefore also includes the multiplexing parameters, the sampling rate, etc.) and also the corresponding equipment used to generate the

Figure 5. DICOM waveform model



data. That is, the class Waveform may contain several multiplexed vital sign channels (represented by the classes MultiplexGroup and Channel in Figure 5)

FDA ECG SPECIFICATION

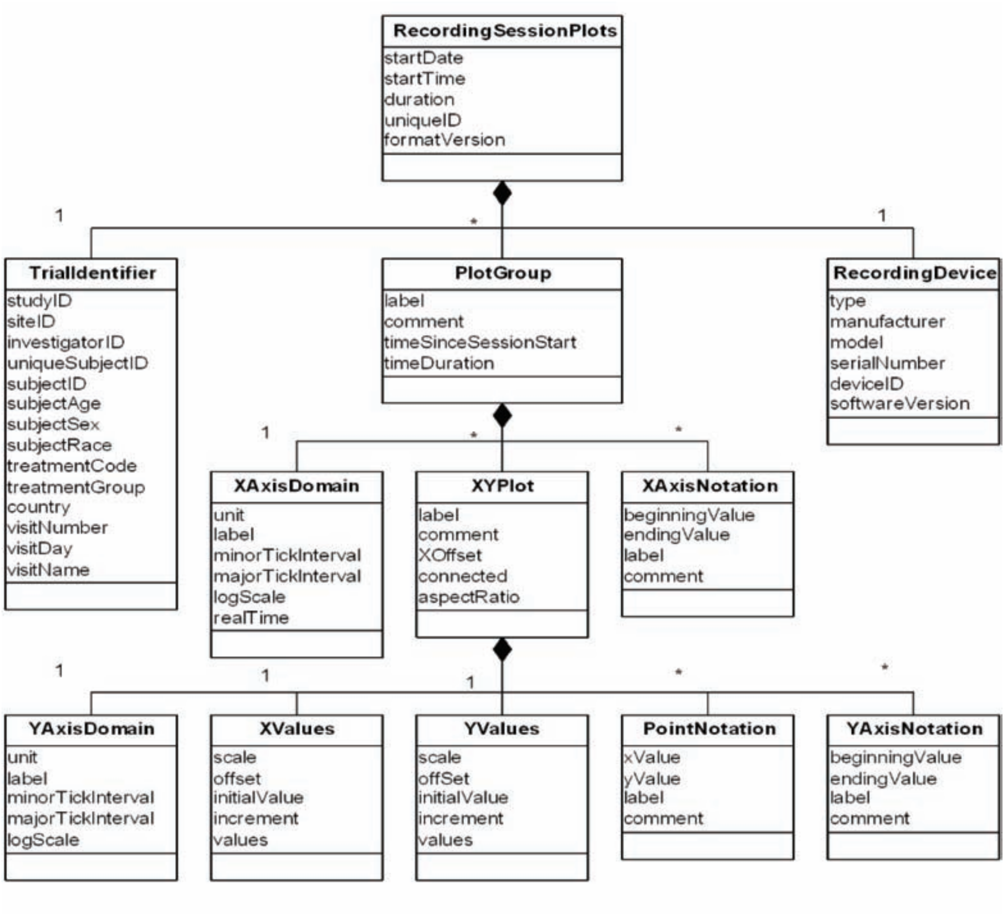
As observed in the previous section, the DICOM waveform standard is to some extent based on clinical procedures and accordingly the data is represented in terms of studies, the FDA format for waveforms (Browns, 2002) is based on the 2D property of sampled waveforms; it emphasizes the viewing representation of waveforms.

Figure 6 shows the FDA waveform information model. As in the earlier discussed standards, the FDA model also provides manufacturer information, patient (/subject) identification, and annotations. In the figure, the class PlotGroup models an ECG data set and aggregates data of the class XYPlot, each of which representing a piece of ECG data of a particular lead.

FRAMEWORK IMPLEMENTATION ASPECTS

In this section, we discuss some of the implementation aspects that illustrate the use and the benefit

Figure 6. FDA Waveform model

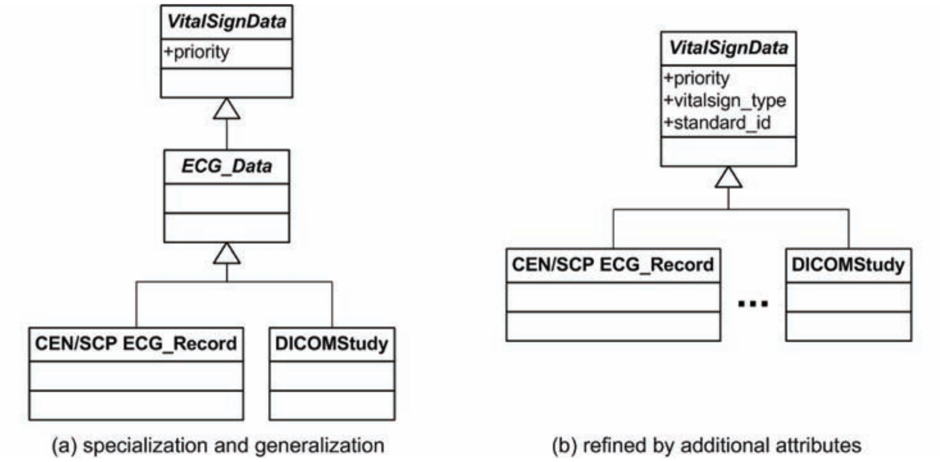


of the framework. First we discuss refinements of the information models presented earlier. These refinements enable the translation and serialization of the abstract syntax to the transfer syntax.

Refinement of the Specialization Constructs

In the earlier discussed information models, we apply the object oriented specialization construct, for example, to distinguish between vital signs that are formatted in accordance with different standards. This specialization can be refined by additional discriminating attributes, for example, an attribute identifying the vital sign type (i.e. vitalsign_type in Figure 7b) and an attribute identifying the format and encoding standard (i.e. standard_id in Figure 7b). The advantage of this refinement is that the encoded attributes in the transfer syntax can be used as header fields in the transfer syntax, for example to indicate that the subsequent payload block of data contains vital sign data formatted in the transfer syntax of the identified standard. This code enables (de-)multiplexing of serialized pieces of vital signs, for example necessary for a 24/7 continuous monitoring of patients. Together with the attribute priority (Figure 7), these discriminating attributes can be used to split a vital sign set, for example necessary in case of severe bandwidth degradation along the healthcare delivery path. This (de-)multiplexing technique is proven useful in multimedia communication using MPEG, which

Figure 7. Refinement with discriminating attributes



(a) specialization and generalization (b) refined by additional attributes

analogously applies process identifiers to join or remove language channels and to merge and split television program channels on the fly.

Refinement of Many to Many Relations

The information model can cope with one to many or many to many associations between sets of vital sign data, for example the similarity between a source set of ECG data formatted in CEN/SCP-ECG and destination data sets formatted in FDA-ECG and in DICOM waveform standard. In this case, a cardiologist may want to visualize both FDA and DICOM sets simultaneously in case that the CEN/SCP-ECG data set is not available on the premises or a rendering tool for the latter format is not available either.

As discussed earlier, the MIME type and subtype construct informs applications which tools to use and how tools should render the data. For example, in e-mail applications, the MIME value "multipart/parallel" indicates that the aggregated data sets have to be visualized simultaneously.

Similar to MIME, we can refine the equivalency class with additional attributes that specify which vital sign sets need to be rendered simultaneously.

Abstract and Transfer Syntax Notations

Other languages are available to express concepts at abstract syntax level, for example XML Schema and ASN.1. Using XML tools a character-based XML document can be derived that contains the vital sign data specified in accordance with the XML Schema. This document can then be serialized by reading it from left to right and from top to bottom, yielding a sequence of characters (transfer syntax) suitable for transfer using internet protocols. Tools are also available to visualize XML Schemas as XML Schema diagrams. However, tool based development kits are also available to develop XML Schemas from UML (Malik, 2008).

Abstract Syntax Notation One (ASN.1) is defined by the International Organization for Standardization ISO (ISO 8824, 1994). It is a notation for specifying data at abstract syntax level. Associated with ASN.1 are encoding rules for generating binary transfer syntaxes from the abstract syntax (ISO 8825, 1994). ASN.1 and its encoding rules provide compact transfer syntax code.

A joint committee of ISO and International Telecommunication Union (ITU-T) has produced several standards on the mapping of XML Schema to ASN.1 and vice versa. A web accessible on-line tool which translates XML Schemas to ASN.1 is for example available (ASN.1, 2008). A framework that accommodates the collection of the previously described tools provides a development environment that enables the translation of vital signs specified via UML class diagrams to concise binary transfer syntax code.

CONCLUSION

We propose a framework for flexible and modular processing, storing and transferring (segments of) medical information in a mobile, distributed and heterogeneous environment. The framework adopts an ICT information representation model, which separates the concerns of information transfer and store from the concerns of expressing, converting, splitting, synchronizing and joining information. The abstract syntax level methods, techniques and mechanisms, which address the latter mentioned concerns, provide the necessary support for processing medical information in an environment that contains multiple standards for data format and encoding. On the other hand, the transfer and local syntax level methods, techniques and tools, associated to the first mentioned concerns, enable transfer and store of medical information in an efficient and dependable way. The framework, which also contains the vital sign information model discussed in this chapter, therefore supports the exchange of medical information in a meaning preserving way despite the use of different format and encoding standards and the fluctuations of the property of the end to end data transfer connections.

This chapter discusses the framework at conceptual level. It provides a generic approach to deal with multiple formats and fluctuating properties of connections. This approach is considered useful for healthcare delivery in which patients are mobile and self managing. It is expected useful for new clinical pathways for mobile and distributed healthcare delivery that involves collaborating actors of different medical specialty, possibly acting in new roles and each of them needing medical information that are represented in accordance with the (new) working practices of their specialty.

The proposed framework, which amongst others is an integrative conceptual structure that binds methods, techniques and mechanisms for interoperability of different format and encodings of medical information, needs to be supplemented further with other ECG and vital sign standards. That is, the framework needs to be populated by relevant format and encoding standards. Consequently, the information model described in this chapter needs to be refined further, for example, to provide tool developers the necessary hooks (e.g. class attributes, object methods and dependency relations) to design medical information conversion, splitting and joining tools. Such refinements not only require details of the format and encoding standards which populate the framework but may also need abstract syntax level knowledge of the ontology of the corresponding bio physiological or bio electrical phenomena, for example, to specify in details the transitivity constraints of the similarity relation.

Another topic for future work is for example the specification of guidelines or rules to up- or down-scale digitized continuous-time vital signs in transfer automatically to match to the fluctuations of the properties of the end to end connections within the tolerance specified by care programs or professionals. These guidelines supplement the framework further and improve its use for mobile healthcare delivery in a heterogeneous environment.

ACKNOWLEDGMENT

The authors thank Bayu Erfianto, who did his MSc project on XML and ASN.1 based representations of ECGs. His project and results have been a starting point for our continued research in this area.

Chapter 2.5

Interpreting Health and Wellness Information

Lena Mamykina
GVU Center, Georgia Institute of Technology, USA

Elizabeth D. Mynatt
GVU Center, Georgia Institute of Technology, USA

ABSTRACT

In the last decade, novel sensing technologies enabled development of applications that help individuals with chronic diseases monitor their health and activities. These applications can generate large volumes of data that need to be processed and analyzed. At the same time, many of these applications are designed for non-professional use by individuals of advanced age and low educational level. These users may find the data collected by the applications challenging and overwhelming, rather than helpful, and may require additional assistance in interpreting it. In this chapter, we discuss two different approaches to designing computing applications that not only collect the relevant health and wellness data but also find creative ways to engage individuals in the analysis and assist with interpretation of the data. These approaches include visualization of data using simple real world imagery and metaphors, and social scaffolding mechanisms that help novices learn by observing and imitating experts. We present example applications that utilize both of these approaches and discuss their relative strengths and limitations.

INTRODUCTION

Rapid developments in the sensing technologies lead to the introduction of sensors and object auto-identification in new areas of human life and activities. One such area that became a topic of extensive research is healthcare. In the healthcare domain, auto-identification takes a form of health and wellness monitoring and applies not only to objects, but also, and even more commonly, to activities, and to bio-indicators of individuals' health. For example, new sensing techniques attempt to determine individuals' diets by audio recording chewing sounds (Amft et al, 2006); individuals' interactions with RFID-tagged objects is used to infer the activities they engage in (Intille, 2003), and various sensors are designed to monitor new

DOI: 10.4018/978-1-60566-298-5.ch005

and traditional vital signs, such as heart rate, blood glucose, or gate.

Oftentimes, introduction of these new sensing techniques can lead to an exponential growth of the volumes of data available for interpreting. At the same time, many of the monitoring applications that utilize such sensors are designed in context of chronic disease management and are meant to be used by lay individuals and their non-clinical caregivers. As a result, the attention of researchers is starting to shift from sensing technologies to ways to incorporate these data into individuals' sensemaking and decision-making regarding their health and disease. After all, the richness of the captured data is of little value unless it can inform decisions and empower choices.

In this chapter we discuss two distinct approaches to enhancing the utility of auto-identification data for lay individuals, discuss recent research projects that utilize these approaches and compare and contrast their advantages and disadvantages. The two approaches we focus on are: 1) introduction of novel data presentation techniques that facilitate comprehension and analysis of the captured data and 2) incorporation of social scaffolding that helps individuals acquire skills necessary for data analysis by learning from experts.

We will begin our discussion by introducing three applications that utilize novel visualization techniques to represent health-related information captured by sensors. These applications include Digital Family Portrait (later referred to as DFP, Mynatt et at, 2000) designed by the Graphics, Visualization and Usability Center of the Georgia Institute of Technology, Fish 'n' Steps (Lin et at, 2006) designed by Siemens Corporate Research, Inc. and UbiFit Garden (Consolvo et at, 2007) designed by Intel Research, Inc. All of these applications use sensors to collect health or wellness data and rely on a particular approach to visualizing the resulting data set, namely they use metaphors of real world events or objects to assist in comprehension.

An alternative approach to facilitating analysis of health data captured by ubiquitous computing applications is by providing social scaffolding mechanisms. One example of such applications is Mobile Access to Health Information (MAHI, Mamykina et al, 2006) designed and developed by the Georgia Institute of Technology and Siemens Corporate Research, Inc. In contrast to DFP, Fish'n'Steps, or UbiFit Garden, MAHI uses relatively simple data presentation techniques. However, it includes a number of features that allow diabetes educators help individuals with diabetes acquire and develop skills necessary for reflective analysis of the captured data.

Evaluation studies of the applications we describe here showed that all of them were successful in reaching their respective design goals and led to positive changes in behaviors or attitudes of their users. While these studies did not specifically focus on data comprehension, such comprehension was the necessary first step in achieving these positive results. In addition, our own experiments comparing different types of visualizations showed that not all of them are equally effective. However, we believe that novel visualizations and social scaffolding have their unique advantages and disadvantages that need to be considered when making a choice as to which strategy to follow. In the rest of this chapter we describe the applications mentioned above in greater detail and talk about the results of their deployment studies. We then describe our attempts to evaluate the effectiveness of different types of data visualization. We conclude with the analysis of comparative advantages and limitations of the two approaches.

VISUALIZING HEALTH INFORMATION

As the world's elderly population increases in numbers, chronic diseases common to older adults stretch the capacity of traditional healthcare. As a result, aging adults and other individuals affected by chronic diseases must take an increasingly proactive stance towards personal healthcare, adopting roles and responsibilities previously fulfilled by professionals. One such responsibility is the monitoring of longitudinal medical records for patterns that may indicate important changes in conditions or that may signal an impending crisis.

Shifting medical monitoring activities to lay individuals is not without consequence. According to a recent report of the Committee on Health Literacy (Nielsen-Bohlman et al, editors, 2004), "nearly half of all American adults ─ 90 million people ─ have difficulty understanding and acting upon health information." Often at issue are the methods with which this health information is visually represented. Traditional techniques represent data using graphs, charts, or tables, all of which can pose impassable barriers to individuals of advanced age or lower socio-economic status and education. However, these individuals have the highest risk of developing chronic diseases, and thus the greatest need to be meaningfully engaged in self-care.

The problem of assisting individuals in comprehending complex and extensive datasets is at the heart of the field of Information Visualization. Building upon a set of principles first developed in the late eighteenth century, modern day visualizations range from common graphs and bar charts to space-time narratives and data maps (Tafte, 1999). Common to these methods is the notion of abstractly representing data so that large quantities of information can be depicted and compared in a condensed space. However, whereas these visualizations may be suitable for educated users, some researchers question their appropriateness for individuals of advanced age and lower education and seek alternative visualization techniques.

People rely on a number of methods when faced with the need to understand complex phenomena. One such method is the use of metaphors, whereby a complex concept is related to a simpler situation exhibiting similar properties. Metaphors permeate modern languages and deeply impact human cognition, lay as well as scientific (Lakoff and Johnson, 1981). Within the world of computer interfaces, metaphors can be found at the core of graphic user interfaces; the ubiquitous "desktop" metaphor is familiar to millions of computer users. Lately, metaphors served as an inspiration to a number of applications that visualize health related information for lay individuals that we discuss below.

Metaphor-Based Visualizations

Throughout history, analogies with real world objects and situations have served as powerful inspiration for visual communication. For example, maps have been grounded in real-world geographic analogies for over a thousand years, making them one of the most persistent and ubiquitous forms of analogical, pictorial communication in the Western world.

In the eighteenth century, Lambert and Playfair, among others, popularized new forms of graphical representation: statistical charts used for communicating economical and political data (Tafte, 1981). The techniques they pioneered later developed into plots, which utilize Cartesian coordinates, time-series, or relational graphics. Whereas previous data visualizations relied heavily on real-world analogies, these new charts required one to learn mappings between particular visual properties (such as position, color, shape or size), and the information represented by these encodings.

Computing technologies naturally lend themselves to relational visualizations because they make it easy to decouple data from representation. In fact, much of the power of computer-based visualizations lies in their ability to produce abstract, high density, relational visualizations efficiently for a wide range of data sets. However, these techniques require a certain level of abstract thinking and appreciation of basic mathematical concepts (Tversky et al, 1991).

While relational visualizations permeate computer-based Information Visualization, there exist alternatives, more commonly explored within the fields of ambient or peripheral displays. For example, InfoCanvas (Stasko et al., 2004) visualizations utilize real world imagery to map information but allow users to create arbitrary mappings. Further departing from the relational tradition, visualizations such as People Garden (Xiong and Donath, 1999), or the Presence Display (Huang and Mynatt, 2003) relay information, such as the flow of conversations or individuals' presence in the office, by using metaphors that compare the information with familiar real world situations.

Metaphors allow individuals to understand one set of experiences in terms of another through a relation of the form "A is B," where B is said to be the source of the metaphor and A is the target. Common examples of metaphors include "time is money," or "life is a journey." According to Lakoff and Johnson (Lakoff and Johnson, 1981), human thought processes are largely, although implicitly, metaphorical. Through the use of metaphors, complex or abstract concepts, such as emotions or thought processes, become more accessible through their relation to concrete objects and situations. Visual metaphors are means to visually represent a linguistic metaphor. One of the most familiar examples of visual metaphors, or metaphor-based data visualizations, is a genealogical tree, which represents a history of a family as a tree with each branch depicting a particular "branch" of the family. The roots of this visualization can be traced to "life is a tree" metaphor common in many languages (Lakoff and Johnson, 1981)

Although there exist examples of symbolic or metaphorical visualizations in User Interfaces, they are rarely seen as superior to relational alternatives in facilitating analysis and comprehension. Instead, they are often valued for aesthetic properties or their ability to blend into the surrounding environment. At the same time, the historical importance of metaphors suggests they may possess particular strengths for audiences or situations which are lacking skills necessary for interpreting relational graphics.

Recently, however, there emerged a number of applications that utilize real-world imagery to convey health and wellness related information to lay individuals. These applications came from different research organizations and were designed by different research teams, perhaps without explicitly targeting usage of metaphors as an inspiration for the design. However, the conceptual similarity in the approaches adopted by these applications is intriguing, and positive results of the deployment studies described by the researchers recommend metaphor-based visualizations as a promising approach for health monitoring applications. We discuss several such applications: Digital Family Portrait by the Georgia Institute of Technology (Mynatt et al, 2001), Fish 'n' Steps by Siemens Corporate Research (Lin et al., 2006) and UbiFit Garden by Intel Research (Consolvo et al., 2008). These applications represent only a limited selection, however we believe together they form a relatively representative sample of this new class of software designed for health and wellness monitoring.

