The real world clinical service data stored in healthcare information systems provides opportunity to analyze spatio-temporal patterns at finer granularity. The investigation of space and space-time epidemiological patterns often gives rise to the explanation of factors that might create an adverse health condition. This study uses routine, aggregated service data to find excess space and time variations in rendered services where the primary diagnosis was lung cancer. From the health care management point of view, if clusters are detected and explanatory factors linked, this understanding allows for better patient care, i.e. serving a particular population with targeted specialists, and preventing spread of disease amongst populations. This research aims to study different clustering methods of the spatial and spatio-temporal patterns of lung cancer particularly for routine clinical service data collected by a Northeast Ohio healthcare organization (Kaiser Foundation Health Plan of Ohio) over a period from 1994 – 2006.

METHODOLOGY: SPACE-TIME CLUSTER ANALYSIS

The question whether diseases such lung cancer or breast cancer are spatially clustered is an active research area (Lawson, Biggeri, Böhning, Lesaffre, Viel, & Bertollini, 1999; Laywson & Denison, 2002; Marshall, 1991; Tango & Takahashi, 2005). Since the detection of spatial and temporal patterns of clusters of lung cancer is sensitive to the clustering algorithm, it is difficult to evaluate results from a single method (Jacquez & Greiling, 2003). Currently, most of the comparative analysis of disease clusters depends on simulated data (Ozonoff, Bonetti, Forsberg, &

Pagano, 2005). Tycznski developed a broad atlas of cancer in Ohio which involved a "smoothing" method where weighted averages of cancer per county were calculated versus geographic location of patients with cancer at the time of diagnosis. However, the clusters are generated by considering only spatial aspect. The temporal characteristics of the cluster are not reported (Tyczynski, et al., 2005).

In recognition of the usual epidemiological definition of cluster, this study adopts the formal definition of cluster which refers to the patterns of location of disease cases, relative to the pattern of non-cases (Wakefield, Kelsall, & Morris, 2000). In principle, since the cases are more clumped than non-cases, the difference between the two patterns is statistically recognizable. Intuitively, a cluster is an excess value which exceeds the normal value for the space and/or time. The closer a cluster population is defined, the excess value will be greater for the cluster population, and the significance will be greater. The closer a cluster population is defined, the greater the excess value will be for the cluster population, and the significance will be greater. Initial assessments of clusters include reviews of cases, boundaries of space and time, estimated number of cases, estimates of standardized mortality ratios, statistical significance, and public communication. Cluster analysis has been frequently used to identify occurrence of morbidity or unusual localized trends in disease patterns (Alexander, 1992).

A considerable amount of research in temporal and spatial context in 'scan' statistics has been invested in identifying disease clusters. The theory has been successfully applied in a wide variety of epidemiological studies for cluster detection (Viel, Arveux, Baverel, & Cahn, 2000; Perez, Ward, Torres, & Ritacco, 2002; Sankoh, Ye, Sauerborn, Muller, & Becher, 2001). It has been identified as the most powerful method for detecting local clusters (Kulldorff, Tango, & Park, 2003; Song, & Kulldorff, 2003). Ideally, this method is suitable where one needs to scan for clusters in space that vary over time. Since the method for detecting clusters is entirely unsupervised, there is no need for *a priori* knowledge for the population size. The method is based on the concept of 'windows' which are defined to contain a fixed population (N^*), and are centered on each area centroid. The algorithm identifies a significant excess of cases within a predefined moving window that exhaustively searches all existing space-time locations and keeps increasing size in space time until it reaches a maximum limit. The maximum number of cases $M = \max_j Y_j(N^*)$ across the windows is used as a test statistic. In this case *j* represents the indexes of the areas defended in N^*. It is also possible to use a fixed number for the population by introducing predefined constraints (e.g., the number population with a circle should be less than a specified fraction of the total population of the study area). Hjalmars et al. (1996) and Kulldorff et al. (1997) applied a similar method to detect childhood leukemia and breast cancer incidence. The test statistic is based on maximum likelihood ratio statistic across all circles.

$$L = \max_j \left(\frac{Y_j}{E_j} \right)^{Y_j} \left(\frac{Y_+ - Y_j}{Y_+ - E_j} \right)^{Y_+ - Y_j} I(Y_j > E_j) \qquad (1)$$

Here, Yj and Ej represent the observed and expected number of cases within the window j . The indicator function I(.) becomes 1 when the observed number exceeds the expected number of cases within the window; otherwise the value is 0. When the window with greatest exceedance is encountered, the sampling distribution of likelihood ratio is determined using a Monte Carlo test of cases across windows under a random distribution assumption. Thus under the repeated permutation, the distribution of likelihood statistic, the null hypothesis is developed. The result is significant at 0.05 levels if the likelihood ratio is among the top 5% of all the values. It is also possible to determine secondary cluster with a lower significance level.

We applied the SaTScan method for a spatial and space-time analysis for detecting local clusters (Kulldorff, 1997). Due to temporal trends, clusters may be generated for a ramp up or down in data trends. For this reason, the space-time permutation model automatically adjusts for these temporal data trends. In the study we used case data, with the spatial location represented by zip code centroid latitude and longitude, and with time represented by service month. The actual number of cases in a cluster is compared with the expected count if the spatial and temporal locations of all records were independent. A cluster is determined to be present in a spatial location, if, during the time period, there are excess cases or recess within the surrounding areas. Using a cylindrical window with a spatial base and time as height, the space-time statistic is defined. The window is moved in space and time, and a cylinder is created for each possibility. The algorithm accounts for multiple testing by calculating the maximum likelihood of occurrence for all possible cluster locations and sizes (Kulldorff, 1997, 2001). In this study, retrospective analysis was performed in terms of months, with periods representing January 1994 through May 2006. In each window, the alternative hypothesis concludes that there is heightened risk.

The Poisson model is used for the space-time permutation probability model as this allows for covariate adjustments, in this case age and gender. This likelihood function is maximized over all windows, and the maximum likelihood window describes the prevalent cluster. The test statistic is calculated by generating a large random sample from the data generated under the null hypothesis. Monte Carlo testing is used to obtain the predicted value. In this study, Monte Carlo replications were generated to produce a P-value to 0.001. Covariates were used since clustering can occur due to covariates. Covariates are adjusted to prevent this false clustering. The time precision was monthly and ranged from January 1994 through May 2006 based on available data at time of collection. The maximum spatial and temporal cluster size was the default 50% of cases (Kulldorff, 2005). The scant statistic generated both primary and secondary clusters and the output was reported in ASCII format, which contains a log likelihood ratio and the significance level for the study area. The output file was finally imported in standard GIS environment of ArcGIS to visualize cluster location for further spatial analysis. The Poisson model was also used for the purely spatial probability model, and follows closely with the space-time permutation model. However this model utilizes a population file which includes information regarding the at risk population, and was taken from the 1999 US Census Bureau Zip Code file, with regard to total 1999 population for each zip code. As this file did not include additional population attributes such as age and gender, the case file along with the population file excluded these for this model (Kulldorff, 1997; U.S. Census Bureau, 1999).

Spatial autocorrelation analysis provides both global and local clusters which can be detected by Moran's I statistic. The global pattern can be detected from Moran's Scatterplot, where the slope of the regression line represents Moran's I. We applied the local indicators of spatial autocorrelation (LISA) method using sample cases in each zip code. The local Moran statistic for location i is given as follows (Wong & Lee, 1999):

$$I_i = z_i \sum_j w_{ij} z_j \tag{2}$$

Where z_i, z_j are the deviations from the mean for associated x, and where z_i is the z-score of x_i. A high Moran's I indicates associated values, whereas a low value indicates non-associated values. The row-standardized matrix, used to estimate weights for each of the unit's neighbors, is defined as wij (Wong, et al., 1999). When the study involves the measurement of Moran's I for rates, the underlying assumption of stationarity may be violated due to intrinsic variance instability of the rates. Since the population at risk in the study area varies significantly across patient zip codes, variance instability may lead to spurious inference for Moran's I. To account for this effect, the Empirical Bayes (EB) standardization was performed (Assuncao, & Reis,) using zip code population as the base variable. The standardized rate was used to calculate the univariate LISA. The spatial autocorrelation analysis utilized local tests for Moran's I statistic, with significance maps generated to the P-value of 0.05 (Anselin, Syabri, & Kho, 2004). Sensitivity analysis was done by changing the number of permutations (9999 times) for different significance cutoff values.

While Moran's I is effective in identifying presences of clustering of similar values clustering, it cannot differentiate between high and low values. Another spatial autocorrelation statistic, the general G-statistic (Getis & Ord, 1992), is able to detect hot and cold spots. The G-Statistic also uses cross-product statistics to measure spatial association, similar to Moran's I. The local G-statistic is the local version of the general G-statistic, and it indicates how the value of each unit is associated with surrounding units within distance *d* (Wong, et al., 1999).

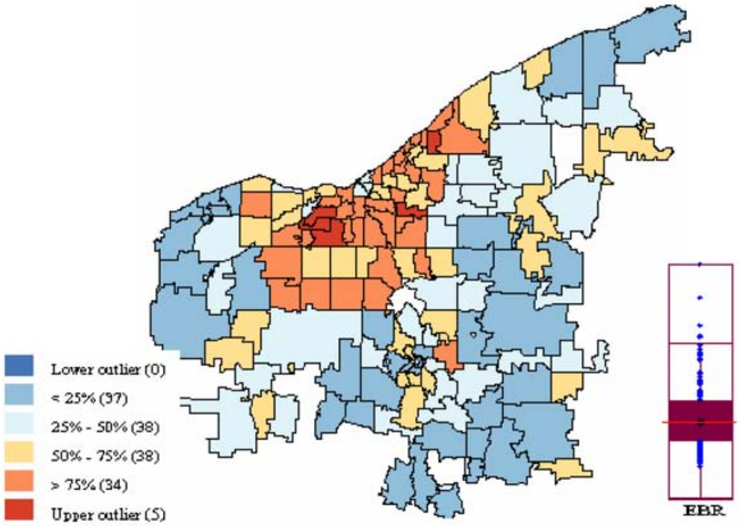
$$G_i(d) = \left(\frac{\sum_j w_{ij}(d) x_j}{\sum_j x_j} \right) \quad j \neq i \qquad (3)$$

Here, $w_{ij}(d)$ is the weight, with distance *d*, and the weight is 1 if *j* is within *d* of *i*; otherwise weight is 0. The cross product of the points *i* and *j* are represented by $x_i x_j$. A high $G_i(d)$ indicates a spatial association of similar high values; a low $G_i(d)$ indicates low and below-average values. A z-score near 0 indicates no spatial pattern; a highly negative z-score indicates low values; and a highly positive z-score indicates high values (Wong, et al., 1999). We applied the local G-statistic using samples cases in each zip code. The standardized Empirical Bayes rate was used to estimate the G-statistics.

DATA COMPILATION AND ANALYSIS

The study included the area of Northeast Ohio. The service data was collected from Kaiser Foundation Health Plan of Ohio with appropriate approval from the Internal Review Board. It includes the routine clinical service data of over the service period of January 1994 through May 2006. The case file contains information about the cases where each record represented an individual service (Kulldorff, 2005). The dataset was anonymised to avoid disclosure of individual information. In addition, a limited number of attributes was authorized for addressing the specific research objective in finding excess space-time variations of lung cancer. Among the attributes available in the case file are primary diagnosis, patient zip code, service month, age, and gender. Service month was the month of service/diagnosis where data was collected and available for use beginning in January 1994 through May 2006; the attribute age represents the age at date of service. In cases where multiple services/diagnoses existed, only the first occurrence for each individual was used to avoid cluster creation through repeat services. The dataset was generated during 07/2006 and included all services rendered or received to date. For services rendered at external locations, several months may have elapsed before service information was received, and may be excluded from this study for this reason. It would be possible to periodically re-run past results to ensure the latest dataset available. Due to system memory requirements (32-bit Windows memory allocation size), and software limitations, individual diagnoses were required to be selected and scanned (Kulldorff, 2005). International Classification of Diseases, (Ninth Revision) Clinical Modification (ICD-9-CM) Code 162.XX was used to represent

Figure 1. Empirical Bayes (EB) smoothed box map of lung cancer in Northeast Ohio during 1994-2006



the diagnosis for lung cancer. The aggregation unit of geographic location used is the five-digit US zip code. The coordinates were then mapped in ESRI's ArcGIS 9.0. Geocoding was performed through assignment of coordinates (latitude and longitude) to each patient zip code. The coordinate file contains the geographic coordinates for each location id specified in the case file. Coordinates were specified using latitude and longitude of each 5-digit patient zip code entered in decimal degrees, and, where identical, one or more coordinates were combined for a single location. Each patient zip code was geocoded to the centroid using a US census 1999 zip code file containing the latitude and longitude. For graphical analysis and to reflect the majority of sample records, a fourteen-county region with contiguous zip codes was used to represent the Northeast Ohio region. The dataset used for the analysis included a total of 2,364 records or unique initial service claims for patients having included the ICD-9-CM Code 162.XX (lung cancer) as the primary diagnosis, and 152 unique patient zip codes.

To account for the inherent variance instability of rates (Bailey & Gatrell, 1995) of lung cancer incidence, empirical Bayes smoothing was performed (Clayton & Kaldor, 1987), whereby the raw rates were adjusted towards the overall average of the study area. The technique consists of computing the weighted average between the raw rates for each zip code and the study area average with weights proportional to the underlying population at risk. In other words, small zip codes (i.e., with a small population at risk) will tend to have their rates adjusted considerably, whereas for larger zip codes, the rates will barely change (Clayton & Kaldor, 2005). The empirical Bayes (EB) smoothed box map in Figure 1 shows that 5 zip codes are in the upper outlier and as many as 34 zip codes are within 75 percentiles.

RESEARCH RESULT

The spatial scan statistic result shows that there exists a cluster of lung cancer in the Northeast

Figure 2. The area of statistically significant (p <= 0.05) lung cancer using a spatial autocorrelation and scan statistic for space and space-time model.

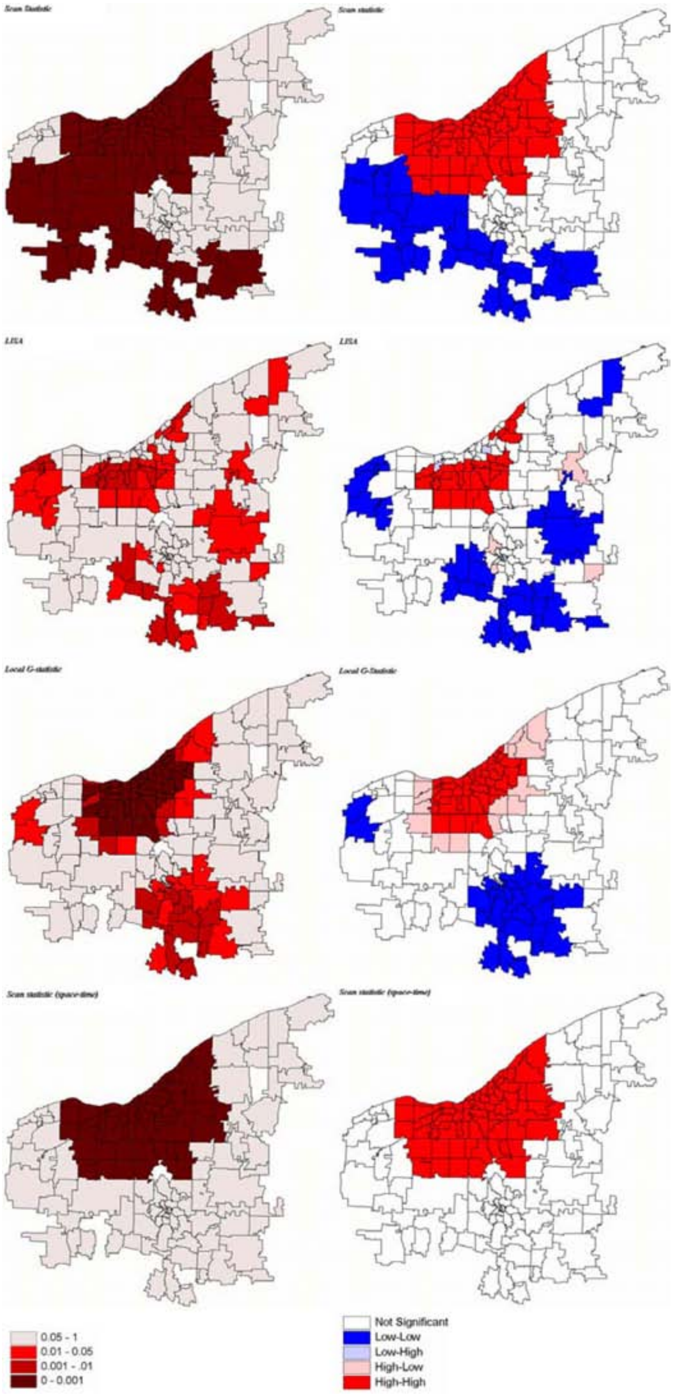


Table 1. P-value distribution of area, sample cases, zip codes, average age and gender attributes of the cluster(s) for each method

P-Value		Space-Time Scan Statistic	Spatial Scan Statistic	G-statistic	LISA

Ohio region. Areas of excess were detected with statistical significance using a spatial Poisson probability model for services with a diagnosis of lung cancer. The results show that a statistically significant cluster exists with a relative risk (RR) of 4.164 at P-value of 0.001 that includes 72 zip codes. The results also listed another statistically significant cluster with RR of 0.186 and P-value of 0.001, and contained 28 zip codes within the contiguous sample area. As expected, the significance levels match closely with the geographic sample distribution. The space-time scan statistic result also shows that there exists a cluster of lung cancer in the region for the space-time scan statistic. With spatial-temporal data and covariates considered, statistically significant areas of excess were also detected using the space-time scan statistic for services with a diagnosis of lung cancer. Clusters were scanned first only for location of patient zip code, and then scanned with the addition of an attribute (age, gender). Furthermore, clusters were scanned using five-year age brackets. The results show that a statistically significant cluster (P-value <= 0.01) exists. The primary cluster detected is a geographically contiguous area in Northeastern Ohio, with a relative risk (RR) of 1.784 and significant P-value of 0.001. The cluster contained 44 zip codes within the contiguous sample area and spanned a time period of 7/1/1999 – 8/31/2002. The location of the cluster changes when including time, as compared with the purely spatial model. The primary cluster shows no geographic change when adjusted for attributes. It was found that adjustment of attributes is not required as the cluster location does not change when attributes are introduced Secondary clusters were identified, but were not statistically significant.

The LISA analysis indicates a cluster of high incidence of lung in the region with statistically significant clusters (P-value <= 0.05), containing 64 zip codes within the study area. The local G-statistic result shows that there exists a hot spot of lung cancer in the region. The results also show that statistically significant clusters (P-value <= 0.05) consist of 89 zip codes. Figure 2 shows the spatial statistic significance graphs for the SatScan, LISA, and local G-statistic. The figure also shows the space-time scan statistic significance graphs. Table 1 shows the significance level measured by the P-value at the 0.001, 0.01, and 0.05 levels. The corresponding percentage area, (where the total area of significance was divided by the total area for which sample cases existed), the number of sample cases, number of zip codes contained, average age, and county by gender are included, with each method listed as a column.

The scan statistic result shows that there exists a cluster of lung cancer in the region for the purely spatial statistic. Areas of excess were detected with statistical significance using a purely spatial Poisson probability model for services with a diagnosis of lung cancer. The results show that a statistically significant high value cluster (P-value <= 0.05) exists and contains 72 zip codes. The results also listed another statistically significant low value cluster containing 28 zip codes within the contiguous sample area. The results list 54 zip codes as not significant. The scan statistic result also shows that there exists a cluster of lung cancer in the region for the space-time scan statistic. The results show that a statistically significant high value cluster (P-value <= 0.01) exists. The cluster contained 52 zip codes and spanned a time period of 7/1/1999 – 8/31/2002. Two of the zip codes contained similar coordinates, which left 50 unique zip code locations. No low value clusters were identified. The LISA result shows statistically significant cluster of lung cancer in the region for the purely spatial statistic. The results show that statistically significant clusters (P-value <= 0.05) exist, and contained 87 not significant, 31 low-low, 2 low-high, 4 high-low, and 28 high-high value zip codes.

The local G-statistic result shows that there exists a cluster of lung cancer in the region for the purely spatial statistic. The results show that statistically significant clusters (P-value <= 0.05) exist, and contain 63 not significant, 31 low-low, 0 low-high, 16 high-low, and 42 high-high value zip codes. Figure 2 shows the purely spatial statistic cluster graphs for the scan statistic, LISA, and local G-statistic. It also shows the space-time statistic significance graphs for the scan statistic.

DISCUSSION

This study detected several high and low association clusters using the spatial and space-time methods. When comparing the various methods of the scan statistic, LISA, and local G-statistic, spatial association areas are somewhat similar geographically. The local G-statistic returned the highest number of records (2002) with regard to significance at the 0.05 level. The scan statistic method also returned a similarly high number of associated records (2000) as the local G-statistic. The LISA method returned a comparatively smaller number of significant records (1242); however when comparing LISA geographically to the scan statistic and local G-statistic, LISA appears to exclude bordering zip codes included in the other methods. Conversely, LISA had the highest number of records (1122) that were not significant, followed by the scan statistic (364) and local G-statistic (362). The scan statistic contained the highest number of high-high cluster records (1896), followed by the local G-statistic (1377) and LISA (1069). The local G-statistic had the highest number of high-low spatial outlier records (419), followed by LISA (31) and scan statistic (N/A). Only LISA contained low-high spatial outlier records (31). The local G-statistic contained the highest number of low-low records (206), followed by scan statistic (104), which the output indicated low only, and LISA (100).

When accounting for temporal trends using the scan statistic, this study detected only one area of excess lung cancer spanning the three-year period of the study using a space-time method. The SatScan space-time statistic returned the fewest number of records (103) and geographic location in terms of significance and clustering, and it was different geographically from the purely spatial methods in that the majority of high value association cases and area was not contained within Cuyahoga County, but rather in Stark and Summit Counties. In addition, no low value association clusters were detected, as with the purely spatial methods. The introduction of time allows for a more focused area and localized study region. Since the health data from managed health care organizations are aggregated at the zip code level, the smallest mapping unit discernible in a GIS map is the zip code polygon of the study area. Compared to long temporal range (1994-2006) of the study, the temporal occurrence of cluster was found significant only within the three years of 1999-2002. The narrow temporal concentration and high relative risk suggests that further investigation is required to understand the causal factor within the time period.

The application of scan statistic is specifically useful when there is a plausibility of a single hotspot. Since the likelihood ratio is derived from a single hot/cold spot, the possibility of detecting multiple hot/cold is ruled out in the scan statistic algorithm. Moreover, scan statistic detects space-time clusters by using cylindrical windows; hence the result needs to be interpreted with respect to the choice a specific shape of the window. While the cluster is detected by rejecting the null hypothesis, the circular spatial window tends to detect a larger cluster than the true cluster by absorbing surrounding regions where there is no elevated risk (Tango & Takahashi, 2005). The relatively large cluster area detected in this study could be interpreted as the result of the boundary effect of the circular window. The effect could be confirmed by comparing the result with a flexibly shaped scanning window which allows for irregular shapes (Tango, et al., 2005). Moreover, the results need to be interpreted by comparison with other spatial cluster algorithms (e.g., spatial filtering [34], generalized additive models (GAM) (Ozdenerol, Williams, & Kang, & Magsumbol, 2005), and Bayesian disease mapping (BYM)) (Besag, York, & Mollie, 1991). When utilizing spatial autocorrelation (LISA), the number of significant records is reduced due to the generation of larger P-values. The spatial autocorrelation of simulated rates creates large variances in LISA values, leading to insignificant P-values, as neighboring values are more likely to be jointly low or high (Goovaerts & Jacquez, 2004). The local G-statistic produces the highest number of significant records, but also produces the highest number of spatial outlier records, which, when accounted for, produce a more similar, but still higher records count than LISA. The local G-statistic uses a z-score scale around 0 to indicate clustering situations, which leads to a classification for all non-zero significant records.

In comparison with Tycznski's study (2005), this study reviewed spatio-temporal clusters of lung cancer cases to identify areas of interest, whereas the former study considered overall mortality rates of all cancer types within Ohio to determine time trends. Several key areas can be synthesized between the two studies to provide further topics of interest. Tycznski notes that lung cancer was the leading cause of death across categories; this fact coincides with the focused interest of this study on the leading cause of cancer death. Tycznski also notes higher mortality rates in Blacks as compared with Whites, and recommends focused efforts on this demographic. In this study a spatial cluster is found surrounding Cuyahoga County, which, when compared with surrounding Northeast Ohio counties, has a greater percentage of the Black population. When incorporating temporal trends into the study, an additional area of interest is identified within Northeast Ohio.

PRACTITIONER IMPLICATIONS

Practioner-based usage of this study falls into two general categories: identification and prevention. Detection of lung cancer, or other chronic diseases identified through spatial and temporal clusters can discover population areas of interest, can gauge the effectiveness of disease reduction methods within a given population area, and is considered an important public health measure. This study compares the results of three different methods to gain greater insight and better reflect spatial and temporal variations, as related to identification and/or monitoring current programs. Increasing disease rates may trigger increased focus or re-direction of current efforts. Decreasing rates may be utilized as validation for current efforts, improvement value, or as a component of a shared knowledge base for other efforts. Early detection programs along with case and disease management programs can also utilize geographic modeling information to determine the overall program design and success factor achievement. The program design may vary by geographic location, or may be used to identify the optimal program methodology for the particular locality (2005).

As an important step in enhanced treatment, efforts have been made to materialize best practices of disease therapies. Identification is made through geographical variances, and can trigger alerts to dedicated specialists for discovery of previously unknown opportunities. Activities following the discovery of identified areas may include patient/provider education, therapy identification, locality factors, and identification for early treatment, among others. This type of geographical evaluation has occurred with early-stage breast cancer. Geographic information systems and associated analysis can instruct physicians, patients, and other medical personnel in resource distribution, costs, health outcomes, and patient satisfaction. The location, service provider, and services performed can be analyzed by geographic area to identify effective methods. Once identified, these methods can be standardized to improve consistency across many locations, in order to gain effectiveness. Further granularity can be provided to allow for reduced area identification, in which specific disease control strategies can be implemented to supplement broader programs (Gregorio, Kulldorff, Barry, Samocuik, & Zarfos, 2001).

Other studies have sought to determine variances between local and global populations. Findings have suggested that differences in survival rates are not a result of biological factors, but rather treatment and prevention factors. These include disease stage at diagnosis, effects of compound diseases, and general treatment factors. Temporal trends are required in addition to spatial trends to locate areas whose intervention would prove most beneficial. Prior studies have examined geographic locations to determine physician and medical shortages. The findings suggest that while the existing supply is in fact adequate, the distribution is not optimal. This creates access restrictions across previously unseen urban, suburban, and rural areas. Literature suggests that the physician specialty combination as well as distribution of non-physician clinicians is vital for health outcomes. Accessibility measures require accuracy to appropriately capture the flows within service areas. Managed care plans have the ability to improve access and utilization of preventative care. These managed care plans generally provide more preventative services which result in improved outcomes over fee or service based plans (Mobley, Root, Anselin, Lozano-Gracia, & Koschinsky, 2006).

Whether a singular method or rather a combination of factors prove effective when adapted to the patient set, it is imperative to provide tools to successfully identify patients and program outcomes through monitoring, and enact additional programs to prevent future diseases and complications. This contributes to the overall management goal of improving quality of care, while reducing overall costs, thus ensuring high-quality, affordable healthcare.

CONCLUSION AND FUTURE DIRECTIONS

The spatial scan statistic, LISA, and local G-statistic were able to detect several areas of high and low value clusters. The space-time scan statistic identified one area of excess lung cancer spanning the three-year period of the study and produced a different result than a purely spatial scan statistic. The cluster remained unchanged and statistically significant even after covariate adjustment. The findings also provide evidence that diagnosis data collected as a result of rendered health services can be used in detecting potential disease patterns and/or utilization patterns throughout space and time. The methods shown are also useful for identifying which areas have the highest occurrence of a particular disease for the placement of facilities or specialists. Time can also be a factor for identifying more specific areas of interest, given a large geographic region. The possible boundary effect of circular window and space time-interaction resulting from geographical population shifts in the study area needs to be investigated. The popularly used Knox method (1964) and other tests for space-time interaction are required to confirm if the space-time clustering of lung cancer in the study area is a result of underlying geographical population distribution (Kulldorff, 1999). Unbiased space-time interaction tests and prospective space-time permutation analysis may also be performed as additional data is made available (Kulldorff, 2005; Hjalmars, & Kulldorff, 1999).

As managed care programs are initiated in areas of interest, additional localized studies can be utilized to track improvements in overall mortality rates as a result of the initiatives. By providing granularity to the zip code level in this study, focused geographic programs can be developed at strategic facility sites and can be modified based on ongoing spatio-temporal surveillance of the population. As health care entities seek to improve healthcare outcomes, these methods provide a useful tool in identifying geographic areas of interest.

While the research objective is not to identify a specific cause-and-effect relationship between lung cancer and environmental conditions such as air pollution or individual smoking habit, further research is needed to establish a space-time specific causal relationship and a latency period of cancer. Given the scope and objective of this study, it was not deemed necessary to collect additional detailed case data. For future study, additional attributes which are not available for the current dataset should be generated from a localized study that would include things such as ethnicity, socio-economic status of individual cases, exposure to tobacco smoke, and population migration. These attributes can be adjusted for in the model in order to determine effects. Localized studies can also determine utilization of services in which lung cancer diagnosis appears. This identification can be useful in managing the care for those with an identified diagnosis and determining frequency of services for those with an identified diagnosis.

ABSTRACT

In this chapter, a non-linear relevance feedback mechanism is proposed for increasing the performance and the reliability of information (medical content) retrieval systems. In greater detail, the user who searches for information is considered to be part of the retrieval process in an interactive framework, who evaluates the results provided by the system so that the user automatically updates its performance based on the users' feedback. In order to achieve the latter, we propose an adaptively trained neural network (NN) architecture that is able to implement the non- linear feedback. The term "adaptively" refers to the functionality of the neural network to update its weights based on the user's content selection and optimize its performance.

INTRODUCTION

The rapid progress in publishing articles and the huge amount of data being stored, accessed and transmitted in the biological and medical domain has led to the advent of applications that perform Natural Language Processing (NLP) in order to enable researchers, doctors and other actors in the aforementioned domain to search and retrieve the relevant content. In this context, the traditional approaches of searching, retrieving and organizing the medical data, using only text annotation, cannot describe the medical content with high efficiency. For this reason, several content-based retrieval mechanisms and approaches have been proposed, some of which work by extracting high level semantic features of the content.

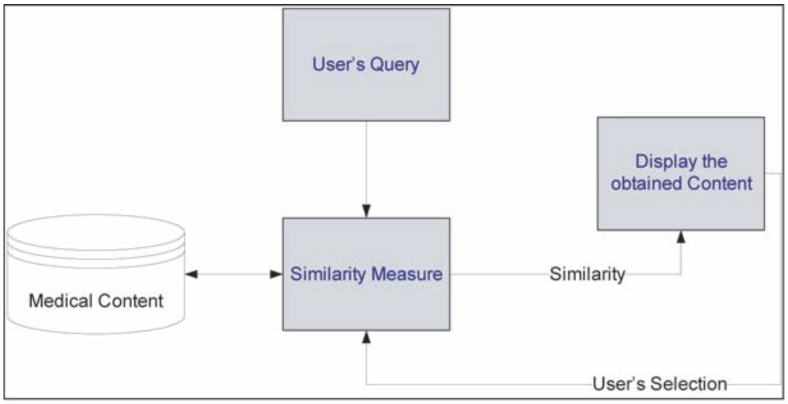
Despite, however, the fact that semantic segmentation has attracted much attention recently, other features that describe the content such as keywords or categories are usually used for implementing content-based retrieval algorithms. To reduce the limitations emerged by using low-level descriptors and simultaneously to increase the performance of content-based algorithms, the human can be considered as a part of the retrieval process, in an interactive framework. This means that initially the user evaluates the results, provided by the system and then the system adapts its performance according to the user's demands. In this framework, a feedback is established from the user to the system based on the most relevant articles, which is usually called relevance feedback. Such an approach, apart from eliminating the gap between high-level and low-level features, it also reduces the problems related to the subjectivity of humans, which often interpret the same medical content in a different way.

To address the content interpretation and classification, new adaptive and interactive management schemes should be introduced, which are capable of updating the system response with respect to the current user's information needs and preferences. One way to achieve adaptability of the system response to the users' needs is to modify the similarity measure used for ranking data. In this way, retrieval, organization and transmission of the information are updated in accordance with the humans' perception of the content through a dynamic real time learning strategy based on the users' interaction.

One of the interactive learning techniques is *relevance feedback* (originated from text-based information retrieval systems), which adapts the response of a system according to the relevant information feedback to it so that the adjusted response is a better approximation to the user's information needs. Usually, relevant information is provided by the user in an *interactive framework*, who evaluates the results according to his/her demands and preferences. Relevance feedback has been widely used in text-based information retrieval systems (J. Rocchio, 1971). Although it is not restricted to description environments where similarity measures are used, in databases where similarity-based queries are applied (Y. Ishikawa, 1998), relevance feedback refers to the mechanism which updates the similarity measure with respect to the relevant/irrelevant information, as indicated by the user. Relevance feedback confronts the subjectivity of humans in perceiving medical content and also eliminates the gap between high-level semantics and low-level features, which are often used for content description and modeling (Y. Rui, 1998). The following figure (Figure 1) presents a block diagram of a relevance feedback scheme.

To perform the relevance feedback mechanism a degree of importance should be assigned to each content descriptor, i.e., a different weighed factor to each element of the feature characterizing the medical content. After the first retrieval, the user assigns a degree of appropriateness for each article, which actual indicates the similarity degree of the respective article to the query. The weights are dynamically adapted based on the users' feedback, who selects the most appropriate articles among those retrieved by the system. Furthermore, we propose an enhancement to the relevance feedback mechanism by introducing nonlinearities in the parametric distance. This is implemented by an adaptively trained neural network classifier, the weights of which are adjusted according to the users' feedback. In this case, the network weights define the degree of importance for each descriptor, while the network output indicates the similarity of the examined article to the query one. The network weights are updated each time a new users' selection takes place so

Figure 1. Design of the relevance feedback mechanism for medical content retrieval systems



that they are closer to the user's selection while simultaneously results in a minimal degradation of the previously learned data.

Concluding, our approach proposes the use of a non-linear relevance feedback mechanism in content-based retrieval systems. To implement this mechanism we use a neural network that is able to dynamically adapt its performance by taking into account both the current knowledge and the previous one. As a result, after the user's feedback, the network output, is optimized since it also takes into account the user's selection. There has to be mentioned, that the proposed relevance feedback mechanism works efficiently independently from the content, which means that it is applicable not only to textual content but to images and video as well. This mechanism can be seen as an additional layer on the retrieval algorithms in medical databases and other sources of content, which improves the overall system performance in terms of the data that are finally obtained by the user.

The remainder of this chapter is structured as follows. The background section presents related work in the field of non-linear relevance feedback as a way to improve systems' performance. The research topic and the focus of our work, is describe thereafter. We present the problem of generalized non-linear relevance feedback and we propose a recursive algorithm for updating the similarity measure to the current users' information needs and preferences. Finally, "Future Trends" section includes a discussion on future research and potentials for the current study, while the chapter is summarized in the "Conclusion" section.

BACKGROUND

As already mentioned, one of the interactive learning techniques is *relevance feedback*, which adapts the response of a system according to the relevant information feedback to it so that the adjusted response is a better approximation to the user's information needs. In this context, recently relevance feedback algorithms have been extended from text-based information retrieval to content-based image retrieval systems. The area of image retrieval is even more complex due to the nature of the content: it is much harder to characterize and make queries on images than on textual information. Given that our approach can be applied to any information retrieval system we briefly present work in this area focusing on the more complex side: the one of the image retrieval in order to show that our approach advances this specific field of research in the most "complex" case. In (I. Cox, 1996), a probabilistic framework was reported based on a Bayesian formulation scheme. In (Y. Rui, 1998), a relevance feedback algorithm is introduced using as metric the weighted Euclidean distance and a heuristic scheme is adopted to perform the weight updating. However, this approach is a heuristic method and as mentioned in the conclusions of this chapter, there is a need for an optimal learning strategy. The first approaches towards this direction have been reported in (Y. Avrithis, 1998; A. D. Doulamis, 1999; Y. Ishikawa, 1998). In particular, in (Y. Avrithis, 1998; A. D. Doulamis, 1999) the weighted Euclidean distance is used as in (Y. Rui, 1998) and the weight updating strategy is performed by minimizing the response of the Euclidean distance metric over all selected samples. Instead, in (Y. Ishikawa, 1998), the generalized Euclidean distance is adopted as similarity metric to take into account the interconnection of different feature elements with each other. Feature element interconnection is also examined in (Y. Choi, 2000). However, the works of (Y. Avrithis, 1998; A. D. Doulamis, 1999) yield unstable performance in case of negative examples, while "smooth" the system response when many positive relevant images are selected. In addition, the work of (Y. Ishikawa, 1998) involves the inversion of the covariance matrix of the selected samples. It is clear, however, that the covariance matrix is not invertible if the number of selected samples is smaller than the size of image feature vectors, which is a common case in real situations. To confront this difficulty, the authors of (Y. Ishikawa, 1998) propose a solution based on the pseudo-inverse of the covariance matrix. Although, however, in theory, such an approach eliminates the singularity problems, in practice, the retrieval performance is not so satisfactory (Y. Rui, 2000). To reduce the aforementioned difficulties, a "hierarchical model" has been proposed in (Y. Rui, 2000) for decomposing the feature vectors into vectors of smaller size. In addition, the algorithm introduces a dynamic switch for performing the weight updating so as to decrease the effect of singularity. A different approach is presented in (Xiang Sean Zhou, 2001), where the relevance feedback problem is addressed using discriminant analysis. In particular, the algorithm proposes Biased discriminant analysis to face the symmetry between positive and negative examples under small training samples, enhanced by a kernel version to facilitate non-linearities. The method non-linearly transforms the feature vector space to adapt the system response to the current users' needs and preferences. However, only the vector norm is exploited in the proposed transformation, while a constant similarity measure is assumed, i.e., the Euclidean distance.

Other relevance feedback algorithms use the cross-correlation measure for similarity. Cross-correlation is a normalized measure, which expresses how similar/dissimilar two feature vectors are. A correlation-based relevance feedback scheme has been reported in (N. Doulamis, 2001), while a recursive learning strategy has been presented in (N. Doulamis, 2001; N. Doulamis 2001) to address the case of multiple feedback iterations. In these methods, the weights (model parameters) express the degree of relevance of the query feature vector to the vector of the selected samples. Again, the aforementioned approaches consider a constant type of similarity measure, e.g., the correlation criterion, regulating only the importance of extracted descriptors to the similarity metric, instead of the similarity type itself.

On the contrary, in this chapter, the problem of relevance feedback is addressed *in the most generic form* by optimally updating the similarity measure type to the current users' information needs and preferences. In this case, instead of adjusting the degree of importance of each descriptor, the similarity measure itself is estimated through an on-line efficient and recursive learning strategy. Therefore, no restrictions on the type of the similarity are imposed, in contrast to the aforementioned approaches, where only a specific type of similarity measure is considered, such as the Euclidean distance (Y. Avrithis, 1998 - Y. Rui, 2000) or the Cross-Correlation criterion (N. Doulamis, 2001 - N. Doulamis 2001). Initially, the similarity measure is assumed to be of any non-linear function type. In the following, the similarity is modeled as a non-linear parametric relation of known functional components (E. Kreyszig, 1989; G. Cybenko, 1989) using concepts derived from functional analysis. More specifically, it has been shown that any non-linear continuous function can be approximated with any degree of accuracy by considering functional components of non-constant, bounded and monotone increasing squashing functions. The contribution of each component to the similarity measure is estimated based on a set of selected relevant / irrelevant samples interactively provided by the user to express the current information needs. As a result, at each feedback iteration, the type of similarity measure is estimated resulting in a *generalized non-linear* relevance feedback scheme.

The contribution of each functional component to the similarity measure is *recursively* estimated through an efficient on-line learning strategy. In particular, the adaptation is performed so that a) the current selected content as expressed by a set of relevant/irrelevant samples is trusted as much as possible, while simultaneously b) a minimal modification of the already estimated similarity measure is encountered. For the satisfaction of the aforementioned conditions, a small modification of the model coefficients is assumed to be sufficient. Then, the first condition is simplified by applying a first order Taylor series expansion to the functional components, which results in a set of linear constraints of the current selected relevant/irrelevant samples. For the second condition, the sensitivity of the error between the system response and the actual degree of relevance, as provided by the user over an indicative learning set, is used. The algorithm results in a constraint minimization problem for the estimation of the coefficients of the functional components and therefore of the type of similarity measure, which approximates as much as possible the current users' information needs and preferences.

IMPROVING THE PERFORMANCE OF MEDICAL INFORMATION RETRIEVAL SYSTEMS

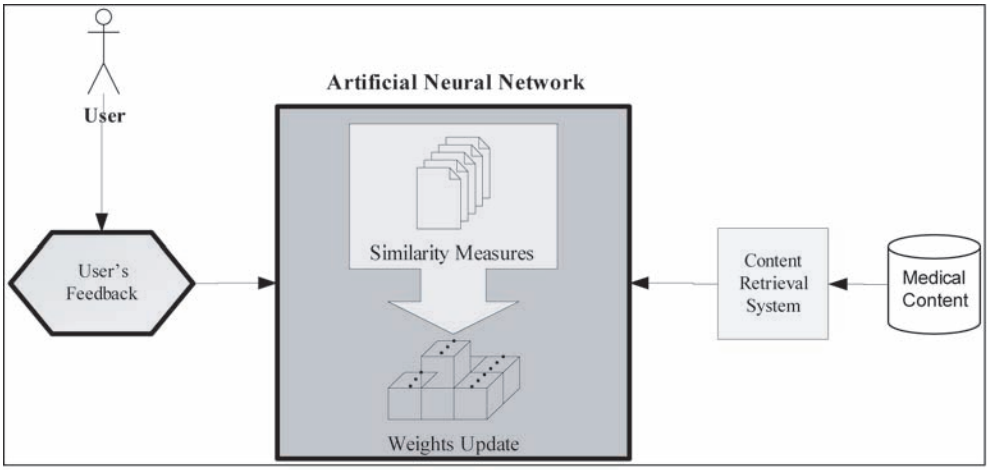
Based on the above, in this section we will briefly present the proposed architectural approach that includes an Artificial Neural Network (ANN) and the relevance feedback mechanism, the combination of which improves the performance of any medical information retrieval system. In general, an ANN is an information processing paradigm that is inspired by the way biological nervous systems, such as the brain, process information. The key element of this paradigm is the novel structure of the information processing system. It is composed of a large number of highly interconnected processing elements (neurones) working in unison to solve specific problems. ANNs, like people, learn by example.

Following the proposed architecture, we will describe the focus of our work which is the ANN's functions and the modeling of the similarity measures through the ANN in order to enable the latter to adjust its weights based on the feedback provided by the user.

Proposed Architectural Approach

The core component of the proposed architectural approach is an Artificial Neural Network used to model the similarity measure of a query for ranking the retrieved data. The aforementioned ANN is adaptable - meaning that the weight factors in its functions are adapted based on the relevance assigned by the user over all selected data. The selected data are the outcome of any content retrieval mechanism in a database / source with medical information. The information regarding the relevance of the results to the user's query is parsed into the ANN from the implemented relevance feedback mechanism as presented in the following figure (Figure 2).

Figure 2. Architectural approach



The process is initiated by the content retrieval system each time a user searches for medical content. Based on his / her search, the content retrieval system replies by providing a set of results. Afterwards these results are evaluated by the user who provides feedback on them to the ANN. The ANN "learns" from this process and updates the weights of its functions in order to provide better results in the next iteration. The key point in this process is how the weights are updated based on the user's feedback.

In the following paragraphs we will present an innovative approach that allows the weights update of the ANN's functions in order to include the user's feedback and improve the performance of content retrieval systems in future queries.

Similarity Measures

Regarding the ANN, one way to achieve adaptability of the system response to the users' needs is to modify the *similarity measure* used for ranking data. In this way, retrieval, organization and transmission of the information is updated in accordance with the humans' perception of the content through a dynamic real time learning strategy based on the users' interaction.

Let us assume in the following a *query by example* type of operation for content-based retrieval. This means that the user provides queries in the form of requests for content, which are analyzed similarly to the samples of the database. Thus, for each query by example, a feature vector is constructed to describe the query content. In the following, a similarity measure is applied to find a set of data that best match the query content. The most commonly used similarity measure for data retrieval is the Euclidean distance, where in its generalized form is defined as (G*eneralized Euclidean Distance*) (Y. Ishikawa, 1998; Y. Rui, 2000)

$$d(\mathbf{f}_q, \mathbf{f}_i) = (\mathbf{f}_q - \mathbf{f}_i)^T \cdot \mathbf{W} \cdot (\mathbf{f}_q - \mathbf{f}_i) \qquad (1)$$

In equation (1), vector $\mathbf{f}_q$ refers to the feature vector of the query, while $\mathbf{f}_i$ to the feature vector of the ith sample in the database. Vectors $\mathbf{f}_q$ and $\mathbf{f}_i$ are estimated as described previously. The **W** is a real symmetric matrix, which contains the weights that regulate the degree of importance of the feature elements to the similarity measure. In case that no interconnection among different feature elements is permitted, matrix **W** becomes diagonal and the resulted similarity measure is called *Weighted Euclidean Distance*. The weighted

Euclidean distance has been adopted in several relevance feedback schemes, such as the works of (Y. Rui, 1998; Y. Avrithis, 1998; A. D. Doulamis, 1999). On the contrary, in (Y. Ishikawa, 1998; Y. Rui, 2000), the generalized Euclidean distance has been involved.

Another interesting similarity measure adopted in the literature for relevance feedback is the cross-correlation criterion, which indicates how similar two feature vectors are and thus provides a measure for their content similarity (N. Doulamis, 2001- N. Doulamis, 2001). Furthermore, correlation remains unchanged with respect to feature vector scaling and translation. For example, adding or multiplying a constant value to all elements of a feature vector affects the Euclidean distance but not the correlation. One way for parametrizing the correlation-based similarity is (N. Doulamis, 2001)

$$\rho_{\mathbf{w}}(\mathbf{f}_q, \mathbf{f}_i) = \frac{\sum_{k=1}^{P} w_k \cdot f_{q,k} \cdot f_{i,k}}{\sqrt{\sum_{k=1}^{P} w_k^2 \cdot f_{q,k}^2} \cdot \sqrt{\sum_{k=1}^{P} f_{i,k}^2}} \qquad (2)$$

where $f_{q,k}$ and $f_{i,k}$ are the kth element of vectors $\mathbf{f}_q$ and $\mathbf{f}_i$ respectively. The variable P in (2) indicates the size of feature vector, while parameters w_k the relevance of the kth element of the query feature vector to the selected ones. An optimal learning strategy for estimating the weights w_k has been presented in (N. Doulamis, 2001; N. Doulamis, 2001) along with a recursive weight updating scheme for multiple feedback iterations.

In many relevance feedback approaches the similarity measure used is of constant type. In these scenarios, only regulation of the weighted factors w_k is permitted, which express the degree of importance of each descriptor to the similarity measure. Instead, a more powerful and efficient approach is to implement an on-line learning strategy, which assumes *any generic non-linear similarity measure* with the capability of adapting its type to the current users' information needs and preferences. In this case, instead of regulating the importance of each descriptor to the similarity measure, at each feedback iteration, the type of similarity measure is dynamically estimated, resulting in a *generic non-linear* relevance feedback scheme. In particular, the similarity measure, say $d(\cdot)$, is modeled as a continuous function $g(\cdot)$ of the difference between the query feature vector $\mathbf{f}_q$ and the feature vector $\mathbf{f}_i$ of the ith sample in the database.

$$d(\mathbf{f}_q, \mathbf{f}_i) = g(\mathbf{f}_q - \mathbf{f}_i) \qquad (3)$$

Equation (3) models any non-linear similarity measure of the query feature vector $\mathbf{f}_q$ and the ith sample in the database $\mathbf{f}_i$ so that the current user's information needs and preferences are satisfied as much as possible. The above equation is modeled through the proposed ANN.

However in equation (3), the feature vectors $\mathbf{f}_q$ and $\mathbf{f}_i$ are involved, which affect the retrieval results. It is clear that the more efficient a feature vector describes the content, the higher the retrieval performance is. In this chapter, we concentrate on the estimation of the most appropriate similarity measure $g(\cdot)$, which satisfies the user information needs and preferences as much as possible for a *given feature* vector representation.

Generalized Non-Linear Relevance Feedback

The main difficulty in implementing equation (3) is that function $g(\cdot)$ is actually unknown. For this reason, initially modeling of the unknown function $g(\cdot)$ is required in a parametric form. Modeling permits the estimation of similarity measure based on a set of relevant/irrelevant selected data.

Similarity Measure Type Modeling

Concepts derived from functional analysis are adopted in this chapter for modeling and parametrizing the unknown function $g(\cdot)$ (E. Kreyszig, 1989; G. Cybenko, 1989). Particularly, it can be proved that any continuous non-linear function can be expressed as a parametric relation of known functional components $\Phi_l(\cdot)$ within any degree of accuracy (E. Kreyszig, 1989). In this case, we have that

$$d(\mathbf{f}_q, \mathbf{f}_i) = g(\mathbf{f}_q - \mathbf{f}_i) \approx \sum_{l=1}^{L} v_l \cdot \Phi_l\left(\sum_{k=1}^{P} w_{k,l}(f_{q,k} - f_{i,k})\right) \tag{4}$$

where number L expresses the approximation order of function $g(\cdot)$. In equation (4), v_l and $w_{k,l}$ correspond to model parameters, while $\Phi_l(\cdot)$ corresponds to functional components. It is clear that the approximation precision increases, as the order L increases. Equation (4) is the equation used in the proposed ANN.

The most familiar class of functional components $\Phi_l(\cdot)$ is the sigmoid functions, which are equal to

$$\Phi_l(x) = 1/(1 - \exp(-a \cdot x)) \tag{5}$$

where a is a constant which regulates the curve steepness. It should be mentioned that the parameters v_l, $w_{k,l}$ of (4) *are not related* to the weighted factors (degree of importance) of the descriptors, which are used in the current relevance feedback approaches, such the ones in (Y. Rui, 1998; I. Cox, 1996 - N. Doulamis 2001). On the contrary, they express the coefficients (model parameters) on which function $g(\cdot)$ is expanded to the respective functional components.

From equation (4), it seems that $P \times L$ parameters are required to approximate any continuous similarity measure of order L. The number of parameters can be reduced by imposing constraints on v_l and $w_{k,l}$, which, however, restrict the type of similarity measure of (4). Particularly, let us assume that the same parameters are assigned to all functional components $\Phi_l(\cdot)$. This means that $w_{k,l} = w_{k,q}$ $\forall l,q$ and therefore $w_{k,l} = w_k$ since they depend only on the feature vector index and not on the index of the functional components. If we further assume that the functional components are linear, we conclude that

$$d(\mathbf{f}_q, \mathbf{f}_i) = \left(\sum_{l=1}^{L} v_l\right) \cdot \sum_{k=1}^{P} w_k(f_{q,k} - f_{i,k}) \tag{6}$$

which simulates the weighted Euclidean distance with free parameters the P variables w_k. In this case, the parameters v_l *d*o not affect the performance of the similarity measure since they just multiply the overall similarity.

Another interesting case results from the assumption that squared functional components $\Phi_l(\cdot)$ are considered, i.e., $\Phi_l(x) = x^2$. In this case, we have that

$$d(\mathbf{f}_q, \mathbf{f}_i) = \sum_{l=1}^{L} v_l \cdot \left(\sum_{k=1}^{P} w_k(f_{q,k} - f_{i,k})\right)^2 = \left(\sum_{l=1}^{L} v_l\right) \cdot \sum_{m=1}^{P} \sum_{k=1}^{P} w_k \cdot w_m(f_{q,k} - f_{i,k}) \cdot (f_{q,m} - f_{i,m}) \tag{7}$$

Other types of similarity measures are obtained by imposing constraints either on the parameters v_l and $w_{k,l}$ or on the type of the functional components $\Phi_l(\cdot)$. Imposing constraints on v_l, $w_{k,l}$ and $\Phi_l(\cdot)$ (and thus restricting the type of similarity measure that (4) models), we reduce the number of free parameters, and therefore the relevance feedback computational complexity. However, the most generic case is derived by setting no constraints on (4), which models any continuous non-linear function. All the other types of similarity measures can be considered as special cases of the generic one. In section 4, a recursive algorithm for estimating the free parameters is proposed for the general case. The same methodology can be applied for the special cases too, taking, however, into consideration the constraints.

Similarity Measure Type Estimation

Using, equation (4), it is clear that estimation of similarity measure is equivalent to the estimation of coefficients v_l, $w_{k,l}$. In particular, let us denote as $S^{(r)}$ a set, which contains selected relevant/ irrelevant samples at the r feedback iteration of the algorithm. The set $S^{(r)}$ has the form

$$S^{(r)} = \{\cdots,(\mathbf{f}_q - \mathbf{f}_i, R_i),\cdots\} = \{\cdots,(\mathbf{e}_i, R_i),\cdots\} \tag{8}$$

where $\mathbf{f}_q$ refers to the query feature vector, $\mathbf{f}_i$ to the feature vector of the ith selected sample and R_i to the respective degree of relevance. Negative values of R_i express irrelevant content, whereas positive values of R_i relevant content. Let us denote as $v_l(r+1)$, $w_{k,l}(r+1)$ the model parameters at the (r+1) feedback iteration. These coefficients are estimated so that, the similarity measure, after the rth feedback iteration, equals the degree of relevance assigned by the user over all selected data,

$$d^{(r+1)}(\mathbf{f}_q, \mathbf{f}_i) = g^{(r+1)}(\mathbf{f}_q - \mathbf{f}_i) = \sum_{l=1}^{L} v_l(r+1)\cdot\Phi_l\left(\sum_{k=1}^{P} w_{k,l}(r+1)\cdot(f_{q,k} - f_{i,k})\right) \approx R_i$$

with $i \in S^{(r)}$ (9)

where $d^{(r+1)}(\cdot)$ expresses the non-linear similarity measure at the (r+1)th feedback iteration of the algorithm.

Usually, the number of samples of set $S^{(r)}$ at the rth feedback iteration is much smaller than the number of coefficients v_l, $w_{k,l}$ that should be estimated. For example, a typical number for the coefficients is around 640 (L=10 and P=64), whereas the number of selected samples at a given feedback iteration is usually less than 10. Therefore, equation (9) is not sufficient to uniquely identify the parameters v_l, $w_{k,l}$. To achieve uniqueness in the solution, an additional requirement is imposed, which takes into consideration the variation of the similarity measure. In particular, among all possible solutions, the one that satisfies (9) and simultaneously causes a minimal modification of the already estimated similarity measure is selected as the most appropriate.

Let us denote as S a set, which contains relevant / irrelevant samples with respect to several queries. The set S is used for the initial estimation of the similarity measure based on a least squared minimization algorithm as described in section 5. At each feedback iteration, the set S is augmented by adding new selected relevant/ irrelevant samples. In order to retain a constant size of S, for computational efficient purposes, the older samples are removed from S as new samples added. Then, the requirement of the minimal modification of the already estimated similarity measure is expressed as

$$\text{minimize } B(r) = \left\| E^{(r+1)} - E^{(r)} \right\|_2 \tag{10}$$

where

$$E^{(r)} = \frac{1}{2}\cdot\sum_{i\in S}\{g^{(r)}(\mathbf{f}_q - \mathbf{f}_i) - R_i\}^2$$

corresponds to the error of the similarity measure over all data of S at the r$^{\text{th}}$ feedback iteration.

As a result, the model parameters of the similarity measure are estimated by the following constraint minimization problem

$$\text{minimize } B(r) = \left\| E^{(r+1)} - E^{(r)} \right\|_2 \tag{11a}$$

subject to

$$d^{(r+1)}(\mathbf{f}_q, \mathbf{f}_i) = g^{(r+1)}(\mathbf{f}_q - \mathbf{f}_i) = \sum_{l=1}^{L} v_l(r+1)\cdot\Phi_l\left(\sum_{k=1}^{P} w_{k,l}(r+1)\cdot(f_{q,k} - f_{i,k})\right) \approx R_i$$

with

$$(f_{q,k} - f_{i,k}) \in S^{(r)} \tag{11b}$$

The constraint term of equation (11b) indicates that, the proposed on-line learning strategy modifies the similarity measure so that, after the adaptation, the users' information needs are satisfied as much as possible. On the contrary, the term of (11a) expresses that the adaptation is accomplished with a minimal modification of the already estimated similarity measure.

Recursive Similarity Measure Adaptation

In this subsection, a recursive algorithm is presented to perform the constraint minimization of (11). Therefore, the scheme yields to a *Recursive Generalized Non-Linear Relevance Feedback* algorithm for information retrieval.

Let us consider that all coefficients $v_l(r)$, $w_{k,l}(r)$ are included in a vector, say $\mathbf{w}(r)$, i.e.,

$$\mathbf{w}(r) = [\cdots w_{k,l}(r) \cdots v_l(r) \cdots]^T \tag{12}$$

Vector $\mathbf{w}(r)$ is decomposed into

$$\mathbf{w}(r) = [vec\{\mathbf{W}(r)\}^T \, \mathbf{v}(r)^T]^T \tag{13}$$

where vector $\mathbf{v}(r)$ and matrix $\mathbf{W}(r)$ are related with the coefficients $v_l(r)$, $w_{k,l}(r)$ as

$$\mathbf{W}(r) = [\mathbf{w}_1(r) \cdots \mathbf{w}_L(r)] \text{ and } \\ \mathbf{v}(r) = [v_1(r) \cdots v_L(r)]^T \tag{14}$$

where

$$\mathbf{w}_l(r) = [w_{1,l}(r) \cdots w_{P,l}(r)]^T$$

and P the feature vector size. Operator $vec\{\cdot\}$ returns a vector formed by stacking up all columns of the respective matrix.

Let us now assume, that the model parameters at the $(r+1)$th feedback iteration, i.e., the $\mathbf{w}(r+1)$, are related to the model parameters $\mathbf{w}(r)$ at the rth iteration as

$$\mathbf{w}(r+1) = \mathbf{w}(r) + \Delta\mathbf{w} \tag{15}$$

where $\Delta\mathbf{w}$ refers to a small increment of the model coefficients. Equation (15) indicates that a small modification of the coefficients is adequate to satisfy the current user's information needs, expressed by (11b).

Adaptation to the Current Selected Relevant/Irrelevant Samples

In the following, we deal with the analysis of equation (11b), i.e., the constraint of the minimization. In particular, based on equation (15), linearization of the functional components $\Phi_l(\cdot)$ is permitted using a first order Taylor series expansion. Then, equation (11b) can be decomposed in a system of linear equations, as indicated by the following theorem

Based on the fact that the constraint expressed by equation (11b) under the assumption of (15) is decomposed to a system of linear equations of the form $\mathbf{c}(r) = \mathbf{A}(r) \cdot \Delta\mathbf{w}$, where vector $\mathbf{c}(r)$ and matrix $\mathbf{A}(r)$ depends only on the model parameters of the previous rth feedback iteration, vector $\mathbf{c}(r)$ expresses the difference between the desired degree of relevance R_i, assigned by the user, and the one provided by the system before the feedback iteration, i.e., using the parameters $\mathbf{w}(r)$.

In particular, vector $\mathbf{c}(r)$ is given as

$$\mathbf{c}(r) = [\ldots c^{(r)}(\mathbf{e}_i)\ldots]T, \text{ for all } \mathbf{e}_i \in S^{(r)} \text{ with}$$

$$c^{(r)}(\mathbf{e}_i) = g^{(r+1)}(\mathbf{e}_i) - g^{(r)}(\mathbf{e}_i) = R_i - g^{(r)}(\mathbf{e}_i) \tag{16}$$

where $\mathbf{e}_i = \mathbf{f}_q - \mathbf{f}_i$

Furthermore, matrix $\mathbf{A}(r)$ is given as

$$\mathbf{A}^T(r) = [\ldots \mathbf{a}^{(r)}(\mathbf{e}_i)\ldots], \text{ for all } \mathbf{e}_i \in S^{(r)} \tag{17}$$

where the columns $\mathbf{a}^{(r)}(\mathbf{e}_i)$ are given as

$$\mathbf{a}^{(r)}(\mathbf{e}_i) = [\mathrm{vec}\{\mathbf{e}_i \cdot (\mathbf{g}^{(r)})^T\}^T \mathbf{u}(r)^T]^T \tag{18}$$

where

$$\mathbf{u}(r) = \boldsymbol{\varphi}(\mathbf{W}^T(r) \cdot \mathbf{e}_i) \quad (19)$$

with $\boldsymbol{\varphi}(\cdot) = [\Phi_1(\cdot)...\Phi_L(\cdot)]^T$ a vector containing the functional components $\Phi_l(\cdot)$ [see equation (5)]. Vector $\mathbf{g}(r)$ is given as follows

$$\mathbf{g}(r) = \mathbf{D}(r) \cdot \mathbf{v}(r) \quad (20)$$

with matrix $\mathbf{D}(r)$ expresses the derivatives of the elements of vector $\mathbf{u}(r)$, i.e.,

$$\mathbf{D}(r) = diag\{\delta_1(r),...,\delta_L(r)\} \quad (21)$$

In (21) $diag\{\}$ refers to a diagonal matrix.

Since in our case the functional components $\Phi_l(\cdot)$ are the sigmoid, the

$$\delta_i(r) = u_i(r) \cdot [1 - u_i(r)] \quad (22)$$

Based on the previous equations, it can be seen that, vector $\mathbf{c}(r)$ and matrix $\mathbf{A}(r)$ are *only* related with the coefficients $v(r)$ and $w_{k,l}(r)$ of the rth feedback iteration.

Minimal Modification of the Similarity Measure

The term of equation (11a), which expresses the minimal modification of the already estimated similarity measure is decomposed under the assumption of equation (15) as follows

The effect of the small weight perturbation to the term of (11a) is provided by minimizing a squared convex function of the form

$$\frac{1}{2}\Delta\mathbf{w}^T \cdot \mathbf{J}^T(r) \cdot \mathbf{J}(r) \cdot \Delta\mathbf{w}\,,$$

where matrix $\mathbf{J}(r)$ is the Jacobian matrix of the error

$$E_i = \frac{1}{2} \cdot (g^{(r)}(\mathbf{f}_q - \mathbf{f}_i) - R_i)$$

over all samples of set S.

The Jacobian matrix $\mathbf{J}(r)$ is given as

$$\mathbf{J} = \begin{bmatrix} \vdots & \vdots & \vdots & \vdots & \vdots \\ \cdots & \dfrac{\partial E_i}{\partial w_{k,l}} & \cdots & \dfrac{\partial E_i}{\partial v_l} & \cdots \\ \vdots & \vdots & \vdots & \vdots & \vdots \end{bmatrix} \quad (23)$$

with the derivatives

$$\frac{\partial E_i}{\partial w_{k,l}} \text{ and } \frac{\partial E_i^{(r)}}{\partial v_l}$$

being expressed by the following equations

$$\frac{\partial E_i^{(r)}}{\partial w_{k,l}} = -t_i(r) \cdot v_k(r) \cdot \delta_l(r) \cdot e_{i,l}$$

and

$$\frac{\partial E_i}{\partial v_l} = -t_i \cdot u_l(\mathbf{e}_i) \quad (24)$$

with $t_i(r) = (g^{(r)}(\mathbf{f}_q - \mathbf{f}_i) - R_i)$ and $e_{i,l}$ the lth element of vector $\mathbf{e}_i = \mathbf{f}_q - \mathbf{f}_i$.

Based on the above, the recursive estimation of the model parameters for each feedback iteration is accomplished by calculating the small perturbation of the model coefficients $\Delta\mathbf{w}$ through the following constraint minimization problem

$$\text{Minimize } D = \frac{1}{2} \cdot \Delta\mathbf{w}^T \cdot \mathbf{J}^T \cdot \mathbf{J} \cdot \Delta\mathbf{w} \quad (25a)$$

$$\text{Subject to } \mathbf{c}(r) = \mathbf{A}(r) \cdot \Delta\mathbf{w} \quad (25b)$$

The main steps of the proposed generalized recursive non-linear relevance feedback scheme are the following:

1. Assume that the rth feedback iteration has been completed and the type of the similarity measure has been estimated as expressed

by the parameters **v**(r) and **W**(r). Then, the model parameters for the (r+1) iteration are updated with the following steps.

2. Estimate vector **c**(r) using (16) and matrix **A**(r) using (17 and 18).
3. Estimate matrix **J**(r) as in (23,24).
4. Apply the reduced gradient method for calculating the small increment of the model parameters Δ**w** (this method is described in the following paragraphs).
5. Update model coefficients using (15) and the model parameters **v**(r + 1) and **W**(r + 1).
6. The new similarity measure is expressed through (4).

The Reduced Gradient Method

Equation (25a) is a convex function since it is of square form (D. J. Luenberger, 1984). Furthermore, (25b) corresponds to linear constraints. As a result, only one minimum exists, which is the global one (D. J. Luenberger, 1984). One solution for minimizing (25) is to use Lagrange multipliers. However, in this case inversion of matrices of large size is involved, which is a process both computationally and memory demanded. For this reason, in this chapter an iterative constraint minimization technique is adopted to perform the constraint minimization of (25). Among other methods, such as the gradient projection (D. J. Luenberger, 1984), the reduced gradient method has been selected due to the fact that it demands less computational complexity, especially in case of few constraints, which is valid in our case.

The reduced gradient method is an iterative process, which starts from a feasible point (solution) and moves in a direction, which decreases the error function of equation (25a), while simultaneously satisfies the constraint defined by the equation (25b). A point is called feasible if it satisfies the constraints of (25b). To commence the algorithm, an initial feasible point Δ**w**(0) is required.

Initialization Phase

In our case, as initial feasible point, Δ**w**(0), the minimal distance from the origins to the constraint hyper-surface $\mathbf{c}(r) - \mathbf{A}(r)\cdot\Delta\mathbf{w} = \mathbf{0}$ is used. Therefore, Δ**w**(0) is given by minimizing the following equation

minimize $\left\|\Delta\mathbf{w}\right\|_2$ or $(\Delta\mathbf{w})^T\cdot\Delta\mathbf{w}$ equivalently (26a)

subject to $\mathbf{c}(r) - \mathbf{A}(r)\cdot\Delta\mathbf{w} = \mathbf{0}$ (26b)

Minimization of the (26a) subject to (26b) is achieved using Lagrange multipliers (D. J. Luenberger, 1984). In this case, the aforementioned minimization problem is written as

$$\Delta\mathbf{w}(0) = \underset{\Delta\mathbf{w}}{\operatorname{argmin}}\left((\Delta\mathbf{w})^T\cdot\Delta\mathbf{w} + \lambda^T\cdot(\mathbf{c}(r) - \mathbf{A}(r)\cdot\Delta\mathbf{w})\right) \tag{27}$$

where the elements of vector λ corresponds to the Lagrange multipliers. Differentiating equation (27) with respect Δ**w** and λ and setting the results equal to zero, we obtain

$$\Delta\mathbf{w}(0) = \mathbf{A}^T(r)\cdot(\mathbf{A}(r)\cdot\mathbf{A}^T(r))^{-1}\cdot\mathbf{c}(r) = \mathbf{Q}(r)\cdot\mathbf{c}(r) \tag{28a}$$

with $\mathbf{Q}(r) \equiv \mathbf{A}^T(r)\cdot(\mathbf{A}(r)\cdot\mathbf{A}^T(r))^{-1}$ (28b)

It should be mentioned that matrix $\mathbf{A}(r)\cdot\mathbf{A}^T(r)$ is of size $\zeta\times\zeta$, where ζ corresponds to the number of the imposed constraints, i.e., to the number of selected relevant/irrelevant data. This number is usually small, and inversion of matrix $\mathbf{A}(r)\cdot\mathbf{A}^T(r)$ does not demand high computational complexity and memory requirements.

Iteration Phase

At the mth iteration of the algorithm, the feasible point $\Delta\mathbf{w}(m)$ is arbitrarily partitioned into two groups; the first group contains the dependent (basic) variables, while the second the independent variables. Without loss of generality, we select the first elements of vector $\Delta\mathbf{w}(m)$ as dependent variables. Therefore,

$$\Delta\mathbf{w}(m) = [\Delta\mathbf{w}^D(m)^T \quad \Delta\mathbf{w}^I(m)^T]^T \qquad (29)$$

where $\Delta\mathbf{w}^D(m)$ is a vector, which contains the dependent variables, while $\Delta\mathbf{w}^I(m)$ the independent ones.

Using the constraint $\mathbf{c}(r) = \mathbf{A}(r) \cdot \Delta\mathbf{w}$, we can express the dependent vector $\Delta\mathbf{w}^D(m)$ with respect to the independent variables $\Delta\mathbf{w}^I(m)$ as follows

$$\mathbf{c}(r) = \mathbf{A}(r) \cdot \Delta\mathbf{w} \qquad (30)$$

where $\mathbf{A}^D(r)$ is the part of matrix $\mathbf{A}(r)$ which related to the dependent variables while the $\mathbf{A}^I(r)$ to the independent ones. Thus, $\mathbf{A}(r) = [\mathbf{A}^D(r)\ \mathbf{A}^I(r)]$. Matrix $\mathbf{A}^D(r)$ is always squared with size equals to the number of constraints ζ, thus $\mathbf{A}^D(r)$ is of $\zeta \times \zeta$ elements. This means that vector $\mathbf{c}(r)$ is of size $\zeta \times 1$. On the contrary, matrix $\mathbf{A}^I(r)$ is of size $\zeta \times \{L \cdot P - \zeta)$, where $L \cdot P$ corresponds to the number of the model parameters. Thus, vector $\Delta\mathbf{w}^I(m)$ is of size $(L \cdot P - \zeta) \times 1$.

At next iterations, the independent variables are updated towards the direction of the respective gradient,

$$\Delta\mathbf{w}^I(m+1) = \Delta\mathbf{w}^I(m) - \eta(m) \cdot \mathbf{r}(m) \qquad (31)$$

In equation (31), scalar $\eta(m)$ regulates the convergence rate of the weight updating, while $\mathbf{r}(m)$ refers to the reduced gradient, which is given as

$$\mathbf{r}^T(m) = \theta^T - \gamma^T \cdot (\mathbf{A}^D(r))^{-1} \cdot \mathbf{A}^I(r) \qquad (32)$$

where vectors θ and γ are provided by splitting the gradient of cost function D into the dependent and independent group

$$\nabla B(r) = \mathbf{J}^T(r) \cdot \mathbf{J}(r) \cdot \Delta\mathbf{w}(m) = [\theta^T \quad \gamma^T]^T \qquad (33)$$

The main steps of the reduced gradient method, which is used in our case for estimating the new network weights, are the following:

1. Initialization Phase
   a. Estimate the initial model increment $\Delta\mathbf{w}(0)$ using equation (28)
   b. Set m=0
2. Iteration Phase
   a. Estimate the reduced gradient $\mathbf{r}(m)$ using equation (32) and (33)
   b. Update the increment of the independent variables at the (m+1) iteration using (31)
   c. Estimate the increment of the dependent variables at the (m+1) iteration using (30)
   d. If the error

$$\left\| \Delta\mathbf{w}(m+1) - \Delta\mathbf{w}(m) \right\|_2 < T \ ,$$

where T a threshold then stop the iteration else Set m=m+1 and reinitiate the Iteration Phase.

Following the above analysis, it is clear that the proposed functions and the reduced gradient method allows the update on the weights of the ANN's equation (Equation (3)) in order to enable the integration of the relevance feedback (Equation (9)) as provided by the user.

EVALUATION

In this section, we briefly discuss some experimental results to evaluate the efficiency of the proposed generalized non-linear relevance feedback scheme for content-based retrieval from a database that contains medical data.

The aforementioned database was deployed in the National Technical University of Athens, enhanced by medical information obtained from the university's library. This information refers to scientific content: research papers, journals and case studies; the archives are used for conducting the presented experiments. The overall data set consists of around 15,000 data covering a wide variety of medical content. We also used a "parsing" service that searches in the database's content and annotates it in order to produce specific categories of the content (we concluded to 80 categories). As described previously in this book chapter, several data descriptors are extracted and organized - to which the proposed relevance feedback approach is applied. Each data descriptor includes segments properties that are used to describe this segment. These properties are the type of article, the keywords, the publication area, the authors and the publication date. To these segments we applied specific queries - as described in detail in the following paragraphs - to improve the performance of any retrieval system.

Objective Evaluation Criteria for the Retrieval Performance

Usually, the quantitative evaluation of a content-based retrieval system is performed through the *Precision-Recall Curve* measure.

Precision for a query *q [Pr(q)]* is defined as the ratio of the number of retrieved relevant images, say *N(q)* over the number of total retrieved articles, say *M* [36]. On the other hand, recall of a query *q [Re(q)]* is the ratio of the number of retrieved relevant articles *N(q)* over the total number of relevant articles in the database for the respective query, *G*(*q*) [36].

$$\Pr(q) = \frac{N(q)}{M}, \ \operatorname{Re}(q) = \frac{N(q)}{G(q)} \qquad (34)$$

In a real content-based retrieval system, as the number *M* of articles returned to the user increases, precision decreases, while recall increases. Because of this, instead of using a single value of Pr(*q*) or Re(*q*), the curve Precision-Recall is adopted.

In equation (34), precision and recall have been estimated for a given query *q*. However, to evaluate the performance of a content-retrieval system, many queries should be applied and the average value of precision/recall should be estimated. Assuming that *Q* queries are submitted, the average precision/recall, APr, ARe are defined as

$$\text{APr} = \frac{1}{Q}\sum_{q=1}^{Q}\Pr(q) \ \ \text{ARe} = \frac{1}{Q}\sum_{q=1}^{Q}\operatorname{Re}(q) \, (35)$$

The following figure (Figure 3) presents the average precision-recall curve as obtained by submitted around 3,000 randomly selected queries to the database at the fifth feedback iteration. As is expected, the best precision for every recall value is achieved using the proposed generalized non-linear relevance feedback scheme. This is due to the fact that in this case the type of the similarity measure is recursively updated to fit the current users' information needs. The second best precision performance is noticed for the correlation-based relevance feedback algorithm of Method 1 (N. Doulamis, 2001). This is mainly due to the fact that, in this case, the similarity measure is based on the correlation metric, which provides a better physical representation of the similarity content. In this figure, we have also depicted the performance of the algorithm of (Xiang Sean Zhou, 2001) - Method 2, which presents a slight worse performance compared to the correlation-based approach. It should be mentioned that for all the compared relevance feedback algorithms, the same feature vector representation was used. As a result, the highest retrieval performance obtained by the proposed non-linear relevance feedback scheme is due to the fact that the adopted similarity measure better models the user's information needs and preferences. This means that the proposed scheme estimates the non-linear relationship of the feature vectors used to describe the medical content characteristics and the actual user's information needs in perceiving the content. For this reason, better retrieval results are derived with respect to traditional approaches, where a similarity measure of constant type is used.