Digital Family Portrait

Digital Family Portrait (DFP, Mynatt et al., 2000) is a pioneering application designed by researchers at the Graphics, Visualization and Usability center of the Georgia Institute of Technology that helps adult children remain connected with their aging parents living remotely. DFP is inspired by the observation that many decisions to transition to assisted care facilities are initiated by adult children who want to ensure wellbeing of their parents. In modern times, when children and parents rarely live together and are often separated by hundreds of miles, they lack the usual lightweight indicators of each other's daily activities. For example seeing

Figure 1. Digital Family Portrait. The picture of the aging parent is surrounded by a digital frame with icons indicating the amount of activity in the parent's house in the last 14 days. Each butterfly represents a day of activity (the current day is indicated with a lighter background color); the size of the butterflies shows the amount of activity captured with motion detection sensors

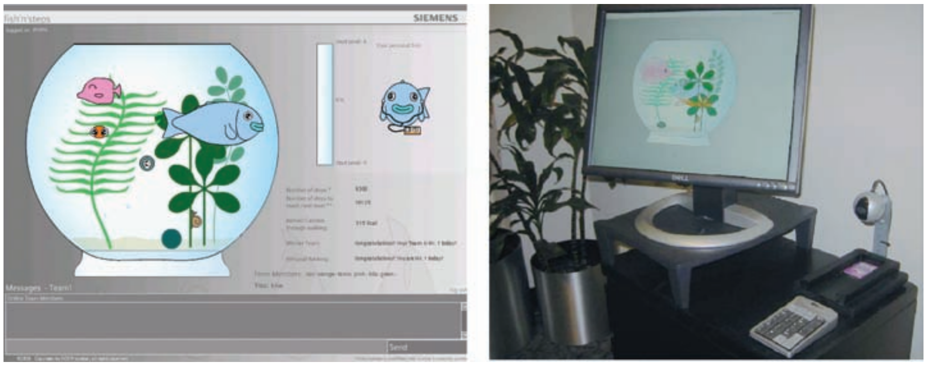
that mom picked up the newspaper in the morning or the light in the kitchen window around dinner time might be sufficient to conclude that things are in order if you live in a house next door. DFP uses modern sensing technology to recreate the feeling of collocation without undue intrusion on the privacy of the aging parents. A number of motion detection sensors placed around the parent's house capture a rough picture of daily activities. The design of the display further supports the notion of lightweight unobtrusive awareness: a digital frame of a parent's picture is enhanced with icons indicating the general amount of activity in the parent's house. The choice of icons includes butterflies, trees, or other simple and aesthetically pleasing images; each icon represents one day, and its size represents the amount of activity (Figure 1). Thus, while each icon taken by itself is not sufficiently informative, together they form a pattern and allow the users to notice changes in the amount of activity overtime.

DFP was deployed with one family for an extended period of over a year. It is easy to imagine that the volume of sensory data collected during this time could be quite overwhelming and difficult to interpret. However, the simple, yet articulate visualization made it easy for both users to cope with the data volume and extract useful aggregated information. During the time of the study, both the parent, Helen, and the child, Will, participating in the study learned to rely on the display for awareness. Helen volunteered that because of the display she felt less lonely, knowing that Will is looking over her. Will found several creative ways for using the display, such as anticipating Helen's return from travel, or inferring when she was out doing errands. While the more detailed and more typical visualization of Helen's movements around the house could provide more detailed information, simple butterflies contributed to the desired piece of mind and sense of awareness.

Fish 'n' Steps

Fish'n'Steps designed by Siemens Corporate Research, Inc. (Lin et al., 2006), is an application that combines ubiquity and simplicity of pedometers, wearable devices that measure one's

Figure 2. Fish'n'Steps. One participant's display after approximately two weeks into the trial in the Fish'n'Steps team-condition, also the public kiosk and pedometer platform, which rotated through each of the team fish-tanks. The components of the personal display include: 1) Fish Tank - The fish tank contains the virtual pets belonging to the participant and his/her team members, 2) Virtual Pet – The participant's own fish in a frontal view on the right side next to the fish tank, 3) Calculations and feedback - improvement, burned calories, progress bar, personal and team ranking, etc., 4) Chat window for communicating with team members



step counts, with the engagement of social computing games. Individuals enrolled in the game use pedometers to measure their daily step count. Fish'n'Steps then links the number of steps taken each day to the growth and emotional state of a virtual pet "belonging" to each individual: a fish in a fish-tank. Additional incentives incorporate social dynamics, such as competition between teams of players.

"Fish'n'Steps" was built as a distributed software application that included several functioning components as well as some "Wizard of Oz" components. Simple commercially available pedometers, Sportline 330, were used to measure the step count of individual participants. To collect data from pedometers, individuals placed their pedometer on a platform at a public kiosk, and took a picture of their pedometer screen, including the unique pedometer ID. The picture was captured and sent to a member of the research team who entered the appropriate data into a database.

The fourteen-week deployment study with nineteen participants showed that the game served as a catalyst for promoting exercise and for improving game players' attitudes towards physical activity. Furthermore, although most player's enthusiasm in the game decreased after the game's first two weeks, analyzing the results using Prochaska's Transtheoretical Model of Behavioral Change (Grimley et al, 1994), suggested that individuals had, by that time, established new routines that led to healthier patterns of physical activity in their daily lives. Once again, as with DFP, the simple visualization allowed to condense large volumes of data captured with pedometers and present a coherent aggregated picture of users' overall activity levels. Such compelling visual presentation had an additional benefit of creating a resemblance of emotional attachment and motivated a number of users to increase their activity.

UbiFit Garden

Another application that utilizes a similar idea was designed by researchers at Intel Research (Consolvo et al., 2008). UbiFit Garden is a mobile application designed to monitor and encourage physical activity by its users. On-the-body sensing component monitors individuals' physical

Figure 3. UbiFit Garden's Glanceable Display. a) at the beginning of the week; b) after one cardio workout; c) a full garden with variety; and d) a full garden on the background screen of a mobile phone. Butterflies indicate met goals

activity and can reliably differentiate between various types of exercise. The display, designed for a mobile phone, represents levels of activity through flowers in a garden: the number of flowers and types of flowers in the garden indicate amount and variety of different types of exercise. Butterflies above flowers signify achievement of activity goals.

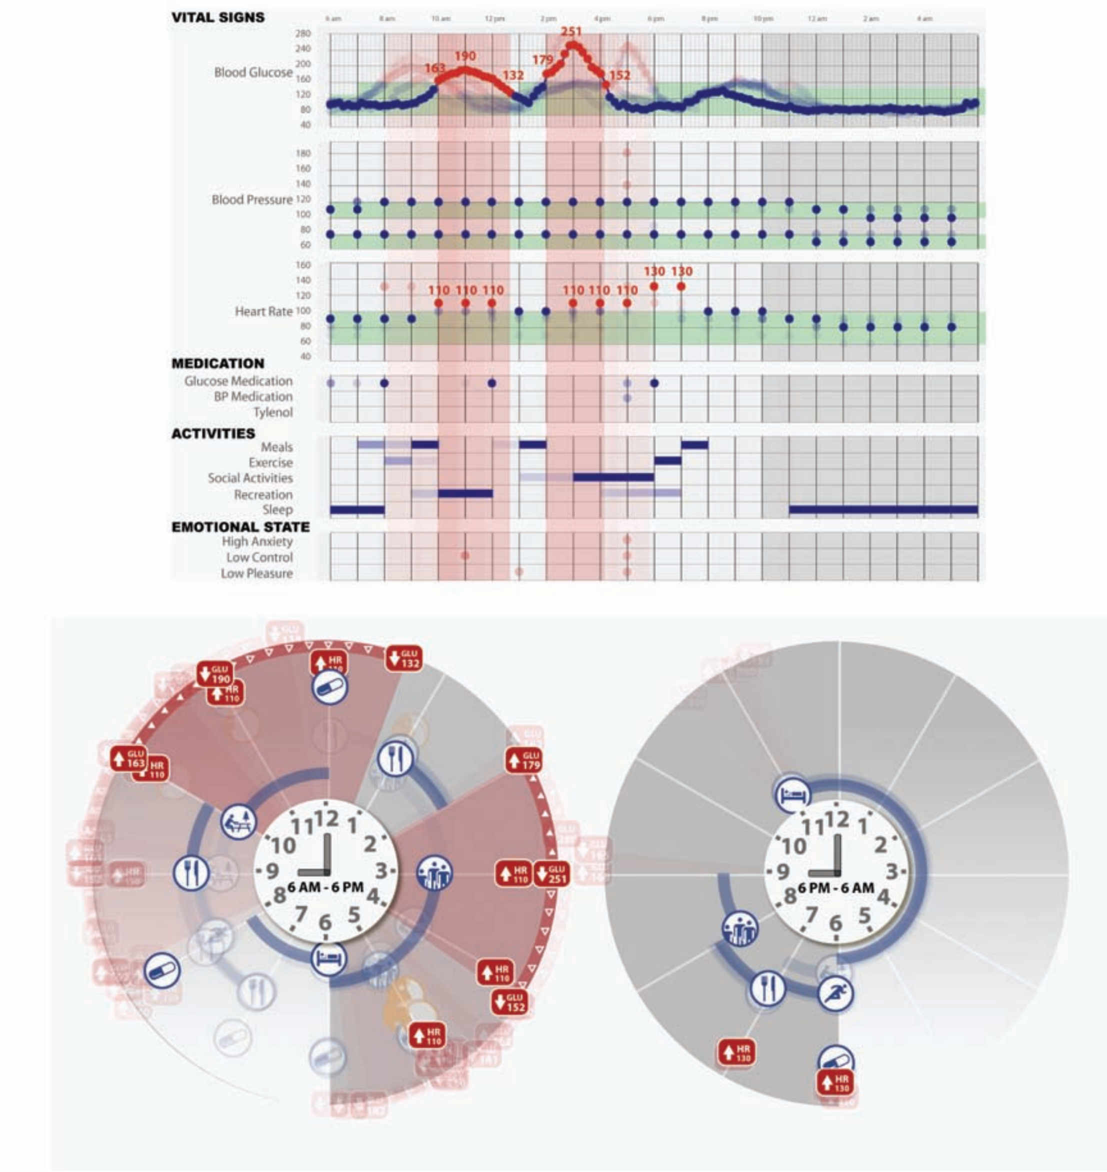
As with the previous two applications, UbiGarden uses simple, familiar imagery to convey specific information in a way consistent with using linguistic metaphors. While the initial deployment studies of UbiFit Garden focused primarily on the activity sensing side of the application, the display received a positive reaction from the users. Once again, large volumes of data were condensed to a simple coherent picture that was informative, aesthetically pleasing, and had an additional capability of inspiring emotional reaction and consequently motivating users.

Evaluating Metaphor-Based Interfaces

The deployment studies of the three applications described above have demonstrated their overall utility for the users. However, they did not specifically focus on the effectiveness of their chosen approach to visualizing the data through the use of metaphors. More generally, while there exist many examples of studies examining relative benefits of different visualizations, to the best of our knowledge none of them focuses specifically on visualizations that use metaphors. To address this limitation we conducted two small pilot studies that examined these questions. In these studies we specifically focused on data comprehension with different visualization types measured by an individuals' ability to answer pointed questions regarding the depicted data using the classic criteria of comprehension such as error rate and time required to answer the questions.

In the first of the studies we designed two visualizations to present diabetes-related data usually targeted by diabetes monitoring applications, such as records of blood sugar values and records

Figure 4. Comparing Relational and Metaphorical Visualizations. Both visualizations (top and bottom) show a day worth of activity records and health indicators (emotional state, blood glucose values, etc.) The visualization on top utilizes more traditional, relational techniques, such using coordinate systems. The visualization below uses a metaphor of a clock to show temporality of the data and uses icons to signify different activities



of daily activities. The first visualization used a more traditional, relational approach (Figure 4, top image); the second visualization used a number of metaphors to represent temporal aspect of the records, and for the design of the icons (Figure 4, bottom image). In a controlled experimental setting the participants were exposed to both visualizations for a limited amount of time and asked to answer a series of questions regarding the data.

Thirty-five participants were paid $125 to participate in a two-hour experimental session. Participants with diabetes were recruited from two age groups, younger adults (17 participants, mean age 36.24 years, range 25-40) and older adults (eighteen participants, mean age 69.18 years, range 60-75). Each participant had been living with diabetes for at least 2 years. Within age groups, our goal was to have individuals who differed in their ability to interpret graphs and data trends. Accordingly, one group consisted of high school graduates with little formal statistical knowledge, and no specialized experience in interpreting data trends or graphs. Another group consisted of individuals with Bachelors or Masters Degree, and some formal statistical training, with the expectation that they would be more capable of using graphs and extracting data from them. To further evaluate their ability to interpret traditional graphical presentations and validate our sampling methods, each participant was given a test taken from the graph understating portion of the Graduate Record Examination (GRE) (ETS, 2004). Participants were split into high (2-4 correct answers) and low (0-2 correct answers) Graphical Facility (GF). This produced an approximate median split, with 16 low and 19 high GF participants. Sex was not a variable of interest, but each group was approximately gender-balanced. We expected that age and Graphical Facility would influence the subjects' success with different visualizations, with subjects of younger age and higher GF performing better with relational graphics and subjects of older age and lower GF performing better with metaphorical graphics.

As expected, younger adults with higher GF required less time to interpret relational visualizations, whereas older adults with lower GF required less time to interpret metaphorical visualizations, without significant reductions in accuracy. In addition, younger adults with high GF showed strong preference towards the relational interface, though this was a general preference among all participants. The only group that showed slight preference towards metaphorical visualization was older adults with lower GF, although that trend was not significant. Somewhat surprisingly, in addition to age and GF, sex appeared to be an important factor in accuracy of the interpretations; the accuracy of the female participants was significantly higher on the metaphorical visualization. Further research is required to account for this finding.

In the second study, we expanded the scope of our investigations to include four different types of visualizations. The first of them (Bar Chart) utilized the familiar bar chart approach; the second one (Relational Graphic) used colors, shapes and forms but without coordinate systems to code information, the third one (Symbolic) used real world symbols and images to depict information, but the symbols were chosen arbitrarily, without any metaphorical connections, and the last one (Metaphorical) used metaphors to communicate information (see Figure 5 below). To account for the possible design bias some of these visualizations were designed by members of our team and some borrowed from the works of others (Huang and Mynatt 2003, Stasko et al, 2004). Based on our previous findings we specifically focused on individuals of advanced age (above 65) with various levels of education. As in the previous study, we expected that individuals with higher levels of education will perform better with more traditional graphics (Bar Chart and Relational), whereas individuals with lower levels of education will perform better with metaphorical visualizations.

Nine participants were recruited from senior centers to participate in the study. Participants' age ranged from 65 to 85 (mean age 70.8), with the majority of the participants being female (7 out of 9). Six participants completed high school and had some college experience, whereas three did not complete high school. The testing took place at the senior centers, and the participants were compensated $50 for participating in the 1½ hour session.

During the session, participants were presented with visualizations one at a time, with an

Figure 5. Comparing Bar Graphs, Relational, Symbolic and Metaphorical Visualizations. The four images represent different ways to visualize planned meeting attendance. Bar Graph (top left) shows three meetings as three separate bar charts with length of bars corresponding to attendance, non-attendance or no decision. Relational (top right) shows the same three meetings as flowers with colors of petals showing attendance (green), non-attendance (red) or no decision (white). Symbolic (bottom left) shows the same three meetings as three windows in a grocery shop with objects in the window showing attendance (watermelons), non-attendance (flowers) or no decision (apples). Metaphorical shows three meetings using metaphors of coffee tables with cups filled with coffee for attendance, cups turned upside down for non-attendance and empty cups for no decisions

explanation accompanying each visualization on the screen. After reviewing explanations, the participants answered four multiple choice questions about each visualization. The questions required participants to interpret the visualization (e.g., “How many people are planning on attending meeting 1?”); identify overall trends in the data (“There is an overall high attendance of the meetings”); or form an inference (“Meeting 2 seems the most interesting based on the planned attendance”). Participants’ accuracy and time per question were recorded. A subjective rating for ease of questions, ease of visualization, and comparative quality of visualizations was captured via a paper questionnaire after each visualization was presented. Time required for answering each question and the accuracy of the answers were captured by the researchers.

For Accuracy, the results showed a significant main effect of the visualization type across education levels [$F(3, 18) = 13.68$, $p < 0.001$]. Pair-wise comparison showed that metaphorical and symbolic visualizations were comparable with bar-charts, while relational graphics led to significantly less accurate answers [$F(1, 6) = 22.65$, $p < 0.01$]. Further analyses revealed a significant interaction between Visualization Type and Education [$F(3, 18) = 5.36$, $p < 0.01$; the means are presented in Table 1]. For individuals with higher education, metaphorical visualizations led to slightly inferior performance as compared to bar graphs. This trend reversed for those with

Table 1. Results presented in the form of mean accuracy for responses and standard deviations

Higher Education			**Lower Education**	
	Mean	St.D	Mean	St.D
Bar Graph	0.63	0.49	0.56	0.50
Relational	0.28	0.45	0.38	0.49
Symbolic	0.63	0.49	0.40	0.49
Metaphorical	0.56	0.50	0.67	0.48

lower education: These participants performed best with metaphorical visualizations; however, the differences in performance within this group were not significant.

There were no significant effects on response time, perhaps owing to large individual differences between participants.

These findings demonstrate considerable differences for older adults in their comprehension of information visualized in different ways. Although the small sample size of this study prohibits strong claims and conclusions, the trends identified in the experiment deserve further investigation. Across educational levels, relational graphics proved to be the most challenging for the older adults. In addition, education proved to play an important role in helping individuals benefit from traditional forms of presentation, such as bar graphs and relational graphics.

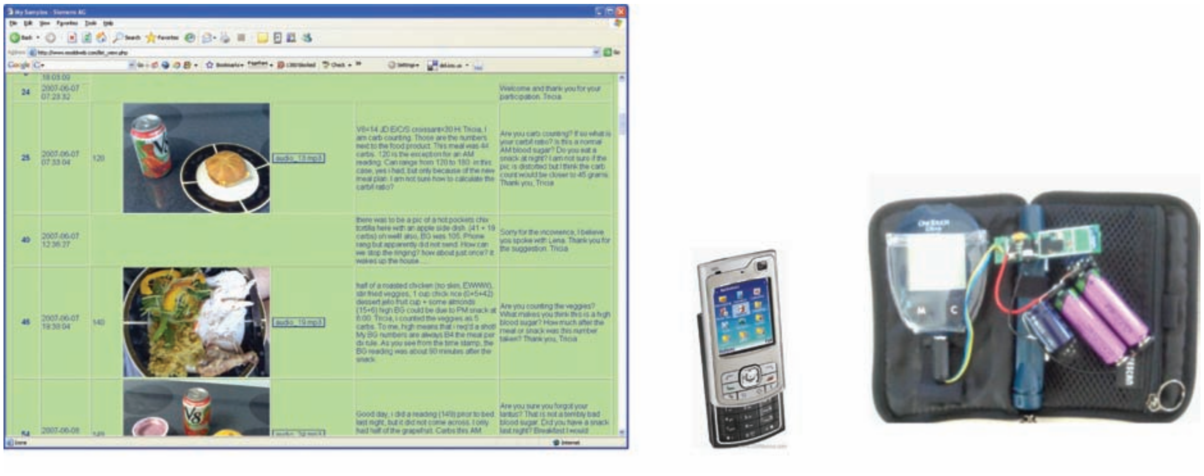
With these two small pilot studies we only scratched the surface of this issue, and uncovered new research questions. For example, in our experiments the participants received a limited exposure to each of the visualizations. Consequently, there remains a question of whether metaphorical visualizations will have similar benefits even after users gained substantial experience with them or their advantages are short-lived. However, even these preliminary results show that at least for individuals of advanced age and lower education metaphorical visualizations are a promising approach to depicting information.

SOCIAL SCAFFOLDING FOR DATA ANALYSIS

The applications we describe above successfully helped their users cope with large volumes of data captured by sensors. However, due to the significant level of data aggregation, these applications may have limited utility in facilitating detailed data analysis. Below we describe a complimentary approach for the design of health monitoring application that focuses not on a particular type of data presentation, but on helping users acquire and develop data analysis skills by observing and imitating experts.