The precision values with respect to feedback iterations for recall 10% and 30% are shown in Figure 4 respectively for the aforementioned algorithms. The results have been evaluated on the entire database by submitting around 3,000 randomly selected queries.

In all cases, the precision increases with respect to feedback iterations, with a decreasing, however, improvement ratio, meaning that beyond a certain limit only a slight precision increase is accomplished. It can be seen that the proposed scheme outperforms the compared ones for each one of the feedback iterations.

THE SYSTEM FUTURE TRENDS

Notwithstanding, it is within our future plans to attempt to implement the NN along with the relevance feedback mechanism so as to allow the provision of the functionality that is described in this chapter as a service. As a result, this service could be used as a "filter" service to any information retrieval service providing the most relevant results to the users based on prior searches. The latter is considered of major importance since many approaches have been presented as ways to handle the information retrieval problem in biomedicine. For example, authors of (Min Hong, 2005) present a complete approach for biomedical information retrieval including classification of technical documents, continuous learning on user's interests and requests and provision of an interactive interface to navigate vast information spaces. Moreover, in (Hagit Shatkay, 2005) information retrieval problems focused in the biomedical field are discussed while literature (Y. Kagolovsky, 1998) describes information extraction from medical text resources. The outcome of these approaches can be optimized by a service that comprises both the method for the relevance feedback and the NN modeling described in this chapter.

CONCLUSION

Information retrieval in biomedicine is an important issue but due, however, to the subjective perception of humans as far as the content is concerned, adaptive management algorithms are required to update the system response to actual users' information needs and preferences. Adaptation of content management is achieved through on-line learning strategies, which modify the similarity measure used for ranking visual data.

Providing optimization capabilities to systems that deal with content retrieval - independently both from the content and from the retrieval technique, is a topic of interest in many research areas. To this direction we proposed an architecture that includes an artificial neural network and a relevance feedback scheme. The outcome of the relevance feedback scheme is encompassed into the neural network in order to allow its adaptability to the changes proposed by the user. In order to achieve the latter, the weights on the NN equation need to change in a way to reflect the user's feedback.

One method for on-line learning is *relevance feedback*, an adaptive mechanism, which modifies the response of a system according to the *feedback* about the *relevance* of selected samples so that the system response is adjusted to the current user's information needs. Although relevance feedback is not restricted to description environments where similarity measures are used, in databases where similarity-based queries are applied, relevance feedback refers to the mechanism which updates the similarity measure with respect to the relevant/irrelevant information, as indicated by the user. In this chapter, we address the problem of relevance feedback in the most generic form by updating the type of similarity measure itself, instead of adjusting the degree of importance of the descriptors to the similarity measure. Therefore, *a generalized non-linear* relevance feedback scheme is discussed.

In particular, functional analysis is used to model the non-linear similarity measure, by expressing it as a parametric relation of known monotone increasing functional components. Then, a recursive model parameter updating algorithm is adopted, which adapts the similarity measure type to the current users' information needs and preferences, as expressed by a set of selected relevant/irrelevant data. The adaptation is performed so that a) the current selected data are satisfied as much as possible and b) a minimal modification of the already estimated similarity measure (i.e., existing knowledge) is accomplished. Assuming that a small perturbation of the model parameters is adequate to satisfy the aforementioned conditions, the algorithm results in a constraint minimization problem for estimating the contribution of each functional component to the similarity measure.

The experimental results indicate that the presented *generalized recursive non-linear* relevance feedback scheme yields promising results and the proposed method provides better retrieval ranking due to the fact that no restrictions on the similarity type are imposed, as happens with the previous approaches and therefore better adaptation to the current users' information needs is accomplished. Another advantage of the proposed algorithm is the fact that it can be recursively implemented in case of multiple feedback iterations, in contrast to most of the previous approaches. This results in a computationally efficient algorithm, which further increases the effectiveness of the proposed method. In addition, the algorithm is robust regardless of the number of selected relevant/irrelevant samples, i.e., small selected samples are enough to accurately update the type of similarity measure, in contrast to some of the previously proposed techniques.

Chapter 7.12

Queuing Theory and Discrete Events Simulation for Health Care:

From Basic Processes to Complex Systems with Interdependencies

Alexander Kolker
Children's Hospital and Health Systems, Milwaukee, WI, USA

ABSTRACT

This chapter describes applications of the discrete events simulation (DES) and queuing analytic (QA) theory as a means of analyzing healthcare systems. There are two objectives of this chapter: (i) to illustrate the use and shortcomings of QA compared to DES by applying both of them to analyze the same problems, and (ii) to demonstrate the principles and power of DES methodology for analyzing both simple and rather complex healthcare systems with interdependencies. This chapter covers: (i) comparative analysis of QA and DES methodologies by applying them to the same processes, (ii) effect of patient arrival and service time variability on patient waiting time and throughput, (iii) comparative analysis of the efficiency of dedicated (specialized) and combined resources, (iv) a DES model that demonstrates the interdependency of subsystems and its effect on the entire system throughput, and (v) the issues and perspectives of practical implementation of DES results in health care setting.

INTRODUCTION: SYSTEM-ENGINEERING METHODS FOR HEALTHCARE DELIVERY

Modern healthcare achieved great progress in developing and manufacturing of medical devices, instruments, equipment and drugs to serve individual patients. This was achieved mainly by focusing public and private resources on research in the life sciences, as well as on design and development of medical clinical and imaging devices.

At the same time, relatively little technical talent and material resources have been devoted to improving operations, quality and productivity of the overall health care as an integrated delivery system. According to the joint report of the National Academy of Engineering and Institute of Medicine (Reid et al, 2005), the cost of this collective inattention and the failure to take advantage of the methods that has provided quality and productivity breakthroughs in many other sectors of economy are enormous.

In this report system-engineering methods have been identified that have transformed the quality, safety and productivity performance of many other large-scale complex industries (e.g. telecommunications, transportation, manufacturing). (Reid et al, 2005). These system-engineering methods could also be used to improve efficiency of health care delivery as a patient-centered integrated system.

Ryan (2005) summarized system-engineering principles for healthcare. A system is defined as a set of interacting, interrelated elements (subsystems) - objects and/or people- that form a complex whole that behaves in ways that these elements acting alone would not. Models of a system enable one to study the impact of alternative ways of running the system, i.e. alternative designs, different configurations and management approaches. This means that system models enable one to experiment with systems in ways that cannot be used with real systems.

The models usually include a graphic representation of the system, which is a diagram showing the flow of items and resources. A mathematical description of the model includes objective functions, interrelationship and constraints. The components of the mathematical model can be grouped into four categories: (i) decision variables that represent possible options; (ii) variables, parameters and constants, which are inputs into the model, (iii) the objective functions, which are the output of the model, and (iv) constraints and logic rules that govern operation of the system.

Large systems are usually deconstructed into smaller subsystems using natural breaks in the system. The subsystems are modeled and analyzed separately, but they should be reconnected back in a way that recaptures the most important interdependency between them. Lefcowitz (2007) summarized, for example, that '…maximization of the output of the various subsystems should not be confused with maximizing the final output of the overall system'. Similarly, Goldratt (2004, p. 211) states that 'a system of local optimums is not an optimum system at all; it is a very inefficient system'.

Analysis of a complex system is usually incomplete and can be misleading without taking into account subsystems' interdependency (see section 3.3). Analysis of a mathematical model using analytic or computer algorithmic techniques reveals important hidden and critical relationships in the system that allows leveraging them to find out how to influence the system's behavior into desired direction.

The elements included in the system model and required information depends on the problem to be solved. For the output of the model to be useful, the model must mimic the behavior of the real system.

According to the already mentioned report by The National Academy of Engineering and Institute of Medicine (Reid et al, 2005), the most powerful system-analysis methods are Queuing Theory and Discrete Event Simulation (DES).

Both methods are based on principles of operations research. Operations research is the discipline of applying mathematical models of complex systems with random variability aimed at developing justified operational business decisions. It is widely used to quantitatively analyze characteristics of processes with random demand for services, random service time and available capacity to provide those services. Operations research methodology is the foundation of the modern management science.

Health care management science is applied to the various aspects of patient flow, capacity planning, allocation of material assets and human resources to improve the efficiency of healthcare delivery.

For the last 40 years, hundreds of articles have been published that demonstrate the power and benefits of using management science in healthcare. Several reviews have appeared that specifically examine DES applications in healthcare, such as Jun et al (1999), Carter (2002) and the recent review by Jacobson et al. (2006) that provides new updates that have been reported since 1999.

In contrast to these reviews that mainly listed DES publications without much discussion on how and why the models actually work and deliver, the objective of this chapter is to present a detailed description of the 'inner workings' of DES models for some healthcare processes starting from basic applications and proceeding to rather advanced models.

It is also a goal to demonstrate the fundamental advantage of DES methodology over queuing analytic (QA) models. This is demonstrated by comparative analysis of both DES and QA applied to the same problems.

The focus of this chapter is DES of the various aspects of random and non-random patient flow variability and its effect on process performance metrics. Using concrete examples and scenarios, it was demonstrated how simple DES models help to gain understanding of the basic principles that govern patient flow with random and non-random variability. It is further demonstrated how more advanced DES models have been used to study system behavior (output) changes with the change of the input data and/or process parameters.

QUEUING ANALYTIC (QA) MODELS AND DISCRETE EVENT SIMULATION (DES)

Queuing Analytic Models: Their Use and Limitations

The term 'queuing theory' is usually used to define a set of analytic techniques in the form of closed mathematical formulas to describe properties of the processes with a random demand and supply (waiting lines or queues). Queuing formulas are usually applied to a number of pre-determined simplified models of the real processes for which analytic formulas can be developed.

Weber (2006) writes that '…There are probably 40 (queuing) models based on different queue management goals and service conditions…' and that it is easy '… to apply the wrong model' if one does not have a strong background in operations research.

Development of tractable analytic formulas is possible only if a flow of events in the system is a steady-state Poisson processes. On definition, this is an ordinary stochastic process of independent events with the constant parameter equal to the average arrival rate of the corresponding flow. Time intervals between events in a Poisson flow are always exponentially distributed with the average inter-arrival time that is the inverse Poisson arrival rate. Service time is assumed to follow an exponential distribution or, rather rarely, uniform or Erlang distribution. Thus, processes with a Poisson arrival of events and exponential service time are Markov stochastic processes with discrete states and continuous time.

Most widely used queuing models for which relatively simple closed analytical formulas have been developed are specified as *M/M/s* type (Hall, 1990; Lawrence and Pasternak, 1998; Winston and Albright, 2000). (*M* stands for Markov since Poisson process is a particular case of a stochastic process with no 'after-effect' or no memory, known as continuous time Markov process). These models assume an unlimited queue size that is served by *s* providers.

Typically *M/M/s* queuing models allow calculating the following steady-state characteristics:

- probability that there are zero customers in the system probability that there are *K* customers in the system
- the average number of customers waiting in the queue
- the average time the customers wait in the queue
- the average total time the customer spends in the system ('cycle time')
- utilization rate of servers, i.e. percentage of time the server is busy

As more complexity is added in the system, the analytic formulas become less and less tractable. Analytic formulas are available that include, for example, limited queue size, customers leaving the system after waiting a specified amount of time, multiple queues with different average service time and different providers' types, different service priorities, etc (Lawrence and Pasternak, 1998; Hall, 1990).

However the use of these cumbersome formulas even built in Excel spreadsheets functions (Ingolfsson et al, 2003) or tables (Hillier, Yu, 1981; Seelen et al, 1985) is rather limited because they cannot capture complexity of most healthcare systems of practical interest.

Assumptions that allow deriving most queuing formulas are not always valid for many healthcare processes. For example, several patients sometimes arrive in Emergency Department at the same time (several people injured in the same auto accident), and/or the probability of new patient arrivals could depend on the previous arrivals when ED is close to its capacity, or the average arrival rate varies during a day, etc. These possibilities alone make the arrival process a non-ordinary, non-stationary with after-effect, i.e. a non-Poisson process for which queuing formulas are not valid. Therefore, it is important to properly apply statistical goodness-of-fit tests to verify that the null-hypothesis that actual arrival data follow a Poisson distribution cannot be rejected at some level of significance.

An example of a conclusion from the goodness-of-fit statistical test that is not convincing enough can be found, for instance, in Harrison et al (2005). The authors tried to justify the use of a Poisson process by using a chi-square goodness-of-fit test. The authors obtained the test p-values in the range from 0.136 to 0.802 for different days of the week. Because p-values were greater than 0.05 level of significance, they failed to reject the null-hypothesis of Poisson distribution (accepted the null-hypothesis).

On the other hand, the fundamental property of a Poisson distribution is that its mean value is equal to its variance (squared standard deviation). However, the authors' own data indicated that the mean value was not even close to the variance for at least four days of the week. Thus, the use of a Poisson distribution was not actually convincingly justified for the patient arrivals. Apparently, chi-square test p-values were not large enough to accept the null-hypothesis with high enough confidence (alternatively, the power of the statistical test was likely too low).

Despite its rather limited applicability to many actual patient arrival patterns, a Poisson process is widely used in operation research as a standard theoretical assumption because of its mathematical convenience (Gallivan, 2002; Green, 2006; Green et al, 1991; McManus et al, 2003).

The use of QA theory is often recommended to solve many pressing hospital problems of patient flow and variability, calculating needed nursing resources, the number of beds and operating rooms (IHI, 2008; Litvak, 2007; McManus et al, 2004; Haraden et al, 2003). However, such a recommendation ignores some serious practical limitations of QA theory for hospital applications.

D'Alesandro (2008) summarized why QA theory is often misplaced in hospitals.

Some authors are trying to make queuing formulas applicable to real processes by fitting and calibration. For example, in order to use queuing formulas for a rather complex ED system, Mayhew and Smith (2008) made a significant process simplification by presenting the workflow as a series of stages. The stages could include initial triage, diagnostic tests, treatment, and discharge. Some patients experienced only one stage while others more than one. However, '… what constitutes a 'stage' is not always clear and can vary…and where one begins and ends may be blurred' (Mayhew and Smith, 2008). The authors assumed a Poisson arrival and exponential service time but then used actual distribution service time for 'calibration' purposes. Moreover, the authors observed that exponential service time for the various stages '…could not be adequately represented by the assumption that the service time distribution parameter was the same for each stage'. In the end, all the required calibrations, adjustments, fitting to the actual data made the model to lose its main advantage as a queuing model: its analytical simplicity and transparency. On the other hand, all queuing formulas assumptions and approximations still remained.

Therefore many complex healthcare systems with interactions and interdependencies of the subsystems cannot be effectively analyzed using analytically derived closed formulas.

Moreover, queuing formulas cannot be directly applied if the arrival flow contains a non-random component, such as scheduled arrivals (see sections 2.2.5, 2.3 and 3.2). Therefore, in order to use analytic queuing formulas, the non-random arrival component should be first eliminated, leaving only random arrival flow for which QA formulas could be used (Litvak, 2007).

Green (2004) applied *M/M/s* model to predict delays in the cardiac and thoracic surgery unit with mostly elective scheduled surgical patients assuming a Poisson pattern of their arrivals. The author acknowledged that this assumption could result in an overestimate of delays. In order to justify the use of *M/M/s* model the author argued that some '…other factors are likely to more than compensate for this'. However, it was not clear what those factors are and how much they could compensate the overestimated delays.

Still, despite their limitations, QA models have some place in operation research for application to simply structured steady-state processes if a Poisson arrival and exponential service time assumptions are accurate enough.

A number of specific examples that illustrate the use of simple QA models and their limitations are presented in the next sections.

Flu Clinic: Unlimited Queue Size with Steady State Operation

A small busy clinic provides flu shots during a flu season on a walk-in basis (no appointment necessary). The clinic has two nurses (servers). Average patient arrival rate is 54 patients per hour with about the same number of elderly and all others. Each shot takes on average about 2 min.

Usually there are quite a few people in the queue waiting for the shot. In order to reduce waiting time and the number of people in the queue, the staff conducted a brainstorming session. It was proposed to have one nurse to perform flu shots only for most vulnerable elderly patients, and another nurse to perform shots for all others. The staff began developing a pilot project plan to test this new operation mode on the clinic floor.

However, the clinic's manager decided first to test this idea using principles of management science and operations research. The manager assumed that analytical queuing formulas would be applicable in this case.

For the current operation mode, the following *M/M/s* analytical model with the unlimited queue size can be used:

Random patient arrivals are assumed to be a Poisson process with the total average arrival rate

λ=54 pts/hr, average flu shot time τ=2 min and the number of servers N=2.

The final (steady-state) probability that there are no patients in the system, p_0, is calculated using the formula (Hall, 1990; Green, 2006)

$$p_0 = [\sum_{n=0}^{N-1} \frac{a^n}{n!} + \frac{a^N}{N!(1-\rho)}]^{-1} \qquad (2.1)$$

where

$$\rho = a / N \;\; \rho = a / N$$

The average number of patients in the queue, L_q, is

$$L_q = a^{N+1} * p_0 / [N * N! * (1-\rho)^2] \qquad (2.2)$$

and the average time in the queue, t, is (the Little's formula)

$$t = L_q / \lambda \qquad (2.3)$$

Substituting in the formulas (2.1) to (2.3) N=2, λ=54 pts/hr, and τ=2 min=0.033 hrs, we get average L_q =7.66 patients, and the average waiting time, t, about 8.5 min. The clinic's average utilization is 90%.

In practice, an excel spreadsheet is usually used to perform calculations using queuing formulas.

The new proposed system that is supposed to perform better will consist of two dedicated patient groups that would form two separate queues, one for elderly patients and another for all others (two separate subsystems with N=1). Arrival rate for each patient group is going to be λ=54 /2=27 pts/hr.

Parameter

$$\rho = a = \lambda * \tau = 27\, pts / hr * 0.0333\; hr = 0.9\,.$$

Using formulas (2.1) to (2.3), we get the average number of patients in each queue Lq =8.1. Thus, the total queue for all patients will be 2*8.1=16.2 patients.

The average waiting time in the queue will be about 8.1/27=0.3 hours= 18 min.Thus, in the proposed 'improved' process the average waiting time and the number of patients in the queue will be about twice of those in the original process.

It should be concluded that the proposed improvement change that might look reasonable on the surface does not stand the scrutiny of the quantitative analysis.

The idea of separating one random patient flow with two servers on two separate random flows, each with one dedicated server, does not result in improvement because two separate servers cannot help each other if one of them becomes overworked for some time due to a surge in patient volume because of random variability of the patient flow.

This is an illustration of the general principle that the combined random work flow with unlimited queue size and no leaving patients is more efficient than separate work flows with the same total work load (see also section 2.3).

An example of using discrete events simulation (DES) to analyze the same process without resorting to analytical formulas will be given in section 2.

Flu Clinic: Unlimited Queue Size with Non-Steady-State Operation

The manager of the same clinic decided to verify that the clinic would operate smoothly enough with a new team of two less experienced nurses who would work only a little slower than the previous one. The average time to make a shot will be about 2.5 min (instead of average 2 min for more experienced staff, as in section 2.1.1). The manager reasoned that because this difference is relatively small it would not practically affect the clinic operation: the number of patients in the queue and their waiting time on the typical working day could be only a little higher than in the previous case or practically not different at all.

The manager plugged the average service time 2.5 min and the same arrival rate 54 pts/hr in the *M/M/s* queuing calculator. However the calculator returned no number at all, which means that no solution could be calculated. Why is that?

An examination of Equation (2.1) shows that if ρ becomes greater than 1 the last term in the sum becomes negative and the calculated p_0 also becomes negative, which does not make sense. (If ρ is equal to 1, the term becomes uncertain and the calculations cannot be carried out at all). The average service time in this example is only slightly higher than it was in the previous case. However, this small difference made parameter ρ greater than 1 ($\rho=1.125>1$). This explains why the calculations cannot be done using this value.

Queuing analytical formulas with unlimited queue size are applicable only for steady-state processes, i.e. for the established processes whose characteristics do not depend on time. The steady-state condition is possible only if $\rho < 1$, otherwise the above formulas are not applicable and the queue grows indefinitely.

In section 2.2.2 it will be demonstrated how DES methodology easily handles this situation and demonstrates growth of the queue.

Flu Clinic: Time-Varying Arrival Rates

In the previous section 2.1.2 parameters of the queuing system (average arrival rate 54 patients per hour and average shot time 2.5 min) made a patient flow a non-steady-state one for which QA model with unlimited queue size could not be used.

However, the clinic's manager realized that the average patient arrival rate varies significantly during a day, and that 54 patients per hour was actually a peak arrival rate, from noon to 3 pm. In the morning hours from 8 am to 10 am the arrival rate was lower, 30 patients / hour. From 10 am to noon it was 40 patients / hour, and in the afternoon from 3 pm to 6 pm it was about 45 patients / hour.

Thus, the manager calculated the average arrival rate for these time periods for the day. It turned out to be (30+40+54+45)/4=42.25 patients/hour. He/she plugged this number in the queuing calculator (along with the average time to make a shot 2.5 min), and obtained the average number of patients in queue L_q =6.1 patients, and the average waiting time about 8.6 min. Because the calculator produced some numbers the manager made a conclusion that this clinic process will be in a steady-state condition and that the waiting time and the number of patients in the queue is acceptable.

But is it a correct conclusion ? Recall that QA models assume that a Poisson arrival rate is constant during a steady-state time period (Hall, 1990; Lawrence et al, 2002; Green, 2006). If it is not constant, such as in this case, QA results could be very misleading. The wait time will be significantly greater in the mid-day period (and/or the steady-state condition will be violated). At the beginning and at the end of the day, though, the wait time will be much smaller. Because the arrival rate is included non-linearly in the exponential term of a Poisson distribution formula, the arrival rate cannot be averaged first and then substituted in the exponential term. (For non-linear functions, the average value of a function is not equal to the function of average values of its arguments).

As Green (2006) stated '…this illustrates a situation in which a steady-state queuing model is inappropriate for estimating the magnitude and timing of delays, and for which a simulation model will be far more accurate'.

It is tempting, as a last resort, to save the use of QA model by dividing the day into time periods in which arrival rate is approximately constant. Then a series of *M/M/s* models is constructed, one for each period. This approach is called SIPP (stationary independent period-by-period) (Green, 2006; Green et al, 1991).

If we apply this approach, the following results can be obtained:

- Time period 8 am to 10 am: L_q =0.8 patients in the queue, waiting time 1.6 min
- Time period 10 am to noon: L_q =3.8 patients in the queue, waiting time 5.7 min
- Time period noon to 3 pm: *no steady-state solution*
- Time period 3 pm to 6 pm: L_q =13.6 patients in the queue, waiting time 18.1 min

Notice how these results differ from those based on the averaging of the arrival rate for the entire day.

However this SIPP patch applied to QA models was found to be unreliable (Green, 2006; Green et al, 2001). This is because in many systems with time-varying arrival rates, the time of peak congestion significantly lags the time of the peak in the arrival rate (Green et al, 1991). These authors developed a modification called *Lag-SIPP* that incorporates an estimation of this lag. This approach has been shown to often be more effective than a simple SIPP (Green, 2006).

Even it is so, this does not make QA models application easier if there are many time periods with different constant arrival rates because many different *M/M/s* models need to be constructed accordingly to describe one process.

It will be demonstrated in section 2.2.4 how DES model easily and elegantly handles this situation with time-varying arrival rate.

ICU Waiting Time

This problem is presented by (Litvak 2007; Weber, 2006) to demonstrate how QA can be used to compare patient average waiting time to get into ICU if it has 5 beds and 10 beds and patient average arrival rate is 1 per day and 2 per day, accordingly. The average length of stay in ICU is 2.5 days. It is assumed that the length of stay in the ICU is exponentially distributed and, of course, that patient arrival is a Poisson process.

In order to apply QA formulas an additional assumption should be used that length of stay follows exponential distribution with the above average value.

Using *M/M/s* model it is easy to calculate that the average waiting time for 10 beds ICU is 0.43 hours, and that for 5 beds ICU is 3.1 hours. Average ICU utilization is 50%.

Thus, the waiting time for the larger unit is about 7 times shorter. Notice, however, that this result is valid only for exponential service and inter-arrival time. If other distributions with the same average are used we should get a different result.

For example, length of stay could be in the range from 2 to 3 days with the average 2.5 days, and be described by a triangle distribution. Or the length of stay could follow a long-tailed lognormal distribution, also with the same average of 2.5 days and standard deviation of, say, 2 days (these values would correspond to log-normal parameters 3.85 and 0.703).

Thus, QA does not distinguish between different distributions with the same averages. This is a serious limitation of QA.

It will be demonstrated in section 2.2.7 how easy it is to use DES for different length of stay distributions with the same average.

DES Models: Basic Applications

In contrast to queuing formulas, DES models are much more flexible and versatile. They are free from assumptions of the particular type of the arrival process (Poisson or not), as well as the service time (exponential or not). They can be used for the combined random and non-random arrival flow. The system structure (flow map) can be complex enough to reflect a real system structure, and custom action logic can be built in to capture the real system behavior.

Table 1.

Inter-arrival time, min	Service time, min
2.6	1.4
2.2	8.8
1.4	9.1
2.4	1.8

At the same time it should be noted that building a complex realistic simulation model sometimes requires a significant amount of time for custom logic development, debugging, model validation, and input data collection.

However, a good model is well worth the efforts because it becomes a powerful and practically the only real tool for quantitative analysis of complex hospital operations and decision-making.

Many currently available simulation software packages (ProcessModel, ProModel, Arena, Simula8, and many others) provide a user-friendly interface that makes the efforts of building a realistic simulation model not more demanding than the efforts to make simplifications, adjustments and calibrations to develop a rather complex but inaccurate queuing model.

Swain (2007), Abu-Taeh et al (2007), Hlupic (2000), Nikoukaran (1999) provided a review and a comparative study of dozens commercially available simulation packages.

A DES model is a computer model that mimics the dynamic behavior of a real process as it evolves with time in order to visualize and quantitatively analyze its performance. The validated and verified model is then used to study behavior of the original process and then identify the ways for its improvement (scenarios) based on some improvement criteria. This strategy is significantly different from the hypothesis-based clinical testing widely used in medical research (Kopach-Konrad et al, 2007).

DES models track entities moving through the system at distinct points of time (events). The detailed track is recorded of all processing times and waiting times. Then the system's statistics for entities and activities is gathered.

To illustrate how a DES model works step by step, let's consider a very simple system that consists of a single patient arrival line and a single server. Suppose that patient inter-arrival time is uniformly (equally likely) distributed between 1 min and 3 min. Service time is exponentially distributed with the average 2.5 min. (Of course, any statistical distributions or non-random patterns can be used instead). A few random numbers

Table 2.

Event #	Time	Event that happened in the system
1	2.6	1st customer arrives. Service starts that should end at time= 4
2	4	Service ends. Server waits for patient
3	4.8	2nd patient arrives. Service starts that should end at time =13.6. Server is idle 0.8 min
4	6.2	3rd patient arrives. Joins the queue waiting for service
5	8.6	4th patient arrives. Joins the queue waiting for service
6	13.6	2nd patient (from event 3) service ends. 3rd patient at the head of queue (first in-first out) starts service that should end at time 22.7
7	22.7	Patient #4 starts service and so on.

sampled from these two distributions are shown in Table 1.

Let's start our example simulation at time zero, t=0, with no patients in the system. We will be tracking any change or event that happened in the system.

A summary of what is happening in the system looks like Table 2.

These simple but tedious logical and numerical event-tracking operations (algorithm) are suitable, of course, only for a computer. However, they illustrate the basic principles of any discrete events simulation model, in which discrete events (changes) in the system are tracked when they occur over the time. In this particular example, we were tracking events at discrete points in time t=2.6, 4.0, 4.8, 6.2, 8.6, 13.6, 22.7.

Once the simulation is completed for any length of time, another set of random numbers from the same distributions is generated, and the procedure (called replication) is repeated. Usually multiple replications are needed to properly capture the system's variability. In the end, the system's output statistics is calculated, e.g. the average patient and server waiting time, its standard deviation, the average number of patients in the queue, the confidence intervals and so on.

In this example, only two patients out of four waited in the queue. Patient 3 waited 13.6-6.2=7.4 min and patient 4 waited 22.7-8.6=14.1 min, so the simple average waiting time for all four patients is (0+0+7.4+14.1)/4=5.4 min. Notice, however, that the first two patients did not wait at all while patient 4 waited 2.6 times longer than the average. This illustrates that the simple average could be rather misleading as a performance metric for highly variable processes without some additional information about the spread of data around the average (a so-called flaw of averages, see also concluding remarks for section 3.1).

Similarly, the simple arithmetic average of the number of waiting patients (average queue length) is 0.5. However a more informative metric of the queue length is the time-weighted average that takes into account the length of time each patient was in the queue. In this case it is (1*7.4+1*14.1)/22.7=0.95. Usually the time-weighted average is a better system's performance metric than the simple average.

DES models are capable of tracking hundreds of individual entities, each with its own unique set of attributes, enabling one to simulate the most complex systems with interacting events and component interdependencies.

Typical DES applications include: staff and production scheduling, capacity planning, cycle time and cost reduction, throughput capability, resources and activities utilization, bottleneck finding and analysis. DES is the most effective tool to perform quantitative 'what-if' analysis and play different scenarios of the process behavior as its parameters change with time. This simulation capability allows one to make experiments on the computer, and to test different options before going to the hospital floor for actual implementation.

The basic elements (building blocks) of a simulation model are:

- Flow chart of the process, i.e. a diagram that depicts logical flow of a process from its inception to its completion
- Entities, i.e. items to be processed, e.g. patients, documents, customers, etc.
- Activities, i.e. tasks performed on entities, e.g. medical procedures, exams, document approval, customer check-in, etc
- Resources, i.e. agents used to perform activities and move entities, e.g. service personnel, equipment, nurses, physicians
- Entity routings that define directions and logical conditions flow for entities

Typical information usually required to populate the model includes:

- Quantity of entities and their arrival time, e.g. periodic, random, scheduled, daily pattern, etc. There is no restriction on the arrival distribution type, such as a Poisson distribution, required by the QA formulas

- The time that the entities spend in the activities, i.e. service time. This is usually not a fixed time but a statistical distribution. There is no restriction to an exponential service time distribution that is typically required by the QA formulas
- Capacity of each activity, i.e. the max number of entities that can be processed concurrently in the activity
- The maximum size of input and output queues for the activities
- Resource assignments: their quantity and scheduled shifts

Analysis of patient flow is an example of the general dynamic supply and demand problem. There are three basic components that should be accounted for in such problems: (i) the number of patients (or any items) entering the system at any point of time, (ii) the number of patients (or any items) leaving the system after spending some time in it, (iii) capacity of the system that defines the number of items that can be processed concurrently. All three components affect the flow of patients (items) that the system can handle (the system's throughput). A lack of the proper balance between these components results in the system's over-flow and gridlock. DES methodology provides invaluable means for analyzing and managing the proper balance.

It will be demonstrated in the following sections that even simple DES models have a significant advantage over QA models. To illustrate this advantage side by side, DES methodology will be applied to the same processes that have been analyzed using QA in previous sections 2.1.1 to 2.1.4

Comparative Analysis of QA and DES Methodologies

Unlimited Queue Size with Steady-State Operation

Let's consider a flu clinic that was analyzed using QA in section 2.1.1.

DES model structure is presented on Figure 1. It simply depicts the arrived patient flow connected to Queue, then coming to the flu clinic (box called Flu_Clinic), and then exit the system. These basic model elements are simply dragged down from the pallet and then connected to each other.

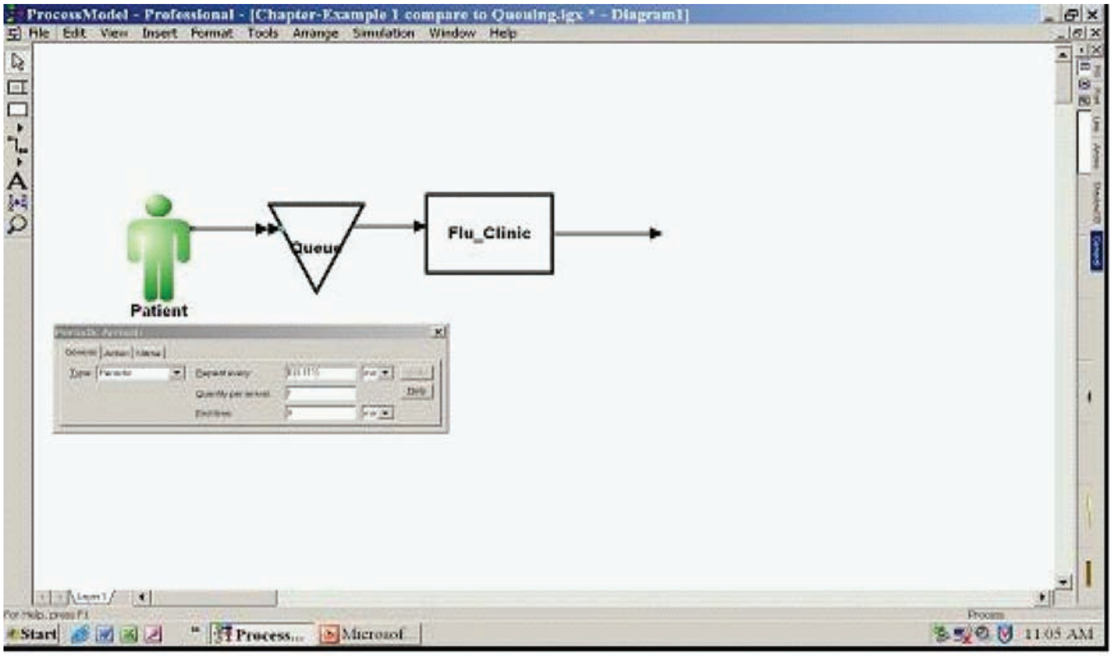
Next step is to fill in the process information: patients arrive periodically, one patient at a random exponentially distributed time interval with the average inter-arrival time 60 min/54=1.111 min, E(1.111), as indicated on the data arrival panel on Figure 1 corresponds to Poisson arrival rate of 54 patients per hour (E stands for exponential distribution). In the Flu_Clinic data panel the capacity input was 2 (two patients served concurrently by two nurses), and the service time was exponentially random with the average value 2 min, E(2). This completes the model set-up.

The model was run 300 replications at which a statistically stable simulation output was reached. Multiple replications capture the variability of patient arrivals and service time. Results are presented on Figure 2.

It is seen that the number of patients in the queue steadily increases until a steady-state operation (plateau) is reached. The average steady-state number of patients in the queue is 7.7 with some small fluctuations around this average (top plot).

The average waiting time is presented on Figure 2 (bottom plot). Similarly, the average steady-state waiting time 8.45 min was reached with some variations around the average. The average steady-state utilization is 89.8%.

Figure 1.Layout of the simulation model of flu clinic. Information on the panel indicates patient arrival type (Periodic) that repeats on average every E(1.111) min (E stands for exponential distribution)



Average number of patients in the queue (top) and average waiting time in the queue (bottom)

Thus, we received practically the same results with DES model as with QA model using about the same efforts. As an additional bonus with DES, though, we could watch how fast a steady-state operation was reached (a so-called warm-up period).

Unlimited Queue Size with Non-Steady State Operation

In section 2.1.2 QA model with the average service time 2.5 min could not produce results because a steady-state operation did not exist.