There are a variety of ways people learn and acquire new skills. Some researchers argue that the acquisition of new skills in personal and even professional worlds is different in nature from formal schooling. Observations of a number of professional (butchers, tailors) and non-professional (Alcoholics Anonymous) communities of practice by Lave and Wenger (Lave and Wenger, 1991) led them to conclude that learning in these communities occurs through observation and imitation in a style known as apprenticeship. They argue that knowledge in these communities is preserved by core members or masters, who mastered the necessary skills in the course of their careers. New members join these communities at the periphery, and engage in observation and imitation of the masters, while often performing small and well-defined tasks. With time and acquisition of new skills, novices move from the periphery closer to the center of the community

Figure 6. Components of MAHI: MAHI website (screenshot of the actual site usage). The columns include: 1) record number, 2) date and time of capture, 3) blood glucose value, 4) picture(s), 5) audio, 6) participant's comments posted directly to the website, 7) educator's comments posted directly to the website; MAHI phone; Glucose meter with Bluetooth adapter



until they in turn become masters and keepers of community's practices.

In our work, we adopted the view of learning as a social activity that happens through observation and imitation. We incorporate features that facilitate these activities into the diabetes-monitoring application, MAHI (Mobile Access to Health Information). MAHI was developed in collaboration between the Graphics, Visualization and Usability Center of the Georgia Institute of Technology and Siemens Corporate Research, Inc.

MAHI is a distributed mobile application that includes a conventional blood glucose meter, such as LifeScan's OneTouch Ultra, a Java-enabled cell phone, such as Nokia N80 and a Bluetooth adapter, such as a modified and custom-programmed Brainboxes BL-819 RS232 Bluetooth Converter to support communication between the glucose meter and the phone (see Figure 6). Individuals with diabetes can use MAHI in two modes, as a diary and as an experience sampling tool. As a diary, MAHI allows individuals to capture their diabetes-related experiences, such as records of activities or questions and concerns they may have through voice notes and photographs (using a cell phone camera) taken with a straightforward and easy-to-use user interface. As an experience sampling tool, MAHI initiates recording sessions when individuals use their blood glucose meter. At that time, MAHI establishes a Bluetooth connection between the meter and the phone, allowing the phone to query the meter for the recently captured readings and prompt individuals to record the reasons for using the glucose meter, and the context of usage by capturing voice notes and photographs. The captured records are packaged by MAHI and transferred to a MySQL database hosted on a dedicated web-server.

The last component of MAHI is a web-based application built using PHP that offers access to dynamic, password-protected websites where individuals and their educators can review captured records, and engage in a dialog by providing comments, feedback and additional questions in a message board style.

Deployment Study

The deployment study was conducted in collaboration with the St. Clare's Hospital Diabetes

Education Center in Dover, NJ. The education program includes a number of personalized sessions with certified nurses and certified diabetes educators and registered dieticians to establish personal care goals, and weekly diabetes education classes, in which the students are familiarized with the physiological nature of the disease and different aspects of care. The two recruitment criteria included age (below 65) and experience owning and using a cell phone (over 1 year) to minimize confounds due to cell phone usability.

The research team invited all the newly enrolled students of the center to participate in the study as part of their educational program; 49 new students volunteered to participate. The study used a between-subjects design. Half of the participants (25) were assigned to the experimental group, provided with mobile phones, glucose meters and Bluetooth adapters and were asked to use MAHI during the four weeks of the program. Another half (24) were assigned to a control group and received all of the benefits of the diabetes education but did not use MAHI. General demographics questionnaires conducted prior to the study showed no significant differences between the experimental and the control groups in regards to age, gender, marital status, educational level, or the severity of their general medical condition and their diabetes.

Once the classes started, the individuals in the experimental group were expected to use MAHI independently, with no additional meetings with the research team beyond their attendance of the classes. During the class time, their glucose meters with Bluetooth attachment were collected for battery exchange. At the same time, the individuals were given an opportunity to ask questions, and discuss their experience with the researchers. The researchers attended and audio recorded all the classes that had recruited participants. Once the classes were completed, the individuals were invited for another qualitative interview and reimbursed $30.

Results

As with other applications mentioned earlier in this chapter, the deployment study of MAHI focused on the general utility of the application for individuals with diabetes and its ability to assist them in the management of their disease. We evaluated the impact of MAHI along three different dimensions: individuals' analytical state, or changes in their understanding of their disease, emotional state, or changes in their attitudes towards the disease and changes in their actual behavior. These three factors can help to recreate a comprehensive picture of one's diabetes management. The actual measures for each of these factors were selected together with the personnel of the Diabetes Education Center and included the following:

- **Analytical state:** A multiple choice questionnaire testing basic diabetes understanding developed by the Diabetes Education Center
- **Emotional state:** The two measures used included the standard Health Locus of Control (Wallston et al 1976) and Diabetes Quality of Life (Burrough et al, 2004) questionnaires
- **Behavior:** As part of the educational program, the personnel of the center helped new students to establish their individual management goals, specifically diet goals based on their established habits and desired results. The achievement of these goals was evaluated by the registered dietician during the post-study interview

In addition, we used the Grounded approach Theory (Strauss and Corbin, 1990) to analyze qualitative data, which included qualitative interviews with the participants and online conversations between participants and educators captured in MAHI. The complete findings of this study are described elsewhere (Mamykina et al, 2008). In this chapter we briefly summarize the results that demonstrate the overall effectiveness of MAHI and specifically focus on ways individuals engaged with the application and learned to analyze the data.

The results of quantitative measures indicated that both groups achieved significant improvements along all three anticipated dimensions. In regards to the specific benefits of MAHI, we found that using the application significantly contributed to individuals' improvement along two particular dimensions. These included achievement of personal diet goals, established at the beginning of the study, and acceptance of a more proactive and responsible stance towards diabetes management indicated by adoption of the Internal Locus of Control. Both of these findings are encouraging since they demonstrate that MAHI not only helped individuals meet their diabetes management goals but also helped them change their attitude towards the disease, a good indicator that the behavioral changes achieved during the study will endure overtime (Wooldridge et al, 1990).

These positive results can serve as an indicator that individuals were in fact able to comprehend the data collected by MAHI and draw meaningful conclusions from it. The analysis of online conversations and interviews with the participants gave us some cues as to what influenced individuals' comprehension. As we expected, the educators played a decisive role in helping individuals engage with the applications and learn the necessary analytical skills.

Many online conversations followed a similar pattern. They started with the identification of a specific problem, most commonly a surprisingly high blood glucose value noticed either by the participant or by the educator. After articulating the problem, the educator engaged in the analysis of the possible causes of the problem in individual's behavior by reviewing records captured by MAHI and filling gaps in the data through extensive question and answer exchanges captured on MAHI website. These exchanges played a critical role in illustrating to the participants the expert way of engaging with the data, formulating relevant questions and hypotheses and testing initial conclusions. For many participants these exchanges became the most valuable experiences of the study:

> *Half the time I didn't even answer her questions. But I knew that those were questions for me; this is how I should be thinking. Now I can look at these records and I know what to look for and how to look for it.*

Thus empowered by the expert example, the participants could incorporate the newly learned strategies into their own data analysis techniques and experiment with the new approaches. During this time, the educators observed participants' progress and provided feedback and recommendations until there was sufficient evidence that the participants adopted the new skills and no longer required any scaffolding. This three-step approach including demonstration of the new skills by the expert, internalization of the skills by the student with coaching from the expert and subsequent removal of the scaffolding have striking resemblance with the teaching style that Collins, Brown and Newman named "cognitive apprenticeship" (Collins, Brown and Newman, 1989). Through observing the experts and imitating their techniques the participants were able to master the volumes of data collected by MAHI and learn to draw meaningful conclusions from it.

DISCUSSION

In the last decade novel sensing technologies enabled the development of applications that help individuals with chronic diseases monitor their health and activities. These applications can generate large volumes of data that need to be processed and analyzed. At the same time, many of these applications are designed for non-professional use by individuals of advanced age and/or lower educational levels. These users may find the data collected by the applications challenging and overwhelming, rather than helpful and may require additional assistance in interpreting it.

We discussed two different approaches to designing computing applications that not only collect the relevant health and wellness data but also find creative ways to engage individuals in the analysis and assist with interpretation of the data. These approaches include the visualization of data using simple real world imagery and metaphors, and social scaffolding mechanisms that help novices learn by observing and imitating experts. Both of these approaches have a number of advantages and limitations that we discuss below.

Presentation of data, in particular data captured by health and wellness monitoring applications that use various sensors, has a number of clear benefits, as is demonstrated by the applications we described above. Their interfaces were able to condense large volumes of data inevitable with any monitoring application to a clear and comprehensible picture that was easy to understand by lay individuals, specifically by individuals of advanced age and lower educational level, who may otherwise have difficulties adopting novel technologies. These interfaces are aesthetically pleasing and consequently more appropriate for non-professional environments, such as homes, or for personal mobile devices. In addition, such visualizations as the ones utilized by Fish ‘n’ Steps and UbiFit Garden can inspire emotional response and further reinforce the behavior change they are designed to inspire. Finally, they tend to be intuitive enough to be used without any training and often require only a simple explanation.

With these advantages, however, come a number of limitations. The study of Fish ‘n’ Steps demonstrated that the emotional attachment can have a negative side: some participants limited their participation in the game because they found crying fish too upsetting. The researchers noted that adopting only positive reinforcements and avoiding negative ones might be a safer strategy. In addition, mapping with visual as well as linguistic metaphors is not precise and could be misinterpreted. Finding an appropriate visual metaphor for all and any data might be a serious challenge: all three applications described here focus on wellness and activity data, which might have more direct mappings to metaphors than more abstract clinical data, for example. Finally, because these visualizations help to condense large volumes of data they inevitably lead to data loss and thus may not be appropriate if the goal of the application is detailed data analysis.

Similarly, MAHI demonstrated that social scaffolding mechanisms can be successful in helping individuals engage with the data and learn to independently interpret it. This approach does not lead to any reduction in the data, consequently it can be used with relatively complex data displays that facilitate detailed analysis. It also avoids the necessity to search for metaphors, which may be challenging in cases of abstract data.

At the same time, the clear limitation of this approach is that it requires a significant commitment and time investment from the expert and depends on the personality of the expert. In MAHI studies, the expert providing advice was a member of the research team and was highly motivated to engage the participants, which may not always be the case. However, if further analysis of conversational patterns between experts and participants reveals a certain level of consistency in experts’ approaches, there is hope that the expert’s role can be fully or at least partially substituted by automated agents. Conversational agents in healthcare is already a vibrant and active research area and future research will show whether these agents can play a role in autoidentifaction applications as well.

KEY TERMS AND DEFINITIONS

Chronic Disease Management: A set of practices that allow individuals with chronic diseases to control the development of their disease and avoid or delay development of complications. For example, for individuals affected with diabetes, disease management usually involves close monitoring of blood sugar levels, adjusting diet and maintaining an exercise routine.

Health Monitoring: A collection of techniques that allow collection of data pertaining to individuals’ health. This collection could be performed manually or with the use of computing technologies. For example, in case of diabetes, health monitoring may include capture of blood sugar levels, records of individuals’ diets and exercise routines.

Information Visualization: A set of techniques for visually presenting certain data or concepts. Common examples of information visualization include graphs, plots, various maps or illustrations. Recently this term became associated with a branch of computer science that focuses on computer-based techniques for generating such presentations. These computer-generated visualizations could be static or interactive and are usually meant to assist in analyzing and comprehending large volumes of data.

Metaphor-Based (or Metaphorical) Visualizations: Presentations of complex data that use common linguistic metaphors and real-world imagery as a their basis. One of the most familiar examples of metaphorical visualizations are genealogical trees that use a “life is a tree” metaphor implicit to many languages to depict a history of a family, using branches of the tree to represent “branches” of a family.

Relational Graphics: Visualizations of data that rely on abstract mapping between the data and particular visual properties, such as position in space, color, shape or size. Examples of relational graphics include different types of graphs, such as line, bar or pie, and most charts.

Social Scaffolding: A set of techniques and methods that allows teachers or experts to support novices or students in their learning process. Common examples of socials scaffolding include coaching, when a coach is observing a student’s performance and provides feedback or learning by example, when an exert demonstrates certain techniques to students.

ABSTRACT

In this chapter we describe a distributed e-healthcare system that uses service oriented architecture as a basis for designing, implementing, deploying, invoking and managing healthcare services. The e-healthcare system that we have developed provides support for patients, physicians, nurses, pharmacists and other healthcare professionals, as well as for medical monitoring devices, such as blood pressure monitors. The system transmits e-prescriptions from physicians to pharmacists over the Internet. It offers multimedia input and output, including text, images and speech, to provide a human-friendly interface, with the computers and networks hidden from the user.

INTRODUCTION

According to Carmen Catizone of the National Association of Boards of Pharmacy (Catizone, 2002), there are as many as 7,000 deaths from incorrect prescriptions in the United States each year. A Washington Post article (Weiss, 1999) indicates that as many as 5% of the 3 billion prescriptions filled each year are incorrect. In the United States Institute of Medicine report, To Err is Human: Building a Safer Health System, Kohn et al. (USIOM, 2000) discuss human errors in the workplace:

> *Human beings, in all lines of work, make errors. Errors can be prevented by designing systems that make it hard for people to do the wrong thing and easy for people to do the right thing.*

The report sees the need to improve the quality of healthcare systems, ease the access to healthcare and healthcare information, and reduce the cost of delivery of healthcare. The Healthgrid review (Healthgrid Association & Cisco Systems, 2004) concludes that large healthcare systems have difficulties in managing personal data, standardizing the data, extracting content-based knowledge, and federating databases.

Computing and networking technology can contribute greatly to the quality of healthcare. The slow adoption of such technology in healthcare is caused in part by the highly decentralized nature of healthcare and in part because healthcare professionals are often uncomfortable with computers and networks, and feel that such technology is not central to their healthcare mission, even though they acknowledge that accurate record keeping and communication are essential to good healthcare.

In this chapter we present a distributed e-healthcare system that we have developed. The system is intended for use by patients, physicians, nurses, pharmacists and other healthcare professionals, as well as by medical monitoring devices. It aims to provide user interfaces that busy healthcare professionals and fearful patients find attractive and convenient to use, as well as more effective and efficient communication between them.

A patient can make an appointment with his/her primary care physician on the Web. The physician can refer the patient to a specialist electronically, if he/she is unable to treat the patient. When the physician prescribes medication, the system communicates an e-prescription over the Internet from the physician to the pharmacy, decreasing the probability of incorrect or lost information. The patient can check his/her prescription status on the Web and arrange for pickup or delivery of the medication.

BACKGROUND

Extensive work has been undertaken on the development of electronic healthcare information systems. Much of the work on such systems has focused on record keeping and databases based on the notion of the electronic medical record (Bourke, 1994; USIOM, 1997; Taylor et al., 2004; Tsiknakis et al., 1997). Work has also been done on access and security (Anderson, 1996; Andersen et al., 2001), as well as on social implications of recording and communicating healthcare information (Bloomfield, 1991). Less work has been done on human-computer interfaces and usability by healthcare professionals and patients, which our e-healthcare system aims to address.

Governmental and private organizations have promoted the use of electronic technology for healthcare, but these organizations typically incline towards centralized or centrally administered systems (Andersen et al., 2001; Detmer, 2003). Because of the fragmented nature of healthcare in the United States and the increasingly international nature of healthcare services and patients, more distributed and interoperable e-healthcare systems based on open international standards are needed (Grimson et al., 2000).

Beyer et al. (2004) discuss the limitations and challenges of developing an architecture for an integrated healthcare network. They identify flexibility, adaptability, robustness, integration of existing systems and standards, semantic compatibility, security and process orientation as key issues in developing a healthcare network. Song et al. (2006) present a survey of computer-aided healthcare workflow. They define workflow properties and provide a summary of requirements for common healthcare practices.

Omar and Taleb-Bendiab (2006) have utilized the service oriented architecture, in conjunction with grid computing technology, for a sensor and actuator framework that monitors the health status of a patient and provides feedback. Our e-healthcare system provides more extensive services that involve patients, physicians, nurses and pharmacists, as well as medical monitoring devices, whereas their system focuses specifically on the use of medical monitoring devices.

Care2x (2007) is an open-source, Web-based university project that implements a modern hospital information system for training medical students and healthcare engineering students. It includes a central data server and a health exchange protocol, and is implemented using the Apache Web server, the PHP scripting language and the mySQL database system. Our e-healthcare system focuses on the interactions between patients, physicians, nurses, pharmacists and medical monitoring devices outside the hospital setting, rather than on a health research data network or healthcare training for the hospital environment.

Subramanian et al. (2006) have developed a model for patient-centered healthcare services using a mobile device to push/pull data to/from a data analysis engine based on the service oriented architecture. Also relevant is the work of Budgen et al. (2007), who have developed a data integration broker for healthcare systems that uses a software service model to collect and integrate data from autonomous healthcare agencies.

THE DISTRIBUTED E-HEALTHCARE SYSTEM

Design

The distributed e-healthcare system that we have developed is based on the service oriented architecture (Srinivasan & Treadwell, 2005), and uses both Web servers and Web services (W3C, 2004) and also Atom/RSS (Bray, 2005). The service oriented architecture is an appropriate model for developing a distributed e-healthcare system, because it supports an open, networked ecosystem of multiple providers and users. Web servers and Web services support collaboration and enable interactions over the Internet by using standard protocols and conventional interfaces to facilitate access to the application logic and information. Atom/RSS provides syndication of content over the Web and enables synchronization of data in different databases.

Our distributed e-healthcare system comprises a Patient module, a Clinic module and a Pharmacy module. It uses desktop/server computers, hand-held mobile devices such as PDAs and smart cell phones, and medical monitoring devices such as blood pressure monitors. To provide more convenient input and output for healthcare professionals, the system employs various multimedia technologies, such as speech software for speech recognition (SRI, 2007) and speech synthesis (AT&T, 2007).

The Patient, Clinic and Pharmacy modules use security and privacy mechanisms to protect the patients' information in the e-healthcare system. Personal healthcare information is confidential, so access to that information must be restricted to authorized users. Users of the system are authenticated, and session information is kept in a log of service calls. Resources in the system are attached to the resource creator, and privileged users can view/modify the data in the system. For applications deployed on devices like PDAs/smart cell phones, authentication and session management are strictly enforced.

Patient Module

The Patient interface of our e-healthcare system, shown in Figure 1, allows a patient to request an appointment with a physician for a specific date/time, by communicating with the clinic Web service. Initially, a patient must make an appointment with his/her primary physician. The primary physician can refer the patient to a specialist, and the patient can arrange an appointment with the specialist.

The patient can see his/her previous appointments, and check the status of a prescription associated with an appointment. The e-healthcare

Figure 1. Patient interface

Welcome Firat Kart
Your last login: June 11, 17:24:50

You have 3 appointments in the next 7 days

Cavit Kart	Tuesday, June 12	10:00
Cavit Kart	Wednesday, June 13	15:00
Cavit Kart	Friday, June 15	13:30

system sends reminders about appointments with the physician, the status of prescriptions at the pharmacy, and messages from the physician or the pharmacist to the patient.

Medical monitoring devices, deployed with wired or wireless network support, are used to report periodically, or in an emergency, the status of the patient. Such devices do not send any patient-identifying information. Information is transmitted along with the serial number of the device, and the association with the particular patient is made by the clinic Web service. Unless the patient registers the device on the medical devices Web page, information from the device is discarded.

In our e-healthcare system, the Patient interface is Bluetooth-enabled to a blood pressure monitoring device, which transmits information from the patient to the patient's laptop or desktop computer. That information is communicated over the Internet to the clinic Web service for examination by the physician. The physician and the patient can see the historical data from the blood pressure monitor as a list and/or in a chart.

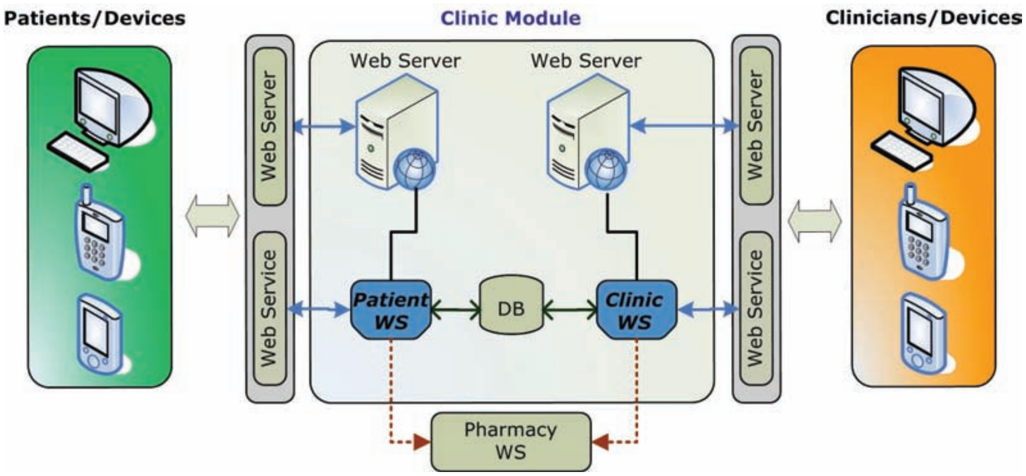
Clinic Module

The Clinic module, shown in Figure 2 provides support for routine activities of the healthcare professionals at the clinic. It maintains healthcare-related information, such as the physician's appointments, the patients that he/she has examined, notes related to the patients, etc. Access to a patient's private information is restricted and secured, as discussed previously.

The Clinic module exposes Web server and Web service interfaces for the clinic staff, the patients and the medical monitoring devices. The Web server interface is intended for users who prefer to use a Web browser to access the e-healthcare services at the clinic. The Web service interface can be used by humans or devices to communicate with, and deliver information to, the e-healthcare system. Applications that are implemented in Java use the Web service to communicate with the Clinic module. The Web server uses the Web service to access the data.

The Clinic module allows a physician or a nurse to create and view a patient's profile, and to add, delete and edit information (height, weight, blood pressure reading, temperature,

Figure 2. Clinic module



diagnosis, etc) about the patient associated with the particular patient profile. The clinic server application runs as a Java servlet and provides Web pages for the physician and the patient to access via the hypertext transfer protocol (HTTP) over the Internet. The patient information is stored in a database at the clinic, including the patient's profile, appointments related to the patient, and prescriptions related to the patient. The clinic Web service communicates with the database over a wired or wireless local-area network using Java database connectivity.

The Clinic client application runs on a handheld mobile device, such as a PDA or a smart cell phone, and exploits multimedia input and output, including speech software in order to provide a human-friendly interface for the physicians and nurses. The Clinic client application also allows the physician to create an e-prescription for the patient corresponding to a particular appointment.

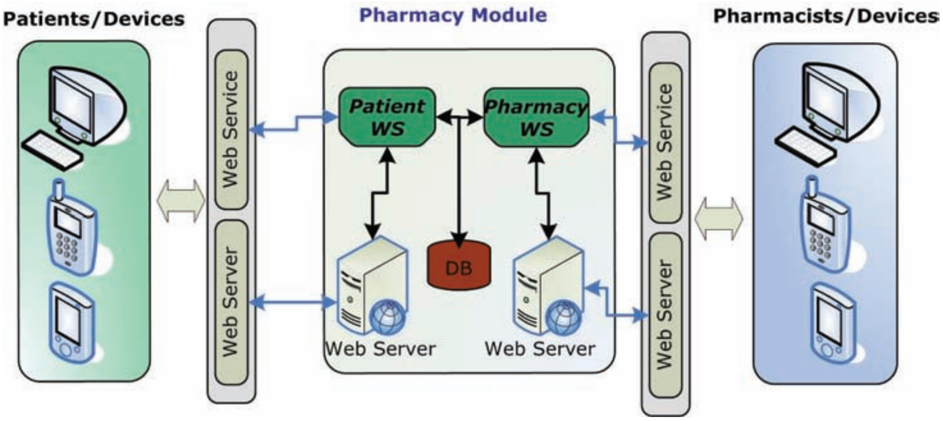
The clinic Web service discovers information about the pharmacies in the area, augments the e-prescription with the name of the pharmacy to which the physician is to send the e-prescription, and sends the e-prescription for the particular patient to the particular pharmacy using the Pharmacy Web service. To locate the pharmacy closest to the patient's home or the clinic, the clinic Web service uses the Yahoo! LocalSearch (Yahoo, 2007) Web service.

The physician can use the Web Server interface to access the e-healthcare system using a browser from a desktop/laptop computer or a PDA/smart cell phone. The physician can use the PDA to enter/retrieve information about the patient during/after an appointment and access this information any time, any where. The use of a PDA with a small keyboard makes it difficult for the physician to input information about the patient. Consequently, in addition to the graphical interface, we have enabled the PDA with speech software. Speech recognition software (SRI, 2007) allows the physician to enter/retrieve information by speaking. Feedback to the physician is provided by means of speech synthesis software (AT&T, 2007). Such speech software eases the task of the physician in completing tasks and encourages the use of the PDA.

Pharmacy Module

The Pharmacy module, shown in Figure 3, exposes Web server and Web service interfaces. The Web server interface allows the users to access the e-healthcare system at the pharmacy using a Web browser. The Web service interface

Figure 3. Pharmacy module



provides access for applications deployed at the pharmacy and can also be used by humans and devices. The Pharmacy module provides services to the pharmacists, patients and devices used at the pharmacy.

The Pharmacy module allows a pharmacist to view the outstanding e-prescriptions from the physicians and to view the e-prescriptions for a particular patient. The Pharmacy server application runs as a Java servlet and provides Web pages for the pharmacist, the physician and the patient to access via the hypertext transfer protocol (HTTP) over the Internet. The e-prescriptions for the patient are stored in a database at the pharmacy for the pharmacist's and the patient's reference. The pharmacy Web service communicates with the database over a wired or wireless local-area network using Java database connectivity.

When the physician submits a new e-prescription to the pharmacy, the Clinic module communicates directly with the Pharmacy module over the Internet. Removing human intervention from the communication between the physician and the pharmacist, and maintaining the information electronically, reduces the possibility of human errors.

The pharmacist can view the outstanding e-prescriptions for the patients, as the Pharmacy module receives them from the physicians. The Pharmacy Web service updates the status of the e-prescriptions as the pharmacist fills them.

When the pharmacist has filled an e-prescription, the Pharmacy Web service sends a notification to the Patient Web service. The patient can also determine, via the Web Server or Web service, whether an e-prescription has been filled and is ready for pick up or delivery. When the patient has collected the medication, the Pharmacy module sends an acknowledgement to the Clinic module, so that the physician knows that the patient now has the medication.

According to the National Community Pharmacists Association, a pharmacy in the United States dispenses an average of 204 prescriptions per day (Alexandria, 2006). Most of these prescriptions are renewals of existing prescriptions. Therefore, the Patient interface also has access to services that provide renewals of existing prescriptions, custom alerts, etc.

Implementation

We have deployed the Web servers and Web services of our distributed e-healthcare system on 3 GHz computers with 2 GB memory. We have deployed the client applications on 2 GHz

Figure 4. Physician's PDA displaying the e-prescription manager and a list of medications

e-Prescription Manager

Listening now, say 'help' anytime

Patient:

Medications:
Lovastatin, 20 mg, once a day, 5 refills
Metformin, 500 mg, 3 times a day, 5 refills

Medication: Metformin

Refills: 5 until July 30 2007

Sig: 500 mg,
3 times a day

computers with 2 GB memory. The client applications communicate with the Web servers or Web services over the wide-area Internet.

For the PDA we used the OQO device, which is a full-featured 3" x 5" personal computer. The OQO device is powered by a 1 GHz Transmeta Crusoe processor, which is powerful enough to run both an embedded speech recognition engine and our clinic client application for the physician. The device features a 800 x 480 resolution screen that is capable of providing the physician with detailed graphical information. The PDA can communicate with a desktop or server computer using wireless (WiFi) communication. The PDA displaying the e-prescription manager and a list of medications is shown in Figure 4.

While it is possible to use any programming and/or scripting language to implement a service oriented architecture or a distributed e-healthcare system, we decided to use the Java programming language for its ability to be deployed on small wireless devices as well as on powerful server computers.

In the following subsections we discuss the particular software technologies that we employed in our distributed e-healthcare system and the considerations that we used in making these choices.

Web Services

Our Web services use the Apache Axis2 Framework (which is the core engine for Web services built on Apache Axiom) and the Apache Tomcat server (Apache, 2007).

Most developers using Web services need to work with data in the form of Java objects, rather than XML documents. Last-generation frameworks, such as Axis and JAX-RPC, implemented their own forms of data binding to convert between XML and Java objects, which was a limited solution for developers. Axis2 is designed to support plug-in data binding using a wide-range of data binding frameworks. To ease the development and debugging of our distributed e-healthcare system, we used plain old Java objects (POJO), based on the Spring Framework (SpringF, 2007).

The data binding support uses customized extensions to the Axis2 WSDL2Java tool. This tool generates Axis2 linkage code based on

WSDL service descriptions in the form of stubs on the client-side and message receivers on the server-side. The client-side stub acts as a proxy for making calls to the Web service, defining method calls that implement the Web service operations. The server-side message receiver acts as a proxy for the client, by calling the actual user-defined Web service method. The client applications use the auto-generated stubs to make Web service calls and create/parse the XML representations of the Java objects.

Speech Software

Our e-healthcare system uses speech software for speech recognition and speech synthesis, as described below.

The e-healthcare system uses the DynaSpeak speech recognition engine from SRI (2007). DynaSpeak supports multiple languages, adapts to different accents, and does not require training by the user prior to use. It incorporates a hidden Markov model (HMM) for separating speech from interfering signals with different statistical characteristics. DynaSpeak is ideal for embedded platforms, because of its small footprint (less than 2 MB of memory) and its low computing requirements (66 MHz Intel x86 or 200 MHz Strong Arm processor). DynaSpeak can be used with either a finite-state grammar or a free-form grammar. We chose to use the finite-state grammar, because it offers greater control over parsed phrases than the free-form grammar does.

The e-healthcare system also uses the Natural Voices speech synthesis engine from AT&T (2007). Natural Voices provides a simple and efficient way to produce natural sounding device-to-human voice interaction. It can accurately and naturally pronounce words, and speak in sentences that are clear and easy-to-understand, without the feeling that a computer is talking to the human. Natural Voices supports many languages, male and female voices, and the SAPI, VoiceXML and JSAPI interface standards. Using Natural Voices, we created text-to-speech software for the prototype device that runs in the background and accepts messages in VoiceXML format.

Medical Monitoring Devices

Our distributed e-healthcare system supports the use of medical monitoring devices, deployed with wired or wireless network support, to report periodically, or in an emergency, the status of the patient. Such medical monitoring devices can include networked electronic blood pressure monitors, glucose monitors, weighing scales, pillboxes, etc.

Currently, our e-healthcare system is enabled with the A&D blood pressure monitor device (A&D, 2007), which transmits readings using a Bluetooth radio. After pairing the Bluetooth device with a Bluetooth adapter on a laptop or desktop computer, the blood pressure monitor transmits data to the specific service. Having received this information, the Client application uploads the readings to the Clinic module for storage and enables access to this information by healthcare professionals and patients.

The output from the blood pressure monitoring device on a patient's laptop or desktop computer is shown at the top of Figure 5. The blood pressure history of the patient as a clinic Web service is shown at the bottom of Figure 5.

Atom/RSS

Enabling physicians, nurses and pharmacists to use PDAs or smart cell phones requires those devices to be able to communicate with the Clinic and Pharmacy modules on their desktop or server computers using a wireless or wired network. It is possible that, at certain times and places, network communication is not available. For example, in an emergency situation, such as a hurricane or an earthquake, a physician cannot expect to have a network connection to his/her desktop or server computer. Physicians, nurses and pharmacists

Diastolic: 56
Pulse rate: 69
Mean Arterial Pressure: 67

Status: Bluetooth is on, waiting for data

must be able to access, and modify, healthcare information offline.

Atom/RSS (Bray, 2005) are syndication technologies, based on XML, that enable the sharing and communication of information between heterogeneous platforms by augmenting that information with meta-data tags so that the information is self-describing. They allow a publisher to make information available on the Web for consumers, so that they can retrieve the information subsequently. The information is delivered from the publisher to the consumer as an XML file, called an Atom/RSS feed.

We have developed a Consistent Data Replication and Reliable Data Distribution infrastructure (Kart, Moser & Melliar-Smith, 2007) that replicates information from one computer to another computer. We can use that infrastructure to replicate information from the physician's desktop or server computer to his/her PDA, thus allowing the physician to view that information when it is offline.

In our infrastructure, Atom feeds are used to synchronize the information on the physician's PDA with that on his/her desktop or server computer. At the start of the day, our software on the PDA retrieves the necessary updates from the clinic Web service on the desktop or server computer via a wired or wireless network. Any modifications to the information on the PDA are stored locally on the PDA. At the end of the day, our software on the PDA generates an update feed for the clinic Web service on the desktop or server computer to read.

FUTURE WORK

Our distributed e-healthcare system currently focuses on the relationships between patients, physicians, nurses and pharmacists. We plan to extend the technology to provide other healthcare services and to accommodate other healthcare professionals. For example, a nurse can use the e-healthcare system to check that a medication and dosage are appropriate before administering the medication to the patient. After the nurse has done so, the e-healthcare system informs the physician that the medication has been administered. Similarly, using the e-healthcare system, the physician can communicate the required laboratory tests for the patient electronically to the laboratory. After the laboratory technician determines the test results, the e-healthcare system returns the results electronically to the physician.

The Pharmacy and Clinic applications can be interfaced to applications used by pharmacists, such as Epocrates Rx (Epocrates, 2007), that provide information on appropriate medications and dosages, and that warn of interactions between medications. The Patient application can be extended to provide reminders to the patient to take medications at appropriate times. A medication dispensing device (e-pillbox), such as that provided by MedSignals (2007), can prompt and monitor the regular and timely consumption of medications, a significant weakness in current healthcare. Such a device can also notify the Physician application when the patient has taken a medication.

Communication between the physician and the patient between the patient's visits to the clinic is also lacking in current healthcare systems. Our distributed e-healthcare system can be extended to provide such communication, so that the physician can monitor the progress of the patient and the patient can report symptoms or receive reassurances. This sort of monitoring can reduce the number of unnecessary visits of the patient to the clinic and can increase the number of patients that should have been, but were not, seen by the physician. If physicians lack communication with patients, hospitals are in even worse shape because they have little contact with patients once they have been discharged. Our distributed e-healthcare system can enable hospitals to remain in communication with their discharged patients and to monitor the progress of their recovery.

We plan to investigate the use of PDAs and smart cell phones to provide continuing communication about the health of the patient. We also plan to investigate wearable monitoring devices that continuously monitor the health of the patient and report any deterioration.

CONCLUSION

We have presented a distributed e-healthcare system that uses the service oriented architecture as a basis for designing, implementing, deploying, managing and invoking e-healthcare services. The service oriented architecture facilitates the development of a distributed e-healthcare system by supporting an open, networked ecosystem of multiple providers and users who can collaborate, using Web servers, Web services and Atom/RSS. Multimedia input and output, particularly graphics and speech, make the e-healthcare system seem less computer-like and more attractive to users who are not computer-oriented.

KEY TERMS

Atom/RSS: Two different, but related, families of feed formats that are used to publish frequently updated digital content on the Web. Both feed formats are based on the eXtensible Markup Language (XML).

E-Healthcare System: A healthcare system based on the application of information and communication technologies that provides a wide range of healthcare services to its users including physicians, nurses, pharmacists and patients. Typically, these services are provided over the Internet.

Electronic Medical Record (EMR): A medical record in digital format.

E-Prescription: Electronic transfer of a medical prescription in digital format from an physician to a pharmacist, in contrast to the current paper-based method.

Service Oriented Architecture (SOA): A software architecture that uses loosely coupled services to support the requirements of business processes and users. Resources on the Internet are made available as services that can be accessed without knowledge of their underlying platform implementation.

Speech Recognition: The process of interpreting human speech for transcription, or as a method of interacting with a computer or device, using a source of speech input, such as a microphone.

Speech Synthesis: The artificial production of human speech. Speech synthesis technology is also called text-to-speech technology because of its ability to convert text into speech.

Web Server: A computer or computer program that accepts hypertext transfer protocol (HTTP) requests from clients (Web browsers), and that serves them HTTP responses along with optional data content, typically Web pages such as HyperText Markup Language (HTML) documents and linked objects, such as images.

Web Service: A software service that executes typically on a remote computer and that can be accessed by clients over the Internet. A Web service is based on standards such as the eXtensible Markup Language (XML) and the Simple Object Access Protocol (SOAP) and, thus, provides interoperable interactions over the network.

Chapter 2.7

Planning Successful Telemedicine and E-Health Systems

Michael Mackert
The University of Texas at Austin, USA

Pamela Whitten
Michigan State University, USA

Emily Krol
The University of Texas at Austin, USA

ABSTRACT

Telemedicine and e-health applications have the potential to improve healthcare organizations' ability to provide advanced services in a cost-effective manner. Given the failure rate of information technology projects in general (25%), successfully launching a new telemedicine or e-health system can be a daunting prospect–especially for organizations without experience with these new technologies. This chapter provides examples of important aspects of pre-project planning that can help set the stage for success in implementing new telemedicine and e-health applications; importantly, the lessons provided in this chapter are provided by discussing both systems that have achieved success and others that have faced significant difficulties. Key points discussed include: the benefits of involving important stakeholders and users in the planning process, effectively contracting with external technology vendors, and successfully managing expectations. Improved pre-project planning can contribute substantially to the eventual project outcome, so this is a step that cannot be overlooked.

INTRODUCTION

As healthcare providers and organizations seek to minimize costs while providing quality healthcare to patients, telemedicine and e-health applications offer promising solutions to these challenges. This chapter will explore pre-project aspects of telemedicine and e-health systems as well as implementations

DOI: 10.4018/978-1-60566-356-2.ch027

that contributed significantly to the technology's success or failure. Lessons learned in exploring these varying factors can be broadly applied to other Information Technology (IT) projects in the healthcare context. These lessons are important, as research has demonstrated that 25% of all IT projects fail (Keil & Mann, 2000).

Telemedicine refers to the provision of healthcare via telecommunication technology – healthcare provided at a distance. Some of the earliest telemedicine work was carried out by Wittson and colleagues in 1961, through the establishment of a video-based telepsychiatry service that linked providers in Nebraska at the Psychiatric Institute in Omaha with a distant psychiatric hospital (Wittson, Affleck, & Johnson, 1961). Since the 1960s, the number of telemedicine projects and services operating in the United States has grown so large it is no longer possible to quantify the exact number (Whitten & Kuwahara, 2003).

Telemedicine has evolved to include a wide array of services, including home-based monitoring of patients with chronic diseases (Hopp et al., 2005; McManus, 2004), providing hospice services via videophones (Bensink & Irving, 2004; Whitten, Doolittle, Mackert, & Rush, 2003), and Picture Archiving Systems (PACS) used to store and transmit images for teleradiology and similar applications (Raman, Raman, Raman, & Beaulieu, 2004). Telemedicine has been used in an assortment of medical applications, including dermatology (Burgiss, Clark, Watson, & Haynes, 1997; Chen, See, & Shumack, 2002), pathology (Joel, Leong, & Leong, 2004; Mireskandari, Kayser, Hufnagl, Schrader, & Kayser, 2004), radiology (Aas & Geitung, 2005; Crowe & Sim, 2004), psychiatry (Greenwood, Chamberlain, & Parker, 2004; Kuulasmaa, Wahlberg, & Kuusimaki, 2004), and physical therapy (Rizzo, Strickland, & Bouchard, 2004). Telemedicine researchers continue to explore innovative and efficacious methods of providing healthcare at a distance, so the capabilities of the technology will continue to improve.