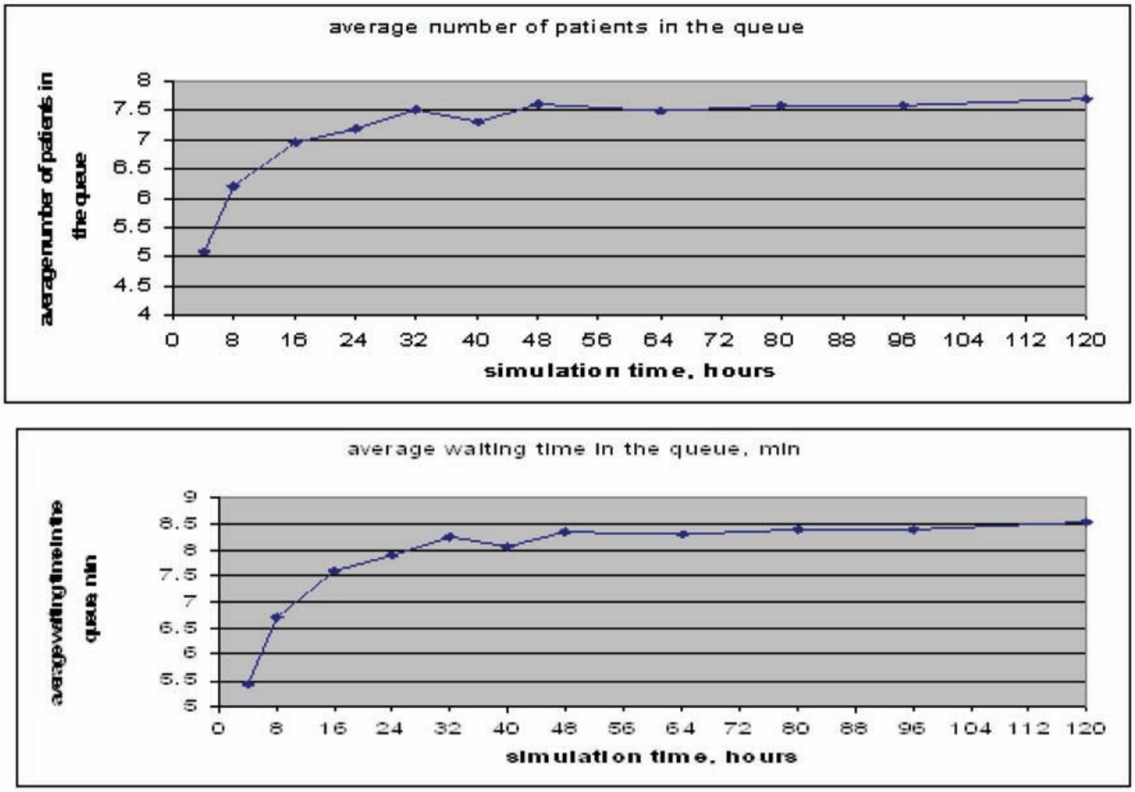
Using the same DES model described in the previous section we simply plug this average service time in the Flu_Clinic data panel making it E(2.5) min, and run the simulation model. Results are given on Figure 3.

Average number of patients in the queue (top) and average waiting time in the queue (bottom).

These plots demonstrate how the patient queue (top plot) and waiting time (bottom plot) grow with clinic operation time. The plots demonstrate no apparent trend to a steady-state regime (plateau). The growth goes on indefinitely with time.

This example also illustrates an important principle of ‘unintended consequences’. An intuition that is not supported by objective quantitative analysis says that a small change in the system input (service time from the average 2 min to 2.5 min) would result in a small change in the output (small increase in the number of waiting patients and their waiting time). For some systems this is indeed true. Systems in which the output is always directly proportional to input are called linear systems. However, there are quite a few systems in which this simple reasoning breaks down: a small change in the value of the system’s input parameter(s) results in a dramatic change (even qualitative change) in the system’s outcome (behavior), e.g. from a steady-state regime to a non-steady-state regime. Such systems are called

Figure 2. Unlimited queue size with steady-state operation



non-linear or complex systems despite the fact that they can consist of only a few elements.

Limited Queue Size with 'Inpatient' Patients Leaving the System

Unlimited queue size is not always a good model of real systems. In many cases patients wait in a waiting lounge that has usually a limited number of chairs (space). QA models designated *M/M/s/K* are available that include a limited queue size, *K* (Green, 2006; Lawrence and Pasternak, 1998; Hall, 1990). However analytic formulas become very cumbersome. If the QA model includes some patients that leave the system after waiting some time in the queue, the analytic formulas become almost intractable.

In contrast, DES models easily handle the limited queue size and patients leaving before the service began ('inpatient' patients).

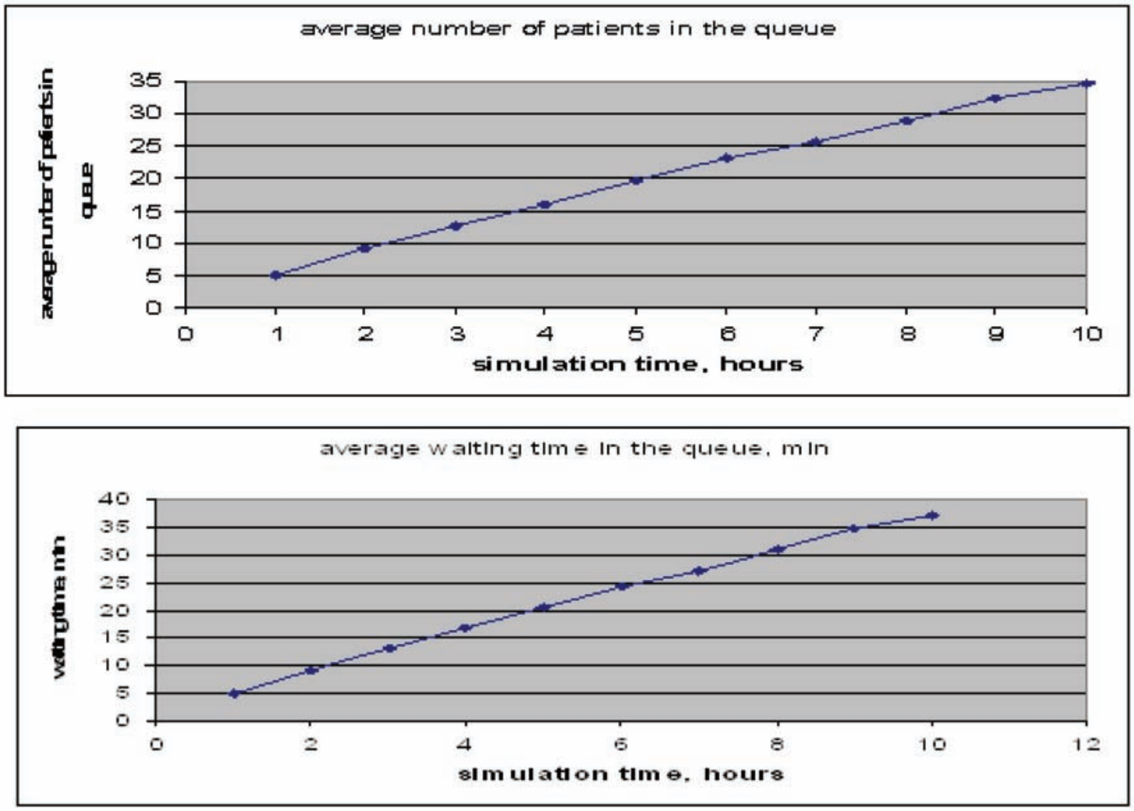
To illustrate, we use the same DES model as in 2.2.1 with only a slight modification to include a new limited queue size and 'inpatient' patients.

Suppose that the queue size limit is 10 (the max number of chairs or beds) and patients leave after waiting 10 min (of course, these could be any numbers including statistical distributions). We put 10 in the field 'Input queue size', and draw a routing 'renege after 10 min'. The new model is now ready to go. Simulation results are presented on Figure 4.

The difference between an unlimited queue size (section 2.2.2) and a limited one with leaving patients is significant.

The plots suggest that limited queue size results in a steady-state solution (plateau). (It could be

Figure 3. Unlimited queue size with non-steady state operation



proved that a steady-state solution always exists if the queue size is limited). The steady-state average number of patients in the queue is about 4.5 (top plot) and the average waiting time is about 5.6 min (bottom plot).

However the model's statistics summary also shows that 10% to 11% of patients are lost because they did not stay in the queue more than 10 min. Thus, this simple DES model gives a lot of valuable information and serves as powerful tool to find out how to better manage the flu-clinic.

Average number of patients in the queue (top) and average waiting time in the queue (bottom).

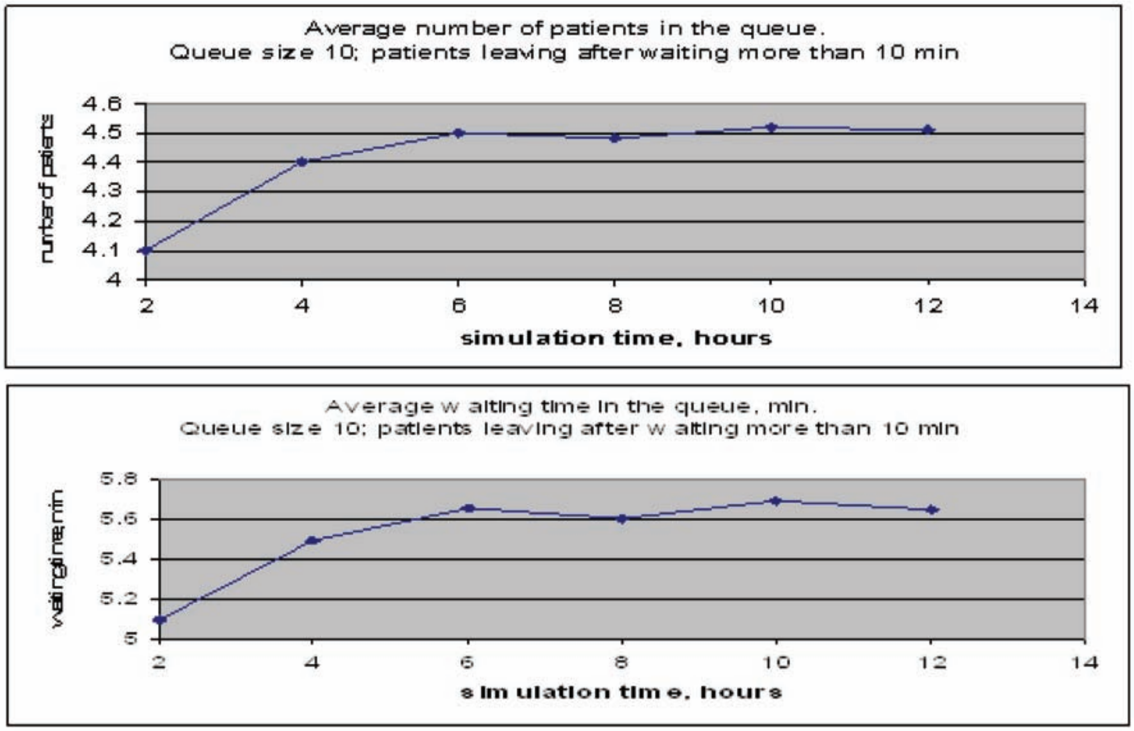
Arrivals with Time-Varying Poisson Arrival Rate

In section 2.1.3 it was discussed why the use of QA model with a Poisson time-varying patient arrival rate is rather unreliable.

Let's see how easy it is to use DES model to address the same problem.

The DES model structure (layout) for time-varying arrival rate is the same as it was used in section 2.2.1. The only difference is a different arrival routing type: instead of periodic arrival with the random inter-arrival time, an input daily-pattern arrival panel should be used. We use one day of the week, and input 60 patients from 8 am to 10 am (30 pts/hour *2); 80 patients from 10 to noon (40 pts/hour*2); 162 patients from noon to 3 pm (54 pts/hour*3); and 135 patients from 3 pm

Figure 4. Limited queue size with 'inpatient' patients leaving the system



to 6 pm (45 pts/hour * 3). The model of the entire day (from 8 am to 6 pm) is ready to go.

The following simulation results are obtained (compare with the approximated QA SIPP model results from section 2.1.3):

Time period 8 am to 10 am: L_q =0.6 patients in the queue, waiting time 0.84 min

Time period 10 am to noon: L_q =2.26 patients in the queue, waiting time 2.75 min

Time period noon to 3 pm: L_q =14.5 patients in the queue, waiting time 15.3 min

Time period 3 pm to 6 pm: L_q =20 patients in the queue, waiting time 25.5 min

It is seen that QA SIPP model over-estimates the queue at the beginning of the day and under-estimates the queue at the end of the day. Of course, only a DES model can provide results for the time period noon to 3 pm.

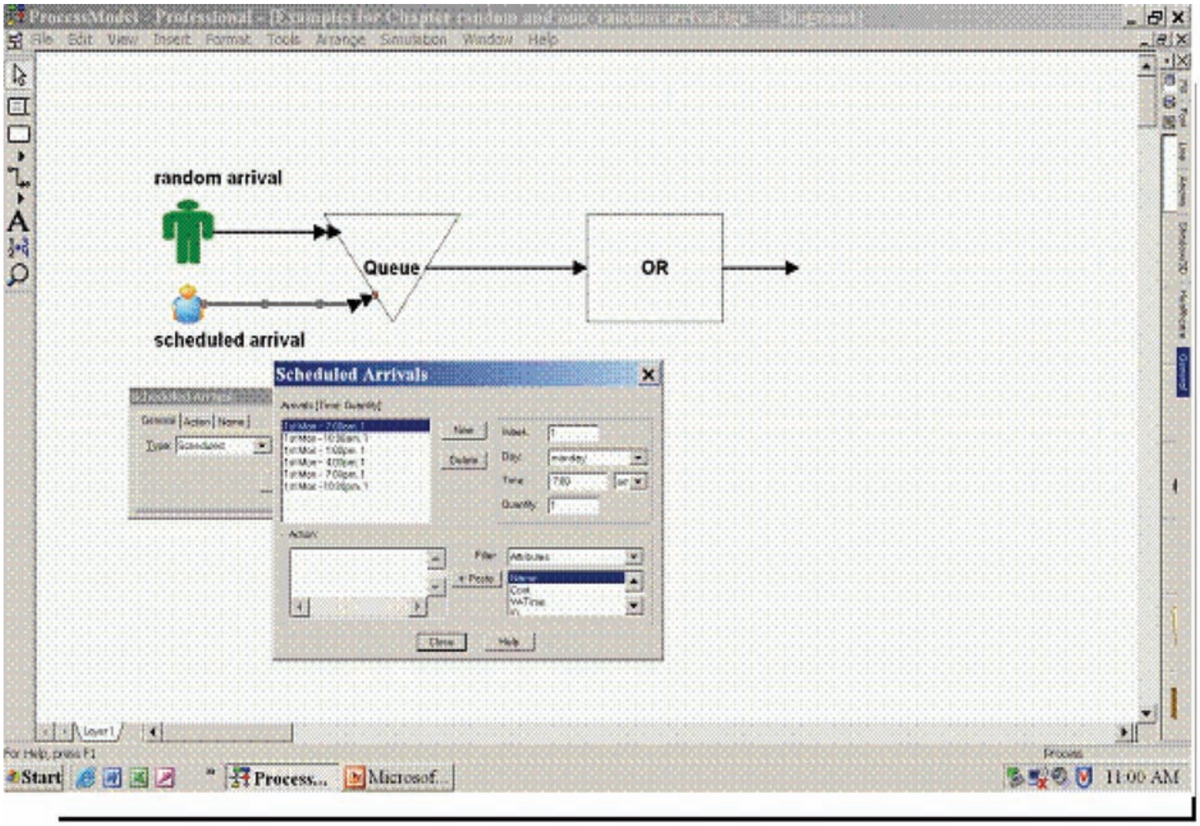
Mixed Patient Arrivals: Random and Scheduled

We frequently deal with mixed patient arrival pattern, i.e. some patients are scheduled to arrive on specific time while some patients arrive unexpectedly. For example, some clinics accept patients who made an appointment, but also accept urgent random walk-in patients. Operating room suites schedule elective surgeries while suddenly a trauma patient arrives and an emergency surgery is required. Such a mixed arrival pattern with a different degree of the variability requires a special treatment.

QA models should not be used if arrival flow contains a non-random component, i.e. it is not a Poisson random. Let's illustrate what happens if this principle is violated.

Suppose that there is one operating room (OR) and there are six scheduled surgeries for a day, at

Figure 5. Mixed patient arrivals: random and scheduled. Two arrival flows, one random, E(4) hours, and one with six patients scheduled at 7 am, 10 am, 1 pm, 4 pm, 7 pm, 10 pm, as indicated on the panel



7 am, 10 am, 1 pm, 4 pm, 7 pm, 10 pm. On this day six random emergency patients also arrived with the average inter-arrival time 4 hours, i.e. E(4) hours. Total number of patients for one day is 12.

If QA model is applied assuming that all 12 patients are random arrivals, then we would get arrival rate 12 pts/24= 0.5 pts per hour. Using the average surgery time 1 hour, E(1) hours, we get the average number of patients in the queue, L_q = 0.5, waiting time in queue, W_q=1 hour, and time in the system, W_s =2 hours.

Now, let's use a simple DES model with two arrival flows, one random, E(4) hours, and another one with scheduled six patients, as indicated on Figure 5.

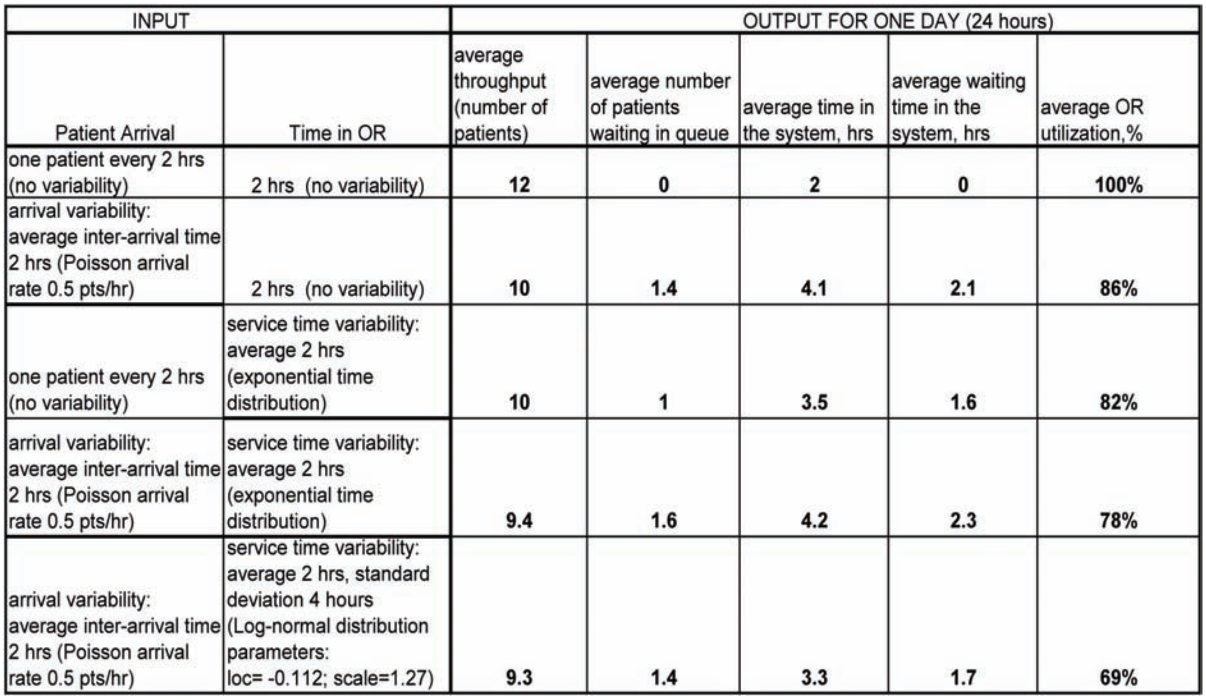
Simulation length was 24 hours. The average number of patients in the queue was L_q = 0.3, waiting time in the queue W_q=0.33 hours, time in the system, W_s =0.55 hours.

Notice how badly QA model over-estimated the time: almost by a factor of 3 for waiting time in the queue, and almost by a factor of 4 for the time in the system !

Thus, QA models cannot account accurately enough for arrival variability that is lower than Poisson variability.

There are some approximate QA formulas that include a coefficient of variation of service time distribution but only for one server (Green, 2006).

Figure 6. Five DES scenarios with consecutively added variability. Simulation performed for 24 hours period



INPUT		OUTPUT FOR ONE DAY (24 hours)				
Patient Arrival	Time in OR	average throughput (number of patients)	average number of patients waiting in queue	average time in the system, hrs	average waiting time in the system, hrs	average OR utilization,%
one patient every 2 hrs (no variability)	2 hrs (no variability)	**12**	**0**	**2**	**0**	**100%**
arrival variability: average inter-arrival time 2 hrs (Poisson arrival rate 0.5 pts/hr)	2 hrs (no variability)	**10**	**1.4**	**4.1**	**2.1**	**86%**
one patient every 2 hrs (no variability)	service time variability: average 2 hrs (exponential time distribution)	**10**	**1**	**3.5**	**1.6**	**82%**
arrival variability: average inter-arrival time 2 hrs (Poisson arrival rate 0.5 pts/hr)	service time variability: average 2 hrs (exponential time distribution)	**9.4**	**1.6**	**4.2**	**2.3**	**78%**
arrival variability: average inter-arrival time 2 hrs (Poisson arrival rate 0.5 pts/hr)	service time variability: average 2 hrs, standard deviation 4 hours (Log-normal distribution parameters: loc= -0.112; scale=1.27)	**9.3**	**1.4**	**3.3**	**1.7**	**69%**

Effect of Added Variability on Process Flow and Delay

Let's now demonstrate how additional arrival variability, service time variability, and/or both would affect the throughput and waiting time in the system. We will be using a simple DES model similar to the model presented on Figure 1.

We consider five scenarios with consecutively added step-by-step patient flow variability:

- Scenario 1. No variability at all. Each patient arrives exactly every 2 hours. Service time (surgery) is exactly 2 hours.
- Scenario 2. There is arrival variability, i.e. a Poisson flow with the average arrival rate 0.5 pts/hr (average inter-arrival time is 2 hours, E(2) hrs). No service time variability, it is exactly 2 hours.
- Scenario 3. No arrival variability. There is a service time variability with the average service time 2 hours, E(2) hours.
- Scenario 4. There are both types of variability. Poisson arrival with the average arrival rate 0.5 patients per hour (average inter-arrival time 2 hours), and service time variability with the average service time 2 hours, E(2)
- Scenario 5. Poisson arrival variability with the average arrival rate 0.5 patients per hour (average inter-arrival time 2 hours). Service time variability is log-normally distributed with the distribution mean value 2 hours and standard deviation 4 hours (these values correspond to the log-normal parameters: location= -0.112 and scale=1.27).

Results for 24 hours simulation time are summarized in Figure 6. It follows from this table that as the variability steps are added to the process, patient throughput decreases, an overall waiting time increases and utilization decreases.

At the same time, the variability distribution should not be characterized only by a single parameter, such as its coefficient of variation (CV). The overall shape of the variability distribution also plays a big role. For example, the coefficient of variation for the lognormal distribution service time (CV=4/2=2) is greater than that for exponential distribution (CV=1). Nonetheless, this did not result in increase of the wait time, as this would follow from an approximated queuing formula (Allen, 1978; Green, 2006). Only DES can accurately account for the effect of the distribution shape and skewness.

ICU Waiting Time

Analysis of ICU waiting time considered in section 2.1.4 using QA could be done using the same model as in the previous section (Figure 1). We simply use capacity 5 or 10, accordingly. Let's start with the exponential distribution of the length of stay with the average 2.5 days to compare with QA results (section 2.1.4).

Let's also use the average inter-arrival time as 1 day or 0.5 days, accordingly.

The following steady-state DES waiting times were obtained: 0.43 hours for 10 beds ICU and 2.94 for 5 beds ICU, accordingly. These are practically the same results as for QA (section 2.1.4).

Now, let's see how different distributions with the same average length of stay affect the waiting time. Recall, that QA cannot answer such practically important questions at all, and it is valid only for exponential distribution or, at best, for distributions with coefficient of variation close to 1 (Green, 2006).

For example, the triangle distribution limited between 2 days and 3 days with the average 2.5 days results in:

- for 10 beds ICU average waiting time is 0.27 hours while for 5 beds unit it is 1.72 hours. Notice, how significantly different these values are from the exponential length of stay with the same average.

Similarly, for the lognormal distribution with the same average 2.5 days and standard deviation, say, 2 days, we get:

- for 10 beds ICU average waiting time is 0.35 hours while for 5 beds unit it is 2.46 hours.

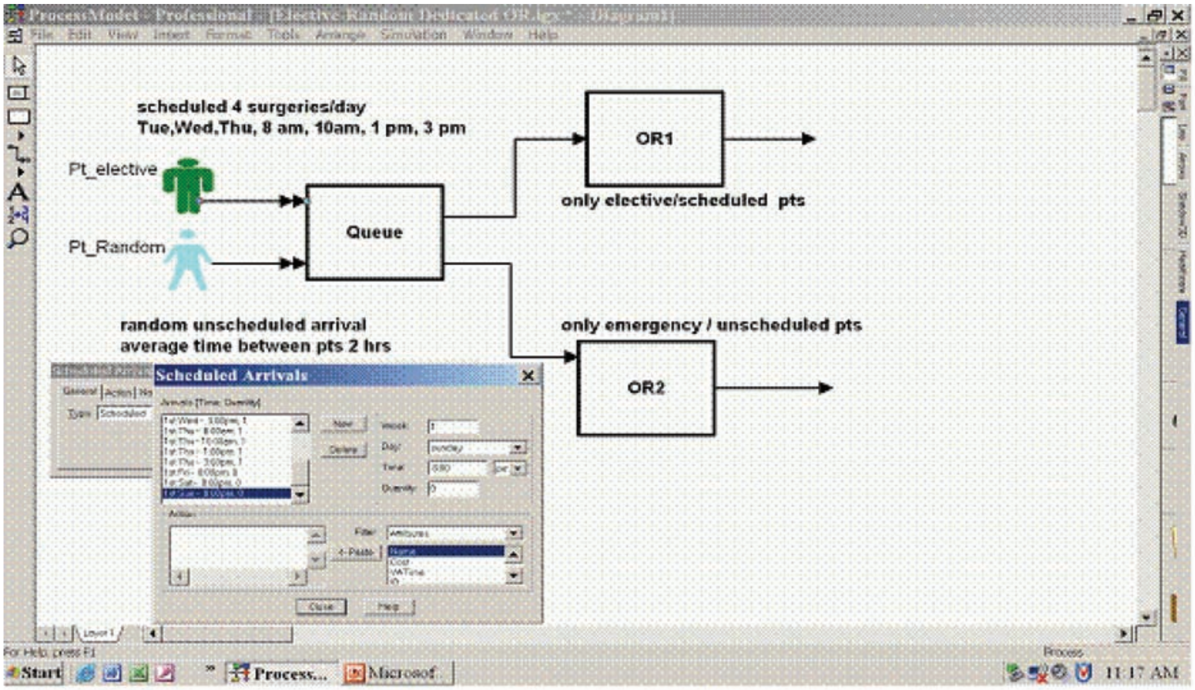
Thus, QA is severely limited in what it cannot account for different distributions of service time and always produces the same result if the same average is used regardless of the effect of different distributions with the same average.

Emergency and Elective Surgeries: Dedicated OR vs. Combined Service OR

In this section we will discuss the use of a simple DES model to address an issue that caused a controversy in literature on healthcare improvement. If patient flow into operating rooms consists of both elective (scheduled) and emergency (random) surgeries, is it more efficient to reserve dedicated operating rooms (OR) separately for elective and emergency surgeries, or to perform both types of surgeries in any available OR?

Haraden et al (2003) recommends that hospitals that want to improve patient flow should designate separate ORs for scheduled and unscheduled (emergency) surgeries. The authors state that in this arrangement '…Since the vast majority of surgeries is scheduled, most of the OR space should be so assigned. Utilization of the scheduled rooms becomes predictable, and wait times for unscheduled surgery become manageable'. The authors imply that this statement is self-evident,

Figure 7. Emergency and Elective surgeries: dedicated OR vs. combined service OR



and provide no quantitative analysis or any other justification for this recommendation.

On the other hand, Wullink et al (2007) built DES model of OR suite for large Erasmus Medical Center hospital (Rotterdam, The Netherlands) to quantitatively test scenarios of using dedicated ORs for emergency and elective surgeries vs. combined use of all ORs for both types of surgeries. These authors concluded that based on DES model results '…Emergency patients are operated upon more efficiently on elective ORs instead of a dedicated emergency ORs. The results of this study led to closing of the emergency OR in this hospital'.

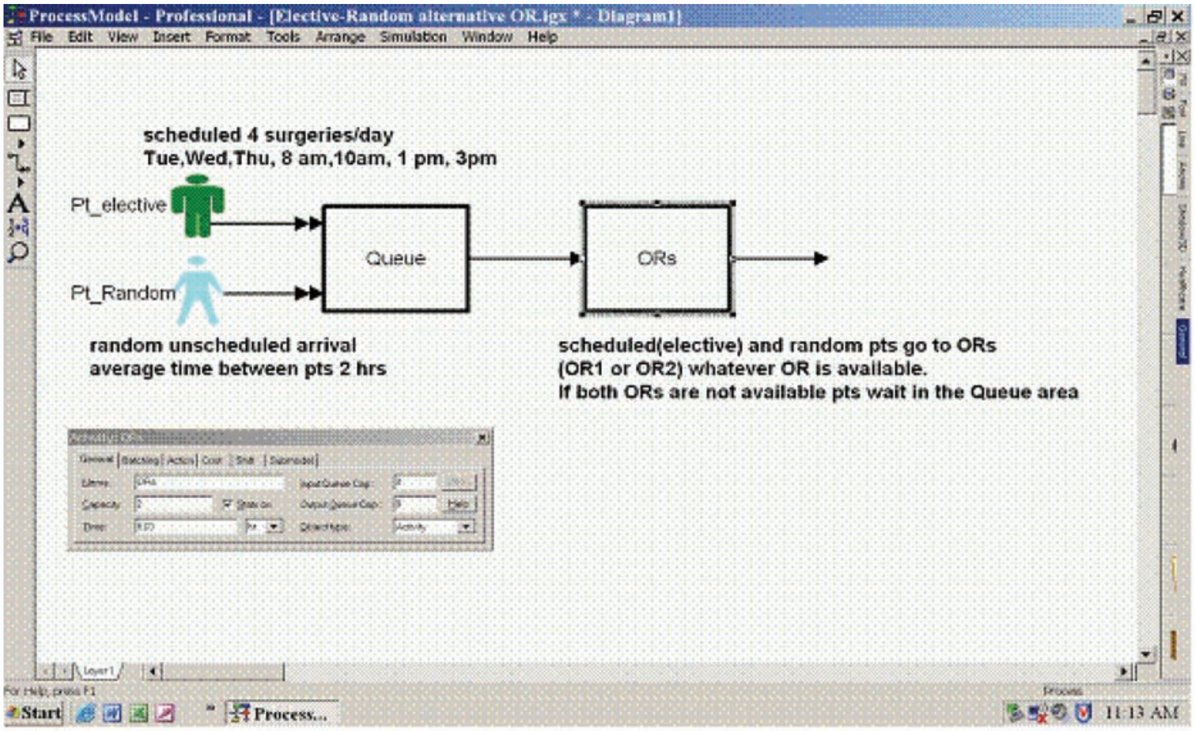
In contrast to the unsupported recommendation of Haraden et al (2003), Wullink et al (2007) presented specific data analysis to support their conclusions: combined use of all ORs for both types of surgery results in reduction of average waiting time for emergency surgery from 74 min to 8 min.

In this section we present a simple generic DES model to address the same issue and verify literature results. For simplicity, we consider an OR suite with two rooms, OR1 and OR2. Patient flow includes both emergency (random) and scheduled patients.

Let's first consider the situation when the majority of surgeries are emergency (random) ones. We assume a Poisson emergency patient arrival with the average inter-arrival time 2 hours, i.e. E(2) hours (Poisson arrival rate 0.5 pts/hr).

Four elective surgeries are assumed to be scheduled three days a week on Tuesday, Wednesday and Thursday at 8 am, 10 am, 1 pm and 3 pm. Both emergency and elective surgery duration is assumed to be random with the average value 2 hours, i.e. E(2) hours. (Wullink et al, 2007 used mean case duration 2.4 hours for elective and 2.1 hours for emergency surgeries)

Figure 8. Emergency and Elective surgeries: dedicated OR vs. combined service OR



scheduled 4 surgeries/day
Tue,Wed,Thu, 8 am,10am, 1 pm, 3pm

random unscheduled arrival
average time between pts 2 hrs

scheduled(elective) and random pts go to ORs
(OR1 or OR2) whatever OR is available.
If both ORs are not available pts wait in the Queue area

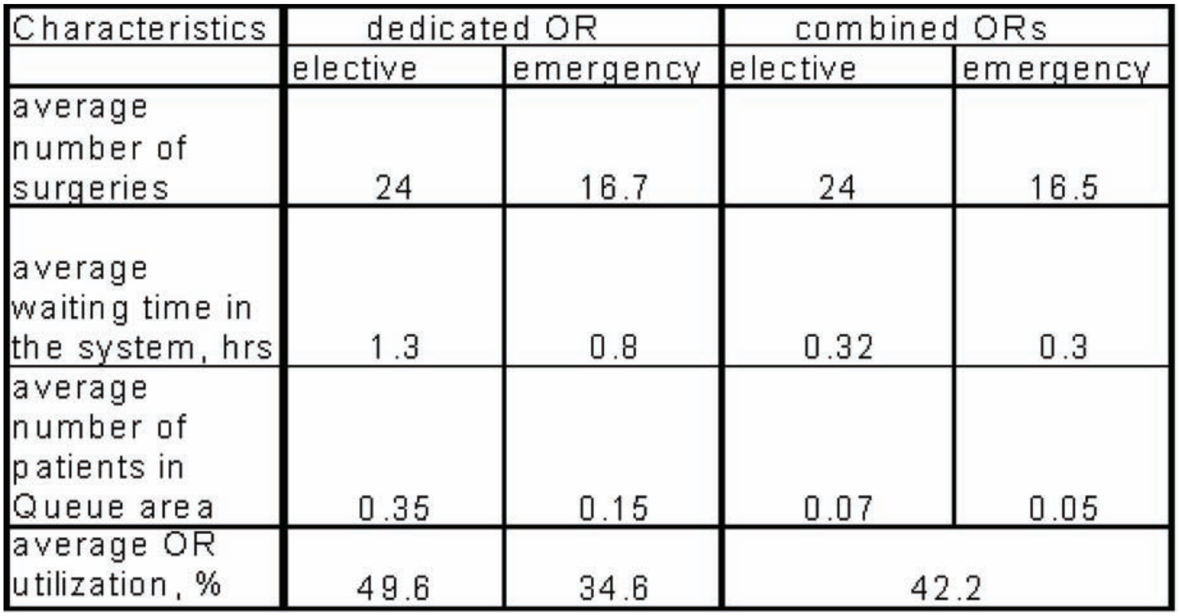
Figure 9. Simulation results: dedicated ORs vs. combined ORs. Most surgeries are emergency ones. Simulation performed for 4 days (96 hours) time period

Characteristics	dedicated OR		combined ORs	
	elective	emergency	elective	emergency
average number of surgeries	12	41.3	12	47.3
average waiting time in system, hrs	0.7	7.1	1.3	1.06
average number of patients in queue area	0.1	3.76	0.16	0.59
average OR utilization, %	24.2	85.8	62.7	

Using these arrival and service time data, let's consider two scenarios.

Scenario 1: two ORs, one dedicated only for elective surgeries (OR1), and another dedicated only for emergency surgeries (OR2), as shown on Figure 7 If the dedicated OR is not available, then the new patient waits in the Queue area until the corresponding dedicated OR becomes available.

Figure 10. Simulation results: dedicated ORs vs. combined ORs. Most surgeries are elective. Simulation performed for 4 days (96 hours) time period



Characteristics	dedicated OR		combined ORs	
	elective	emergency	elective	emergency
average number of surgeries	24	16.7	24	16.5
average waiting time in the system, hrs	1.3	0.8	0.32	0.3
average number of patients in Queue area	0.35	0.15	0.07	0.05
average OR utilization, %	49.6	34.6	42.2	

Scenario 2: also two ORs. However both emergency and elective patients go to any available OR, as indicated on Figure 8. If both ORs are not available, then the new patient waits in the Queue area until one of ORs becomes available.

Scenario 1 model layout: two ORs, one dedicated only for elective surgeries (OR1), and another dedicated only for emergency surgeries (OR2). Scheduled arrival pattern is indicated on the panel.

Simulation was run for 4 days (96 hours) Monday to Thursday (on Friday there were no scheduled elective surgeries) using 300 replications. DES results for these two scenarios are given in Figure 9.

Examination of the results is instructive. While the number of elective surgeries is the same for both scenarios, the number of performed emergency surgeries is higher for combined OR scenario. The average waiting time for elective surgery increases about 2 times for the combined OR scenario (from 0.7 to 1.3 hours); however, the average waiting time for emergency surgery drops dramatically from about 7 hours down to 1 hour ! (Compare this dramatic drop with Wullink et al (2007) result). The average number of patients waiting for emergency surgery is significantly lower for combined OR scenario. Dedicated elective OR is under-utilized (~24%) while dedicated emergency OR is highly utilized (~85%), resulting in a significant increase in waiting time for emergency surgeries. OR utilization in the combined OR scenario is a rather healthy 63%.

Scenario 2 model layout: two ORs. Both emergency and elective patients go to any available OR. Information of the panel indicates capacity of ORs (2) and the average surgery (service) time E(2) hr

Now, let's consider the situation when the majority of surgeries are elective.

We have the same two scenarios with two ORs (dedicated and combined) with the average surgery duration 2 hours, E(2) hours.

However this time 6 daily elective surgeries are scheduled Monday to Thursday (no Fridays) at 7 am, 9 am, 11 am, 1 pm, 3 pm, 5 pm. Emergency (random) surgeries are less frequent with the average inter-arrival time 6 hours, E(6), i.e. Poisson arrival rate about 0.167 patients per hour.

Simulation results for 96 hours (4 days), 300 replications are given in Figure 10.

Notice that in this case the average waiting time for combined ORs drops about 3 to 4 times both for emergency and elective patients, as well as the average number of patients in the Queue area.

Overall, these DES results support the conclusions of Wullink et al (2007) that performing emergency surgeries in the combined OR scenario is more effective than in the reserved dedicated emergency OR. These authors provided a detailed instructive discussion on why dedicated OR scenario performs worse especially for emergency surgeries, while intuitively it seems that it should perform better, like Haraden et al (2003) assumed.