While certainly related to telemedicine, e-health is a different field and type of application. Eysenbach (2001) provides a well-recognized definition of e-health:

> *e-health is an emerging field in the intersection of medical informatics, public health and business, referring to health services and information delivered or enhanced through the Internet and related technologies. In a broader sense, the term characterizes not only a technical development, but also a state-of-mind, a way of thinking, an attitude, and a commitment for networked, global thinking, to improve health care locally, regionally, and worldwide by using information and communication technology.*

The Internet has become increasingly ubiquitous, with recent reports indicating that 70% of American adults use the Internet at least occasionally (Pew Internet and American Life Project, 2007). A large majority of those using the Internet (8 in 10) have used it as a source of health information, and every day six million Americans seek health information on the Internet (Fox, 2006; Schloman, 2003). In this context e-health, much like telemedicine, can be a useful tool and model for thinking about improving healthcare – both to advance the quality of care and contain costs. Examples of promising e-health applications include websites designed to enable provider consultations (Heinzelmann & Kvedar, 2004), providers communicating with patients via e-mail (May, Finch, Mair, & Mort, 2005), online patient support groups (Arrington, 2004).

Given the potential for telemedicine and e-health, it is not surprising that healthcare providers and organizations are enthusiastic about these technologies. But the fact remains that adoption and usage of these systems is often disappointing, as even those systems that might be considered successful during the research phase often fade once initial grant funding disappears (Grigsby et al., 2002).

The overall purpose of this chapter is to provide useful examples of decisions made in the earliest stages of planning telemedicine and e-health applications that have contributed to the eventual success or failure of the described projects. This includes points about the benefits of involving important stakeholders and users in the planning and development process, effectively contracting with external technology vendors, and successfully managing expectations. Most of the examples come from four telemedicine and e-health projects:

- **TeleKidcare:** TeleKidcare is a school-based telemedicine system that makes use of interactive videoconferencing technology to provide medical consultations to children in Kansas schools.
- **Upper Peninsula Telehealth Network (UPTN):** The UPTN is a telemedicine and telehealth network operating in the Upper Peninsula of Michigan. The project has evolved over time from pilot testing the potential for telemedicine in 1994 to a network of 42 sites (Marquette General Health System, 2007).
- **Bedside Teleconsultations in Nursing Homes:** This system was designed to provide medical consultations directly to rural nursing home residents' bedsides. From August 2003 to March 2006, though, the project struggled through the process of installation, testing, and troubleshooting; the system was never used to complete an actual clinical consultation.
- **e-Health Solutions for Low Health Literate Patients:** Health communication researchers and professionals are exploring new methods for communicating health information to this hard-to-reach audience. One promising strategy is interventions designed specifically to meet the needs of low health literate individuals.

Overviews of each case and project provide the proper context for understanding the key points about a particular factor that contributed significantly to the final project outcome. References to other reports of these cases are provided where appropriate.

PRE-PROJECT PLANNING: INVOLVING KEY STAKEHOLDERS

Many pre-project decisions can have a large impact on the eventual success of a new telemedicine or e-health system, and one such decision is which stakeholders should be involved in the planning process. The exact list will vary depending on the system being designed, but stakeholders could include:

- Doctors
- Nurses
- Medical support staff
- Administrators
- Patients
- Caregivers
- Technology support staff
- Policymakers
- Members of the community

There are a variety of reasons stakeholders should be involved in the planning process for a new telemedicine. One of the main reasons is that involving stakeholders – especially the end users of a system – in the planning process can help increase likelihood of implementation once the system is eventually installed. Instead of feeling like they are having a new system forced upon them, involvement in pre-project planning can make end-users can feel involved throughout the development process of the system and increase their investment in its success. Involving stakeholders can also help avoid problems integrating the technology into the organization, one of the most common issues with telemedicine systems (May, Finch, Mair, & Mort, 2005).

One good example of involving key stakeholders in the planning process comes from the TeleKidcare system, a school-based telemedicine system deployed in Kansas (Whitten & Cook, 1999; Whitten, Cook, Kingsley, Swirczynski, & Doolittle, 2000; Whitten, Kingsley, Cook, Swirczynski, & Doolittle, 2001). The TeleKidCare system uses interactive videoconferencing for consultations with Kansas University Medical Center (KUMC) physicians and health offices in elementary and secondary schools. It was originally designed to provide electronic consultations for acute medical problems, however it has evolved to offer other services, such as management of behavioral problems. TeleKidcare has grown from four original pilot sites in 1998 to over thirty schools in urban and rural areas.

Mackert and Whitten (2007b) recently explored the factors that have contributed to the success of TeleKidcare, and the importance of involving stakeholders emerged as one of the most significant elements of the long-term success of the system. As project planners sought to design the TeleKidcare system, they involved a variety of key stakeholders. One project planner described this process:

> *[We conducted] interviews with people up and down the school districts, interviews at each school, meetings with the principals, meetings with the teachers… I can't exaggerate how many meetings there were.*

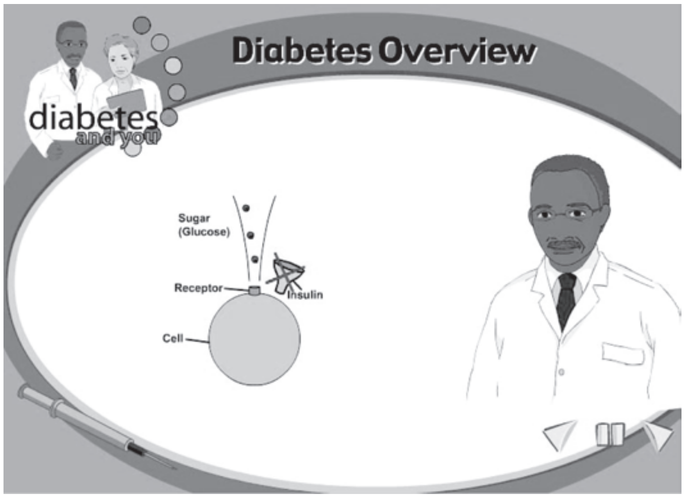
> *It was strategic in terms of who we included, in the early planning [the other project manager] and I sat down to talk about who all should be involved in the planning, who should be on the planning team. We had a few big meetings with everyone and then smaller meetings. We had a pediatrician and a nurse and someone from psychology and someone from telemedicine and someone from billing and someone from the school district.*

As stated earlier, a key benefit of involving stakeholders in the planning process is that it can personally invest users in the system's success. TeleKidcare planners made a concerted effort to involve school nurses, the eventual end users of the system, in the planning and development process. This helped ensure TeleKidcare would work – both the technology itself and the processes around building TeleKidcare into the school nurses' duties.

The importance of having the right stakeholders in place went beyond involving school nurses in the planning process. TeleKidcare managers carefully selected new sites for the system, focusing on those schools with the greatest chance of success. Components of a school with potential to make significant use of TeleKidcare were a nurse with the appropriate skills to use the system in their work, as well as school administrators who could appreciate the value of TeleKidcare in their school.

Success of a telemedicine system is largely dependent on those who are invested in the project. When key stakeholders are involved throughout the planning process, it helps increase acceptance of the end result among all interested parties. Careful consideration of who key stakeholders are is vital, as overlooking an important person or group of people can result in serious problems when attempting to deploy new technology in the healthcare organization. KUMC's work with TeleKidcare is a great example of how involving stakeholders can help set the project up for eventual success.

Figure 1. Diabetes and You



PILOT TECHNOLOGY WITH ACTUAL USERS

As engineers and technicians build and deploy a new telemedicine system, they often have a clear picture of how the system should and will work for end users. Not surprisingly, these individuals have little trouble operating the systems they design. The actual end users' first experience with a new system can be quite different, however. Because of this, it is extremely important to pilot test new applications with end users.

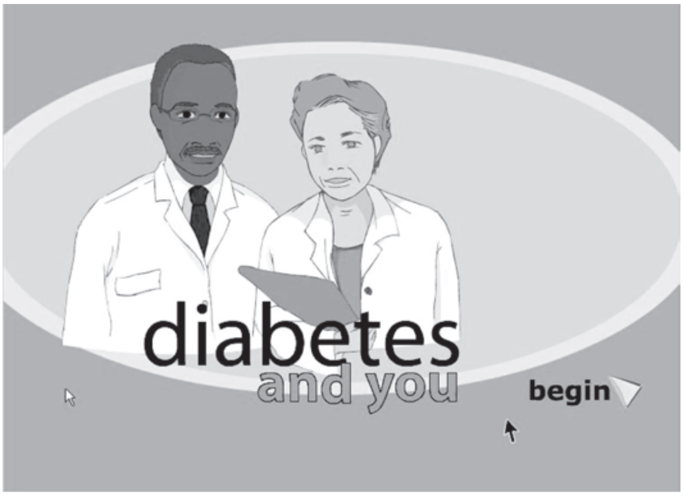
A particularly illustrative example of this principle comes from the study of e-health interventions designed to provide health information to low health literate audiences. Low health literacy – which focuses on the ability of individuals to obtain, process, and act on health information – is a growing problem that costs healthcare systems through incorrect use of medications, unnecessary emergency room visits, and poor management of chronic diseases (Nielsen-Bohlman, Panzer, & Kindig, 2004). Zarcadoolas et al. (2006) discuss the fact that health literacy is more complex than the ability to read, consisting of functional literacy, scientific literacy, civic literacy, and cultural literacy.

As health communication professionals seek better ways to provide information to low health literate audiences, one promising strategy appears to be websites designed specifically to meet the needs of low health literate audiences. Research has demonstrated the potential for these websites to provide information about diabetes and childcare to low health literate individuals (Whitten, Love, Buis, & Mackert, in press) and more general audiences (Mackert, Whitten, & Garcia, in press).

These websites were designed to be meet the needs of low-literate users by providing information primarily via audio delivered by animated health providers. The content was assembled by a team of healthcare researchers and professionals, and the websites themselves were designed in Flash. The goal of the designers was to make the sites accessible even to those users with little or no computer experience, so much of the navigation was accomplished via VCR-style controls (Figure 1). The first website, "Diabetes and You," included instructions for users on how to use their mouse to click on the rewind, play, pause, and forward buttons to move through the website.

After several rounds of design and review among the research team, the website was pilot tested with low health literate users recruited at

Figure 2. Diabetes and You introduction screen



food banks and a Medicaid healthcare clinic. Most participants had at least some computer experience, but others required brief instructions on the use of the computer and the mouse.

While most users were able to navigate the website with little difficulty, many of the participants with no computer experience became extremely confused during the introduction. For users who just received instruction on how to use a mouse, the website designers' decision to put an animated mouse arrow on the screen to demonstrate navigation (e.g., "Click the forward arrow to proceed.") was extremely confusing; these individuals were just introduced to the concept of the mouse moving the arrow on the screen, then the website introduced a second arrow of which they had no control (Figure 2).

It is unlikely that the "Diabetes and You" design team could have foreseen this particular difficulty faced by novice computer users. Given their own computer proficiency, the design and demonstration of the navigation system (including the "extra" mouse arrow on the screen) was not confusing. Only in testing the website with actual users was this design flaw exposed, and the next generation website did not include such a design element.

A similar issue came about when designing the navigation system. Website designers used a picture of a traffic warning sign as an icon to lead into the "Signs and Symptoms" section of the website. One of the healthcare professionals who helped design content for the intervention insisted that a picture of a pancreas be used as the icon for that section of the website. Eventually the website designers included a picture of a pancreas in an early version of the website, which immediately confused users (who thought it looked like a sponge). The website designers went back to using the traffic warning sign as an icon for the "Signs and Symptoms" section, and this became another example of how experts can often have a difficult time completely understanding the knowledge and expectations of users.

It can be difficult for system designers to completely understand the needs of eventual users and anticipate all of the unusual or unexpected things they might do in using a system. As such, there is simply no substitute for testing systems with potential users. The earlier, and more frequently, this can happen during the development process, the better.

LET USERS DETERMINE THE BEST WAYS TO USE A SYSTEM

As a new telemedicine or e-health system is being designed and tested, it may seem natural to begin developing procedures and best practices for actually using the technology. Indeed, there must be some sort of procedures in place so that users can be trained and prepared to integrate the system into their existing work practices. As discussed earlier, involving actual end users in the development and testing processes will help ensure that training and usage manuals reflect how the system will actually be used.

It is important, however, that any formal or official procedures for using the technology be flexible enough to let users appropriate the technology in useful and unexpected ways. As the development and pilot testing process is never going to be perfect or encompass all potential situations in which a system might be used, administrators and project planners must empower end users to determine the best ways to use technology once it is in the field.

As an example, the school nurses involved with the TeleKidcare system discussed earlier routinely found uses for the system that were not anticipated. Unanticipated applications of the technology included:

- Nurses use the equipment as a diagnostic aid in their offices, such as using the system locally to see things on the television screen using the otoscope.
- Nurses use the system to contact other school nurses for second opinions on cases where they need assistance.
- Nurses continue to use the school videoconferencing network that was originally set up for training purposes. Over time this has become an informal mentoring network to help new TeleKidcare nurses get up to speed and successfully adopt the technology.
- Nurses used TeleKidcare for a videoconference between a KUMC physician and parents of a sick child, so the physician can explain the necessity of bringing their child to the doctor for ailments that cannot be handled via telemedicine.

One nurse described this last situation:

We also have TeleKidcare for those hard cases where [the doctors] are not able to diagnose a child, and I know that sometimes their limitation is that this child probably can't be diagnosed with telemedicine. But I'll bring the parent in so they can have a consultation with the physician. Sometimes they need to hear it from the physician that this child has a medical issue that needs to be seen by a doctor [in person].

Clearly, part of the continued success of TeleKidcare has been due to the fact that administrators are very open to the idea of nurses innovating and appropriating the technology. Given the fact that adopting new technology into existing work practices can be a challenge, it definitely is not for everyone. One nurse spoke of this fact, saying:

It's not for everybody. We have a nurse right now that's at a preschool, and she has an opportunity to go to a telemedicine school, and she said she doesn't want [to move]. So it's not for everybody. I think the nurses that are interested and believe in it, the ones that see the outcomes, are the ones that are really more involved. I have one nurse right now that has telemedicine, she's split between schools and it's too much work. I think it just depends on that individual – how much she believes in it, and how much work she's willing to put into it.

Recognizing the importance of having the ideal nurse in the school to let TeleKidcare achieve significant utilization, the presence of a capable nurse becomes one of the major considerations when looking at a new potential TeleKidcare site. TeleKidcare administrators' awareness of the importance of a capable school nurse can help them avoid bringing telemedicine to schools that would not use the system to its full potential.

While some systems will need to be used by all staff, the case of TeleKidcare highlights the fact that targeting the correct early adopters and users can make a significant difference in project success. Even for a more large-scale technology implementation (e.g., an Electronic Medical Records system), such systems can be implemented on a clinic-by-clinic or department-by-department basis; targeting the clinics or departments most likely to successfully adopt the technology – and appropriate it in novel ways – can help the following clinics and users get up to speed more quickly.

One of the most effective ways that administrators and planners can encourage this type of use is to provide users with a rough framework of how the system "should" work. In making this framework available to users, and explaining to them that the goal is to provide flexibility in bringing the technology into their work, users can feel empowered to experiment with telemedicine and determine what works best for them and their patients. This is particularly true in a system with multiple sites, where the organizational culture and processes at different sites might vary dramatically. One of the TeleKidcare project managers spoke of this fact:

It takes an extensive amount of planning. It takes a lot of research, and actually going out and doing site visits and seeing what's going to work. What works in Kansas City, Kansas, does not work anywhere else. What works in one community does not work in the next. So I think it's a lot of planning and a lot of interviewing, a lot of seeing what resources are out there [at the schools and in the community]. So what we have to do is make a template [of] how to do things. [We can] say, "This is how we do things up in Kansas City. This is, so far, what we have seen to be the best working process."

Now we're introducing in Bellingham, which is a whole other process. We might have to adapt it a little bit to that community, or have them take our template and [adapt] it for themselves. It just depends on if the community is using our resources or they're using the local ones.

Essentially it comes down to the simple fact that overly-rigid models for technology use are likely to achieve only what they were designed to accomplish – consistent usage in the specified manner in expected situations. Project managers and planners who are willing to let users experiment with telemedicine, though, are more likely to oversee a more creative and active system.

EFFECTIVELY CONTRACTING WITH EXTERNAL TECHNOLOGY VENDORS

Contracting with external technology vendors may be a necessity, especially for healthcare organizations with little experience deploying telemedicine and other advanced e-health systems. This is not necessarily a bad thing, as partnerships between healthcare organizations and technology vendors can be extremely collaborative and effective.

As one example, Kinsella et al. (2004) describe the customization of a home monitoring device designed for elderly patients. The study described how a home health agency worked at length with its technology vendor to test the product and customize it for its patients. The authors insightfully note that "using this disciplined planning and implementation approach required more effort and time than simply installing technology" (Kinsella, Lee, & Ecken, 2004, p. 287).

While successful cases demonstrate that such partnerships can indeed work, it can be more instructive to consider partnerships that have not worked. Mackert and Whitten (2007a) provide an overview of one such failed partnership, between university researchers (and their partner nursing homes) and the primary regional telecommunication services provider (named Company X for the purposes of this report). The proposed project would have linked four rural nursing homes with urban specialists, providing videoconference consultations directly to nursing home residents' bedsides. The problems encountered in this project provide a number of important lessons.

Because of the status of the telecommunication industry at the time, most local markets were dominated by a single service provider. Given the likelihood that Company X would eventually supply transmission lines for the system (no matter what company or companies might provide hardware and networking within the nursing homes), researchers involved Company X in the process of preparing the grant. Cost estimates provided by Company X made it possible to ensure service would be available at project sites and prepare the budget for the grant. This was an important aspect of submitting a competitive grant application and planning a successful system. A manager from Company X spoke of their interest in assisting in the process of planning the system and applying for the grant:

And I know his [the company's leader on the RFP response] intention, which is often the case, is that we try to engage ourselves within the planning process, so it makes it easier to respond to the bid. And I know [he] had tried to do that.

Then we even worked a little bit with [a member of the researchers' institution] in purchasing. Simply because he wasn't real familiar with the video, you know the whole network and everything like that.

Once awarded the grant, researchers published a Request for Proposals (RFP) to invite interested companies to compete for the project contract. This was a very straightforward process, as the system architecture had already been planned for the purpose of submitting the grant. Companies were thus forced to compete for the work based primarily on price, as opposed to creativity in meeting the overall objectives of the researchers. After reviewing three responses to the RFP, Company X received the contract; this was due to the lower price of their proposed solution and their unique ability to provide a turnkey, end-to-end solution. Speaking at the end of the project about the RFP process, though, one manager from Company X stated:

I think the thing that we probably find makes things go better generally is if the RFP process specifies just some general characteristics that you [the customer] would be looking for in order to partner with somebody on the project. Then the design becomes a little bit more collaborative, both sides sitting down as we're doing the design and just working through exactly what the applications are and being able to interact and say, "Okay, here's your choice. If you want to move at this speed, here's what we'd recommend. If you want this [other] speed, here's what we'd recommend."

I would say just generally we find that people are very collaborative in the design process, and sit down and give and take through how we want this designed versus just being given the system [design or requirements]. That generally tends to work out a little better.

Aside from the RFP process, another issue arose due to the nature of the contract between the researchers and Company X. The contract was relatively straightforward for a fixed sum of money to complete a working system. There were no incentives in place to encourage more efficient work by Company X, nor penalties for poor performance or failure to deliver a working system. The simple contract was a result of receiving and spending research grant funds. However, the simplicity of the contract provides interesting insights into why more efficient contracts are required.

Most important is the simple fact that a technology vendor is likely to have technical expertise well beyond that present in the healthcare organization. While this expertise is the reason that the healthcare organization is partnering with the technology vendor in the first place, this imbalance in expertise can make it challenging for the healthcare organization to effectively monitor the vendor's performance on the contract and validate their expertise. One member of the research team spoke of this issue in relation to a specific piece of hardware required for the network:

When [Company X] had talked about that product they really talked about it as if they knew what they were doing. And I think that as things progressed we had a hard time just getting it, and then technical support was nonexistent and it really turns out that they [Company X's engineers] didn't have very much experience with that product at all. That was quite surprising to me.

There's always a place for beta and field trial, and every vendor is going to work on equipment that they've never worked with before, but they didn't up front clearly disclose the fact that they didn't have a lot of experience with that product.

In situations where there is a significant imbalance in the technical expertise of the two organizations, it is necessary for contractual incentives to encourage efficient performance on the part of the vendor. At that point the technology vendor will carefully monitor its own performance, a necessity given the healthcare organization's relative inability to do so.

The results of this particular project should not discourage healthcare organizations from partnering with external technology and telecommunication service providers, of course, but it does point to the fact that such partnerships can be more complicated than expected. The process of finding and contracting with a technology vendor requires planning and thorough consideration of how a healthcare organization can put the right incentives in place to encourage vendor performance.