Wullink et al (2007) pointed out that besides reserving OR capacity for emergency surgeries arrivals, ORs need to reserve capacity to cope with the variability of surgery duration. In the combined OR scenario, reservation might be shared to increase the flexibility for dealing with unexpected long case duration and emergency surgery, whereas the dedicated scenario does not offer the opportunity to use the overflow principle (compare this with two simplified scenarios considered earlier in section 2.1.1 using QA model).

On top of that, a dedicated OR scenario may cause queuing of emergency surgeries themselves because of their random arrival time. If emergency surgeries were allocated to all available ORs (combined scenario), then it would be possible to perform them simultaneously reducing thereby a waiting time.

Wullink et al (2007) acknowledge that '… interrupting the execution of the elective surgical case schedule for emergency patients may delay elective cases. However, inpatients are typically admitted to a ward before they are brought to the OR. Although delay due to emergency arrivals may cause inconvenience for patients, it does not disturb processes in the OR'.

As DES modeling indicates, delay in scheduled cases in the combined ORs (if the majority of surgeries are emergency) is usually not too dramatic (e.g. from 0.7 to 1 hour), while reduction of waiting time for emergency surgeries is very substantial (from 74 min to 8 min according to Wullink's DES model, or from about 7 hours to 1 hour according to our simplified DES model with generic input data described in this section).

If the majority of surgeries are scheduled ones, then there is not much delay in combined ORs at all both for scheduled and emergency surgeries.

Examples presented in Section 2 illustrate a general fundamental principle: the lower variability in the system (both arrival and service), the lower delays (see also Green, 2006). In other words, lowering variability is the key to improving patient flow and to reduce delays and waiting times.

One of the root causes of why intuition usually fails to account for the effect of variability even in very simple systems is a general human tendency to avoid the complications of uncertainty in the decision making by turning it into certainty. Average procedure time or average number of arrived patients is typically treated as if they are fixed values ignoring the variability around these averages. This ignorance often results in erroneous conclusions. DES models, however, naturally handle complex variability using statistical distributions with multiple replications.

DES MODELS: ADVANCED APPLICATIONS

In this section more advanced features of DES models will be presented, such as custom-built action logic to capture fine details of system behavior, conditional and alternate routing types, multiple entities entries, multiple scheduled arrivals and highly skewed service time distributions that accurately reflect real data rather than assuming some hypothetical data distribution.

It will also be demonstrated how a specific problem statement leads to simulating different 'what-if' scenarios to address practically relevant issues for ED and ICU (sections 3.1 and 3.2), as well as interdependencies of patient flow for ED, ICU, OR and floor nursing units (NU) (section 3.3).

DES of Emergency Department Patient Flow: Effect of Patient Length of Stay on ED Ambulance Diversion

Emergency Department (ED) ambulance diversion due to 'no available beds' status has become a common problem in most major hospitals nationwide. A diversion status due to 'no available ED beds' is usually declared when the ED census is close to or at the ED beds capacity limit. ED remains in this status until beds become available when patients are moved out of ED (discharged home, expired, or admitted into the hospital as inpatients). Percent of time when ED is on diversion is one of the important ED patient performance metrics, along with the number of patients in queue in ED waiting room, or ED patient waiting time. ED diversion results in low quality of care, dissatisfaction of patients and staff, and lost revenue for hospitals.

Patients' length of stay (LOS) in ED is one of most significant factors that affect the overall ED throughput and ED diversion (Blasak et al, 2003; Gunal and Pidd, 2006; Garcia et al, 1995; Miller et al, 2003; Simon et al, 2003). There are generally two major groups of patients with different LOS distributions: (i) patients admitted as inpatients into the hospital (OR, ICU, floor nursing units), and (ii) patients stabilized, treated and discharged home. Mayhew and Smith (2008) also recognized a key difference between these two groups.

In order to effectively attack the problem of ED diversion reduction, the LOS of these two groups should be quantitatively linked to ED diversion. Then the target LOS limits can be established based on ED patient flow analysis.

A number of publications are available in which the importance of having ED LOS target was discussed. Kolker (2008) provided a detailed analysis of the literature.

One instructive article published recently by Mayhew and Smith (2008) evaluates the consequences of 4 hours LOS limits mandated by the UK National Health Services for the UK hospitals' Accident &Emergency Departments (A&ED). One of the main conclusions of this work was '… that a target should not only be demanding but that it should also fit with the grain of the work on the ground… Otherwise the target and how to achieve it becomes an end in itself '. Further, '…the current target is so demanding that the integrity of reported performance is open to question'. This work vividly illustrated the negative consequences of the administratively mandated LOS targets that have not been based on the objectives analysis of the patient flow and an A&ED capability to handle it.

Despite a considerable number of publications on the ED patient flow and its variability, there is not much in the literature that could help to answer a practically important question regarding the target patient LOS: what it should be and how to establish it in order to reduce ED diversion to an acceptable low level, or to prevent diversion at all ? Therefore, a methodology that could quantitatively link the patient LOS limits and ED performance metrics would have a considerable practical value.

Description of the ED Patient Flow Model

Kolker (2008) described the entire ED system. It included a fast-track lane, minor care, trauma

rooms and the main patient beds area. Total ED capacity was 30 beds.

Because the objective of this work was simulating an effect of patient LOS on diversion for the entire ED, the detailed model layout was significantly simplified. A widely recognized guideline in DES modeling is to keep the model as simple as possible while capturing the simulation objectives (Jacobson et al, 2006). This was reiterated by Dearie et al (1976) who stressed the importance of capturing only relevant performance variables when creating a simple but not necessarily the most complete model. Following this guideline, a simplified model is presented on Figure 11.

There are two modes of transportation by which patients arrive into ED indicated on Figure 11: walk-in and ambulance. When ED patients' census hit ED beds capacity limit (total 30 beds), an ambulance was bounced back (diverted), as it is indicated on Figure 11 Ambulance diversion continued until the time when the ED census dropped below the capacity limit. An action logic code was developed that tracked the percentage of time when the census was at the capacity limit. It was reported as percent diversion in the simulation output file.

All simulation runs start at week 1, Monday, at 12 A.M. (midnight). Because ED was not empty at this time, Monday midnight patients' census was used as the simulation initial condition on January 1, 2007: ED was pre-filled by 15 patients.

Each patient in the arrival flow was characterized by its week number, day of week, and admitting time on the record, as indicated on the panel on Figure 11. The following descriptive attributes (also indicated on the panel on Figure 11) were assigned to each patient on the arrival schedule to properly track each patient's routing and statistics in the simulation action logic:

- Mode of transportation: (i) walk-in, (ii) ambulance.
- Disposition: (i) admitted as inpatient, (ii) discharged home

Arrived patients take available free beds reducing ED free capacity.

Discharged patients (released home or admitted as inpatients) moved out of the simulation system according to their disposition conditional routings. The patients' flow 'in and out' of the ED formed a dynamic supply and demand balance.

Total number of patients included in the simulation was 8411 for the two-month period from January 1 to February 28, 2007. This number of patients was representative enough to make results valid for subsequent months and years (Mayhew and Smith (2008) used three months 2002 database to calibrate the queuing model; however, the total number of patients was not given).

Overall Simulation Approach and LOS Distribution Density Functions

The critical element of the dynamics of the supply and demand balance was the time that the patients spent in ED. This time was fitted by a continuous LOS distribution density functions, separately for admitted as inpatients and discharged home patients.

The best fit distributions were identified using the Stat:Fit module built in the simulation package: admitted inpatients best fit LOS was log-logistic, while best fit LOS for patients discharged home was Pearson 6 (Johnson et al, 1994). These distributions were built into the simulation action logic.

Because these LOS distributions represent a combination of many different steps of the patient move through the entire ED process from registration to discharge (including both value-added and non-value-added steps and delays), there is no simple interpretation: these are simply the best analytical fit used to represent actual patient LOS data.

Random numbers drawn from these distributions were used to perform multiple replications in each simulation run. It was identified in 'cold' runs that about 100 replications were needed for each simulation in order to get a stable outcome.

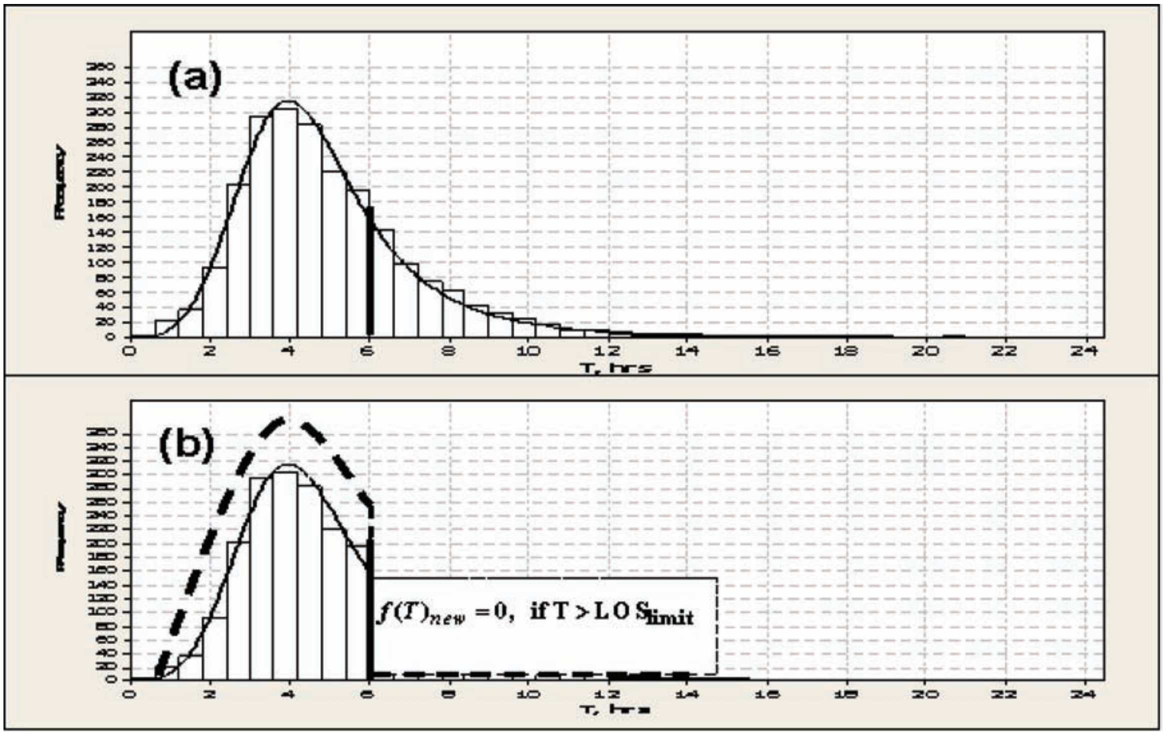
Because the objective was to quantify the effect of the LOS limits (both for discharged home patients and admitted as inpatients) on the percent diversion, the LOS limits were used as two simulation parameters.

An overall simulation approach was based on a full factorial design of experiments (DOE) with two factors (parameters) at six levels, each imposed on the original (baseline) LOS distribution functions. Response function was the simulated percent diversion. Imposing LOS limits (parameters) on original (baseline) LOS distribution functions means that no drawn random LOS value higher than the given limiting value was allowed in the simulation run. Therefore, the original LOS distribution densities should have recalculated for each simulation run as functions of the LOS limits (parameters).

One might be tempted to assume that if a randomly drawn LOS number was higher than the given LOS limit value this number should be made equal to the LOS limit. However, such an approach would result in a highly skewed simulation output because a lot of LOS numbers would be concentrated at the LOS limit value.

Instead, a concept of conditional distribution density should be used. If a random LOS number was in the interval from 0 to LOS_{lim}, this number was used for a simulation replication. However if

Figure 12. Distribution density function and imposed LOS limit



a random LOS number was outside the interval from 0 to LOS $_{\text{lim}}$, this number was not used, and the next random number was generated until it was in the given interval. This procedure generated a new restricted random variable that is conditional to being in the interval from 0 to LOS $_{\text{lim}}$.

Given the original LOS distribution density, $f(T)_{orig}$, and the limiting value,

LOS $_{limit}$, the conditional LOS distribution density function of the new restricted random variable, $f(T)_{new}$ will be

$$f(T)_{new} = \frac{f(T)_{orig}}{\int_0^{LOS_{\text{lim}}} f(T)_{orig} dT}$$, if T is less or equal to LOS

$f(T)_{new} = \mathbf{0}$, if T is greater than LOS $_{\text{lim}}$

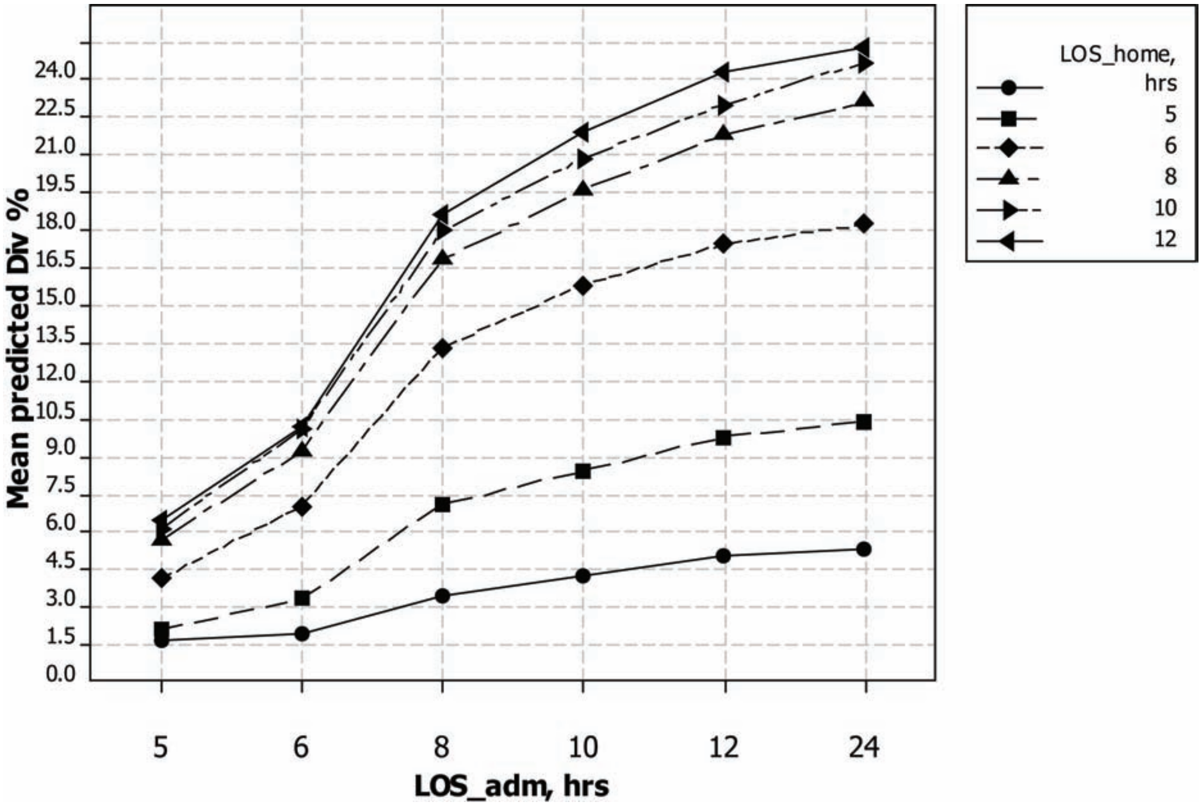
Conditional distribution density $f(T)_{new}$ depicted on Figure 12 (bottom panel, dotted bold line) is a function of both original distribution density and the simulation parameter LOS $_{\text{lim.}}$ (upper integration limit of the denominator integral).

These denominator integrals were preliminary calculated and then approximated by the 3-rd order polynomials that were built in the simulation action logic (Kolker, 2008).

The model's adequacy check was performed by running the simulation of the original baseline patients' arrival. The model's predicted percent diversion (~23.7%) and the reported percent diversion (21.5%) are close enough (in the range of a few percentage points). Thus, the model captures dynamic characteristics of the ED patients' flow adequately enough to mimic the system's behavior, and to compare alternatives ('what-if' scenarios).

Along with the percent diversion calculation, a plot of ED census as a function of time (hours/

Figure 13. Summary plot representing simulated % diversion as a function of two parameters LOS lim (home) and LOS lim (adm)



weeks) was also simulated (Kolker, 2008). This instructive plot visualizes the timing when the ED census hits the capacity limit, and therefore ED diversion had to be declared. The plot also illustrated that at some periods of time (mostly late night time) the ED was actually at a low census.

A full factorial computer design of experiments (DOE) was performed with two factors: LOS $_{lim}$ (home) for discharged home patients and LOS $_{lim}$ (adm) for patients admitted into hospital. Each factor had six levels. Simulated percent diversion was a response function.

A summary of results is presented on Figure 13. It follows from this plot that several combinations of parameters LOS $_{lim}$ (home) and LOS $_{lim}$ (adm) would result in low percent diversion.

For example, if LOS $_{lim}$ (home) stays at 5 hours (low curve) then LOS $_{lim}$ (adm) could be about 6 hours with the practically negligible diversion about 0.5%. Notice that Clifford et al (2008) established the goal for ED LOS 6 hours for inpatients to eliminate ambulance diversion and this metric is considered exceptional if less than 5% of patients exceed this limit. Any other combination of LOS $_{lim}$ (home) and LOS $_{lim}$ (adm) could be taken from the graph to estimate a corresponding expected percent diversion.

Thus, simulation helped to establish a quantitative link between an expected percent diversion and the limiting values of LOS. It has also suggested the reasonable targets for the upper limits LOS $_{lim}$ (home) and LOS $_{lim}$ (adm).

(a) thin solid line: original LOS (top panel). Bold vertical line: imposed LOS limit 6 hrs
(b) re-calculated restricted LOS: bold dotted line

Analysis of the LOS pattern in the study hospital indicated that a significant percentage of ED patients stayed much longer than the LOS targets suggested by the simulation. For example, ~24% patients of a study hospital exceeded LOS $_{\text{lim}}$ (adm) of 6 hours, and ~17% of patients exceeded LOS $_{\text{lim}}$ (home) of 5 hours. These long over-targets LOS for a significant percentage of patients were a root cause of ED closure and ambulance diversion.

Established LOS $_{\text{lim}}$ targets could be used to better manage a daily patient flow. The actual current LOS is being tracked down for each individual patient. If the current LOS for the particular patient at the moment is close to the target limiting LOS $_{\text{lim}}$ a corrective action should be implemented to expedite a move of this patient.

Multiple factors could contribute to the looming delay over the target LOS, such as delayed lab results or X-ray / CT, consulting physician is not available, no beds downstream on hospital floor (ICU) for admitted patients, etc. Analysis and prioritizing the contributing factors to the over the target LOS $_{lim}$ is an important task.

Notice that the average LOS that is frequently reported as one of the ED patient flow performance metric cannot be used to manage a daily patient flow. In order to calculate the average LOS, the data should be collected retrospectively for at least a few dozens patients. Therefore, it would be too late to make corrective actions to expedite a move of the particular patient if the average LOS becomes unusually high (whatever 'high' means). In contrast, if the established upper limiting LOS $_{lim}$ targets were not exceeded for the great majority of patients, it would guarantee a low ED percent diversion, and the average LOS would be much lower than the upper limiting LOS $_{lim}$.

Marshall et al (2005) and de Bruin et al (2007) also discussed the shortcomings of reporting LOS only as averages (the flaw of averages) for the skewed (long tailed) data (see also an illustrative example in section 2.2).

EDs of other hospitals differ by their patient mix, their LOS distribution and bed capacity. However the overall simulation methodology presented here will be the same regardless of a particular hospital ED.

Such a general methodology would be more practically useful for other ED than some predetermined generalized 'one size fits all' target values.

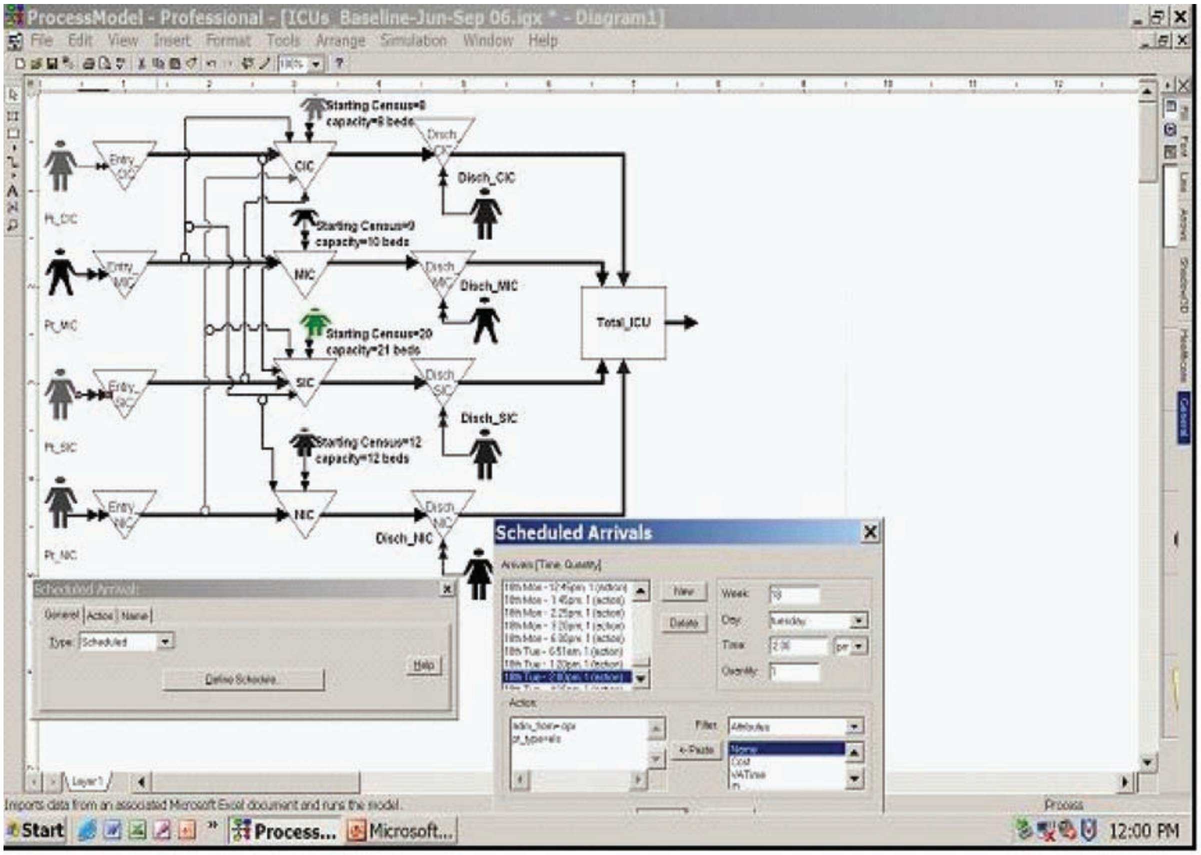
The negative consequences of the 'one size fits all' approach were summarized by Mayhew and Smith, (2008): '…the practicality of a single target fitting all A&ED will come under increasing strain'.

DES of Intensive Care Unit (ICU) Patient Flow: Effect of Daily Load Leveling of Elective Surgeries on ICU Diversion

Intensive Care Unit (ICU) is often needed for the patients' care. Demand for ICU beds comes from emergency, add-on and elective surgeries. Emergency and add-on surgeries are random and cannot be scheduled in advance. Elective surgeries are scheduled ahead of time. However, they are often scheduled for the daily block-time driven mostly by physicians' priorities. (Daily block time is the time in the operating room that is allocated to the surgeon or the group of surgeons on the particular days of the week to perform a particular type of surgical services). Usually elective surgery scheduling does not take into account the competing demand for ICU beds from the emergency and add-on cases.

Because of the limited capacity of the ICU beds, such a disconnection often results in the Emergency Department (ED) closure (diversion) for patients due to no beds in ICU. This is a typical example of a system bottleneck caused by the

Figure 14. DES layout of the ICU patient flow model



interdependency and competing demands between the material (patient) flows in a complex system: the upstream problem (ED closure) is created by the downstream problem (no ICU beds) (see section 3.3).

Usually two types of variability affect the system's patient flow: natural process flow variability and scheduled (artificial) flow variability (Litvak et al, 2001; Litvak and Long, 2000; Haraden et al, 2003).

Patients can be admitted into ICU from the Emergency Department (ED), other local area hospitals, inpatient nursing units, and / or operating rooms (OR). Patients admitted into ICU from ED, other local area hospitals, and inpatient nursing units are primary contributors to the natural random flow variability because the timing of these admissions is not scheduled in advance and is unpredictable.

Admissions into ICU from the OR include emergency, add-on, and elective surgeries. Elective surgeries (cases) are defined as surgeries that could be delayed safely for the patient for at least more than 24 hrs (or usually much longer).

Emergency and add-on surgeries also contribute to the natural process flow variability. Because this type of variability is statistically random, it is beyond hospital control. It cannot be eliminated (or even much reduced). However, some statistical characteristics can be predicted over a long period of time that could help to manage it.

Elective surgeries that require post-operative admission into ICU contribute to the scheduled (artificial) flow variability. Elective surgery scheduling is driven mostly by individual priorities of the surgeons and their availability for other commitments (teaching, research, etc). This variability is usually within the hospital management control, and it could be reduced or eliminated by a proper management of the scheduling system.

It is possible to manage the scheduling of the elective cases in a way to smooth (or to daily load level) overall patient flow variability. A daily load leveling would reduce the chances of excessive peak demand for the system's capacity and, consequently, would reduce its diversion.

There are quite a few publications in which the issues of smoothing surgical schedules and ICU patient flow are discussed. Kolker (2009) provided a detailed analysis of the literature.

Nonetheless, there is not much in the literature that could help a scheduler to directly answer an important question: what maximum number of elective surgeries per day should be scheduled along with the competing demand from emergency surgeries in order to reduce ICU diversion to an acceptable low level, or to prevent diversion at all ?

Therefore, a methodology that could quantitatively link the daily number of elective surgeries and ICU patient flow throughput (or diversion) would have a considerable practical value.

Description of the ICU Patient Flow Model

Layout of the ICU model of the study hospital is represented on Figure 14.

The entire ICU system includes four specialized ICU units: Cardio ICU (CIC), Medical ICU (MIC), Surgical ICU (SIC) and Neurological ICU (NIC). Capacity (the number of beds) of each ICU unit was: CIC=8, MIC=10, SIC=21 and NIC=12. Total ICU capacity was 51 beds.

All simulation runs start at week 1, Monday, at 12 A.M. (midnight). Because ICU was not empty at this time, Monday midnight patients' census was used as the simulation initial conditions: CIC=8, MIC=9, SIC=20 and NIC=12.

Patients admitted into each ICU unit formed an entity arrival flow. The week number, day of the week and admitting time characterize each patient in the arrival flow.

Each discharged patient is also characterized by the week number, day of the week and discharge time.

Patient flow 'in and out' formed a dynamic supply and demand balance (supply of ICU beds and demand for them by patients). If there was no free bed at the time of admission in the particular primary ICU unit, then the patient moved into other ICU units using alternative type routings (depicted by the thin lines between the units, Figure 14).

Patient move followed the following action logic that simulated the established hospital's rules to deal with the overcapacity of the ICU units:
if no beds available in CIC move to SIC

- if no beds available in MIC move to CIC else move to SIC else move to NIC
- if no beds available in NIC move to CIC else SIC

Panel indicates an example of scheduled SIC arrival: week number: 18; Day: Tuesday; Time: 2:00 pm. Patient attributes (bottom of the panel): adm_from = OR (Operating Room); pt_type = els (elective scheduled)

When the patient census of the ICU system hit or exceeded a critical limit, then an ICU diversion was declared due to 'no ICU beds'. The critical limit in the study hospital was defined as the number of occupied beds, which is two beds less than the total capacity, i.e. 49 beds. The two 'extra' beds were left as a buffer in the anticipation of more admissions coming soon.

Diversion status was kept until the time when the ICU census dropped below the critical limit. An action logic code was developed that tracked the percentage of time when the census was at or exceeded the critical limit. It was reported as the percent diversion in the simulation output file.

The following descriptive attributes were assigned to each patient on the arrival schedule to properly track each patient's routing and statistics in the simulation action logic:

- Patient type attribute: elective surgery (els) or emergency surgery (ems).
- Patient 'admitted from' attribute: emergency department (ED), operating room / recovery room (opr), external hospital, rehabilitation, any floor nursing unit.

The total number of admitted patients included into the ICU simulation model was 1847 during the 18 weeks period (about four months worth of data). The total number of elective cases was about 21% of all ICU admission for the 18 week period.

Because elective cases in the study hospital were scheduled by block-time for the same days of the different weeks, the weekly data have been drilled down to analyze their variation for the same days of the different weeks, i.e. from one Monday to another Monday of the following week, from one Tuesday to another Tuesday, and so on.

It follows from these data (Kolker, 2009) that there was a significant variability in the scheduling practice of elective surgeries from one Monday to another Monday, from one Tuesday to another Tuesday, and so on. For example, 8 cases were scheduled on Monday 6/5, 2007 while only 2 cases were scheduled on Monday 6/26, 2007, and only 1 case was scheduled for Monday 9/18, 2007.

A similar picture was observed for other days of week and other ICU units: NIC, MIC, CIC. This highly uneven scheduling practice resulted in straining the ICU system on busy days and underutilizing the system on light days. The overall variability of the schedule was quantified as the standard deviation of the daily number of elective cases over the entire period.

A model adequacy check was performed using the original baseline patient arrival database. The model's predicted percent diversion for the different time periods (from 1 month to 4 months long) was then compared with the actual percent diversion. The later was reported by the ED as the percent of time when the ED was closed to the ambulances due to 'no ICU beds'.

It could be concluded (Kolker, 2009) that the model captures dynamic characteristics of the ICU patient flow adequately enough (within 1 to 2 percent from the actually reported values) to mimic the system's behavior and to compare alternative ('what-if') scenarios.

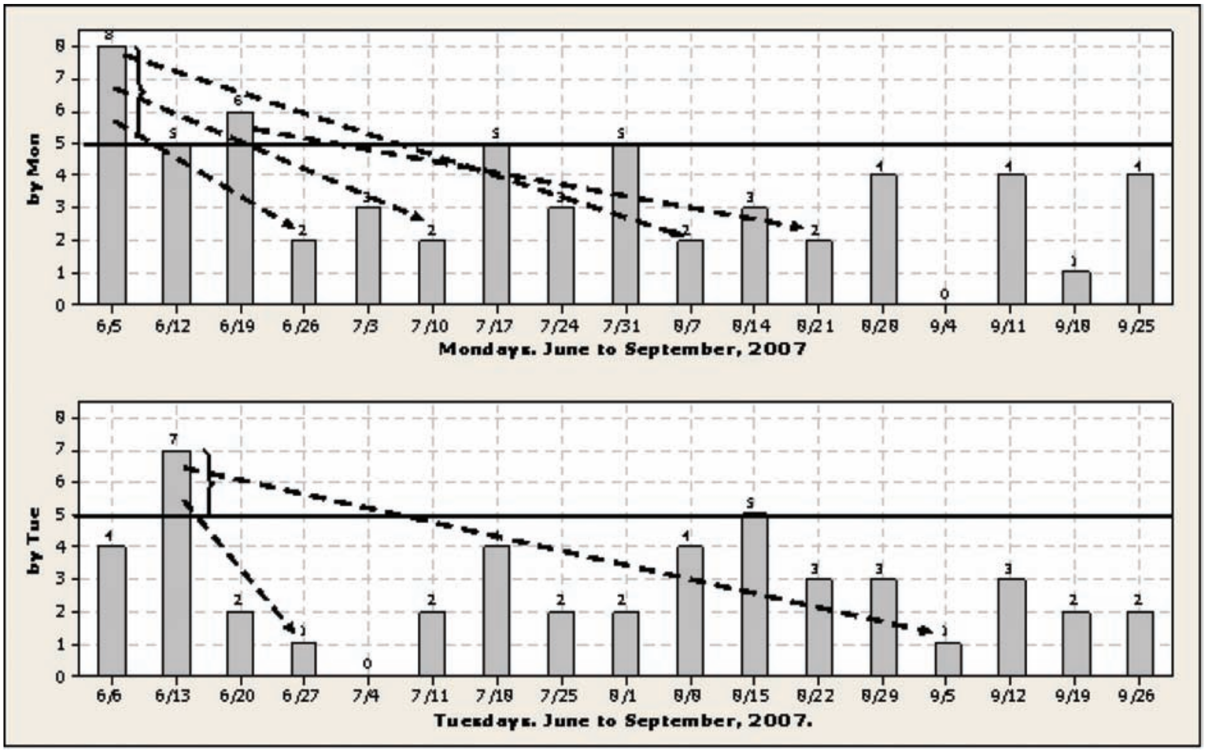
Along with the percent diversion calculation, a plot of ICU census as a function of time (hrs/weeks) was also simulated (Kolker, 2009). The plot visualizes the timing when the ICU census hits or exceeds the critical limit, and therefore ICU diversion had to be declared. The plot also illustrates that at some periods of time the ICU is actually underutilized having low census. These peaks and valleys of the census impose a significant strain on the effectiveness of the ICU operations.

Once the model was checked for its adequacy, it was used with enough confidence to simulate 'what-if' scenarios. The approach was to actively manipulate only the day and time of elective surgeries (leaving all emergency and add-on surgeries timing unchanged). The objective was to quantify the effect of the elective surgeries schedule smoothing (or, equivalently, daily leveling, or daily capping) on the ICU diversion.

The first 'what-if' scenario was: what would the percent diversion be if not more than 5 elective surgeries per day were scheduled for SIC (cap 5 cases) and not more than 4 elective surgeries were scheduled for NIC (cap 4 cases)?

For SIC three 'extra' elective surgery patients were moved from the Monday 6/5 to other Mon-

Figure 15. Diagram of the move of the number of elective surgeries for the daily level (cap) 5 cases (Mondays and Tuesdays shown)



days, such as 6/26, 7/10, and 8/7. One 'extra' elective surgery patient was moved from 6/19 to 8/21.

Similarly, two 'extra' elective surgery patients were moved from Tuesday 6/13 to Tuesdays 6/27 and 9/5, accordingly, as illustrated on Figure 15.

Similar moves were performed for Wednesdays, Thursdays, and Fridays, as well as for NIC. As a result of these moves, new smoother schedules were obtained. Notice that the standard deviations of the new schedules were now much lower than they were for the original schedules (Kolker, 2009).

Simulation runs for the new smoothed schedules resulted in the much-reduced diversion: about ~3.5%. The simulated census clearly indicated that the critical census limit was exceeded less frequently and for a shorter period of time. This is the reason for the reduced diversion compared to the original un-smoothed schedule.

Notice that the total number of elective surgeries remains the same. Not a single surgery was dropped but rather 'extra' surgeries were re-scheduled from the busy days to lighter later days to make the overall schedule for the same time period smoother.

Is it possible to lower diversion further?

The next 'what-if' scenario was: what will the percent diversion be if not more than 4 elective surgeries per day were scheduled, both for SIC and NIC (cap 4 cases)?

A similar move of the 'extra' surgeries from the days in which the daily level of 4 surgeries was exceeded to the later lighter days has resulted in the new schedule that was even smoother than the previous one with the leveling limit of 5 surgeries per day. Standard deviation was reduced by ~40% for Mondays, and ~35% for Tuesdays, Wednesdays, and Thursdays, respectively vs. the baseline original schedule. This should have helped to further reduce diversion. Indeed, the simulation runs demonstrated that the diversion dropped down to the level of ~1.5%.

Is the predicted low ICU diversion ~1.5%, with the SIC and NIC daily leveling of not more than 4 elective surgeries per day an acceptable solution? Technically, it is. However, some 'extra' surgeries would have bumped to more than 2 months apart, e.g. from early June to early August (Figure 15). The problem is that not all patients could wait that long even though the surgery is elective. Also, from the practical standpoint, daily leveling of not more than 4 surgeries per day is sometimes too restrictive.

Therefore a next series of 'what-if' scenarios was considered: is it possible to get a low diversion about ~ 1% by bumping 'extra' cases to the block-time days which are not further than 2 weeks apart (Dexter et al, 1999) ? It was also considered increasing the daily leveling back to 5 elective surgeries per day in order to make the limit less restrictive.

The elective schedule with the additional restriction 'not more than two weeks apart' is less smooth. It has a higher standard deviation (1.59) than the schedule without restriction for which the standard deviation was 1.42. Notice that the original un-smoothed schedule had the highest standard deviation 1.97.

Simulation runs of the 'what-if' scenario corresponding to the restricted 'within two weeks' schedule and SIC daily leveling 5 elective surgeries resulted in ICU diversion of only ~8%. This is a relatively small gain compared to the original baseline un-smoothed schedule with ~10.5% diversion. This small reduction of the diversion was a reflection of a lower smoothness (higher standard deviation) of this schedule. Thus, load leveling to 5 elective surgeries per day with bumped 'extra cases' within 2 weeks apart was not effective enough alone.

In order to reduce the percent diversion back to low single digits while still keeping daily leveling at 5 elective surgeries per day and moving 'extra cases' within two weeks apart, an additional factor was considered. This factor was a more rigorous implementation of ICU admission and discharge criteria. It was suggested that patients with the likely LOS less than 24 hrs were excluded from ICU admission but moved to the regular nursing unit (see section 3.3). This scenario resulted in a significant reduction of ICU diversion, down to about ~ 1%.