SETTING REALISTIC EXPECTATIONS

One of the easiest mistakes to make when beginning a new telemedicine application is to be overly ambitious in what the project can realistically accomplish. This is particularly true when writing a new grant and looking to initiate a project that will create excitement among the healthcare organization and funding agencies. Specifically, it is tempting to suggest that a new telemedicine system will serve large numbers of patients at lower costs than traditional models of healthcare.

The case of the UPTN, operating in the Upper Peninsula (UP) of Michigan since 1994, provides an instructive example of why it might be better to set realistic expectations up front. The UP of Michigan is an extremely rural area with an aging population, severe weather, and transportation challenges. Marquette General Health System (MGHS), the largest healthcare provider in the UP, was initially interested in telemedicine as a way to eliminate lost productivity as providers traveled back and forth to educational events.

The project manager who began investigating telemedicine recalled early efforts to stay "under the radar" with the preliminary attempts to secure pilot grant funding. While MGHS management did not outright discourage these efforts, they were clear that this would be nothing more than a test, a bridge to be crossed if and when grant funding was awarded.

These early pilot efforts and grants were viewed as a chance to test the technology, and the potential for telemedicine to help address needs that MGHS had identified. Rather than assuming a telemedicine application will solve specific problems and investing heavily in it, testing it first provides a more realistic model for building telemedicine and e-health capacity.

To provide an interesting counterpoint to MGHS's efforts with the UPTN, a second network was initiated in Michigan in the mid-1990s as the result of an organizational strategic plan. A grant supported the first three years of network operation, with long term sustainability addressed through significant network fees. This network has survived and succeeded with educational and administrative services, yet clinical applications have not developed and site expansion has been limited. Since this research did not explicitly study the second telemedicine network operating in Michigan, its troubles developing clinical applications and adding new sites could certainly be due to a variety of other factors. Still, the difference in strategy for initiating and building these two networks reflects a fundamental difference in the two operations, and could reasonably be believed to explain at least some portion of the networks' differing outcomes over time.

The UPTN has consistently grown within its means, gradually adding new services and independent sites. The alternative strategy – trying to do too much, too quickly – could be more prone to network collapse if system usage cannot justify the high costs of a larger system when grant funding expires.

Mackert and Whitten (in press) discuss a variety of reasons the UPTN has succeeded, but this realistic attitude in the early stages of the project can provide an important lesson to others. Successfully managing expectations must be a key managerial imperative in launching a new telemedicine or e-health system, particularly if the healthcare organization and its employees have little experience with such technology. The UPTN's early pilot work and eventual growth – which was similar to the TeleKidcare's small number of pilot sites and subsequent expansion – speaks to the benefits of "starting small," letting users achieve early success with realistic goals, and make it possible for the system gain momentum over time.

CONCLUSION

There are many factors that contribute to the eventual success or failure of telemedicine and e-health projects. Some of these can simply be beyond the control of healthcare organizations, such as a large regional or national telecommunication services provider not able to provide sufficient bandwidth to a remote facility. But many of the factors that determine the fate of such systems can indeed be controlled – or at least managed – by healthcare organizations, including organizational culture, work processes, and putting the proper incentives in place to encourage the adoption of new technology.

Effective management of telemedicine and e-health systems does not begin once the system begins to service end users. Quite the contrary, some of the most important decisions to be made in implementing such a system must be made long before the technology will help provide healthcare to patients. What is the best way to work with an external vendor in deploying the technology? How can end users of the system be involved in design and pilot testing? How should users be trained to use the system? How can the expectations of organization members and patients be managed effectively? Finding good answers to such questions will help set a new telemedicine project on the path to success.

Healthcare organizations certainly have good reason to consider telemedicine and e-health systems in determining the best ways to provide high quality healthcare under continuous pressures to reduce costs. Given the potential, it is easy to imagine how the system will operate when it is up and running smoothly. The important thing for project managers to recognize, however, is that it can be a long journey from deciding to initiate such a project to completion. Successfully managing the earliest stages of such an endeavor can make it much more likely that their final vision will indeed be realized.

KEY TERMS AND DEFINITIONS

E-Health: Health services delivered through the Internet and related technologies.

Health Literacy: The ability to obtain, process, and then act appropriately on health information.

Telemedicine: Provision of healthcare services at a distance via telecommunication technology.

This work was previously published in Handbook of Research on Information Technology Management and Clinical Data Administration in Healthcare, edited by A. Dwivedi, pp. 433-446, copyright 2009 by Medical Information Science Reference (an imprint of IGI Global).

Chapter 2.8

Shared Healthcare in a Regional E-Health Network

Kari Harno
Helsinki University Central Hospital, Finland

ABSTRACT

Healthcare information exchange is transforming the practice and structure of healthcare delivery. This chapter introduces the building of a regional e-health network between public healthcare providers as well as the necessary legal foundation and governance for this successful deployment in a Finnish Hospital District. An overview is presented of prerequisite building blocks, such as policies supporting the knowledge-intensive e-health services and the creation of a partnership between shareholders enabling regional e-health delivery. The roadmap to a national e-health network is paved on the premises of these experiences and lessons learned are transferred to described concepts when migrating to a national e-health network. Understanding these principles and critical success factors (i.e., the role of stakeholders, governance, and financing) is essential for guidance to implement viable cross-organizational information exchange. In this context ICT not only fulfills the objective of cost containment, but also creates positive impacts on patient care and service quality.

DOI: 10.4018/978-1-60566-356-2.ch024

BACKGROUND

Knowledge is fueling growth and social development in every region of the world. Finland has successfully evolved from a resource driven economy to a knowledge driven economy spearheaded by information and communication companies such as Nokia. However, it is the use of ICT rather than its production that is decisive in the long-term economic growth.

The transformation may be explained by global financial and economic restructuring, but also by less typical national policies including a strong welfare state and in particular the very strong emphasis on education (Dahlman, 2005). The welfare state is not a unitary concept, but rather a mixture of values, accomplishments and aspirations varying somewhat from country to country (Giddens, 2007). The traditional welfare state is essentially a collective insurance system, which has been slow in adapting to changes initiated by the knowledge driven economy and specifically the use of information technology.

Health policies in most countries have been more or less oriented to here-and-now problems as they occur and health care provider interests tend to prevail over those of clients. Present day healthcare is provided by information-based organizations requiring clear, simple common objectives that translate into actions, so as to optimize the joint performance.

The productivity of the public sector, organized and performing in this fashion, has been declining in the 21st century (Mäkitalo & Ruottinen, 2006), although productivity is the key to meet the increasing financial requirements of the welfare society that stem from the consequences of the demographic changes in Europe.

In the post-industrial welfare society we should be expecting empowered clients through a series of mechanisms, such as availability of information, personalization of services and choice (Giddens, 2007). The average person's ability to access data and communicate electronically is proliferating exponentially. In Finland, 80% of the population is using the Internet and every second citizen owns a PC. Although more than 100 personal health records (PHR) and related technologies have proliferated in the United States and abroad, only a small proportion of the population uses PHRs (Connecting for Health, 2006). Therefore, this leapfrog change to consumer directed healthcare is expected to take some more time and in the meantime we need to adopt provider-sponsored clinical data networks in healthcare.

TRANSFORMATION OF HEALTHCARE WITH ICT

It is widely acknowledged that one of the greatest challenges facing healthcare information technology today is the effective sharing of clinical and administrative information among healthcare providers. Although timely sharing of patient data has been slowed down by issues such as security, privacy and confidentiality, lack of standards has created obstacles to achieving interoperability between different information systems.

Information Sharing in Networks and Healthcare Practice

Knowledge-based organizations are composed mainly of specialists who develop their own performance through feedback from colleagues and also from clients. Hospital care in university clinics mirrors this kind of knowledge-intensive service model with highly educated specialists and coordinated practice. Members of these networks are separated from primary care physicians through organizational boundaries, but also to some degree by practice and identity that divide.

Looking at learning we see the analogy in two types of work-related networks that, with the boundaries they inevitably create, are critical for understanding learning, work, and the movement of knowledge (Brown & Duguid, 2002). First, there are the networks that link people to others whom they may never get to know but who work on similar practices. These are the "networks of practices" and they are notable for their reach which may be fortified by information technology. There is some reciprocity in consultations across such a network. Although these networks produce little new explicit knowledge, they are operationally very efficient in supplementing tacit and collective learning to this process.

These networks represent practices between hospital and primary care physicians or other professionals. Healthcare information sharing by ICT is most suited to support, develop and strengthen the networks of practice. However, healthcare has been slow in undertaking such exchanges because supporting reach and information sharing extracts resources and knowledge from hospital care and results in the reduction of demand for hospital services. Therefore, such loosely coupled networking systems may make the hospital vulnerable and therefore formal agreement and strategic alliance negotiations are necessary early on.

Second, there are the more tight-knit groups formed, again through practice, by people working together on the same or similar tasks. These are what we call "communities of practice". Here coordination is tight, ideas and knowledge is distributed in productive and innovative fashion. While information technology and information sharing is very good in reach, it may suit less well to the dense interaction already in place between practices in the same clinic.

New Integrated Models for Organizations

According to Angelo Rossi Mori (2008), two approaches to innovation are possible in healthcare (http://emea.himss.org/enewsletters/index.htm#f1). The first deals with healthcare informatics and the second approach stems from new organizational models for an economically sustainable evolution of healthcare, such as chronic disease management. The ICT solutions should cope with continuity, collaboration and communication among the actors and this will support the synchronization of activities across facilities.

The traditional functional structure in health care provider organizations should first shift to a structure that medically integrates the care of patients with particular medical conditions and is able to coordinate care over the continuum (Porter & Teisberg, 2006). This is what health information exchange de facto is presently capable of advancing and a growing number of providers are moving to this model, although some argue that this will tend to fragment health care delivery.

Why has Transformation in Healthcare Been Slow?

Tax-funded health care systems are considered easier for the government to steer and reform. However, some core problems hindering the transformation stem from structural changes. Healthcare in Finland was radically decentralized in 1993 when central government relinquished to the municipalities many of its regulatory and management powers in relation to the delivery of health and social services, and changed to a non-earmarked, block-grant system for providing state financial support to local government (OECD, 2005).

Responsibility for healthcare lies in the hands of the municipalities, making the national government dependent on their cooperation. It is the 300+ municipalities, and the 20 hospital districts which represent them, which have been given the main lead in the financing, provision and management of health. Decentralization on the scale found in Finland strengthens local decision-making and ownership at the cost of problems in diseconomies of scale and lack of expertise. In the field of ICT it may be expected to result in lack of common definitions and standards, lack of national data base, lack of national transparency and comparability and barriers to diffusion of some innovations (OECD, 2005).

Barriers in healthcare may also be seen to be due to cultural differences between professional groups and as resistance to development of new organizational models (Harno, 2006). The proposed regional technologies would have allowed the construction of a new working environment, supporting the collaboration between multidisciplinary team members (patient and professionals), defining common care targets according to predefined and stratified plans for patient management and providing access to tools to optimise the resources available. However, the municipalities could not come to terms at this stage with the hospital district on governance and funding of the new registry.

The municipalities were free to invest in technology at a time, when local ICT progress and interoperability issues would have demanded guidance. Although the level of investments in information and communication technologies has been relatively low (approximately 2% of all expenditure) in the healthcare sector, the lack of direction and standards led to a broad spectrum of one-off systems with little technical interoperability. The first ICT strategy (Ministry of Health and Social Welfare, 1995) underlined the importance of creating seamless care between providers, but lacked an action plan and was issued too late to halt the progress in municipalities initiated already in 1981.

As a consequence of this, by 2001 diverse electronic patient record systems were in active use in 63% of primary care providers. In 2005 96% of primary healthcare centres were using electronic patient records and it was the main way of recording patient data in 99,4% of them (Hämäläinen, 2007). Even in the private health sector 88% of the clinics were applying EPRs in daily practice. By the end of 2007, the coverage of electronic patient records in public primary and specialized care organizations in Finland was expected to approach 100%.

GOVERNMENT ACTIONS IN FINLAND

The role of the state as the norm-setting and regulatory authority has been strengthened during the 21st century and the responses in different nations to healthcare challenges are also slowly but surely converging (Busse & Schlette, 2007). Examples of this are the introduction of country-wide hospital plans, as well as the national IT plan ARGE ELGA in Austria (Hofmarcher & Rack, 2006) and the increase in state-level legislative action regarding health IT in the USA (http://www.ehealthinitiative.org/2007HIESurvey). While there was virtually no legislation at the state level related to health IT prior to 2005, in 2005 and 2006 thirty-eight states introduced 121 bills specifically focused on health IT, and of those 36 bills passed into law in 24 states. Since the beginning of 2007 a total of 208 bills have been introduced across all 50 states that refer to the adoption or implementation of health IT.

A specificity of the Finnish model in rapid structural transformation beginning in the mid nineties has been the early application of a systems view, i.e. acknowledgement of the importance of interdependencies among stakeholders in various stages of innovation process and funding these simultaneously. In healthcare such instruments have been only recently assigned (Kuitunen & Haila, 2007) and national investors of healthcare are currently coordinating their efforts and setting the stage for emulating the innovative business environments into healthcare.

In Finland, the Act on Experiments with Seamless Service Chains (2000) provided the legislative foundation for the building of regional co-operation in matters of information management, with the aim that information concerning the client in social welfare or healthcare can be transferred electronically from one organization to another. This provisional Act included technical requirements for the regional *e*Health network, for citizen access services by an *e*Card, and requirements for applying care managers and seamless chains in health and social care.

As a result of the Act on Seamless Service Chains the design of a regional record locator service (RLS), a database that originated in the networking project Macropilot in Satakunta (1999), was launched. In HUS the service was originally developed as part of an EU funded Inter-Care project together with participating vendors. Although the project system was originally in use since 2001, the present version was implemented in 2003. The Government provided start-up funding for the connecting organizations in the piloting hospital districts such as the Helsinki and Uusimaa Hospital District and its UUMA project in the Uusimaa province.

CASE UUMA: HEALTHCARE INFORMATION EXCHANGE

The Hospital District of Helsinki and Uusimaa comprise 23 hospitals in the province of Uusimaa, which includes the capital city Helsinki, in Southern Finland. It includes three leading academic and research hospitals in Finland. As a joint authority it provides specialized care services to the 1.4 million citizens in its 32 member municipalities. The Hospital Information System and *e*Business applications in use within the Hospital District are described in a sector report by *e* – business w@tch in 2006 (www.ebusiness-watch.org).

One of the present academic hospitals (Peijas Hospital) was digitalized already in 1990 and by the end of 2008 the electronic patient records project (ESPA) will have accomplished that health care information is accessible from any of the 15.000 PCs or by any of the 22.000 health care professional users in the Hospital District. Although municipal health centres were digitalized earlier, most of them were applying different electronic patient records in their care. The promotion of regional procedures using ICT was seen necessary to support continuity of care.

Definitions

Integration has been defined by the HIMSS EHR Implementation Toolkit Task Force as the process of bringing together related parts into a single system in order to make various components function as a connected system (HIMSS, 2008). The degree of integration may vary and seven integration levels have been identified. Our focus has been creating comprehensive regional health information exchange (RHIOs), i.e. legally separate organizations sharing encounter information with each other and approaching high degree of interoperability. Based on the degree of interoperability we have achieved level 6.

Interoperability means the ability of information and communication technology (ICT) systems and of business processes they support to exchange data and to enable the sharing of information and knowledge (http://www.i2-Health.org/) originating from the European Interoperability Framework (European Interoperability Framework, 2004).

Messaging Processes Integrating Primary and Secondary Care with *e*Referrals

We have set up a wide-area referral network between primary care and three university hospitals. This network was initially launched in 1990, but it took several years to promote significant exchange of information beyond the conventional media. In 2002 67.000 *e*Referrals were transferred between the Helsinki University Hospitals and primary care. The solutions extended from the initial VPN use to EDIFACT standard and finally transition to standardized HL7 messages utilizing C-way message transfer systems (HUSway) through a single Network Access Point (HUSnap). In 2007, 200.000 *e*Referrals and approximately the same range of discharge *e*letters were exchanged between primary and secondary care providers.

The electronic referral not only speeds up the transfer but also offers an option for communication between the primary care physician and the hospital specialist. By sharing information and knowledge remote eConsultations between primary and secondary care physicians evolve into a new virtual working space for integrated delivery of *e*services between the health care providers. Besides transferring data or information between providers, networking partnerships have to be structured by mutual agreements.

The underlying model of the electronic referral process is:

- The referrer initiates an e-request
- The organization receives it
- The organization allocates it for reply
- The responder replies to the initiator

The *e*referral module has been in production for over ten years and has gone through extensive assessment studies by us (Harno, 2000) or analyzed by third parties (Roine, 2001; Wootton, 2001). In these studies the *e*referral system has decreased the need for secondary care services by reducing first visits to outpatient clinics by 36% and in less urgent cases by 50%. The system allows more patients to be treated at less expense. Because all patients are thoroughly examined beforehand, the numbers of repeat visits as well as direct costs remain lower. We have shown convincingly that the interactive use of an *e*Referral system improves access to an adequate level of care and even large scale use results in more timely appointments. By prospective follow-up studies we have been able to prove that the quality of health care using remote *e*Consultations is consistent with outpatient face-to-face visits.

Regional *e*Health Network

The core of the regional *e*Health service is the Navitas record locator service (Harno & Ruotsalainen, 2006). The record locator service (RLS) is a service that queries the locations of patient records within the eHealth network. The purpose of the RLS is to allow the physician or other healthcare professional to retrieve data on a patient from other institutions that the patient has visited. The physician sends a query to the RLS, which returns a list of record locations acquired from the patient information system, but not the data itself. The view provided by the RLS is a read-only view, structured in a user-friendly and visual way.

At the first stage, the RLS only informs the doctor that her patient has medical records at one or more institutions. The contents of these records are not revealed by the RLS. Retrieval of data contained in the electronic health records is a separate process of the RLS and requires the patient's informed consent. This exchange of information occurs directly between the requesting physician and the institution that stores the record by clicking a link, a window will open up to display the actual clinical information.

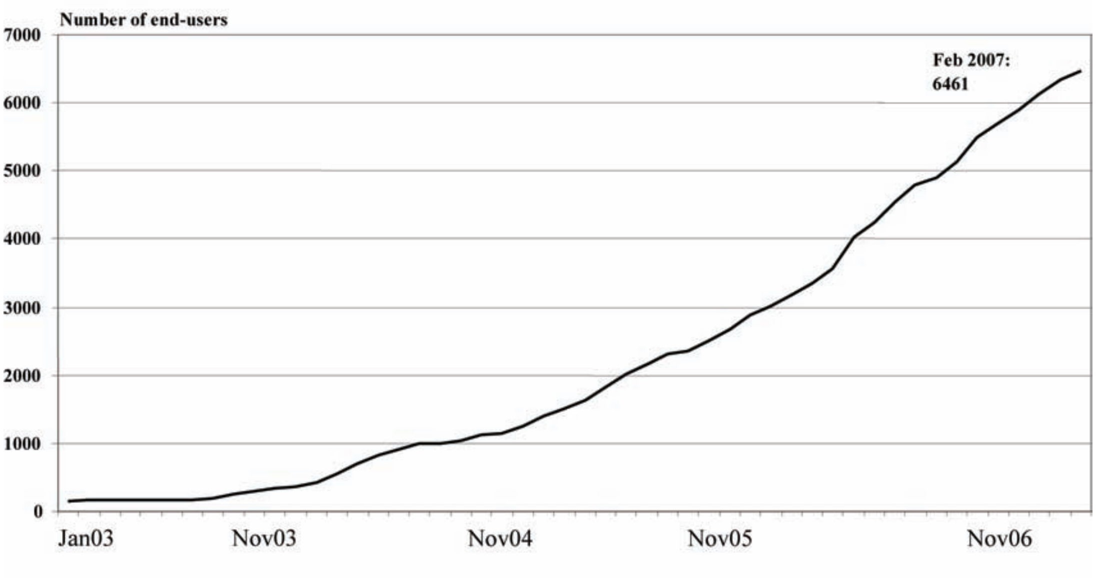
The RLS is a centralized database containing links to patient data stored in their legacy systems. Provider access is possible by web browsers and patient information includes (primary care/hospital) visits, critical data, EOE (laboratory and imaging), images and reports, laboratory results, referrals and discharge letters. All data is sorted according to social security coding, which is standard procedure in Finland. Standard API connections between primary care information systems and the RLS data are installed. The documents are produced in CDA R1, more recently in CDA R2 format, and messages transferred in a standard pattern (XML/HL 7).