There is a trade-off between these two scenarios. From the practical standpoint the higher level-loading elective schedule (5 surgeries per day) would be easier to implement than the lower level-loading one (4 surgeries per day) because the former is less restrictive. However, the former assumes that the ICUs admission criteria/exclusions are rigorously applied while the latter does not require exclusion from the current ICU admission practice.

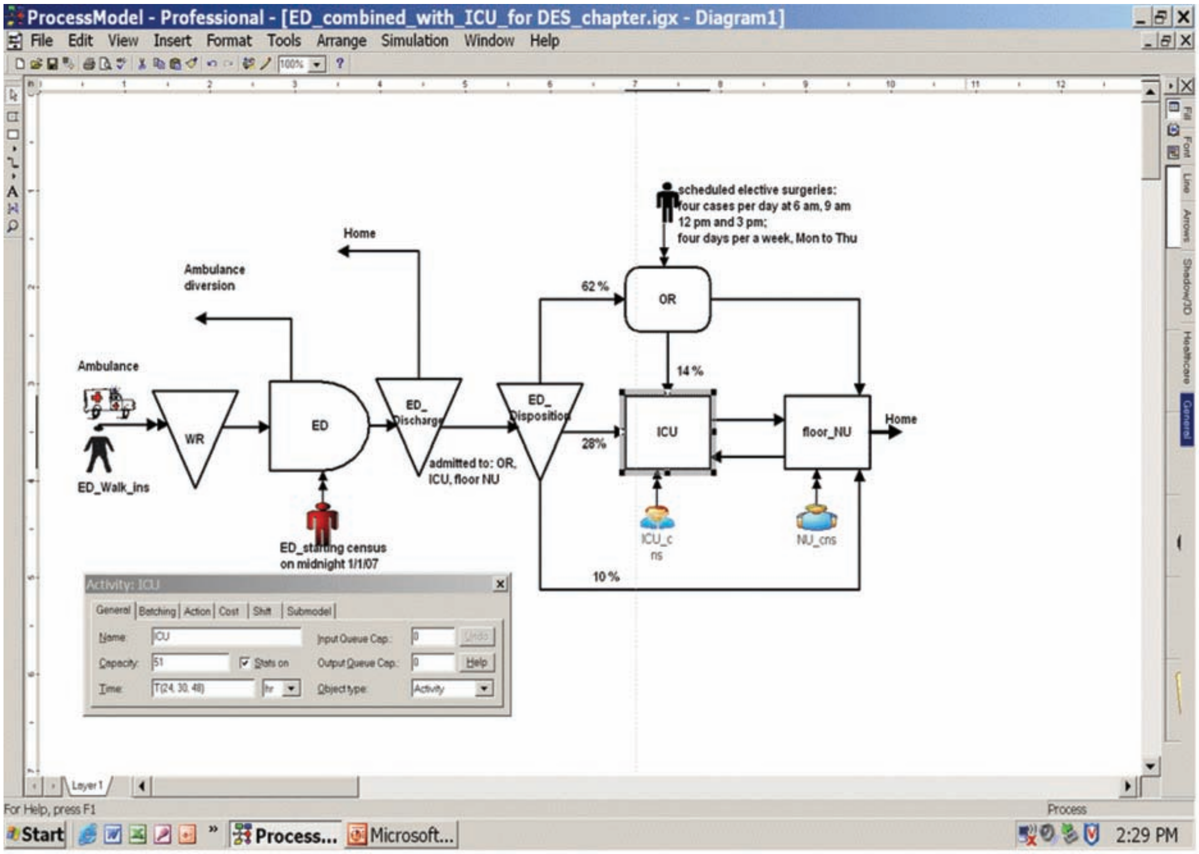
One more valuable application of this DES model could be determining a more appropriate allocation of the number of beds between CIC, SIC, MIC, and NIC units, compared to the current historical allocation.

Once the DES model is validated, it becomes a powerful tool for the hospital operations decision-making.

DES of the Entire Hospital System Patient Flow: Effect of Interdependencies of ED, ICU, Operating Rooms (OR) and Floor Nursing Units (NU)

It was discussed in Introduction that large complex hospital systems or multi-facility clinics are usually deconstructed into smaller subsystems or units. Most published DES models focus on

Figure 16. DES layout of a high-level patient flow map of the entire hospital system



Activity: ICU

General | Batching | Action | Cost | Shift | Submodel

the separate analysis of these individual units (Jacobson et al, 2006). However, according to the principles of analysis of complex systems, these separate subsystems (units) should be reconnected back in a way that captures the most important interdependency between them. DES models that capture the interaction of major units in a hospital, and the information that can be obtained from analyzing the system as a whole, can be invaluable to hospital planners and administrators.

This section specifically illustrates a practical application of this system-engineering principle.

DES models of the ED and ICU patient flow have been described separately in details in sections 3.1 and 3.2. It is well known that these subsystems are not stand-alone units but they are closely interdependent, as well as the Operating Rooms (OR) and floor nursing units (NU).

A high-level patient flow map (layout) of the entire hospital system is shown on Figure 16 One output of the ED model for patients admitted into the hospital (ED discharge) now becomes an ICU, OR and NU input through ED disposition. About 62% of admitted patients were taken into operating rooms (OR) for emergency surgery, about 28% of admitted patients moved directly into ICU, and about 10% of patients admitted from ED into floor nursing units.

OR suite size was 12 interchangeable operating rooms used both for ED emergency and scheduled surgeries.. There were four daily scheduled OR admissions at 6 am, 9 am, 12 pm and 3 pm, Monday to Thursday (there were no scheduled surgeries on Fridays and weekends).

The best fit of the emergency surgery duration was found to be a Pearson 6 distribution.

Elective surgery duration depends on surgical service type, such as general surgery, orthopedics, neuro-surgery, etc. For the simplicity of this model, elective surgery duration was weighted by each service percentage. The best fit of the overall elective surgeries duration was found to be a Johnson SB distribution (Johnson et al, 1994).

About 14% of post surgery patients were admitted from OR into ICU (direct ICU admission) while 86% were admitted into floor NU. However some patients (about 4%) were readmitted from floor NU back to ICU (indirect ICU admission from OR).

Patient length of stay (LOS) in NU was assumed to be in the range from 1 day to 10 days with the most likely 5 days represented by a triangle distribution. NU overall capacity was 420 beds. At the simulation start, NU was pre-filled with starting census 380 patients (see also sections 3.1 and 3.2).

Baseline DES resulted in ED diversion about 24%, ICU diversion about 11% (see sections 3.1 and 3.2), and floor NU diversion about 14.6%.

If limiting ED LOS had aggressive targets 5 hours for patients discharged home and 6 hours for patients admitted to the hospital (see section 3.1) then ED diversion became practically negligible (less than 0.5%). However because of interdependencies of patient flows, ICU diversion increased to 12.5% and floor NU diversion remained about the same, 14.9%. Thus, aggressive process improvement in one subsystem (ED) resulted in worsening situation in other interrelated subsystems (mostly, ICU).

If instead of the above aggressive limiting ED LOS a more relaxed target is used, say, LOS not more than 6 hours for discharged home and not more than 10 hours for admitted to the hospital, then simulated ED diversion would become about 7%, ICU diversion is about 11.1%, and floor NU diversion remained practically unchanged, 14.8%. While ED diversion now became worse, it is still better than it was at the baseline level by about a factor of 3. At the same time, this less aggressive ED target LOS did not, at least, make the ICU and floor NU diversion much worse.

Thus, from the entire hospital system standpoint the primary focus of process improvement activities should be on ED, and then on floor NU followed by ICU.

At the same time, ED patient target LOS reduction program should not be too aggressive and it should be closely coordinated with that for floor NU and ICU. Otherwise, even if ED reports a significant progress in its patient LOS reduction program, this progress will not translate into improvement of the overall hospital system patient flow. This illustrates one of the fundamental principles of the Theory of Constraints (Goldratt, 2004).

On the other hand, if ICU policy of declaring diversion is changed from 49 occupied beds to full capacity of 51 occupied beds, then ICU reported diversion will drop down to ~9.6%, leaving unchanged diversions of all other units in the system.

This illustrates that reported performance metric (percent of time at full capacity or some others) depends not only on physical capacity and patient flow variability but also on the hospital administrative policy.

Of course, many other scenarios could be analyzed using DES model to find out how to improve the entire hospital system patient flow rather than each separate hospital department.

PRACTICAL IMPLEMENTATION OF DES RESULTS IN HEALTHCARE: ISSUES AND PERSPECTIVES

As it was already pointed out and supported by extensive literature review (Jun et al, 1999; Jacobson et al, 2006), DES modeling as a methodology of choice in healthcare has been extensively used to quantitatively analyze healthcare delivery processes and operations and to help decision-makers to justify business decisions.

However, for DES to reach its full potential as the key methodology in healthcare, the results of simulation must be practically implemented. Unfortunately, the number of publications that report successful implementation of DES results is much lower than the number of publications that report successful development of DES models. For example, in the survey of two hundred papers reporting the results of DES studies in healthcare, only 16 reports of successful implementations were identified (Jacobson et al, 2006). Fone (2003) found that Operational Research has had limited success in the implementation of results in practice in the healthcare setting. Sachdeva et al (2006) also states that '…Healthcare Operational Research (OR) has had limited success in achieving an adequate level of acceptance by stakeholders, particularly physicians, leading to implementation of results'.

A likelihood of successful implementation or effectiveness of DES project (E) can be related to two major factors:

(i) the likelihood that DES model adequately captures all relevant features of process (system) and properly verified and validated to actual clinical data, i.e. technical quality of the model (TQ), and
(ii) the likelihood of acceptance of the results of the DES study by key stakeholders and decision-makers (A), i.e., $E = TQ * A$.

A similar relationship in which acceptance term (A) also included accountability was presented by Mercy Medical Center (2007).

Most reported DES studies focus on TQ, and the likelihood of developing a good verified and validated DES model is high (although not guaranteed). However, if the likelihood of acceptance of the model results is low (for whatever reason), then the overall success and impact of the DES project measured by effectiveness of its implementation will also be low regardless of technical merits of the DES model itself.

A number of recommendations were developed to increase the likelihood of DES results implementation success. Some of these recommendations include (Jacobson, 2006): the system being simulated actually needs decision, the DES project must be completed before a deadline, data used for simulation are credible, and, most importantly, the key stakeholders and the decision-maker must actively participate in the project.

Lowery (1996) noted that involvement of the upper management in the project is critical for its success. Litvak (2007) argues that if hospital executives are not involved in the process (queuing theory or simulation), the analysts could do their calculations but they would not be used for decision-making.

Carter and Blake (2004) published an interesting summary of their experience in practical implementation of simulation projects. They have used four projects to highlight the practical lessons of applying operations research methodologies in health care: '…Experience suggests that OR techniques can be successfully applied in the health care setting. The secret is to understand the unique nature of the health care business and its impact on models, decision makers, and the development of implementation policies'. Further, '…decision making in hospitals is characterized by multiple players; …incorporating the objectives of all decision makers is vital in this environment'.

Thus, procedure and methodology of applying DES requires decision-makers to work closely with the simulation analyst to provide details of the system, often for the first time. As a result, the decision-makers are likely to gain a new perspective on the relationship between the available resources and the capability of the system (Jacobson et al, 2006).

The experience of the author of this chapter has also shown that at least two main conditions are needed: (i) the stake-holder (project owner) must have a genuine incentive for process improvement and realize that there is no real alternative to DES modeling, and (ii) a dedicated and flexible data analyst must participate in the project. The data analyst must not only have a full access to raw data stored in various data bases but be also qualified enough to convert these data bases into a data file (usually Excel) with the fields that match the fields developed by a simulation specialist who designed the model. Thus, a successful DES project truly takes teamwork by the professionals.

Rakich et al (1991) studied the effect of DES on management development. The authors concluded that conducting a simulation study not only develops decision-making skills, but also forces to recognize the implication of system changes. It was noted that if decision-makers developed their own DES models, implementation occurred much more frequently. Mahachek (1992) noted that one of significant barriers in the implementation of DES is the decision-makers' perception that '… simulation is an additional layer of effort rather than an organizer of all your current efforts'. According to Lowery (1996), DES projects start as a means of documenting assumptions, organizing the decision-making process and identifying potential problem areas. She is quite right when she passionately writes that '…It is amazing how much time is spent in the planning process (especially in meetings) arguing over the differences in opinion, where these differences are due to disagreements over assumptions never actually acknowledged….While disagreements may still ensue over the content of the assumptions, the arguments become focused when the assumptions… are in front of all participants'.

Healthcare has a culture of rigid division of labor. This functional division does not effectively support the methodologies that cross the functional areas, especially if they assume significant changes in traditional relationships (Kopach-Konrad et al, 2007). Furthermore, the role and status of DES professionals in healthcare delivery is not usually well defined and causes sometimes skepticism and fear.

Relatively few health care administrators are equipped to think analytically about how health care delivery should function as a system or to appreciate the relevance of system-engineering methods in healthcare. Even fewer are equipped to work with engineers to apply these tools (Reid et al, 2005). Thus, it is often difficult for many administrators to appreciate the DES approach contributions to the health care delivery process analysis. On the other hand, DES professionals often have little, if any, education in health care delivery. This sometimes results in the lack of clinically relevant factors related to patient care included in DES model, '…which are at the heart of physician decision-making' (Sachdeva et al, 2006).

This underscores the importance of considering social and communication issues in the acceptance and implementation of any socio-technical system (Kopach-Konrad, et al, 2007).

One approach proposed to overcome some of these issues was applied to pediatric ICU (Sachdeva et al, 2006). It includes a combination of 'hard' and 'soft' operations research. The initial simulation model of pediatric ICU patient flow was modified based upon input from the active participation of physicians working in this ICU. During interviews with stakeholders it was acknowledged that there are factors called 'soft' that are difficult to model in an objective unambiguous way. Therefore, soft OR was used to capture concerns that could not be captured using traditional DES methodology. Cognitive mapping was chosen as the soft OR approach. Cognitive maps attempt to capture beliefs, values, and expertise of stakeholders by conducting structured interviews. Cognitive mapping was used for two main purposes: (i) to assist in the identification of issues that were previously not captured using traditional DES models, and (ii) comparing results from the outcomes research, hard and soft OR to enhance greater buy-in and acceptance by the key stakeholders.

The results of cognitive mapping helped not only identify new issues not captured by hard OR but also supported many of the results from hard OR that were counter-intuitive to pre-existing beliefs.

Thus, results from this study support the view that a combination of hard and soft OR allows a greater level of understanding leading to acceptance and willingness to implement DES results. This is consistent with the recommendations of the UK Engineering and Physical Science Research Council (EPSRC) (2004) regarding soft OR and application in healthcare. '…It has always been one of the main characteristics of OR to seek for opportunities to integrate soft and hard methods' (EPRSC, 2004).

CONCLUSION

This chapter covers applications of the most widely used system-engineering methods, such as queuing analytic theory and DES models, to healthcare,. It demonstrates the power of DES models for the analysis of patient flow with variability and subsystem interdependency.

Many health care organizations are making serious strategic decisions such as new construction to expand capacity, merging with other hospitals etc., without using system engineering and, particularly, DES modeling analysis to evaluate an impact of these decisions.

However, DES models and management science principles are widely used in other industries, and demonstrate a great value in providing important insights into operational strategies and practices.

Complex dynamics of delivery of care processes makes them an important area of application of DES modeling and management science methodologies to help identify both trends in capacity needs and the ways to use existing capacity more efficiently.

At the same time, it is acknowledged that one of the major current challenges is a relatively low acceptance of DES results by the medical community and hospital administration. Practical implementation of DES results in health care settings is sometimes rather slow and difficult.

There are various reasons for this situation, both technical and psychological. Some of them have been discussed in section 4.

Nonetheless, more and more healthcare organizations have started to recognize the value and predictive power of system engineering and DES models through concrete and realistic examples. The fast changing landscape of the healthcare industry will help promote the organizational changes needed for adoption improvement recommendations based on DES models. Hopefully this chapter contributes a little toward achieving this goal.

KEY TERMS AND DEFINITIONS

Operations Research: The discipline of applying mathematical models of complex systems with random variability aimed at developing justified operational business decisions

Management Science: A quantitative methodology for assigning (managing) available material assets and human resources to achieve the operational goals of the system based on operations research.

Non-Linear System: A system that exhibits a mutual interdependency of components and for which a small change in the input parameter(s) can result in a large change of the system output

Discrete Event Simulation: One of the most powerful methodologies of using computer models of the real systems to analyze their performance by tracking system changes (events) at discrete moments of time

Queuing Theory: Mathematical methods for analyzing the properties of waiting lines (queues) in simple systems without interdependency. Typically uses analytic formulas that must meet some rather stringent assumptions to be valid.

Simulation Package (also known as a simulation environment): A software with user interface used for building and processing discrete event simulation models

Flow Bottleneck / Constraint: A resource (material or human) whose capacity is less than or equal to demand for its use.

This work was previously published in Handbook of Research on Discrete Event Simulation Environments: Technologies and Applications, edited by E. Abu-Taieh and A. El Sheikh, pp. 443-483, copyright 2010 by Information Science Reference (an imprint of IGI Global).

Chapter 7.13

Towards Process-of-Care Aware Emergency Department Information Systems:

A Clustering Approach to Activity Views Elicitation

Andrzej S. Ceglowski
Monash University, Australia

Leonid Churilov
The University of Melbourne, Australia

ABSTRACT

The critical role of emergency departments (EDs) as the first point of contact for ill and injured patients has presented significant challenges for the elicitation of detailed process models. Patient complexity has limited the ability of ED information systems (EDIS) in prediction of patient treatment and patient movement. This article formulates a novel approach to building EDIS Activity Views that paves the way for EDIS that can predict patient workflow. The resulting Activity View pertains to "what is being done," rather than "what experts think is being done." The approach is based on analysis of data that is routinely recorded during patient treatment. The practical significance of the proposed approach is clinically acceptable, verifiable, and statistically valid process-oriented clusters of ED activities that can be used for targeted process elicitation, thus informing the design of EDIS. Its theoretical significance is in providing the new "middle ground" between existing "soft" and "computational" process elicitation methods.

INTRODUCTION

Information system (IS) design principles call for requirements definition as an intermediate stage in the design and development of IS (Mertins, Bernus, & Schmidt, 1998). The requirements definition is a document that outlines all the needs that users require of the prospective system. The requirements definition is designed to allow for the translation of the physical needs of a process into an automated environment. Programmers should be able to work from this document without going back to the users for clarification. The requirements definition can thus "be compared to a schematic of a plan or a diagram of how a technical device works" (Langer, 2008).

The requirements definition commonly takes the organisation from a functional view of activities (who, in which department, does what) to a process-oriented view of operations (what happens, when, and where). This shift from functional data structuring to process event recording is best described in process models. Process models are formalised representations of the activities enacted by a human or a machine that are considered important to the achievement of the objective of the process (Dumas, van der Aalst, & ter Hofstede, 2005). The process models provide a structured framework for IS specification and design, one example is ARIS, a widely used reference architecture and methodology (Scheer, 1999), and allow configuration of the IS to support or control the flow of work in the operational process (Rozinat & van der Aalst, 2008). Comprehensive process models combine different views (Poulymenopoulou, Malamateniou, & Vassilacopoulos, 2003; Seltsikas, 2001) that describe:

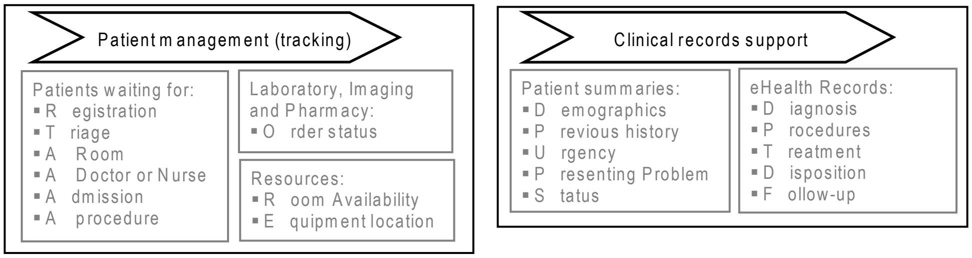
1. what activities are being performed within a process and their interactions (an activity view);
2. what data are relevant as inputs to, or outputs from these activities (data and output views);
3. who performs each activity and where it is performed (an organisational or resource view); and
4. when and how the process activities are being performed (a control view).

Information systems designed for hospital emergency departments (ED), also known as emergency rooms (ER) or accident and emergency departments (A&E), are commonly called emergency department information systems (EDIS). EDIS as they exist today mainly address two aspects of ED operations: (i) providing for tracking of patients and (ii) making patient information available to clinicians and administrators (Figure 1).

The first function, having patient information available online, promotes efficiency of operations through enhanced data entry capabilities, transferability between hospital departments and locations, and potential for bedside update of patient records. Electronic health records have wide reaching implications for EDIS design that are being addressed through various electronic health record initiatives (e.g., OpenEHR in Australia; GEHR in Europe; and HL7 in the USA).

The second function of existing EDIS relates to patient flow management. Most systems provide a list of patients awaiting treatment along with presenting problem, urgency, and disposition. This allows clinicians to select patients for treatment and to see when test results are available. Many systems can provide tracking while patients are in the ED. Patient tracking is passive with the system

Figure 1. Current EDIS deal with patient management retrospectively. There is an absence of information about the pathways future treatment might take and likelihood of patient admission.



reporting the location of patients in an effort to assist with efficient use of resources.

Unfortunately, existing EDIS do not have predictive functions. This limits their capacity to provide prediction of workflow (where patients will go next) and optimisation of throughput (by minimising queues within the system) and resource use (by making sure that resources are aware of the impending need). In this article, we argue that existing EDIS are unable to provide such benefits because every workflow is instantiated with every patient presentation (or "instance"). By this, we mean that the EDIS sees every patient presentation as a unique instance that will follow an undefined sequence of activities and use unknown resources—there are no "template" processes programmed into the EDIS that might be followed, even if the treatment is highly reproducible. In making EDIS "process aware," the system is able to apply process templates to patients and so is capable of predicting the pathway that a patient might follow through the ED, what resources might be required, and what the overall state of the ED might be at any time. Process awareness does not imply only that the system designers considered processes when they specified the system requirements, but rather that the systems allow for explicit definition of the process logic, execution, and monitoring.

If EDIS are going to progress beyond the limitations of existing systems, then work flows need to be defined so that patient instances can be linked to specific treatments. Once this is achieved, it will be possible to build higher level understanding of ED operations. This understanding will allow decision support functions such as prediction of resource need, optimisation of bed use, and warning of impending blockage.

The principles of IS design described in the opening paragraphs clearly indicated that the ability to logically represent the groups of activities that occur in the course of patient treatment within ED through a clear and comprehensive *activity view* constitutes a necessary (although not sufficient) condition for moving EDIS to a process aware basis.

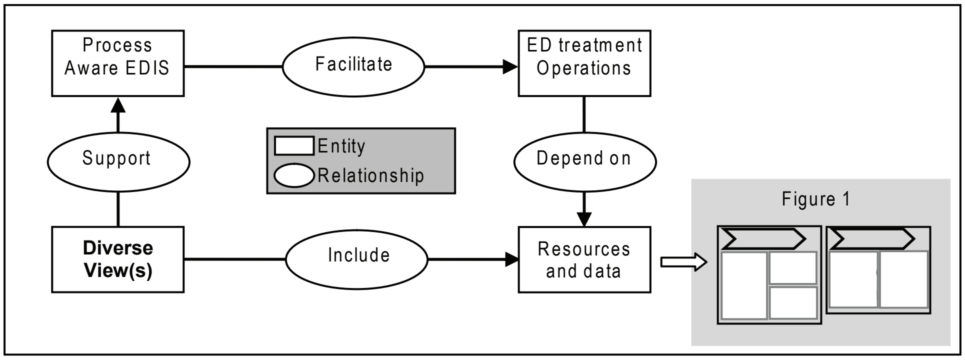
The *objective* of this article is to: (i) describe an activity view that supports the requirements definition of process aware systems and (ii) provide a method for the development of this activity view.

The search for clusters of activities within existing ED patient data records represents a new middle ground between "soft" (or ethnographic) methods for the elicitation of process models (Bustard, Oakes, & He, 1999) and "hard" methods such as workflow (or process) mining (Business Process Management Center, 2003) that arrive directly at process models from data analysis. The article's contribution to practice lies in the potential to design process aware EDIS since the activity view developed in this article fits with standard IS design methodologies. The formulation in this article of an activity view for EDIS design is new because of the lack of existing of comprehensive process models for patient treatment in EDs (Djorhan & Churilov, 2003).

Background: Context and Motivation for Process Aware EDIS

EDIS focus on patient management and data retrieval and storage (Amouh, Gemo, Macq, et al., 2005). Patient management aspects of EDIS have functions that prioritise patients according to their urgency, allocate beds and rooms, and register occurrence of key events such as nurse and doctor assessments and patient departure. EDIS data management revolves around the transport and storage of electronic patient records and the ordering and reporting of pathology tests and imaging investigations. Supplementary hardware such as wireless devices can track patients and enhance the gathering of data for both patient and data management (Amouh et al., 2005). The systems do not forecast patient flow and resource use, nor do they facilitate exchange of information with outside organisations. EDIS functionality

Figure 2. Process aware EDIS are supported by diverse views: organisational, data, control, activity and output views. Existing EDIS tend to be derived solely from listings organisational (resource) and data views and so are only able to encompass a part of ED operations.



supports resource allocation and patient selection for treatment based on priority (Aronsky, Jones, Lanaghan et al., 2007, gives an example of this), but it fails to coordinate patient movement and patient treatment (for instance, there is no tracking of patients sent for X-rays, estimation of the time they will take at the X-ray location, nor booking of space at the next resource, such as the plaster cast room, that they might require once their X-rays have been assessed.).

An extreme view of an “ideal” process aware EDIS would be one that is able to incorporate every step in patient care in which human hand-offs are automated, each step in patient treatment automatically logged and tracked, and timing and sequencing of steps analysed for performance evaluation. Human interactions with networked electronic devices such as personal computers, CT scanners, lab systems, telephones, IV pumps, and wireless patient tracking tags would be linked to the EDIS for automation of process control. Order entering by physicians, bar-coding of medication by nurses, patient registration by clerks, and surgery scheduling for surgeons should be linked and coordinated automatically. Overall, the EDIS should be able to sequence, monitor, track, alert, and reroute any step in each of the patient care processes (Rucker, 2003).

This extreme view, while attractive to proponents of workflow systems (systems that automatically direct work throughout a process), is unlikely to be achieved in the real world. The ED environment is simply too complex, too many decisions need to be made by clinicians based on patient observations that are impossible to include in any IS, and patient variation is too vast to be included in a single configurable workflow. However, this extreme view can guide thinking towards EDIS that support real processes and provide avenues for decision support while remaining sufficiently flexible to sustain the unique treatment needs of individual patients. This is impossible without understanding the interaction of activities involved in the processes, as depicted in the explicit process aware EDIS/activity view relationship presented in Figure 2.

Thus, *the research problem* addressed in this article is to how to elicit an activities view for an EDIS. The following sections will discuss (i) the methods available for elicitation of activity views and (ii) the work that has been done to group ED treatment processes.

THE ELICITATION OF ACTIVITY VIEWS AND VIEWS OF ED ACTIVITIES

Activity View Elicitation

The most common way in which activities are elicited is through interviews with experts and people who perform the work (Earl, 1994; Kotonya & Sommerville, 1998; Weerakkody & Currie, 2003). This is frequently termed an *ethnographic approach* (Schuler & Namioka, 1993). As a technique for building the Activity View, it is prone to subjective views of the work that may be distorted according to social dynamics unrelated to the work (Rennecker, 2004) and may encounter situations where the interviewees are unable to provide generalized pictures of the work (Gospodarevskaya, Churilov, & Wallace, 2005). EDs appear to fall into the latter class.

Process mining (van der Aalst et al., 2003) is a purely computational technique that is able to extract feasible "as is" process models directly from workflow data without resorting to interviews. It has its roots in a data mining idea that associations between variables in a relation can be counted and granted some level of confidence (Agrawal, Imielinski, & Swami, 1993). Combination of this concept with inference algorithms (Angluin & Smith, 1983) provided a way in which time-series data could be mined (Cook & Wolf, 1998) to retrospectively build a picture of sequences of events in software (Agrawal, Gunopulos, & Leymann, 1998). This idea has been extended so that the branches, loops, and joins common in most processes may be inferred from event logs (de Medeiros, van der Aalst, & Weijters, 2003).

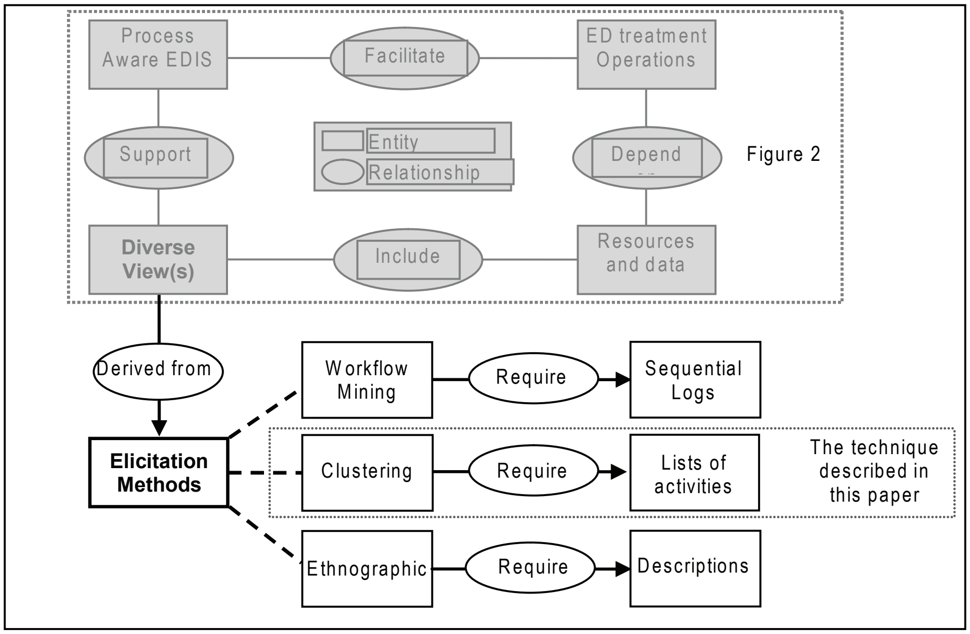
Process mining requires access to a log that records the sequence of defined tasks in workflow for a large number of cases. Such data is readily accessible for most work that takes place within or on computer systems, as evidenced by business activity management software tools for the analysis of logged data such as ARIS-Process Performance Manager (IDS-Scheer, 2004). Process mining provides an excellent solution to process elucidation in situations where workflow is fully automated ("mature" information system applications) but little process elicitation help is available for less mature "case handling" applications where process is undefined or much of the work is performed by an expert who initiates activities based on the particulars of each job (van der Aalst et al., 2003).

Detailed event logs are seldom available for activities that take place outside computer systems. Fortunately, "computer external" activities are often logged in databases for billing and other purposes. Such information may be captured in batches after the activities have been completed but lack information about sequence or timing of events. The existence of these nonsequential "activity logs" provides an avenue for the identification of patterns of activity. Activity logs of this sort are commonly associated with ill-defined processes where experts make complex decisions while performing the work (such as hospital EDs). The binary "event" logs do not have the detail necessary for process mining and the mere volume of data is likely to make the logs inscrutable to traditional data analysis techniques (past efforts in this regard are discussed in the next section), but they do provide an avenue for the identification of patterns of activity if non-traditional methods are used. The use of these logs in clustering of activities falls between the "soft" ethnographic and "hard" process mining that were introduced above (depicted in Figure 3). The clustering "compromise" approach will be described later in this article, but it is first necessary to describe existing views of ED activities in order show to current understanding of ED processes.

Existing Views of ED Activities

There are well over a thousand diagnoses listed in the Victorian Emergency Data Set guidelines

Figure 3. An extension of Figure 2, showing that elicitation is achieved through social and technical elicitation extremes. The middle ground is explored in this paper.



(2007), and many other governments have a similar proliferation of diagnoses. It is not feasible to incorporate separate activity views for every one of these diagnoses in a requirements definition because this will probably lead to a situation where overhead costs for the control systems surpass the benefit of efficient coordination of every variant (Becker, Kugeler, & Rosemann, 2003). Simplification is necessary to reduce the large number of diagnoses and permutations of treatment to a number suitable for cost effective implementation in an IS. Some grouping of the activities involved in patient treatment is needed in order to reduce the complexity of the requirements definition. Without this grouping, it is difficult to conceive systems that can indicate what the next step in patient care may be, where it should take place, and who should be responsible for it.

Groupings and simplifications have been attempted many times in the past. Analysts have used output data such as "the time treatment takes," and input data such as "the complexity of presentation" to group patients (for example, Hoffenberg, Hill, & Houry, 2001; Walley, 2003). These approaches address the activities related to patient movement (whether patients are likely to be admitted to hospital or not, or whether they may be treated in a chair, rather than a bed, for example) but not the detailed activities involved in patient treatment.

Patient movements have been analysed in simulation studies (Brailsford, Churilov, & Liew, 2003; Mahapatra, Koelling, Patvivatsiri et al., 2003; Sinreich & Marmor, 2004), but the models, in keeping with the philosophy of discrete event simulation, tend to imitate the physical movement of patients through the ED, rather than the treatment provided to patients. The studies result in recommendations on how to reduce wait or facilitate throughput but they fail to provide insight into the management of patients in accord with their treatment requirements.

Clinicians have tried to get a simplified picture of ED operations by grouping patient "cases," characteristically according to combinations of age, urgency of complaint, diagnosis, time in

ED, and outcome of visit linked to cost (Bond, Baggoley, Erwich-Nijhout et al., 1998; Cameron, Baraff, & Sekhon, 1990; Jelinek, 1995). These clinical classification schemes have failed to group patients by similarity of treatment because they have used the use of cost as an objective function. Low and high cost attributes trade off, so dissimilar patients end up in similar groups.

Clinical guidelines (Clinical Pathways) exist that detail every aspect of patient treatment and act as checklists for common chronic ailments (for example, the Action plan for anaphylaxis available at http://www.medicalobserver.com.au/clinicalguidelines. Porter, Cai, Gribbons et al. (2004) provide an example of decision support for a single treatment). Clinical Pathways provide a notion of a sequence of prescribed activities involved in patient treatment that would be ideal for a process aware EDIS. Unfortunately, they only cover a small number of narrow treatments so they do not provide the variety of ED treatments that would need to be included for predictive decision support. A different approach is needed to unravel the complexity of patient treatment in EDs. Such an approach is described in the following sections.

METHOD DESCRIPTION: FROM CLINICAL PROCEDURES TO AN ACTIVITY VIEW FOR A PROCESS AWARE EDIS

Mertins et al. (1998) suggest that it is possible to build information systems from a subset of the organisational, data, control, activity, and output views (defined as aspects of process models in the Introduction). This approach is apparent in the design of most existing EDIS, where the data and organisational views are well represented (for exampl, the linking of Figure 1 to the resources and data component in Figure 2), but the activity view is less well represented or not present at all (Rucker, 2003). The resulting EDIS' cannot be process aware because treatment activities have not been functionally related in the activity view, treatment objectives are not available for the processes, and supporting applications (bedside monitoring, for instance) cannot be integrated into the process. Elucidation of the activity view is necessary to allow coordination of the resources, communication, and technology associated with treatment.

Since the activity view is, in its simplest form, a collection of objects such as activities, objectives, and software applications, clinical procedures that are manually recorded (as described at the end of the previous section) may be used to provide a library of activities. Even though there is a wide range of patients and presentations, much of the patient treatment related work in EDs is based on application of a short list of medical procedures such as patient observation, administration of drugs, and laboratory and imaging investigations. Just 62 procedures are used for reporting ED treatment in Victoria, Australia (Metropolitan Health and Aged Care Services Division of the Victorian State Government, 2007). Thirty six procedures account for 99% of all procedures in Victorian hospitals. Almost 17% are classed as "Other," which includes observation of patients by medical staff; 6% are "No procedures"; some 10% are drug administrationl; and over 9% X-ray imaging. Other significant procedures are venipuncture, intravenous catheter access in preparation for infusion of fluid or drugs, and echocardiogram diagnostics (figures derived from Victorian Emergency Medical database for 2002).

An activity view that simply lists all these procedures would result in processes models based on a vast number of possible permutations of causal linkages between all procedures. Individual procedures could have associated objectives but it would be difficult to understand how the objectives were related to each other. Some form of simplification is necessary to advance the activity view beyond this primitive.

The grouping of procedures into treatment specific clusters is a way of providing this simplification—procedures are logically linked as activities within treatments. While the grouping of activities in this way does not provide a true process view (the activities are not sequenced), it significantly reduces the number of permutations in order to provide a simplified view of ED operations. It is this simplified view that has eluded designers of ED information systems up to now. Each group of activities, or treatment cluster, may be scrutinised to determine the most likely (or most desirable) sequence of activities.

The grouping of procedures for this activity view may be achieved through nonparametric clustering. One nonparametric technique is self organising mapping (SOM) (Kohonen, 1995). The SOM is a grouping technique that is algorithm driven and relies on data rather than domain-specific expertise. The objectives of the technique are to minimise diversity within groups and to maximise differences between groups. The technique generally employs large datasets, works well with many input variables, and produces arbitrarily complex models unlimited by human comprehension (Kennedy, Lee, Van Roy et al., 1998).

Self organising maps provide a visual understanding of patterns in data through a two dimensional representation of all variables. Records that have similar characteristics are adjacent in the map, and dissimilar records are situated at a distance determined by degree of dissimilarity. Viscovery SOMine, the software tool used in this analysis, employs a variant of Kohonen's Batch-SOM (Kohonen, 1995), enhanced with a scaling technique for speeding up the learning process (Eudaptics Software Gmbh, 1999).

The concept of providing a simplified activity view of treatment through the grouping of procedures is illustrated in the next section.

VALIDATION THROUGH EXAMPLE: CLUSTERING CLINICAL PROCEDURES TO BUILD AN ACTIVITY VIEW

Victorian Emergency Medical Data (VEMD) made up of de-identified records of all ED presentations across 31 anonymous hospital campuses was obtained and five similar-sized campuses (by number of records) were selected for analysis and comparison. Each record contained demographic particulars and details of the visit such as "apparent severity of complaint," "key time points," and "disposition," plus all medical procedures performed, but cost data was not available.

All cases where patients underwent more than one procedure were included for analysis. This was generally around 60% of all patient presentations. The 13 least-used procedures were omitted from the analyses, as was the "NONE" procedure. These exclusions totalled less than 1% of procedures in cases where patients had more than one procedure. Random samples of approximately 10,000 cases having Departure Status "Discharged home" were extracted. Where there were less than 10,000 cases with this departure status at a campus, all cases were included for analysis.

The data was saved into a tab delimited format. Each record had 50 fields—a record identifier and 49 procedures coded as "0" for "not performed" to 1,2,3...16 for repeated applications. The procedure data was sparse, but the number of records gave some assurance that patterns of recurring groups of procedures could be found. Self organising mapping was applied to the data using the same clustering settings. These settings included:

- The initial map height that gave the initial number of vertical nodes in the two dimensional representation of the data (the number of horizontal nodes was automatically set from the map ratio);

- A scaling factor that specified the increase in horizontal number of nodes as the clustering algorithm progressed through each growth step (the vertical number of nodes was adjusted according to the desired map ratio);
- The influence radius of the neighbourhood interaction of the intermediate maps (the reach of the Gaussian neighbourhood function). A high intermediate tension "averages" the data distribution, while a low tension allows adaptation to display finer features.
- The number of iterations and the Wegstein factor (a convergence parameter in the batch SOM algorithm comparable to the momentum factor as it is commonly used in supervised neural network algorithms).

Between 13 and 27 clusters were identified across the five data sets. The clusters were validated through a range of internal measures of cluster quality. These measures were analogous to traditional indicators of cluster quality such as the Rand Statistic, Jaccard Coefficient, and the Folkes and Mallows Index; however, they operated on two dimensions, rather than the single figure of the traditional measures. Maps that displayed the frequency of records across two dimensional cluster space, the quantisation error, the proximity of nodes to neighbours, and curvature of the map through n-dimensional space were scrutinised to ensure that the spread of clusters was even, the clustering error within reasonable limits, and the cluster shapes regular.

This clustering of procedures into prototype "workflows" was verified through discussions with a specialist in emergency medicine and found to be clinically sensible. It was concluded that the clusters reflected "as is" core ED treatments. Similar sets of procedures were apparent in clusters across campuses. Typical prototype workflows that were common across multiple campuses are (figures in brackets indicate likelihood of procedure):

- 12 Lead ECG (1.0), with Peripheral IV catheter and Venipuncture (0.6);
- 12 Lead ECG and ECG monitoring (1.0), with Venipuncture (0.9);
- Peripheral IV catheter and IV drug infusion (1.0), with Venipuncture (0.7);
- Suture, Steri-strip, glue (1.0) with Dressing (between 0.6 and 0.9);
- Plaster of Paris (1.0) and X-ray (0.9) with Drug administration (around 0.5);
- Splint (1.0), X-Ray (0.8) with Drug administration (between 0.2 and 0.6);

These clusters each comprise between 2% and 9% of patients and add up to between 20% and 30% of patients. In addition to these widespread clusters, there are typically two to three large clusters at each campus that provide for some 25% of presentations. These large clusters often include drug administration, venipuncture and full ward test (urine) or 12 Lead ECG, but the proportions differ between campuses. It is important to note that these clusters represent "core treatment" activities within the EDs. These treatments employ resources most frequently

The truncated example in Table 1 indicates that the patient was likely to be experiencing breathing difficulties (possibly an asthma attack) and might have been classed as urgent or nonurgent (note that this is in direct contrast to previous studies, which have segmented patients by urgency—a patient movement, rather than patient treatment orientation). Nebulised medication was provided to all patients. This treatment was supported with X-rays, drugs, venipuncture, electrocardiogram, peripheral intravenous catheter, and full ward tests. Two campuses also indicated that intravenous injections were commonly recorded in this group. The numbers in Table 1 may be considered to represent the likelihood between 0 and 1 of patients in that cluster undergoing the procedure.

In the example given in Table 2, it can be seen that there is much agreement across campuses re-

Table 1. Nebulised medication procedures across three hospital campuses, A, B, and C

	Campus	**A**	**B**	**C**
Procedure Description	% Patients	2.9%	2.4%	3.6%
Nebulised Medication	NEB	1.00	1.00	1.00
X-ray	XRAY	0.43	0.26	0.47
Oral/ sublingual/ topical/ rectal drug administration	DRUG	0.81	0.89	0.80
Venipuncture	VB	0.28	0.21	0.29
12 Lead ECG	ECG	0.16	0.14	0.15
Peripheral intravenous catheter (IV access)	IV	0.28	0.22	0.24
Full ward test - urine	FWT	0.06	0.09	0.06
Intravenous infusion	IVS	0.13		0.12

garding the reporting of "head injury observation" (HIO), despite the varying percentage of patients (second column of the table). The campus in the last row displays anomalous random blood glucose (RBG) and Spirometry (SPR) that may indicate different patient and treatment profiles.

Similar studies were carried out for admitted as well as discharged patients and core treatments identified that overlapped the above and expanded to reflect the treatment accorded to patients who were later admitted to hospital. The studies were reinforced with text mining exercises that compared patient reason for presentation with their treatment and through simulation of treatment activities. It was also found that the nonexclusive nature of the core treatments (i.e., one procedure might be used in multiple core treatments) that arose for the clustering technique made the technique far superior (in defining treatments that were clinically realistic) to other methods that were attempted such as association mining and CART.

This section set out to describe the realisation of the idea that a simplified activities view could be developed if procedures involved in patient treatment were clustered into process-oriented groups. Distinct clusters of procedures were identified in the treatment of patients at a number of EDs. The grouping was validated and verified and considered a reasonable "as is" simplification of ED activities into core treatments (Ceglowski, Churilov, & Wassertheil, 2007, describes simulation of ED operations based on treatment clusters). The implications of these findings are discussed in the next section.

DISCUSSION: HOW CLUSTERED ACTIVITIES SUPPORT SYSTEMS DESIGN

In providing core treatments, the previous section has expanded the simple activity view of individual procedures to one with grouped procedures in a handful of frequently applied core treatments. The simplification reduced the number of objects from 62 procedures to around 20 core treatments. This reduction in complexity facilitates the association of activities with other aspects of the activities view such as process goals because each core treatment represents a process-oriented class of treatment.

The primary benefit of identifying prototype workflows and linking them to patient attributes has been the potential for predictive decision support. Certain core treatments take longer than others take and have a higher rate of hospital admission associated with them. When many patients requiring such long duration treatments reside in the ED concurrently, then throughput slows and

Table 2. Head injury observation across five campuses

Campus	% Patients	HIO	XRAY	IV	IVI	VB	DRS	SUT	ECG	FWT	INF	DRUG	CT	IVS	RBG	SPR
A	2.3%	1.0	0.4	0.5	0.0	0.4	0.1	0.1	0.3	0.2	0.2	0.5	0.1	0.3	0.2	0.0
B	0.9%	1.0	0.4	0.4	0.1	0.3	0.2	0.2	0.1	0.3	0.1	0.5	0.1	0.2	0.1	0.0
C	4.2%	1.0	0.5	0.4	0.0	0.5	0.1	0.0	0.4	0.1	0.2	0.6	0.2	0.2	0.0	0.0
D	3.4%	1.0	0.3	0.1	0.2	0.2	0.1	0.1	0.1	0.1	0.0	0.0	0.0	0.0	0.0	0.0
E	0.6%	1.0	0.4	0.3	0.0	0.4	0.2	0.1	0.3	0.3	0.1	0.4	0.2	0.1	0.5	0.5

Key: HIO = Head Injury Observation; XRAY = X-ray examination; IV = Peripheral intravenous catheter; IVI =IV drug infusion; VB = Venipuncture; DRS = Dressing; SUT = Suture, sterstrip, glue; ECG = 12 lead Electrocardiogram; FWT = Full Ward Test of urine; INF = Infusion of fluid (not blood); DRUG = Oral, sublingual, topical, rectal drug administration; CT = Computerised tomography scan; IVS = Intravenous drip; RBG = Test of Random Blood Glucose; SPR = Spirometry

the ED becomes prone to blockage—regardless of its capacity. By linking patient presentation to core treatments and the time they take, it is possible to update prediction of potential blockage as each new patient presents at the ED.

An extension of this high level prediction is the potential for prediction of future workflow requirements. Having patient presentation linked to their most likely future treatment allows their future workflow to be mapped and planned for, so handoffs can be identified, responsibilities indicated, and resources specified. In this way the organisational, data, and output views may be linked to core treatments.

The core treatments add knowledge about common treatment activities that can be further explored using various techniques, such as ethnographic studies or additional data investigations. The control view can be structured once sequencing and mapping of cause-effect linkages has been done (possibly through expert clinical input) because the roles and responsibilities may be identified and linked to each activity within the treatment. This moves EDIS towards process aware systems that can not only coordinate patient treatment and movement, but predict them, too.

The clustering technique may further be extended through use of techniques such as association mining to provide more detailed segmentations of the groups and better understanding of the business rules, especially if the data is linked to attributes such as urgency, age, and whether the patient was admitted or not. The insights provided by such investigations give rise to another, more refined, activity view where patient attributes may be causally linked to treatment activities, making prediction of patient routings feasible.

CONCLUSION

This article indicated that existing EDIS suffer from inadequate understanding of patient treatment processes that manifest as EDIS that are unable to predict future patient treatment and patient movement needs. It was noted that development of an activities view would assist movement towards process aware, predictive EDIS. A suggestion was made that clinical procedures recorded for other purposes could be used to populate the activity view, but simplification was necessary in order to reduce the number of possible process models that could be deduced. A method for simplification was described that resulted in procedures being grouped in clinically acceptable core treatments that covered 99% of ED treatment operations.

The utility of these core treatments in providing an activity view was discussed.

This article has described a route to take existing EDIS (which deal primarily with the management of historic data such as patient records and the queue of patients awaiting treatment) to event-based systems that can "look forward" to predict what pathways patients might take through the ED. EDIS that are capable of managing workflows (predicting the work to be performed at each successive stage of treatment) facilitate:

- Logistics management, by "booking" resources for when patients will need them;
- Predictive reporting, by linking presentation problem and severity with likely length of stay, probably treatment, and whether a patient might be admitted to a ward; and
- Management decision support, through the ability to assimilate the status of patients in the ED with the new presentations awaiting treatment.

Clustering represents an additional tool in the elicitation of process models for EDIS design. It is one that is not limited in breadth in the way that ethnographic studies often have to be—all history (as it exists) can be included in the analysis. Nor does clustering have the requirement of workflow mining that detailed logs exist—simple activity records will suffice to provide a working activities view to supplement existing organisational, data, and input views for EDIS design. Transforming such a supplementation into a truly integrated process aware EDIS design presents a challenging direction for future research.

Chapter 7.14

Predicting Voluntary Participation in a Public Health Program Using a Neural Network

George E. Heilman
Winston-Salem State University, USA

Monica Cain

Russell S. Morton
Winston-Salem State University, USA

ABSTRACT

Researchers increasingly use Artificial Neural Networks (ANNs) to predict outcomes across a broad range of applications. They frequently find the predictive power of ANNs to be as good as or better than conventional discrete choice models. This article demonstrates the use of an ANN to model a consumer's choice to participate in North Carolina's Maternity Care Coordination (MCC) program, a state sponsored voluntary public health service initiative. Maternal and infant Medicaid claims data and birth certificate data were collected for 59,999 births in North Carolina during the years 2000-2002. Part of this sample was used to train and test an ANN that predicts voluntary enrollment in MCC. When tested against a hold-out production sample, the ANN model correctly predicted 99.69% of those choosing to participate and 100% of those choosing not to participate in the MCC program.

INTRODUCTION

Information technology (IT) plays a pervasive role throughout the health care industry. In addition to providing the data storage and data processing capabilities needed to support the business management, customer relations management, human resource management and office automations requirements of health care organizations, IT also is used increasingly to support decision making functions.

Most decision support methodologies rely on the mathematical modeling of historical data. Many of these systems, such as the widely accepted Acute Physiology and Chronic Health Evaluation (APACHE) system, are based on binary LOGIT regression estimations or other statistical analysis techniques. This type of modeling requires the specification of *a priori* functional relationships between dependent and independent variables based on assumptions such as correct model specification, error-free measurement of independent variables, and normally distributed, heteroscedastistic, independent, zero-mean residuals. It is more likely, however, that health care decisions will depend on a variety of factors involving complex, hidden interrelationships of both socio-demographic and health related characteristics.

To address issues of nonlinearity and complex relationships in study data, many modelers have turned to other methods of analysis that fall under the broader categorization of "artificial intelligence" (AI). AI, which attempts to give computers human-like reasoning capabilities, includes techniques such at expert systems, fuzzy systems, genetic algorithms, case-based reasoning and a variety of classifier systems like the Artificial Neural Network (ANN) used in this study.

Because of advantages like ease of optimization, prediction accuracy, easy knowledge dissemination, workload reduction and decision support, Artificial Neural Networks have been widely accepted and used for more than a decade in the health care arena (Lisboa & Taktak, 2006). When used in medical applications, ANNs are known to provide decision support assistance that can produce highly accurate results (Kaur & Wasan, 2006). Several studies show ANNs offering better predictive performance than other modeling alternatives (Alkan, Koklukaya, & Subasi, 2005; Alpsan, Towsey, Ozdamar, Tsoi, & Ghista, 1995; Goss & Vozikis, 2002). Examples of medical applications of an ANN include the analysis of trauma data (Chesney et al., 2006; Eftekhar et al., 2005) and the diagnoses of cancer (Lisboa & Taktak, 2006), diabetes (Kuar & Wasan, 2006), gastrointestinal hemorrhage (Das et al., 2003), and myocardial infarction (Baxt, 1991; Baxt, Shofer, Sites, & Hllander, 2002).

While medical diagnosis is probably the most common health care application for Artificial Neural Networks, they also have been used successfully in other health care service areas. Examples include identifying individuals at risk for high medical costs (Crawford, Fuhr, Clarke, Hubbs, 2005), identifying sources of future high cost treatments within a given health plan population (Kudyba, Hamar, & Gandy, 2006), evaluating if patient debt is likely to be repaid (Zurada & Lonial, 2005), and predicting nursing staff levels (Seomun, Chang, Lee, Kim, & Park, 2006).

ANNs are generally well accepted and frequently used in the health care industry, but one sector that does not seem to have taken advantage of this technology is public health care services. While facing the expected pressures for professionalism and quality service, public health care also faces the additional burdens of budgetary restrictions and legislative oversight. As a result, public health care, like other sectors of health care, is intensifying its focus on the enhancement of operating efficiency through effective resource allocation. One way to enhance efficiency is to more accurately identify resource demands. Because Artificial Neural Networks excel at identifying relationships in historical data for purposes of classification and prediction, it follows that using an ANN to predict participation in a public health program should improve predictive capability, reduce inefficient resource allocation, and decrease variability in treatment processes (Kudyba et al., 2006). North Carolina's Maternity Care Coordination (MCC) program represents one such public health care initiative.

The Maternity Care Coordination program attempts to coordinate prenatal care for eligible Medicaid clients. MCC provides counseling, referrals, and resource assistance for women considered to be at high risk for poor birth outcomes. Participation in the program, however, is voluntary. The goal of this study is to develop an artificial neural network that can predict Medicaid women's voluntary enrollment in the MCC program.

MATERNITY CARE COORDINATION: ENHANCING PRENATAL CARE

States have attempted to address the issue of poor neonatal outcomes by incorporating comprehensive, coordinated prenatal care programs into their Medicaid plans. These prenatal care programs are enhanced beyond the scope of the traditional medical model to include services such as health education, psychosocial risk assessment, enrollment in WIC (the Special Supplemental Food Program for Women, Infants, and Children), and other types of health promotion interventions. Unfortunately, attempts to evaluate the effectiveness of comprehensive prenatal care coordination have had mixed results (Buescher, Roth, & Williams, 1991; Clarke, Miller, & Mahan, 1993; Herman & Berendes, 1996; Korenbrot, Gill, & Patterson, 1995; Nason & Alexander, 2002; Schulman, Sheriff, & Momany, 1997).

The North Carolina Maternity Care Coordination program (MCC) is an example of an early prenatal care coordination program, and is the focus of this study. MCC has the objective of reducing barriers to Medicaid clients' use of health and social services. The program is geared toward helping eligible women receive nutritional care, psychosocial counseling, and other resource assistance. For example, women in MCC are encouraged to seek eligible services such as transportation, housing assistance, and job training. Counseling may include social and emotional support, stress reduction methods, and coaching in healthy behaviors. Referral for WIC enrollment is emphasized, and most women enrolled in MCC receive nutritional counseling through WIC (Buescher & Horton, 2002).

Medicaid women who are perceived to be at very high risk for a poor birth outcome are most likely to be referred to the MCC program by their physician. Participation in MCC is, however, voluntary and thus at the discretion of the Medicaid-enrolled woman. If she chooses to participate in MCC, she will have access to expanded prenatal care; if she chooses not to participate, she will receive the standard package of care available through the state's Medicaid program.

Various observable maternal medical and socioeconomic risks may influence a pregnant woman's decision to participate in an enhanced prenatal care program and may even be the same risk factors that prompted the health care provider to recommend the program in the first place. In actuality, however, it may be the unobserved relationships among these factors that influence her final decision to participate in an enhanced prenatal care program.

A variety of complex, hidden personal factors may not be reflected in the medical or intake records. These may include health or domestic issues that the woman is not willing to reveal or able to discern. For example, a woman at higher risk for a poor birth outcome may be facing stressors in the local environment such as violence, use of alcohol or illicit drug activity in the community. These factors may influence her choice to participate, even while remaining unobserved by the health care provider. In this study we test whether neural network learning is able to model complex nonlinear patterns between the predictor variables and the choice to participate in MCC.

STUDY DATA

This study uses data developed by the North Carolina State Center for Health Statistics (SCHS) called the Composite Linked Birth File. The Composite Linked Birth File is comprised of the linkage of a unique birth certificate record to any Medicaid-paid infant claims records, MCC and

WIC enrollment records, or infant death certificate record. The data include a census of all births in the state of North Carolina in the years 2000-2002. The total number of North Carolina resident live births was 120,247 in 2000, 118,112 in 2001, and 117,307 in 2002. Among these, Medicaid-paid births based on the infant's Medicaid status numbered 49,188 in 2000, 51,720 in 2001, and 48,883 in 2002. Births to women enrolled in the Maternity Care Coordination program were 24,694 in 2000, 24,328 in 2001, and 19,637 in 2002. Thus, approximately 50 percent of North Carolina Medicaid women who delivered during the study period were enrolled in the MCC program.

The sample includes only Medicaid births to white and African-American women aged 15-45 years. Three selection criteria were established to address issues of bias in the sample selection. First, women who enrolled in the MCC program after 32 weeks gestation are not included, thereby excluding late joiners. Second, only live singleton births are included. And third, births to women who received no prenatal care are excluded. In addition to the selection criteria described above, records with missing data for any study variables are excluded. The remaining observations are 137,249 Medicaid births, including 57,635 births to women participating in the MCC program for years 2000-2002. We randomly selected 60,000 observations for use in the study's data sample.

METHODOLOGY

Predictor Variables

The state of North Carolina collects up to 300 pieces of maternal and infant information for each birth included in the Composite Linked Birth File. We selected 19 variables that previously have been identified as important in predicting if a woman is at risk for a high risk pregnancy and, therefore, more likely to participate in the MCC program (Paneth, 1995; Schwethelm, Margolis, Miller, & Smith, 1989). These predictor variables fall into three general categories: 1) location, 2) overall health, and 3) pregnancy-related health.

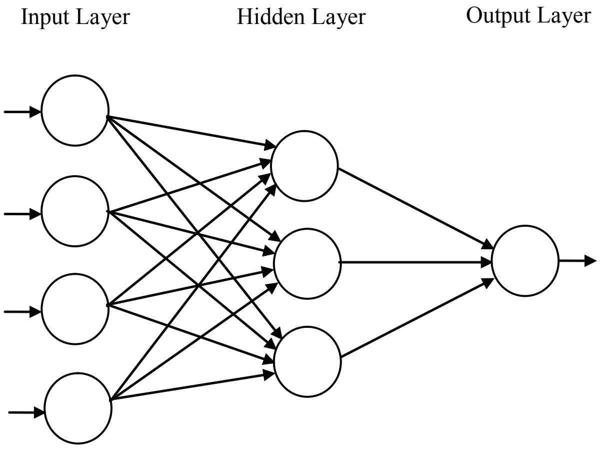
Specifically, the predictor variables include mother's zip code (MOMZIP), county of residence (COUNTY), mother's age (MOMAGE), mother's race (MOMRACE), last year of mother's schooling (MOMEDUC), marital status (MSTATUS), self-reported tobacco use (TOBACCO), self-reported alcohol use (ALCOHOL), the month prenatal care began (MMPNCBEG), presence of medical risk factor(s) (MEDRISK), and a previous death of a live newborn (PREVDETH). The input variables include several other dummy variables (0 or 1) indicating the presence of specific medical conditions such as anemia (ANEMIA), cardiac problems (CARDIAC), diabetes (DIABETES), chronic hypertension (HYPERCH), pregnancy-related hypertension (HYPERPR), eclampsia (ECLAMPSIA), preterm birth or small for gestation age in a previous pregnancy (SGA), and renal disease (RENAL). MCC is the outcome variable, where 1 indicates that the woman chooses to participate in the MCC program and 0 indicates the choice not to participate in the program.

Artificial Neural Network Model

Backpropagation network learning is a commonly used algorithm that has been proven to be a reliable tool for general classification applications (Alspan et al., 1995; Hornik, Stinchcombe, & White, 1989; Medsker & Liebowitz, 1994; White, 1990). For this study, the NeuroShell2 software package was used to define and test a three layer, feed forward, back propagation Artificial Neural Network model.

Figure 1 shows a simple propagation network of the type used in this study. In the diagram, the circles are neurons (mathematical processing units) and the lines connecting the neurons are numeric weights. The models are typically composed of: 1) a layer of input neurons, wherein each input neuron represents one predictor variable, 2)

Figure 1. Diagram of a simple propagation artificial neural network



one or more hidden layers of weighting neurons, and 3) an output layer containing a neuron for each dependent variable to be predicted. Our neural network model includes an input layer with 19 neurons, one hidden layer containing 100 neurons, and an output layer containing one neuron to predict MCC participation.

During the training phase of network development, the ANN must be trained to predict actual output values based a correctly described set of weighted connections in the input and hidden layers. In the beginning the weight values are randomly set, the input values of the first case in the training set are presented to the network's input layer, and the calculated output of each neuron is fed forward through the network until an output value is derived. Next, the computed output value is compared to the actual value of the output variable in the training case. The error value (the squared difference between actual and calculate output) is then propagated backward through the network and small adjustments are made to the weights so that, in the future, the network will come closer to calculating the correct output value. This process is repeated for each case in the training set, and the training set is processed over and over while the weights are continually tweaked.

Periodically, a holdout (test) set of cases is run against the network to determine if the predictive power of the network is still improving. The network will never learn an exact predictive function, but it will slowly approach one. The purpose of the test set is to make sure that the network is not over trained in recognizing relationships within its training set at the expense of loosing its predictive power with new data.

The original sample used in this study consisted of 60,000 observations. This number is a limitation of the NeuroShell2 software. After the sample was selected one observation was found to have a 4-digit zip code and was dropped, leaving a total of 59,999 observations. Table 1 presents the descriptive statistics for the variables used in the analysis.

Seventy percent (70%) of the observations (42,000 patterns) were used to train the network and twenty percent (20%) of the observations (12,000 patterns) were used as a test set to evaluate model training. Ten percent (10%) of the observations (5,999 patterns) were used as a production set to validate the trained model. The neural network software randomly selected the observations for each of these three data sets.

Training continued through 35 epochs of the training set. The model's weights were evaluated against the test set every 200 events. After 62,000

Table 1. Descriptive statistics for variables

Variable	Min. Value	Max. Value	Mean	Std.Dev.
Zip Code	22717	65109		
County	0	100		
Mother's age	15	45	23.57821	5.350374
Mother's Race 1= white 2= African American	1	2	1.361606	0.480470
Mother's years of schooling	0	16	11.42652	5.421363
Marital Status 1=married 2= single	1	2	1.600160	0.489869
TOBACCO 1=yes 2 = no	1	2	1.793197	0.527171
ALCOHOL 1=yes 2 = no	1	2	1.867	0.347672
Dummy Variables 0=no; 1=yes				
MMPNCBEG	0	9	2.808147	1.577052
MEDRISK	0	1	0.123819	0.329377
PREVDETH	0	1	0.018384	0.134335
ANEMIA	0	1	0.027617	0.163875
CARDIAC	0	1	0.003533	0.059338
DIABETES	0	1	0.024734	0.155314
HYPERCH	0	1	0.008467	0.091626
HYPERPR	0	1	0.050718	0.219422
ECLAMPSI	0	1	0.004917	0.069948

RENAL	0	1	0.003217	0.056625
MCC	0	1	0.429857	0.495060

events had been processed with no changes to the weight structure, training was stopped. Finally, the production set was processed through the trained model to produce the network's predictions for each pattern in the production file.

RESULTS

NeuroShell2 provides a number of statistical tools to assess the predictive ability of the network model. Table 2 presents a summary of their values. Following the table is a narrative description of the statistics.

The coefficient of multiple determination, R^2, compares the accuracy of the model to a

Table 2. Production set assessment statistics

Output	5999 patterns processed
R2	0.9917
correlation coefficient r	0.9960
r2	0.9920
Mean Squared Error	0.002
Mean Absolute Error	0.012
Min. Absolute Error	0
Max. Absolute Error	0.846
Percent within 5%	41.357
Percent within 5% to 10%	0.100
Percent within 10% to 20%	0.017
Percent within 20% to 30%	0.183
Percent over 30%	0.783

benchmark model consisting of the mean of all the samples. An R^2 value of 1 indicates a perfect fit, near 1 indicates a very good fit, and near or below zero indicates a very poor fit.

The square of the correlation coefficient, r^2, provides a measure of the strength of the relationship between the actual and predicted outputs. An r^2 closer to 1 indicates a strong linear relationship, while an r2 closer to 0 indicates no linear relationship.

Min Absolute Error is the minimum absolute value of (actual - predicted) for all patterns in the production set. Max Absolute Error is the maximum absolute value of (actual - predicted) for all patterns. Mean Absolute Error is the mean of the absolute value of (actual - predicted) for all patterns. Mean Squared Error is the mean of $(\text{actual - predicted})^2$ for all patterns.

NeuroShell2 also lists the percent of network predictions that differ from the actual answers within a range of specified percentages. When an actual answer is 0, a percentage difference cannot be calculated. As a result, the total computed percentages may not total 100%.

The 5999 patterns in the production set included observations for 3453 women who rejected participation in MCC and 2545 women who chose to participate in MCC. The model correctly predicted all 3453 nonparticipants (100%) and 2537 of 2545 participants (99.69%).

CONCLUSION

States face increasing pressure to limit growth in their Medicaid budgets while still meeting the health care needs of vulnerable populations. Thus, predicting the number of eligible recipients of public health care services becomes a significant challenge for program managers, especially when participation is voluntary. To meet this challenge, the use of predictive models has become much more important in an ever-widening variety of public health programs. Conventional prediction methods, which excel at identifying causal effects and linear relationships among variables, require *a priori* model specification and may not be able to detect underlying complex relationships among predictor variables. When prediction accuracy is more important than assessing causal effects, Artificial Neural Networks offer the user a powerful prediction tool without the need to understand all the subtle relationships that may exist within the target population. Additionally, significant advances in computer hardware and software technology have made Artificial Neural Networks an increasingly powerful, available, affordable, useful and user-friendly tool. Public health care resource allocation and planning can be greatly enhanced by the predictive power of ANNs, particularly in terms of voluntary program participation.

This study develops an Artificial Neural Network to predict voluntary enrollment by Medicaid women in North Carolina's Maternity Care Coordination (MCC) program for enhanced prenatal care. Observations from 59,999 randomly selected Medicaid births from the years 2000-2002 were used in the development and testing of the ANN. The model contained 19 predictor variables related to location, overall health, and pregnancy-related health to predict voluntary participation in the enhanced prenatal care program. The model correctly predicted the mother's choice to participate in MCC over 99% of the time.

Using the superior predictive power of Neural Networks, managers can make better funding, staffing, and other resource allocation decisions based on timely, correct predictions of program participation. Neural Network models can be updated as new information is obtained and retrained to recognize new relationships among predictor variables that may result from evolving changes in participant characteristics or program modifications.

This research path may be extended in many directions. Because so little research has been published on the use of Artificial Neural Networks in the prediction of voluntary participation in public health care programs, one obvious extension is to expand the study of ANNs in the prediction of voluntary participation in other types of health care programs. Other extensions of the study could also be made to predict voluntary program participation in other areas outside of health services, such as education, child care, utility subsidies, and transportation.

Chapter 7.15

An Exploration of Demographic Inconsistencies in Healthcare Information Environments

Larbi Esmahi

INTRODUCTION

Healthcare providers typically use technology in a ubiquitous manner. They choose to rely upon the task-specific capabilities of a specific system, rather than the integration of all systems in the solution space. A typical example of this would be the advancement of ultrasound technologies for 3-D modeling. Whilst the capabilities of the imaging solutions are highly beneficial to the individual's unique needs for healthcare, the integration of this system into a greater solution, or system-of-systems, is often overlooked (Maier, 1998; Maier, 2005). As such, the demographic data accompanying the information may be in a format inconsistent with the requirements for the electronic medical record. Workflow Management Systems attempt to simplify and control the primary data entry methods to the data environment (Choennia, Bakkera, & Baetsa, 2003; Graeber, 1997). However, the design of these systems focuses on an interpretation layer to gather data from varying input sources, including voice and text. There is no guarantee that this information will propagate throughout the system-of-systems, as required. Common information protocols such as Digital Imaging and Communications in Medicine (DICOM) (NEMA, 2004) and Health Level Seven (HL7.org, 2006) provide a framework by which medical data is communicated. However, these standard protocols are subject to interpretation that allows for a high degree of variance in the presentation of data. This creates problems of data redundancy, and confuses the authoritative provisioning of data with referential copies.

The electronic healthcare record (EHR) is a merged presentation of the information obtained through various systems in the healthcare enterprise

(Hasselbring, Peterson, Smits, & Spanjers, 2000). Imaging and demographic data contribute to the contents. Additionally, the physician comments, markup, and modality reports also contribute to the record. These individual pieces of the EHR are drawn from many disparate systems throughout the enterprise. The record information system (RIS) or alternatively a health information system (HIS) will be the primary demographic repository for patient information. As such, this text and contextual information will be used as the primary data source for downstream comparison. The Picture Archive and Communication System (PACS) will be used as a repository for imaging data (Miltchenko, Pianykh, & D'Antonio, 2002).

As the global economy and global business practices increase, individuals tend to be more transient. Their medical histories are an important precursor to successful health care provisioning. Contingent upon this medical history record is the successful integration of data from varied sources, including the mobile patient's information. This information must be portable, presentable, and independent of the initial data program from which it was obtained. By far, the greatest concern relates to data inconsistency and subsequent inaccuracy in an environment of disparate systems.

In the next section of this article, we will discuss the Health Level Seven communication protocol. In the third section, we will discuss the protocol DICOM. The application of these protocols into solutions for healthcare information repositories is presented in the fourth section, where both PACS and RIS systems are discussed. The problem of Data Disparity that causes inconsistencies in the intersystem communications will be discussed in the fifth section. The design of the XML Bus solution will be presented in the sixth section. The successes and shortcomings of this design are discussed in the conclusion.

HEALTH LEVEL SEVEN

The HL7 protocol provides an information standard for communicating patients and sites level information into and out of a health information system within the system-of-systems model (HL7 Canada, 2002; HL7.org, 2006; Neotool, 2007). HL7 allows for a loosely framed communication standard between medical IT systems. Without the provisioning of this ANSI standard, interoperability between systems was performed in an ad hoc manner.

The HL7 standard is based on the concept of events referred to as triggers (HL7, 2006, 2007). Each of these triggers fires a process that effects some particular communication of information. For example, the relocation of a patient to a new hospital would require the dissemination of information concerning that location throughout the healthcare system-of-systems. This event would be one of such triggers. A trigger may relate to a single record, as in this example, or it may relate to multiple records. A patient may have a name change due to marriage. This would require an update to all existing records in the information system to ensure data consistency.

Each trigger is composed of segments. The segment is a variable length field separated by a discernable character, such as a comma or pipe. In a manner similar to comma separated values (CSV) files, data can be delineated and also referenced externally though API functions. The content of each segment shall contain ASCII characters. The HL7 committee defines the acceptable character set as "The ASCII displayable character set (hexadecimal values between 20 and 7E, inclusive) is the default character set unless modified in the MSH header segment" (HL7, 2006). The HL7 trigger is represented in Table 1.

Each field may contain multiple subfields, delimited by a caret character. In the case of a name, |*DOE^JOHN^^^^*| the content between the two pipe symbols is the field of data, whereas the data *DOE* and *JOHN* are considered subfields.

Table 1. Sample HL7 trigger (Interfaceware, 2006)

```
MSH|^~\&|EPIC|EPICADT|SMS|SMSADT|199912271408|CHARRIS|ADT^A04|1817457|D|2.3|

    ||2688684|||||||||||||||||||||||||199912271408||||||002376853
```

The MSH is the message header segment, providing basic instructions on the contents within the trigger message.

This example also makes reference to three other key items: the *PID* that is the patient identifier, the EVN identifying that an event is included in this message, and the PV1 filed, which is followed by information about the patient's stay at the hospital.

One of the important contents within this message is the event type. As per the example, the message type provided is A04. HL7 defines many different message types, each with unique content. There are 51 defined Admission, Discharge or Transfer (ADT) events for HL7 in the V2.5 standard. The following table (Table 2) describes some of these events.

Without elaborating further on some of the many messages available to the HL7, it becomes clear that many distinct attributes are communicated in this protocol. Static entities such as Patient ID, Accession number, and event dates are provided in the same framework as dynamic information, such as location. The messaging protocol is also intended to communicate changes in state, through the provisioning of state-in-time attributes that have an expectation of permanence (Evola, 1997). These attributes, such as Patient ID, may have referential integrity for a site perspective. However, in the conglomerate or regional model of healthcare, that identifier now becomes nonreferential from a global viewpoint, and as such, introduces disparity at a higher system-of-systems level.

Table 2. HL7 message types

Message Type	Definition
Admit/visit notification (event A01)	Assign a bed to an admitted patient
Transfer a patient (event A02)	Patient changes their physical location
Discharge/end visit (event A03)	Patient leaves the facility
Register a patient (event A04)	Patient is brought into the facility, but not given a bed
Pre-admit a patient (event A05)	Patient is not admitted (In the facility), but demographic information is registered in the information system prior to their arrival for procedure.
Change an outpatient to an inpatient (event A06)	If a patients status changes, normally due to severity, they will be given a new location at the facility
Change an inpatient to an outpatient (event A07)	As per A06, defines a state change in the patient location.
Update patient information (event A08)	Represents a change to any of the demographic information related to a patient. This may be name, address, or other field.
Patient departing tracking (event A09)	Patient in transit outbound
Patient arriving - tracking (event A10)	Patient in transit inbound

DICOM

DICOM exists as an information distribution mechanism for medical devices (Ratib, Ligier, Rosset, Staub, Logean, & Girard, 2000). It is important to note that DICOM can be viewed as a technical protocol for layer seven communications or a solution to information exchange.

The DICOM protocol was developed in a joint effort between the American College of Radiology (ACR) and the National Electrical Manufacturers Association (NEMA, 2004). The protocol was introduced as a hardware interface, a minimum set of software commands, and a consistent set of data formats for communication between medical devices. This standard was intended to provide a framework to an emerging technology, medical information technology, allowing the sharing of data amongst Picture Archive Communication Systems and compliant sources.