Each participating organization has its own electronic health record. Besides the EHR, HUS has many other clinical information systems e.g. the laboratory system and HUSpacs, which have all been connected to the RLS. At the moment there are 15 different patient information systems in some 55 organizations connected to the RLS. A specific adapter software has been installed locally into each of the systems through which links are fed into the RLS.

Navitas has a regional user database and centralized authentication and authorization services; this enables the participating organizations to have complete control over their own users. The health care professionals can access Navitas from their personal workstations using a web browser. The data transfer is encrypted and only private, dedicated networks are used to transmit the data.

The service was originally launched in 2003 and presently most (29/31) of the municipalities in the Hospital District, as well as 24 HUS hospitals, are connected to the RLS and apply it for regional exchange of information. Currently there are 6.800 professional users in both secondary and primary care (Figure 1). Two private health care clinics and non-profit hospitals are connected to the RLS for eReferrals, discharge letters and image exchange. In addition, two other Hospital Districts are linked with the Hospital District of Helsinki and Uusimaa through the eReferral and discharge system.

Figure 1. Cumulative increase of end-users in health care provider organizations of the hospital district of Helsinki and Uusimaa since the first implementation of the Regional eHealth Network in January 2003



Health Information Exchange

The municipalities and hospitals were not initially networking except when referring patients to the hospitals or when mailing discharge letters to primary care. The return of discharge summaries was meagre and varied according to specialty from 10% to 50% return for referred patients, but increased to 100% after the deployment of the *e*Referral system. Our preliminary study demonstrated that multi-professional teamwork and secure information flow in the network was needed for community patients with several health problems (Valta, 2003). The most relevant information was the patient medical history, contact information, information support for home care and availability of services.

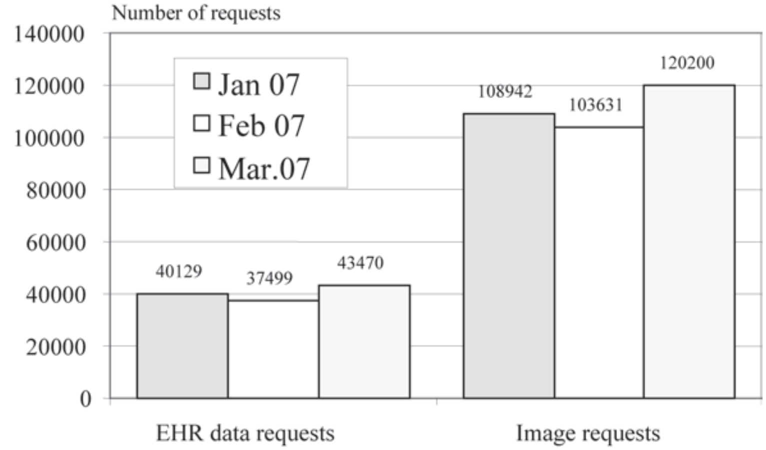
In 2007 roughly 50% of the data exchange in the Hospital District between primary care and RLS consists of imaging. The monthly volume of images transferred is 140.000 and the rest of the RLS information exchanged was distributed among the EHR information available through the RLS with over 60.000 monthly requests (Figure 2). Over 7.000 daily HIE requests were recorded. The technical and non-technical barriers appear to be overcome, since the downtime for the regional network in 2007 was less than 99, 99%. However, downtime of legacy EPR systems inaccessible during those intervals was not included.

Recently, the *e*Health Initiative reported that in 2007 34% of the respondents were exchanging laboratory data and 32% data related to outpatient episodes. Exchange of emergency department episodes, outpatient laboratory results, and radiology results are 30%, 28% and 28%, respectively.

Funding and Business Case Development

The governmental funding was intended for investments on the infrastructure, but not for operational costs. This funding solved our initial concern in 2002, which was still four years later in the USA the most significant challenge for health information exchange initiatives. 90% of

Figure 2. Number of monthly requests for healthcare information exchange by healthcare professionals to the regional Record Locator Service segmented according to their distribution for either images in the regional PACS archive or EHR data in legacy systems.



the organizations participating in the fourth annual survey of health information exchange at the state, regional and local level perceived creating sources of upfront funding to be either a very or moderately difficult challenge.

The creation of information exchange in health care requires both capital for investments and means to support the financial requirements of ongoing operations. To achieve a national health information network in the USA would cost according to expert estimates $ 156 billion in capital investment over 5 years and $ 48 billion in annual operating costs (Kaushal, 2005). Approximately two thirds of the capital costs would be required for acquiring functionalities and one third for interoperability.

The start-up support uncovered the next challenge – developing a sustainable business model. In the USA many communities are unable to collaborate, because of intense regional competition, disinterest by key stakeholders and overtly fragmented or large, local healthcare markets (Glaser, 2007). This may appear obvious within a market-oriented healthcare system, where reimbursement system rewards both volume and fragmentation and serves as a disincentive for sharing health information across healthcare stakeholders.

However, even the municipalities responsible for public provision and funding of healthcare were concerned about the business model for the regional *e*Health network. Although there was some evidence that implementing an *e*Referral and *e*Consultation system improves health care processes between secondary and primary care and contains health care costs (Harno, 2000), it was still unproven whether the regional *e*Health network would be able to reduce operational costs and improve clinical performance.

The paradise of shared information and a more egalitarian working environment just wasn't there in the beginning, because standards support for HL 7 messaging between EPR's and record locator services, on the one hand, and patient data in hospital information systems, on the other hand, were partly missing. This was not inspiring initial pilot organizations to invest, because there were only limited returns for their costs to be expected.

The business model for the regional eHealth network had to be based on transactional cost calculations originally made for the picture archiving system (PACS) implemented in the

Hospital District. HUSpacs, the PACS of the Hospital District of Helsinki and Uusimaa (HUS) is one of the largest regional PACS installations in the world. In total, over 1,000,000 examinations are handled per year, representing around 20 terabytes of imaging data completed on about 300 connected modalities.

Information technology was driving the transaction costs of centralized image storage and transfer down to such an extent that regionalizing health care information exchange could be estimated to contain costs. Radiology in all the hospitals of HUS was transformed filmless by 2004. Since the pricing of film development and delivery to primary care became more expensive than adding user licenses to the regional eHealth network for viewing these images, the business case was proven to be healthy and sustainable.

The funding is no longer dependent on non-operating revenue from the Ministry of Social Affairs and Health, and the financial sustainability appears viable, since it derives its revenues for ongoing operations from HUS (29%) and municipal primary care (71%).

It is therefore somewhat surprising that the viability of RHIO 1.0 in the USA appears questionable, because the majority of the about 200 RHIOs is expected to vanish in the years ahead, unable to address the challenges (Glaser, 2007). It is anticipated, that the majority of the clinical data exchange in RHIO 2.0 will be the result of targeted initiatives undertaken by organizations that have very specific business goals.

Low-hanging fruits from economic scale benefits to public health care providers were reaped by centralizing imaging and laboratory services in HUS, i.e. all metropolitan area municipal laboratories have been transformed to point-of-care testing and sample collecting points, while sample analyzes have been centralized and automated in HUS laboratories.

Horizontal integration by concentrating specialized services like orthopedics and urology within the three university hospitals was accomplished three years after the electronic health record was first deployed in HUS. This change was pursued not only for cost containment, but foremost to improve the quality of care, since surgeons need a certain number of operations to maintain skill levels in operational procedures.

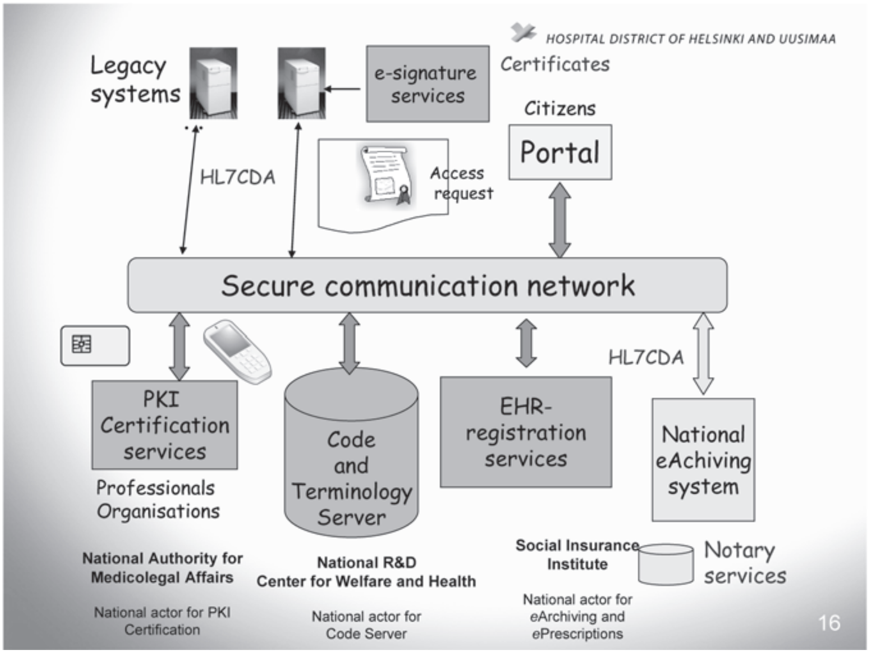
Now four years after the *e*Health network was launched the metropolitan municipalities are planning to allow their citizens to visit the closest emergency or laboratory unit because healthcare information exchange no longer inhibits these processes. Patient-centered processes are finally substituting traditional organizational focused services with the aid of healthcare information exchange.

Governance

The Regional Health Information Organization (RHIO) is the provider-centric organization creating and managing the regional healthcare data exchange in regionalized networks. These networks are often referred as RHIOs and this would connect multiple provider institutions in a region. The collaboration of regional healthcare stakeholders come together to address issues of governance, funding, privacy policies, data sharing agreements and the management of the exchange technology infrastructure (Lang, 2007) .

The essential building blocks for the creation of a RHIO between stakeholders, i.e. sufficient social capital and ability, are needed to create partnerships and effective working relationships. In Finland, the Act on Seamless Service Chains regulated data sharing and privacy policies. Formalizing the governance within a loose group of collaborators (in 2001 five municipalities and the Joint Authority) was pursued by a contractual arrangement. This contract laid out common values and policies to bond the parties, created a framework for the governing bodies and addressed the funding between stakeholders. However, consensus had to be achieved between the stakeholders, because the RHIO possessed

Figure 3. A schematic description of the architecture for the Finnish National eHealth Network



no independent decision making power over the municipalities or Joint Authority.

NATIONAL HEALTH INFORMATION EXCHANGE

Steps Taken by the National Health Project 2002-7

To promote better access to patient information, the Ministry of Social Affairs and Health has produced national specifications on the requirements for content and structure of information systems concerning open interfaces, data protection, information security and architecture. Security, privacy, authentication, and system management were centralized. Local providers submit data to, and request data from, the central repository (national *e*Archive) using the centralized network (secure communication network) with 24/7 availability (Figure 3). The service-oriented architecture (SOA) and Web services form the network-interaction standards.

Effective sharing of clinical and administrative information had been progressing slowly, but so far no uniform presentation of data enabling disparate stakeholders to apply their legacy systems and have consistent presentation of data existed due to lack of common terminology and different classifications. Therefore, the National Health Project also focused on national certification and distribution of common classification and codes, as well as on uniformed structured core data in EPR's (Häyrinen, 2004).

The goal for semantic interoperability requires means of moving granular data and a framework to fully understand information. The core data refer to uniformly defined structured data contained in the patient records. These data may be presented in a specified form and encoded using classifications, nomenclature and glossaries that are currently in general use.

The core data are created during treatment events and may be used as a link to clinical data, to view the essential information on the patient, to include in discharge summaries or treatment plans, to create certificates or to link with decision-support-systems. The uniformed structure allows sharing of this information with other providers and building a longitudinal patient record. All vendors in Finland are obliged to include the uniformly structured data set in their products by the end of 2008.

The data elements included in this phase consist of patient identifier, care provider identifier, treatment period and event identifier (seamless chain identifiers), problems and diagnoses list, health risk factors (allergies, smoking and alcohol use), physiological measurements (for example blood pressure, weight), examinations and procedures, medications etc. The list of structured data is intended to be expanded in 2010 to include uniform datasets for dentists, diabetes and cardiovascular disease prevention.

The uniformly structured data builds upon the Clinical Data Architecture (CDA), which Finland adopted as Release 1 form in 2000 and experiments are on way with distributed decision support using CDA Release 2. The national *e*Health network relies on HL7 CDA Release 2, which is a limited subset of HL7 V3 and builds upon other HL7 standards, including HL7 Reference Information Model (RIM).

CDA documents contain data that can be readily integrated into document management systems and record locator services. These documents with the most pertinent information on current and past health status will form the basis for sharing patient information.

Legal Issues and National Actors

Specifications of the national health information architecture and services were drawn in 2006. Most entities of functional requirements such as authentication, authorization, locating health information, auditing and logging were embedded in legal issues which were simultaneously prepared. The government's bill on the processing of personal data relating to health care was passed and came into force in July 2007. The law (http://www.finlex.fi/fi/laki/kokoelma/2007/20070023.pdf) sets the foundation for the deployment of the National Care Records Service and the National *e*Prescription and Transmission Service by 2011.

Three National Actors were appointed responsible for these services: The Social Insurance Institute as actor for *e*Archiving and *e*Prescriptions, The National R & D Center for Welfare and Health as actor for codes and terminology and National Authority for Medicolegal Affairs as actor for PKI certification for professionals and organizations. It will be mandatory for public and private sector healthcare providers to connect to the services from their legacy systems which need to be certified before the patient records will be archived into the national archive.

Limited projecting of *e*Prescriptions between two municipal health centres and local pharmacies will be initiated in August 2008 and in 2009 health records may be transferred between piloting health care providers and *e*Archive.

The national *e*Archive will disclose records if necessary legal and other conditions exist. The centralized eArchive as the point of record sharing in Finland needs careful security and data protection for secure transactions. For identification of health professionals the Public Key Infrastructure (PKI) on a national basis has been implemented for testing in several hospitals. Later a role based access control service will be added. The data structure of data sent to the eArchive should include a new metafile with multi-faced security policy. This metafile should consist of the following information:

- Security policy information
- Unique identification of data producer, patient and organization

- Context and purpose information of the data
- The nature of data
- Information for purposes data can be disclosed
- Information when patients consent is required for disclosure of data

Other National Projects

The National Public Health Institute has started a project to build a health information portal for citizens. The objective is to make online health education and expert advice available to citizens. Citizens will be empowered by providing access to their own clinical information stored in the centralized *e*Archive and unlimited right to check who, when and why, has accessed his or her data. This access is made available by the Social Insurance Institute using the WEB and the citizen portal. The citizens will be more informed of their health and this may result in to an increasing demand for personalized health services.

Finally, this opens an option for a personalized health record (PHR) to be connected with the national eArchive. The services and architecture have been specified, but no decisions have yet been made on the networked PHRs and their role as tools for transformation.

Migration Policies

The process to determine the migratory procedures from regional to national health information network application use is currently under construction and will be finished by July 2008. After necessary conclusions specifications will be drawn. However, the process of information sharing and archiving of EPR documents will be enabled by the centralized *e*Archive instead of the regional eHealth network.

The RLS may be transformed to a centralized indexing service and a shift in the administration of patients' consents for sharing information within the *e*Health Network is to be expected. The role of the regional network could be seen more as an enabler in healthcare delivery of services in orchestrating processes and work flow.

Certification criteria have been adapted by the National R & D Center for Welfare and Health to regulate clinical software document transaction from legacy systems into the National *e*Archive. Clinical software systems should, however, be supervised locally, although centralized procedures have been recommended for systems that pose high clinical risk and provide limited opportunity for competent human intervention (Miller & Gardner 1997).

NEXT STEPS AND FEATURES

The updated strategy and communication architecture for healthcare drawn by the Ministry of Social Affairs and Health has set targets for semantic interoperability. All Finnish EHR-systems must implement a common core data set and communication between EHR-systems will be based on a standardized message system (e.g. HL7CDA-messages, XML-formats and SOAP envelopes).

The purpose is to create a health space where information may be shared safely in multiple care settings and improve both outcomes and safety. Structured text capability in a RAND research project was shown to have the potential to reduce adverse drug events, increase preventive care, increase adherence to evidence based medicine and improve disease management (Benge, 2008). The target is not to increase amounts of information, but rather leaving increasing amounts un- or underrepresented. Efficient communication relies on core data sets with less data, but more contexts.

Personalized care represents the next opportunity to achieve gains when evidence-based treatments are customized to the patient at a deep level of specificity, and behaviour changes generated by decision support delivered at the point of care (Krohn, 2008). To bridge this gap in analytic depth and accuracy, the industry is turning to predictive informatics (PI). For PI to personalize the healthcare, capturing semantically correct data from every relevant source into a centralized data repository are the first steps.

As soon as health care as a whole takes the step from information- to knowledge-based organization, its decision processes, management structure and way to work has to change. At the moment, generation of knowledge models in healthcare has been slow, but the advent of personalized medicine may be anticipated to progress more readily when the knowledge base of genomics is heading our way.

The Nobel Prize-winning economist Ronald Coase developed the notion of transaction costs in the 1930s and according to this theory when transaction costs become low enough, the glue between organizations will dissolve (Brown & Duguid, 2002). Since information technology is relentlessly driving these costs down we may be expecting less formal organizations and more professionals in market relations with citizens.

KEY TERMS AND DEFINITIONS

Core Data Set: Organized and structured data of the most relevant facts about a patient's health information and healthcare prepared by health care providers to enable easy access to information, to foster continuity of care, and to enhance efficiency of health information exchange.

Electronic Health Record: An aggregate electronic record of health-related information on an individual that is created and gathered cumulatively across more than one health care organization.

Healthcare Information Exchange: The electronic movement of health-related data and information among organizations according to agreed standards, protocols, and criteria.

Integration: The process of bringing together related parts into a single system in order to make various components function as a connected system.

National eHealth Network: A network of networks that will connect health care providers, pharmacies, citizens and others who have, or use, health-related data and services including a national data repository for care records and ePrescriptions operated under a legal framework and based upon common standards for interoperability.

Personal Health Record: An electronic, cumulative record od health-relarted information on an individual, drawn from multiple sources, that is created, gathered, and managed by the individual.

Regional eHealth network: Health information exchange within a self-defined region in order to achieve higher quality and greater efficiency in health care delivery.

Regional Health Information Organization: An organization that brings together health care stakeholders within a defined geographic area and governs the electronic exchange of health-related information among them for the purpose of improving health and care.

Seamless Services: Continuity of care between providers.

Shared Care: Closer collaboration between providers and also clinical integration for the development of clinical networks to improve the quality of services.

Tele-Practice Technology:

A Model for Healthcare Delivery to Underserved Populations

Thomas W. Miller
University of Connecticut, USA

Robert D. Morgan
Texas Tech University, USA

Jennifer A. Wood
South Texas VA Healthcare Center, USA

ABSTRACT

Telehealth is viewed as the removal of time and distance barriers in the provision of health care and patient education to underserved populations. Examined is a twenty first century clinical consultation model of health care. Offered are specific applications within a broad spectrum of services utilizing telehealth technology. Important technology shifts for administrative paradigms, clinical models, and educational information technology for healthcare services through telehealth technology are examined. The future of telehealth and its interface with various critical components of society needs to examine the potential benefits over risks in providing healthcare consultations and services through the educational settings available. Addressed is a technology model, which demonstrates the capability of reducing time and distance barriers in the provision of health care and education through telehealth technology. The use of telehealth technology in rural settings is seen as a viable medium for providing needed diagnostic and clinical consultation for underserved and rural.

INTRODUCTION

Examined is the application of telepractice technology in a rural community clinical and educational system. Telepractice is viewed as the removal of time and distance barriers in the provision of health care and patient education to underserved populations (Nickelson, 1996). Offered is a video teleconferencing model of health care for underserved populations and where professional consultation with a team of professionals may benefit rural educational systems and their students. Offered are specific applications within a broad spectrum of services utilizing telepractice technology. Finally, shifts in administrative paradigms, clinical models, and educational information technology for healthcare services through telepractice technology are explored. Distance learning technology has provided society with new applications for clinical and educational consultation that enhance the quality of services offered to rural school systems through telepractice (National Advisory Committee on Rural Health, 2004). Whitten, Cook, Shaw et al. (1998), Sargent (1999), Miller & Miller (1999) Shaw, Goodwin, Whitten, & Doolittle (1999) and Whitten & Cook (1999) Miller, Miller, Sprang, & Kraus (2003), Sammons & DeLeon (2004), Miller, DeLeon, Morgan, Penk, & Magaletta (2006) have all addressed telepractice service application for rural school districts, their students and families. Through this medium of service delivery, children and adults in need of specialized care that might not be readily available to them can receive the specialty consultation of experts using telepractice technology. The purpose of this model is to provide health care practitioners with a consultation model for health related delivery services for children and adults in rural and underserved geographical areas internationally.

Telepractice technology provides an electronic medium for healthcare practitioners and their patients to realize health assessment, diagnosis, intervention, consultation, supervision, education, and information across distances, has become a well recognized vehicle for delivering services and disseminating information to a variety of consumer populations as well as professionals and practitioners (Nickelson, 1998; Miller & Hutchins, 2008)). Given its ability to transcend many of the economic, cultural, and geographic barriers that often prohibit or restrict the provision of health care, the use of telepractice has begun to reshape traditional systems of care. Moreover, due to its unique capacity to negate many of the traditional obstacles in service delivery, telepractice is often a desirable option for the provision of health care to rural, confined, underserved and isolated groups (Miller & Holcomb, 2007).

Well noted is that a large proportion of telemedicine studies have focused on evaluating the effectiveness of telecommunications technology in delivering health services to rural and specialty populations (Wood, 2000). Numerous studies suggest that telemedicine or telepractice applications can be utilized to deliver health care services that are accessible to rural or underserved populations that the quality of care delivered via video teleconferencing is similar to or surpasses that of face-to-face services (Bischoff, Hollist, Smith, & Frank, 2004; Miller, Miller, Kraus, & Sprang, 2003; Norman, 2006) and that both consumers and providers are satisfied with services rendered via video teleconferencing.

From its initial use, one of the major advantages of video teleconferencing has been its ability to improve access to health care services for people living in rural or remote areas where health care professionals are often scarce or absent. In the words of Nickelson (1998), "Telehealth is simply a tool that…makes it easier to practice already established professional skills across distance and to serve individuals and organizations who may not, but for telehealth, have access to such services" (p. 527). This ability to transcend geographic barriers has been the basis for three decades worth of demonstration projects targeted at rural populations. The use of this technology to improve access to health care has since expanded to include other isolated groups, such as inner city families (McLaren, Blunden, Lipsedge, & Summerfield, 1996; Straker, Mostyn, & Marshall, 1976), prison inmates (Ax et al., 2007), and homebound elderly (Maheu, Whitten, & Allen, 2001). Overall, these projects suggest that the use of telehealth is an effective means of improving access to both health care services as well as improving the exchange of information between providers (Blackmon, Kaak, & Ranseen, 1997). Efforts to assess the quality of telepractice services compared to traditional face-to-face services indicate that there is little difference in diagnostic and assessment outcomes across the two treatment modes (Ball & Puffett, 1998; Biggins, 2000; Zarate, et al., 1997 and that telehealth applications may serve to enhance the continuity and efficiency of care (Ghosh, McLaren, & Watson, 1997).

Clinical satisfaction with telepractice applications, the research assessing patient and provider satisfaction with video teleconferencing services reveals uniformly positive results (Miller, 2006; Morgan, Patrick, & Magaletta, 2008; Wood, 2006). In one of the earliest studies of patient satisfaction with telehealth, Solow, Weiss, & Bergen (1971) reported that patient acceptance was impressively high even among highly paranoid patients. Since that time, further research has indicated that satisfaction with telepractice services remains high even when patients are acutely or chronically psychotic or agitated (Kavanagh & Yellowless, 1995).

Clinical satisfaction data are especially relevant in the public sector where services are often lacking. As a response to service deficits, prison systems (e.g., the Federal Bureau of Prisons, the Texas Department of Criminal Justice) have developed sophisticated telehealth networks. It is noted that offenders are generally satisfied with mental health services received via teleconferencing (Leonard, 2004; NIJ, 2002). Of particular importance is that incarcerated mentally ill offenders, historically perceived as resistant to mental health services, reported no significant differences in the working alliance between treatment provider and client, post session mood or treatment satisfaction when receiving psychiatric or psychological services regardless of method of service delivery (i.e., telemedicine vs. face-to-face) (Morgan et al., 2008). Similar findings have been found among parents and children who participate in telepsychiatric consultations (Blackmon, Kaak, & Ranseen, 1997), geriatric clients (Wood, O'Quin, & Eftink, 2004), inner-city families (Straker, Mostyn, & Marshall, 1976), active-duty military personnel (Jerome, 1999), veterans (Wood, 2006), and adults with mild to moderate mental retardation and their mental health care providers (Wood & Hargrove, 2006).

A Telepractice Model for Healthcare

With the noted high level of user acceptability and distinct ability to transcend geographic and social barriers, a visionary telepractice model for public education that focuses on the role of psychology and its interdisciplinary partners can be used to create a national, regional, state and local stratified network of health care professionals and other stakeholders engaged in a nationwide public education campaign (Miller, 2007). The Telehealth Intervention Project (TIP) is a proposed model designed to offer teleconferenced psychological and health related informational and demonstrational sessions focused on a broad spectrum of health related topics. Teleconferening technology is uniquely suited to reach underserved populations and rural practitioners offering relevant evidence-based psychological information to the community. The telehealth network can be used to educate a range of target populations including clients, service providers, educators and community personnel including children and families, school populations, prison inmates, legislators, public officials, and inpatients and outpatients in various public and private sector programs.

As modeled in Figure 1, telepractice provides a sophisticated medium for reaching these targeted populations (consumers and providers) by making psychology a household word. Outlined below are mechanisms (processes) for successfully implementing the Telehealth Intervention Project, a proposed model for implementing a dimension of the public education campaign to reach underserved target groups in need of health and prevention education information nationally.

Use of Telepractice in Health Education and Prevention

Health communication encompasses the study and use of communication strategies to inform and influence individual and community decisions that enhance healthy behaviors and to provide education toward achieving prevention of disease and illness.. It links the domains of communication and health and is increasingly recognized as a necessary element of efforts to improve personal and public health (Kreuter, Strecher, & Glassman, 1999). Health communication can contribute to all aspects of disease prevention and health promotion and is relevant in a number of contexts, including (1) health professional-patient relations, (2) individuals' exposure to, search for, and use of health information, (3) individuals' adherence to clinical recommendations and regimens, (4) the construction of public health messages and campaigns, (5) the dissemination of individual and population health risk information, that is, risk communication, (6) images of health in the mass media and the culture at large, (7) the education of consumers about how to gain access to the public health and health care systems, and (8) the development of telepractice applications (Miller, Burton, & Kraus, 2004; Wood, Miller, & Hargrove, 2005; Miller, 2007).

Utilizing health communication can help raise awareness of health risks (including physical and psychological) and solutions, provide the motivation and skills needed to reduce these risks, help consumers find support from other people in similar situations, and affect or reinforce attitudes. Health communication also can increase demand for appropriate health services and decrease demand for inappropriate health services. It can make available information to assist in making complex choices, such as selecting health plans, care providers, and treatments. At a macro level, health communication can be used to influence the public agenda, advocate for policies and programs, promote positive changes in the socioeconomic and physical environments, improve the delivery of public health and health care services, and encourage social norms that benefit health and quality of life (Piotrow, Kincaid, Rimon et al., 1997).

Effective health communication may also inform health care providers for improved service delivery. The Institute of Medicine criticized current health care training and reported that training of health professionals requires a "major overhaul." Specifically, the IOM stated that health care professionals are not properly trained with regard to changes in patient demographics and health related needs, evolving expectations within health care systems, evolving practice methods and technological advances, or enhanced quality control. Improved health communication among health professionals may alleviate these shortcomings, and telehealth offers a mechanism for improved training that is immediate and accessible. For example, the TIP could be used to offer health professionals an opportunity to discuss physical and psychological issues for targeted populations, interactive education, and face-to-face consultations with specified experts.

Public Education via the Internet

The environment for communicating about psychology and health has changed significantly. These changes include dramatic increases in the number of communication channels and the number of health issues vying for public attention as well as consumer demands for more and higher quality physical and psychological health information. Psychology has the potential of communicating through the home, the school, and the work environment through group, organizational, community, and the Internet interactive telehealth options (Stamm, 1999). For instance, health care providers can take advantage of digital technologies, such as CD-ROM, World Wide Web, and listservs to target audiences, tailor messages, and engage people in interactive, ongoing exchanges about health. Brief sessions via web-based interactive video can provide easier access to needed information and reduce health care cost, travel time, and expenses.

Research indicates that health communication best supports health promotion when multiple communication channels are used to reach specific audience segments with information that is appropriate and relevant to them. Evidence based decision-making suggests that effective psychological health promotion and communication initiatives adopt an audience-centered perspective, which means that promotion and communication activities reflect audiences' preferred formats, channels, and contexts. Targeting specific segments of a population and tailoring messages for individual use are two methods to make reaching home based health promotion care through telepractice activities relevant to audiences. Advances in health informatics are changing the delivery of health information and services and are likely to have a growing impact on individual and community health. Advantages include (1) improved access to personalized health information, (2) access to health information, support, and services on demand, (3) enhanced ability to distribute psychologically accurate information quickly, and (4) just-in-time expert decision support and advice. The health impact of interactivity and customization through teleconferencing technology can achieve making psychology a household word.

Health Information a Telepractice Model

The goals of community based and professional organizations should dovetail with Healthy People 2010 and other similar initiatives worldwide with the focus on using communication strategically to improve health. This can be accomplished through advocacy for: households with Internet access, health literacy, and the quality of Internet health information resources (DeLeon, Crimmins, & Wolf, 2003; Karlinky, 2004; Hilty, 2004). According to the Computer and Internet Use Supplement to the Current Population Survey, U.S. Department of Commerce, Bureau of the Census (US Department of Commerce, 2002), approximately 26 percent of households had access to the Internet at home. Importantly, the greatest growth in Internet access was for lower income households (approximately 25 percent between 1998 and 2001). Continued growth in household access to the Internet is critical to improve psychological health as technical literacy, or the ability to use electronic technologies and applications, will be essential to gain access to health information. This is particularly important for lower income individuals who may be lacking health insurance or financial means for regular health care. Internet availability in the home is an important indicator of equitable access to health information among targeted populations. The health and technology literacy of persons with inadequate or marginal literacy skills data indicate that approximately 90 million adults in the United States have inadequate or marginal literacy skills (Lenhart, 2003). Psychology can play a role in the implementation of this initiative by increasing the proportion of health communication activities that include research and evaluation. Effective health communication programs are built on sound research and evaluation (Casper, 2004; Web Based education Commission, 2000).

The provision of clinical counseling and patient education about health behaviors could enhance adherence and compliance with healthy behavior (both physical and psychological). Culturally appropriate and linguistically competent community health promotion programs, substance abuse treatment, HIV counseling and testing in prisons, worksite promotion of nutrition education and weight management, public access to information and surveillance data, perception of risk associated with substance abuse and tobacco targeting adolescents and young adults are all potential targets for psychology in the home

(Deleon et al., 2003).

Establishing a Telepractice Intervention Program

Establishing a telepractice intervention model should begin by identifying existing programs and/or local and national technological resources. Although not formally described as TIP networks, organizations such as the Department of Veterans Affairs and the Texas Department of Criminal Justice are currently using technology to disseminate health care information to providers as well as the consumers they serve. Within the VA, employees have access to an intranet, which contains training modules, informational handouts, clinical guidelines, etc. In addition, employees have the ability to participate in local and national informational broadcasts, videoconferences, and conference calls. With regard to patient care, the VA has developed an Internet-based program called My Health*e*Vet, which serves as a gateway to veteran health benefits and services as well as a tool for enabling veterans to better understand and manage their health. It provides access to trusted health information, links to Federal and VA benefits and resources, a Personal Health Journal, and an online VA prescription refill program. Eventually, veterans will be able to view their appointments, co-pay balances, and access portions of their VA medical records online (My Health*e*Vet, 2006). By examining programs such as these, it is possible to identify the technological resources needed, learn from challenges existing programs have overcome, and to manage various types of informational programs. In addition to reviewing established programs for implementation strategies, it is important to identify existing technological networks, which might be more effectively used to disseminate health information to consumers and providers. For example, many states now include videoconferencing or cable networks in public school systems, public libraries, health care facilities, and other community facilities for efficient connection capabilities. Such existing networks could be utilized to broadcast health information programs targeted toward specific populations or providers. For providers who may not have access to large-scale telehealth resources, there are simple strategies for utilizing existing resources to obtain and disseminate health information. For example, health care providers who wish to obtain information on evidence-based practice or innovative techniques may consult reputable websites or join one of the many professional list serves designed to promote dissemination of information. Providers may also refer their clients to reputable websites (e.g., National Heart Association, National Center for PTSD Research) in order to assist them in gathering information or obtaining support.

The issues for rural health care populations and for rural school systems present additional complexity. Rural school systems are often faced with providing qualified care to their student population and are not able to have ready access to needed expertise. The need for such specialized expertise to address a seriously disruptive student in a rural school setting was more than 500 miles away and transportation was only available by car. Realizing the complexity of problems and the fact that there were no board certified child psychiatrists in the area, it was proposed that through the use of an innovative telecommunications approach, needed clinical consultation could be provided to this school system using telehealth technology. The clinical consultation team included a child clinical psychologist on site working with a school psychologist, an advanced practice nurse, clinical social worker, special education specialist and the consultation of a child psychiatrist by video link from a university based psychiatry clinic through a cost effective model of telehealth. Through the use of this specialized telemetric link using video telephones, the needed interdisciplinary clinical consultation and service could be provided to the rural school system and its staff. The services included diagnostic and treatment planning and classroom observation of the student in question with a secure telehealth video link to the specialist.

Summarized in Figure 1 above is the conceptual model that exemplifies a community based telehealth technology system. Telehealth links in this model exist between health care specialists at the university based medical center, physicians at the rural community clinic and psychologist social worker and advanced practice nurse at the rural district. Within this configuration a secure two-way video link exists for interactive staffing of patients and pediatric emergency care. In addition, Internet based case conferences with a video link can provide necessary and essential face-to-face discussions, video images and streaming video of case materials for review. The combined web based and interactive videoconferencing allows for clinicians and school personnel to exchange information that can be to the benefit of both educational and health care planning and consultation. Each of these segments is noted in the model presented in Figure 1. This model provides children with special needs in rural settings the necessary and appropriate consultation to the benefit of client, clinician and families in our society.

This collaborative partnership between educators and clinicians may be enhanced and facilitated by the use of telehealth using video telephones designated for confidential patient care and planning. School related personnel may wish the consultation of a local or regional specialist and may use Internet video technology through a community clinic. In some cases, the need to have specialized psychiatric consultation services from a medical center-based child psychiatric clinic linked to a community clinic and to a school district may be offered through telehealth technology. In this case, patient health information, patient education materials, clinical records can be shared through electronic medical records sent to consulting clinicians, thus providing them with an opportunity to review information individually and then respond to relevant clinical issues. A clinical staffing of the child involving the referring clinician in the rural setting, the community

Figure 1.

consulting specialists and the university-based specialist can be beneficial and more effective when time and distance barriers are removed via the use of telehealth technology.

The need for telehealth technology is obvious in the face of the major obstacles clinicians face in providing a high standard for health care delivery in a time efficient and cost-effective manner (Miller, 1998; Miller, Miller, Kraus, Burton, Sprang, & Adams, 2003). Emerging systems of managed health care that interface with the educational system have the potential to benefit from the needed services for children as noted in the Young and Iresaon (2003) study. Telehealth is seen as the use of various models of telecommunication, which connect the consumer with the health care provider through live, two-way video transmission, across, distances and which permit diagnosis, treatment, and other health care services. This definition stresses a focus on delivery of services across distances with a sense of concern for ethical provision of services and confidentiality of the health care needs in our society.

The benefits of video teleconferencing technology for clinical health care and for educational settings include: Increased access to clinical consultative services and health education programs for school and community organizations and populations; Improved and expanded psychiatric health care services to underserved areas in rural communities and areas; provision of a feasible and sustainable system of clinician-directed consultations using video conferencing; access to current approved education and training programs for health care providers in settings where access to advanced clinical training may be a barrier due to geographic location; reduction of the isolation for educators and health care providers in rural areas through the development of innovative consultation video conferencing systems that enhance clinical support and consultation regarding the diagnostic, treatment, consultative and educational services available to clinicians and other health care providers in certain geographical regions; and use of telepractice technology in rural communities to decrease the time, inconvenience, expense and risks of travel, as well as other associated problems that distance and isolation cause in obtaining psychological and other health care services.

PRACTICE GUIDELINES FOR TELEPRACTICE

Community based telepractice technology services offers a visionary consultation model for providing standardized and special needs coverage to children by linking metropolitan and flagship university medical centers and specialist services with rural school districts. This definition stresses a focus on delivery of services through distance consultation technology with a sense of concern for the ethical provision of services and confidentiality of the health care needs of the patient provided with such services. As an alternative way of providing traditional health services, telepractice is considered by some to be a solution to America's toughest health care challenges: increasing access to clinical consultation service and involving health care professionals while decreasing the costs involved in providing quality care (Office of Rural Health Policy, 1994). In order to insure standardization of care based on evidence based research and experience, practice guidelines offer a way of incorporating quality care, consistency in educational material and standard models for information technology.

The clinical use of practice guidelines generates algorithms that are used to provide case management based on evidence based research. The goal is to make the client management guideline the accepted professional behavior and a reward in itself. To the extent that this is successful, five components occur: (a) the guideline is widely used and becomes habitual, (b) multidisciplinary professionals can use it to anticipate care events, (c) clinicians can use it as a shorthand or outline to guide their decisions and their communications to others, (d) the logistics for delivering the guideline components are convenient and reliable, and (e) the guideline defines the measure of performance and incorporates information collected that can be used for its evaluation and improvement. The individualized plans clinicians may use also contribute information for guideline revision.

Case management through algorithms presents a systematic perspective. Algorithms try to answer the questions, "What is the best way to systematically handle this problematic condition?" Algorithms have a problem solving orientation coupled with functional specific actions or critical pathways to be taken. If desired results are produced, the problem was managed effectively. If the desired results are not produced, adjustments can be made to achieve the desired results.

The point to be made is that in our professional roles, it is important to be a creative problem solver who can translate relevant research into functional interventions. The model practice guideline summarized in Figure 2 identified the situation that the clinician recognizes that it would be more efficient if telemedicine had a place in the treatment intervention process. Note that a question is asked as to whether a telepracticeoption exists in the patients' locality. If yes then the clinician begins the review with the client of the differences between tradition and telemedicine delivery of care. Informed consent is provided and compliance with all state and federal laws is to be reviewed. Then the clinician assesses the appropriate needs of the medium for what need to be accomplished. Appropriately training the patient in the use of telemedicine and the equipment follows this. Risk management options are offered, Practice session is to occur to assure the patient can use the telemedicine option. The use of web based educational programs is provided. Finally there is a review and monitoring process in place so the clinician can monitor its use. Through this configuration, issues related to liability for negligence or liability for abandonment would be considerable reduced and hopefully eliminated.

Liability Issues in the Use of Telepractice

Liability is a primary risk factor for clinical healthcare practicioners utilizing telepractice. Risk management strategies should educate psychologists and consumers about telemedicine equipment. Who will provide training, what mechanisms are used to evaluate the effectiveness of training, and how to document deficits in knowledge following completion of initial training. Another concern with respect to liability involves "liability for abandonment." Abandonment may occur when the clinician would unilaterally terminate the relationship with a client or the relationship was terminated without reasonable notice; and termination occurred when further attention was needed. Psychologists using telemedicine technology continuously monitor the clients' ability to participate in telemedicine activities and confirm their understanding of their responsibilities in the use of telemedicine equipment. While there are certain advantages, telepractice is subject to many of the same shortcomings associated with face-to-face care as well as several technology-specific limitations. Most notably, users should be aware of and attend to the following issues prior to establishing a telehealth network or practice.

Security Privacy, and Confidentiality