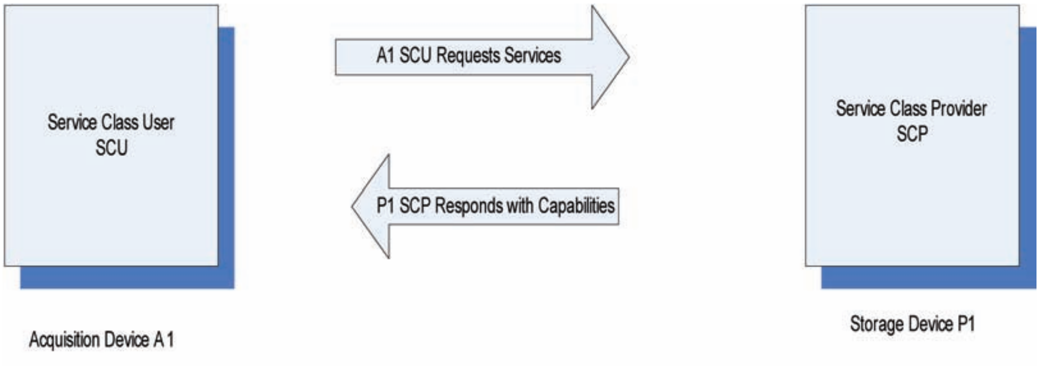
The DICOM protocol is used by a multitude of devices within the hospital enterprise for information transfer, sharing, and coordination (Jung, 2005). Some of the systems that rely on the protocol include modalities (Ultrasound, X-ray, CR, CT, and so on), Picture Archive Communication Systems, Film Printers, and Digitizers (media conversion systems) (Iacucci, Nielsen, & Berge, 2002). Although the implementation of the protocol is proprietary for each manufacturer, the standards as provided by the NEMA organization assist in ensuring general interoperability and definition of expectation for each DICOM function.

The first layer of protocol discussion relates to the negotiation of capabilities between the acquisition device and the subsequent receiver. Two concise roles are defined within DICOM to elucidate the responsibilities of each participant in the information exchange: the Service Class User (SCU) and the Service Class Provider (SCP). The SCU is the requestor of services for the purposes of information storage. In essence, it has information, and solicits a predefined receiver to accept this information. The SCU negotiates the acceptance of the sender's data, typically in one or more ways (Revet, 1997).

The storage transmission starts with a request from the SCU. The SCU identifies itself and asks for a specific function, through a composite request. The request consists of an object and an associated action. For example, a C-STORE message may consist of a request for data storage, and a subsequent object, such as an ultrasound image. The SCP, or storage provider, accepts the association request from the resource, assuming the storage host trusts it.

As illustrated in Figure 1, the bidirectional request-response behavior is typical of the DICOM protocol. The SCP not only accepts the initial request, but also responds with a list of capabilities for that request. The response consists of a list of Service Object-Pair (SOP) classes, reflective of the

Figure 1. SCU-SCP communications



storage ability of the SCP system. Also included in this request-response exchange is the choice of transfer syntax used for communication. Since there is a multiplicity of available syntaxes in the DICOM standard, some systems require the presence of an explicit value representation in the message. Others rely on an implicit understanding between data dictionary implementations, as provided partly by the DICOM standard, and partly by the SCP developer (McCormick, 2006).

DICOM data is broken into six major groups: File, Study, Acquisition, Image, Object, and Presentation. Each of these groups is well defined in terms of permissible content by the DICOM committee, as published in the DICOM standards and Supplements. Seven major groups are used to categorize DICOM Data elements. Group 0002 identifies file level attributes. Group 0008 identifies attributes relating to the study. Group 0010 identifies the patient attributes. Group 0018 relates to the acquisition of specific attributes related to the image. Group 0020 contains object level information, including the hierarchal relationship attributes that allow the linking of this image or object to the other objects in the series, study, and patient. Group 0028 elements provide display information crucial to the proper visual presentation of the image. Medical software uses this information to apply default settings. Group of Private Data Elements (odd numbered groups), allow the vendor to include information that can be used in a proprietary manner (i.e., to display the images, in case that vendor's system is part of the total System-of-Systems solution).

In summary, the DICOM protocol allows not only for the communication of patient, study, series, and image level information, it also defines the mechanism by which that information may be exchanged (Kolesnikov, 1997; Kolesnikov, Kelle, & Kauranne, 1997). This data is the primary source for study information as it related to the patient.

PACS AND RIS

PACS systems are built as a central repository for DICOM information (Gell, 2000). They are typically deployed as a means of replacing typical film based media. Through the implementation of the Storage Class User (SCU) and Storage Class Provider (SCP) mechanisms defined in DICOM, the PACS system receives images for later retrieval. PACS provides an electronic means of long-term storage. This storage serves as the integrated lifecycle management mechanism for a continued inbound stream of data (Miltchenko et al., 2002). The PACS is also the recipient of messages from the RIS. These messages represent unique events, such as a patient name change. Upon reception of such events, the PACS system is expected to start a process that will eventually update the demographic data using the previous name to the new patient name. The PACS answer to subsequent queries related to the updated patient records is subject to the proper interpretation of the data, as identified through the use of explicit data types, as well as the data dictionary. In fact, the use of DICOM data dictionaries allow for explicit metadata definition of data streams received. In the case of PACS, data dictionaries assist in defining the understanding of data content, both by type and content (Kennedy, Seibert, & Hughes, 2000).

Health Information Systems (HIS) organize demographic records for the purpose of centrally collecting a repository of electronic information. Radiology Information Systems (RIS) build upon this purpose for the radiology patient by scheduling orders. As information repositories, these systems (HIS and RIS) are constantly updated with both new and changing information. RIS systems can also provide worklists to modalities containing patient names and other demographic information of importance. In order for modalities to communicate outwards to information systems, they rely upon the DICOM protocol (Miltchenko et al., 2002; Tornhola, 2004). This may require the HIS system to accept DICOM events. Alternatively, data translation systems occasionally transform DICOM messages to the appropriate HL7 data construct, normally understood by the HIS system. The DICOM standard assists PACS implementations in providing a referential target, but only provides DICOM consistency of the data that is independent of the RIS. The RIS always relies on the HL7 protocol and its messaging mechanism for informing the PACS of changes, as well as receiving events from DICOM devices.

The messaging mechanism between different systems offers the translation medium that serves to both interpret and re-represent the data. However, the interpretation is based on an understanding of the message context inbound. This is a highly subjective interpretation. Resultantly, events and interpretation can result in inconsistency in this messaging based approach.

CAUSES FOR DATA DISPARITY IN THE SYSTEM-OF-SYSTEMS APPROACH

As discussed in the previous sections, the event and messaging framework used in the health enterprise system does not warrant the consistency between different instances or parts of the patient records. In this section, we will examine some of the events that may end with data disparity in the health enterprise system.

Data Silos in Healthcare Information Systems

Protocols such as DICOM and HL7 exist for the purposes of exchanging information within the PACS and RIS information silos in the hospital enterprise. These protocols ensure data confidence for downstream systems, but are not designed to provide referential data cross system in the system-of-systems model. These protocols provide a framework by which medical data is communicated, but are subject to strict programmatic interpretation. System implementations interpret the protocol standards in unique ways, allowing for a high degree of variance in the presentation of data from multiple independent data sources. This creates problems of data redundancy, inaccuracy, and confuses the authoritative provisioning of data with referential copies. By far the greatest concern relates to data inconsistency and subsequent inaccuracy in an environment of disparate systems. Unique data keys used for data alignment or referential integrity may be drawn from human assumptions that are faulty.

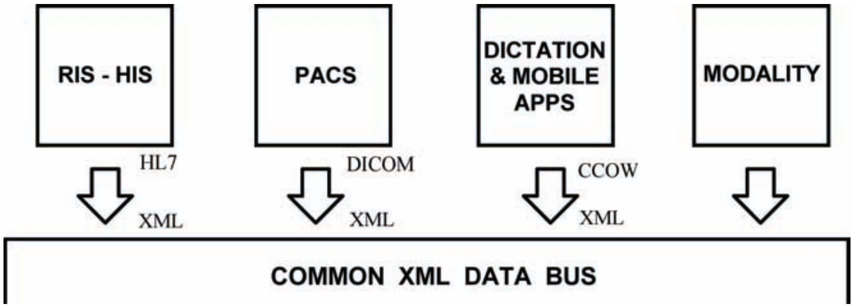
Inconsistent Record Identifier for the Patient's Data

Name change: In the system-of-systems, the patient name is always used as a key or part of the key for querying the patient data. Patients sometime change their names, especially after a marriage or divorce. When such an event occurs, demographic references strongly tied to that person's medical history will need to be changed or updated in order to insure the continuous access to relevant historical data.

In order to synchronize a patient's name throughout the system-of-systems enterprise, an HL7 N-event entitled "Patient Update" needs to occur. This type of event will ensure that all records containing "patient name" are updated to reference "the new patient name."

Legacy system for scanning film and paper data: Many of the enterprise records for patients in the hospital exist on documents. Admission, discharge, and transfer records may exist solely on nonelectronic medium. These information sources must be manually updated each time an event occurs, such as a patient name change. More information exists in the way of medical film. Not only is the image data present, but often the demographic information for the patient is burnt into the film.

Figure 2. XML data bus



OCR technologies can be helpful in dealing with the shear volume of ADT records for the patients. However, the electronically introduced data will need to be reconciled with the existing HER records.

Data Inconsistency Generated by Automatic Triggers or Cascading Events

Study cancel: On a less frequent basis, patient examinations are not conducted. This could be due to a myriad of causes, including patient absenteeism, acquisition device failure, as well as general infrastructure failure. In any of these events, a decision is made to cancel the acquisition of data relevant to the patient. In these cancellation scenarios, an N-event message is then scheduled. However, when the message is received by the PACS system, the study or appropriate identifier may not be present, as defined in the N-Event. This may be caused if the study acquisition has not yet begun. Also, the billing system may not receive the correct event-message. As such, we have an event-ordering problem.

Study split or merges: Data flow allows for the division and recombination in the process of medical diagnosis. A patient may have had a very long CT exam that extends into body parts outside the area of expertise for the radiologist. As such, it may be beneficial, both medically and financially, to split the study into two distinct studies for the patient. The inverse may also occur, resulting in a study merge. Study or series acquisition may be interrupted for one or more reasons, including equipment failure, resource contention, or multiple system acquisition. In any of these events, two or more distinct studies may need to be merged into a single study record.

A question arises regarding the synchronization of data between these models. It is unclear whether one or more IS records in this environment would exist for each study. As such, we encountered a many-to-one disagreement. Billing systems would need to be correctly informed that only one, albeit larger, procedure was performed. Also, only one read or transcription should have occurred in this model.

Data Exchange and Transfer of Patient Records

In some medical situations, a patient will need to be relocated from one hospital environment to another. In this dataflow scenario, the patient's records may be imported to the new environment. Alternatively, a new record may be created at the newest site. Also, the imaging data is sometime transmitted to the DICOM SCP of the receiving site's PACS. The transmitted and imported data needs then to be reconciled against the new site's information system in order to correlate records to demographic data, so that any patient movement or other procedures can be referenced to the same patient.

Character Set Translation and Legacy Systems Tagging

ISO_IR disagreement and database character translation: ISO character sets refer to the specific procedure for mapping a sequence of bytes to a sequence of characters. The DICOM standard includes a specific tag necessary to identify the character set used in the header. This is of extreme importance to the demographic consistency of the data interpretation and action throughout the enterprise.

By way of example, consider a query for all patients whose last name starts with Ł (from ISO 8859-2, decimal 163). If the system were not capable of understanding this character, perhaps through a limited understanding of only ISO_8859-1, then this character would escape the query, possibly with undesirable results. Worst yet, any patient name update including the character Ł would also be problematic.

Private DICOM tagging: Many modality vendors choose to include proprietary information in the DICOM header of the images and objects they transmit. This information is only of use to a system that is programmed to take advantage of it. It allows for a tighter sub-system-of-system model, but at the expense of the greater solution.

Time Synchronization

Time is a critical component to a successful diagnosis. All members of the health enterprise solution normally have their own time keeping facility. However, in the system-of-systems, the use of time stamps is critical to insure the coordination of transactions and order of precedence. These time stamps should be synchronized within the whole system-of-systems.

Other Technical Issues

Data reintroduction for disaster recovery purposes: In the event of system failure, one or more entities within the system-of-systems will need to be repopulated with original data. Upon completion of this, a synchronization effort will need to occur between it and one of more members within the environment. This activity requires coordination of the various information systems within the hospital enterprise.

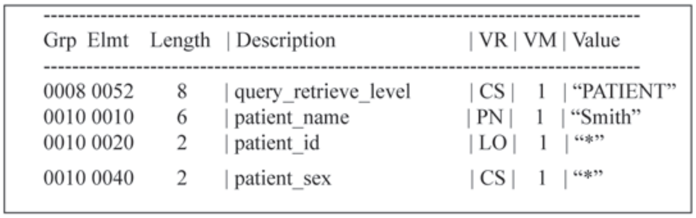
RIS feed interruption: The RIS messaging mechanism is a necessary prerequisite in the system-of-systems for data continuity. Upon failure of any RIS system in this environment, the update events will not properly register for all receiving systems in the enterprise, resulting in an environmental data inconsistency.

AN XML BUS FOR RESOLVING SOME OF THE DATA DISPARITY ISSUES

One of the prevalent issues in message-oriented systems is defining one or more protocols by which messages can be processed. Adherence to standards, bridging between protocols and configurations all raise issues in a multiple systems environment. In the healthcare enterprise, the interdependency of systems for successful patient care only serves to exasperate the situation. XML and semantic Web technology presents a great potential for solving some of the disparity issues (Heitmann, 2002; Pianykh, Castañeda-Zuniga, W. D., D'Antonio, & Tyler, 2001a; Pianykh, Miltchenko, & Castaneda-Zuniga, 2001b; Tornhola, 2004). In this section, we present a solution based on the use of an XML bus for data transfer. Figure 2 presents the XML bus design from a dataflow perspective.

The data bus would allow for a common data conduit. The connection to this conduit would be accomplished through adapters that provide common data typing. Each connection into the data bus would require an adapter that allows for consistent conversion from source protocol to XML.

Figure 4. DICOM response from EHR application C_Find



```
----------------------------------------------------------------------------------
Grp  Elmt   Length  | Description               | VR | VM | Value
----------------------------------------------------------------------------------
0008 0052     8     | query_retrieve_level      | CS |  1 | "PATIENT"
0010 0010     6     | patient_name              | PN |  1 | "Smith"
0010 0020     2     | patient_id                | LO |  1 | "*"

0010 0040     2     | patient_sex               | CS |  1 | "*"
```

DICOM to XML Conversion

The adapter, as shown in the arrow in Figure 2, is a translation engine that understands both XML and the healthcare-specific protocol, in this case, DICOM. Using open source tools such as DCM4CHE, conversion of DICOM to XML is readily possible.

The following code is a truncated output of the dcm2xml.jar transformation performed on a sample DICOM file.

HL7 to XML Conversion

Version 3.0 of the HL7 standard is a pure XML implementation (Heitmann, 2002). As such, the major concern relates not to the transformation of the trigger, but to the interpretation. This is somewhat addressed in the Reference Information Model of HL7 3.0. In versions prior to 3.0, a methodology is necessary to interpret the trigger events as XML. The HL7 organization has devised rules in order to properly encode the HL7 triggers in XML. These rules would enable an adapter framework to implement commonality of meaning across the data bus, as shown in Figure 2.

Modality to XML Data Bus Adapter

There is commonality between the DICOM to XML Adapter, and the Modality to XML adapter. Both use DICOM as a protocol for communication, and as such, may rely partially on the implementation details for each other. Modalities also have unique features, such as Modality Performed Procedure Steps (MPPS), which must also be taken care of in any successful implementation (Noumeir, 2005). The modality adapter must be able to communicate these specific events directly to the data bus. Any subsequent queries upon the data bus would then be able to accurately provide procedure start and procedure end dates and times through the Modality to XML adapter shown in Figure 2. (see also Table 3)

Context to XML

Many applications rely on the Clinical Context Object Workgroup (CCOW) for interoperability notification. This standard and an extension of the HL7 framework allows singular CCOW-aware applications to interact with other CCOW-aware applications for the purposes of information sharing (Grimson, Stephens, Jung, Grimson, Berry, & Pardon, 2001). This standard is extremely beneficial in the system-of-systems approach, as it represents a common notification mechanism for changes in status. It also has value in voice dictation systems as a means of coercing dictation information into the patient framework through the identification of common attributes, such as patient name and study instance-unique identifiers.

Proof of Concept

The following interface provides a rudimentary proof of concept for the Enterprise Healthcare Record Viewer application. The intent of this application is not to commit a full implementation, but rather to provide a framework by which further research may be committed. (see Figure 3)

The EHR interface provides three query mechanisms. The XML Data Bus function performs a direct SQL query to the data repository, as stored through a future XML to SQL transformation. The second interface queries the PACS SCP through a standard C_FIND. Figure 4, an excerpt of the DICOM conversation ensuing from that query, details the Group and Element data transferred.

The last query mechanism queries the RIS system. Connectivity to the RIS is accomplished through an HL7 Query message.

CONCLUSION

Medical information systems exist as information silos within the global health enterprise, making the task of designing an effective and accurate Enterprise Health Record Viewer very difficult. Each healthcare enterprise system in the system-of-systems acts as a referential entity for the information it contains, but only for the specific domain for which it is specialized. For each system in the enterprise, downstream distributed applications typically rely on the one specific data silo as a means of identifying and enacting decisions within an application framework. Whilst this ensures one to one consistency of data between the application and a centralized data repository, it does not ensure consistency within the enterprise.

In the enterprise health record, two systems were found to be of importance. Radiological clients communicated primarily with a PACS system via DICOM as a means of obtaining study level data for patients. Radiology workstations communicated with RIS systems via HL7 in order to record patient-level attributes. Data consistency was often accomplished through the implementation of translation systems converting one protocol to another. In fact, protocols such as DICOM, CCOW, and HL7 exist as standards for information sharing, but the exact implementation of message conversion from one standard to another is often an area of information redundancy. Data conversion solutions were also viewed as a possible cause for information loss or inaccuracy due to the incongruity in frameworks between the systems and their protocols. In the translation and representation between systems in the enterprise, data conversion is not always possible. Enterprise inconsistencies also exist as a direct result of data workflow. HIMMS and IHE are leading the way in standardization of data consistency and authority in the healthcare enterprise by defining information pathways and messaging content within the medical information environment.

The development of an Enterprise Record Viewer illuminated the necessity for authority of data. Although protocol translation was seen as a contributing factor to inconsistencies, the production of a solution became reoriented around the creation of a central authority in order to ensure consistency. This hierarchal approach avoided the concern over data consistency in the enterprise by creating another independent silo for data display. Connectivity to the RIS and PACS systems allowed the viewer to query independently of the XML Data Bus in order to allow alternative means of exploring data that may not have been messaged properly.

The production of the framework for the XML data bus is representative of a methodology or approach for an Electronic Healthcare Record. Further effort is necessary to expand upon this singular solution to resolve the data disparity issues driven by the system-of-systems approach in the hospital enterprise. The XML data bus design provides a framework for solving some of the identified causes for data disparity. Patient name changes are addressed through the transmission of this data to the bus. All queries can then be programmed to query via the bus. Similarly, patient moves and study cancellation messages can be communicated into the bus for dissemination and subsequent query. While the bus design alleviates these areas by creating a singular entry point for enterprise systems, other causes for data inconsistency cannot be solely addressed through the XML data bus design. Consistencies in data dictionaries, ISO_IR disagreement and private DICOM tagging practices require future research. These areas may benefit from an assessment of the W3C semantic Web design. Another concern remains with data movement and event ordering. Issues such as time synchronization and RIS message repetition may benefit from an asynchronous transactional approach as implemented through the use of a message queuing. Legacy film based scanning practices would benefit from an examination of form based workflow technologies, and would integrate more readily into an XML construct such as the proposed XML data bus.

Future implementations are recommended to focus on the remote user's requirements as a means of both centralizing data, and also on providing a readily accessible, consistent, and lightweight viewpoint to data. This latter objective will facilitate a successful adoption through the consistent presentation of patient demographic data. As Scotland, England, Estonia, Canada and others begin the process of providing centralized socialized healthcare through the amalgamation and adoption of countrywide healthcare solutions, Enterprise Healthcare Record Viewers and identification of data authorities inside the system-of-systems healthcare enterprise will become critical to the successful provisioning of healthcare to patients.

KEY TERMS

Clinical Context Object Workgroup (CCOW): More commonly known as Clinical Context Management, enables the clinical end-user to experience the simplicity of interacting with one system, when in reality he or she may be using multiple independent applications through varying interfaces. Defined by HL7 standards, CCOW ensures secure and consistent access to patient data from varied sources.

Clinical Document Architecture (CDA): Also known as the Patient Record Architecture (PRA), provides an exchange model for clinical documents (such as discharge summaries and progress notes). CDA brings the healthcare industry closer to the realization of an electronic medical record.

Comma Separated Values (CSV): This file format is often used to exchange data between differently similar applications. CSV files have become somewhat obsolete, due to XML data exchange possibilities.

Digital Imaging and Communications in Medicine (DICOM): A standard for the distribution and viewing of medical images, such as CT scans, MRIs, and ultrasound. It describes a file format for the distribution of images and provides access to Storage Media independently from specific media storage formats and file structures.

Health Level Seven (HL7): A standard for exchanging information between medical applications. It is an event driven protocol that defines the format and the content of the messages that applications must use when exchanging data with each another in various circumstances.

Modality Performed Procedure Steps (MPPS): The MPPS service works in concert with the Modality Work List service to provide exam status updates. MPPS are used for two purposes: updates the exam state of patient and forward messages to another application entity, such as a RIS or other work list provider.

Modality Work List: The Modality Work List service provides patient demographic information to imaging modalities in the form of a work list. Modality work lists also allow technologists to sort their workload by time period, specific date or time, patient name or identifier, and modality.

Network Time Protocol/Simple Network Time Protocol (NTP/SNTP): NTP is an Internet protocol used to synchronize the clocks of computers to some time reference. SNTP (Simple Network Time Protocol) is basically also NTP, but lacks some internal algorithms that are not needed for all types of servers.

Picture Archive and Communication System (PACS): A network of computers dedicated to the storage, retrieval, distribution, and presentation of images. A PACS system provides a single point of access for images and their associated data. It also interfaces with existing hospital information systems, such as the hospital information system (HIS) and the radiology information system (RIS).

Service Class Provider (SCP): In DICOM, the relationship between both partners is defined by the Service Class description. The SCP plays the "server" role to perform operations and invoke notifications during an Association. An example of a Storage Service Class Provider would be an image storage device. The SCP role includes enabling the applications to receive DICOM objects locally from devices (image sources, workstations, servers, and so on) through the DICOM protocol.

Service Class User (SCU): In DICOM, the relationship between both partners is defined by the Service Class description. The SCU plays the "client" role to invoke operations and perform notifications during an Association. An example of a Storage Service Class User would be an image acquisition device. In this case, the image acquisition device will create and send a DICOM image by requesting that a Service Class Provider store that image.

Service Object-Pair (SOP): SOP classes identify the capabilities of the specific distributed processing for a certain Service Class. When partners agree to use a SOP class, both sides must ensure they will play their role as described, using the context of the enclosing Service Class. In each SOP Class definition, a single Information Object Definition or IOD is combined with one or more services.

Workflow Management System: A system that completely defines, manages, and executes "workflows" through the execution of software whose order of execution is driven by a computer representation of the workflow logic. The workflow is concerned with the automation of procedures where documents, information, or tasks are passed between participants according to a defined set of rules to achieve, or contribute to, an overall business goal (Hollingsworth, 1995).

Chapter 7.16

Analysing Clinical Notes for Translation Research:

Back to the Future

Jon Patrick
The University of Sydney, Australia

Pooyan Asgari
The University of Sydney, Australia

ABSTRACT

There have been few studies of large corpora of narrative notes collected from the health clinicians working at the point of care. This chapter describes the principle issues in analysing a corpus of 44 million words of clinical notes drawn from the Intensive Care Service of a Sydney hospital. The study identifies many of the processing difficulties in dealing with written materials that have a high degree of informality, written in circumstances where the authors are under significant time pressures, and containing a large technical lexicon, in contrast to formally published material. Recommendations on the processing tasks needed to turn such materials into a more usable form are provided. The chapter argues that these problems require a return to issues of 30 years ago that have been mostly solved for computational linguists but need to be revisited for this entirely new genre of materials. In returning to the past and studying the contents of these materials in retrospective studies we can plan to go forward to a future that provides technologies that better support clinicians. They need to produce both lexically and grammatically higher quality texts that can then be leveraged successfully for advanced translational research thereby bolstering its momentum.

INTRODUCTION

This volume gives a picture of the current progress in using Natural Language Processing to provide better access to written materials that are on the whole published under formal assessments and processes. Such materials are more amenable to different NLP tasks than the genre of content produced by clinicians working at the point of care with very sick and dying patients. The point-of-care texts are distinctly different in two important ways - *weaker adherence to grammatical structure*, and *the complexity and veracity of* lexical form. A further difference is in the objectives of the processing tasks themselves. The papers of this volume have defined the necessary task as that of information retrieval in and of itself. Processing clinical notes has a much larger number of objectives which makes it both more complex but also provides a greater number of opportunities to be creative and contribute to enhancements to the field of health care. Translational research, or more colloquially known as "bench to bed" research, is looming to be by far the most important field for improving our health care. This is the process of linking together the research performed in the laboratory to the processes and treatments conducted at the bedside. Much of this work is seen as personalized medicine that will produce drugs targeted at an individual's personal genome, however research into this ideal healthcare is highly restricted without technology that enables linking of the patient records created at the point-of-care with the models of drug-genome interaction built in the laboratory. NLP is a most important bridge between these two end points in the search for better healthcare. Without effective and accurate processing of the point-of-care records to provide evidence of the effectiveness of drugs and the course of diseases in patients under drug treatment there can be no development of evidence based drug treatment, and translational research will progress more slowly than it would otherwise.

This paper presents some of the models we have developed for representing the different processing needs of clinical staff and describes the lessons we have learned from problems encountered in analysing a large corpus of 44 million words of clinical notes.

BACKGROUND

The task of performing natural language processing over clinical notes goes back to 1983 Chi, E. C., Sager, N., Tick, L. J., & Lyman, M. S.; Gabrieli, E. R., Speth, D. J., 1986) with the work Chi, Sager, Tick and Lyman, and it is only gradually increased in activity to this date. However, in 2008 with have had the first conference specifically targeted at the "Text and Data Mining of Clinical Documents" with a conference organized by the Turku Centre for Computer Science, in Finland (Karsten, H., Back, B., Salakoski, T., Salanterä, S., & Suominen, H., 2008). Much of the work prior to the 1990s has been superceded by later shifts in processing power and new ideas on the software development for this task. The review of the literature in this paper is restricted to later topics that are particularly relevant to automated processing of the language of clinical notes.

In 2001, Taira and Soderland published their approach to information extraction from clinical notes in the radiology domain. They proposed a general structure for such applications which was later used by many other research groups (Huang, Y., Lowe, H., Klein, D., & Cucina, R., 2005; Arnold, C. W., Bui, A. A. T., Morioka, C., El-Saden, S., & Kangarloo, H., 2007; Thomas, B. J., Ouellette, H., Halpern, E. F., & Rosenthal, D. I., 2005; Sinha, U., & Kangarloo, H., 2002). Their proposal had five steps of processing for a complete data retrieval system: *Structural analyzer,* Lexical analyzer, Parser, Semantic interpreter and Frame constructor. They performed an evaluation on this structuring and reported obstacles in: deep understanding of the domain, ability to deal with ungrammatical writing styles, shorthand and telegraphic writings, finding solutions for assumed knowledge between the writer and reader, and handling a large vocabulary. Following their work, different studies have expanded their proposed system to other clinical domains or addressed the reported issues (Sun, J. Y., & Sun, Y., 2006) and in some cases reported new obstacles.

Table 1. Summary of survey of the literature on processing clinical note

NLP Topics	Major Issues	Proposed Solutions	
Lexical & Phrasal	Orthography, Keyboard competency & Spell Checking	Regular expression and UMLS based dictionaries	
	Verbalization of named-entities & Drug names	No Clear Answer	
	Abbreviations & Shorthand	Regular expressions and disambiguation algorithms	
	LOTE issues: Phonological Transformation	No Clear Solution	
	Neologisms & productive morphology	No Clear Solution	
	Issue with Multi-word expressions & Capturing Phrases	Complex parser and external knowledge source	
		compositional mapping	
		Part of speech tagging	
		statistical natural language parser	
Semantics	Word sense disambiguation	Variety of algorithms	
	Mapping issue among Terminologies, Thesauri, Ontologies & classifications (TTOCs)	Frames	
		semantic definitions	
		Diagrams	
		combination of lexical, logical & morphological	
	Negation	regular expression matching	
		grammatical parsing	
	Concept Recognition	Statistical	Rule based
		Lexical	
		Hybrid	

Our discussion of a structure for a medical information extraction system has some parts in common with Taira and Soderland. Moreover, we describe the commonalities in efforts which have been made to address existing issues in the life cycle and the operational objectives of an information extraction system. Table 1 shows a summary of this survey.

Lexical & Phrasal Issues

In clinical notes there is a high complexity to orthography not found in other prose materials such as press reports and formal publications. Some of these domain specific issues are:

1. A large number of mistakes especially for long words.
2. Special abbreviations for entities such as chemical names.
3. Specialist shorthand for idiosyncratic cultural items
4. LOTE (Language other than English) staff using different phonological transformations
5. Keyboard competency
6. Specialty complex terms with variable greco-latin roots
7. Neologisms
8. Verbalization of named entities, especially drug names

9. Productive morphology combined with neologisms
10. Staff access and use of correct materials

In the past decade, researchers have tried to address some of the above issues in many different ways. A short summary of these efforts follows.

Lexical Verification

NLP is used to perform a variety of low level tasks in information retrieval systems such as term identification. Ananiadou et al in 1994, Frantzi and others in 1998 and Savova et al in 2003 reported different approaches in term identification (Savova, G., Harris, M. R., Johnson, T., Pakhomov, S.V., &. Chute, C. G., 2003; Ananiadou, S., 1994; Frantzi, K., Ananiadou, S., & Tsujii, J., 1998). All reported the affect of orthographic variations in their results. In 2002, Ruch described an IR system which was able to cope with textual misspellings. He demonstrated the extent to which dealing with spelling issues can improve the performance of an IR system (Ruch, P., 2002).

In 2007, Tolentino, Matters, Walop, Law, and Tong described a prototype spell checker which used UMLS and WordNet as primary and secondary domain specific dictionaries, and regular expressions as a look up method. The result was satisfactory except they reported relatively slow processing and low performance.

Lexical verification in clinical notes deals with different types of data for which some researchers suggested different approaches. In 2005 Zhou and Han introduced a new approach in extracting three groups of data from clinical notes: *numeric values, medical terms and categorical values.* Their approach considered three different approaches for these three different groups of data. It was extended in 2006 and they reported satisfactory results (Zhou, X., Han, H., Chankai, I., Prestrud, A., & Brooks, A., 2006).

Abbreviation Identification

Pustejovsky et al. (2001) described a solution for identifying abbreviations based on regular expressions and syntactic information which lead to an increase in the accuracy of identification of noun phrase boundaries. Chang et al. (2001) described an algorithm that uses linear regression, Park and Byrd (2001) and Yu et al. (2002) introduced some rule-based algorithms for extraction of abbreviations. Schwartz in 2003 described a very simple but effective algorithm for identifying abbreviations in the biomedical domain. Systems have also been developed to map abbreviations to full forms such as AbbRE (abbreviation recognition and extraction) by Yu et al (2002). There does not seem to be any comprehensive or specific studies on mnemonics in clinical contexts.

Phrasal Level

Dealing with multi-word expressions (MWE) and phrases has been a principal focus of researchers in recent years. Multi-word expressions have been traditionally recognised though standard terminologies. However non-standardized MWEs (e.g. weights and measures, administrative entities) are major issues in phrase processing.

Identification of NPs in both simple and complex forms is one of the challenges in this field where achieving a high precision is the main goal (Yu et al., 2002). In past work MetaMap (Aronson, A. R., 2001), MedLee (Friedman, C., Alderson, P. O., Austin, J. H., et al., 1994) use phrase identification as one of their important steps. MedLee has a Component for Phrase-regularization which regularizes the output forms of phrases that are not contiguous. Moreover MedLee uses a compositional mapping approach which is the combination of central finding (mapped term e.g. enlarged) with its attributes (e.g. severe) or body location modifier (e.g. heart) compared to a concept dictionary and if there are new matches with more accuracy then the combination of words they would be captured as a phrase.

Part of speech tagging for phrase identification also has been used since 1994 when Sager et al. reported a preliminary investigation on mapping clinical terms to SNOMED III (Sager, N., Lyman, M., Nhan, N. T., et al., 2004).

In 2005, Huang et al addressed this issue by using a statistical natural language parser trained on a nonmedical domain in conjunction with using a UMLS Specialist Lexicon. Their results were promising when their custom-designed system achieved almost similar performance figures for both medical and general domains (Huang, Y., Lowe, H., Klein, D., & Cucina, R., 2005).

Semantic Level

Concept Recognition

There are a number of different approaches in concept matching. Between 1990 and 1994, a project at the University of Pittsburgh (Lowe, H. J., Buchanan, B. G., Cooper, G. F., & Vries, J. K., 2005; Miller, R. A., Gieszczykiewicz, F. M., Vries, J. K., & Cooper, G. F., 1992;Kanter, S. L., Miller, R. A., Tan, M., & Schwartz, J., 1994) compared two available methods in concept matching - lexical and statistical - evaluated and combine them. The results of their efforts were two different systems: PostDoc (lexical) and Pindex (statistical). Each program takes free text as input from a patient's electronic medical record, and as output it returns a list of suggested MeSH terms. Cooper and Miller (Cooper, G. F., & Miller, R. A., 1998) followed the Pittsburgh's Project in 1998 and performed evaluation on both statistical, lexical and the hybrid methods.

Lexical analysis is one of these approaches. The lexical approach is computationally fast and useful for real-time applications (Huang, Y., Lowe, H., Klein, D., & Cucina, R., 2005); however, this approach may not provide optimal results without combination with other methods (Zou, Q., Chu, W. W., Morioka, C., et al., 2003). An example of this combination is Purcell et al.'s study. In 1995 Purcell and Shortliffe reported their experience in considering context in concept matching where they used concepts encoded in headings of clinical documents to elevate the accuracy (Purcell, G. P., & Shortliffe, E. H., 1995). Following their study, Berrios combined Purcell's technique together with a vector space model and a statistical method to match text content to a set of query types (Huang, Y., Lowe, H., Klein, D., & Cucina, R., 2005; Berrios, D. C., 2000). In 2003 *IndexFinder* was developed by Zou et al. to add syntactic and semantic filtering to improve performance on top of lexical mapping (Huang, Y. et al., 2005; Zou, Q., et al., 2003). Before this point some important research had been done with researchers focused on applying more sophisticated NLP techniques to improve concept recognition accuracy. Friedmen (1994) by using phrase identification tried to improve the concept matching.

In 2001, Nedkarni et al. performed a feasibility study on using UMLS in a computational strategy to identify concepts in medical narrative text. They concluded that the level of noise in the UMLS database impacted on the accuracy of their system and considerable filtering needed to be performed to define a UMLS subset that is suitable for concept matching. In 2007 *Osornio et al.* developed a local interface for SNOMED CT to let users design their own concept subsets or to modify the database to make it more amenable to their concept matching needs.

In 2006, Elkin et al. evaluated the Content Coverage of SNOMED in representing a clinical problem list. They reported encouraging results but they reported improvements to synonymy and adding missing modifiers would lead to a better coverage of SNOMED and address some common problems. Later In 2007, Patrick et al. proposed a system to translate free text clinical notes into SNOMED CT as a web service.

They installed their system in an intensive care unit (ICU) to be tested and evaluated in a real scenario. They reported restricting the concept mapping to noun phrase chunks can rule out many false positives and also increase the speed of processing. They also reported on issues like many pre-coordinated terms and qualifications cross noun phrase boundaries.

MedLEE (Friedman, C., et al., 2003) a system developed by Friedman et al. to encode clinical texts, is a well known example of a concept matching through structure detection. Along with MedLEE there are a few other applications (Taira, R. K., & Soderland, S. G., 1999; Taira, R. K., Soderland, S. G., & Jakobovits, R. M., 2001; Christensen, L., Haug, P. J., & Fiszman, M., 2002) which encode modifiers together with core concepts in noun phrases (NPs). The MedLee authors and others in 2005 have extended this approach to other clinical domains and reported encouraging results however they reported that there were many different fields open for improvement and research (Hripcsak, G., Kuperman, G. J., & Friedman, C., 1998; Hripcsak, G., Austin, J. H., Alderson, P. O., & Friedman, C., 2002; Friedman, C.$^{, 2000).}$

MetaMap (Aronson, A. R., 2001) is another concept matching method by structure detection which identifies UMLS concepts in text and returns them in a ranked list in a five step process. Step 1: parsing text for syntactic tagging and then indicating the most important parts of a phrase. Step 2: extracting all possible variants of a phrase and scoring them, Step 3: retrieve all concepts from UMLS which has at least one listed variant. Step 4: evaluate the candidates based on their score. Step 5: combine best candidates to generate the closest concept in UMLS.

Word Sense Disambiguation (WSD)

Although word sense disambiguation is a general field in which a great deal of work has been done, it is still a major field of study and open to research in clinical domain. Ruch et al. (2001) reported that clinical notes compared to unrestricted or general texts is much less ambiguous, however Weeber et al. (2001) reported that the world's largest medical thesaurus (UMLS), has more than 7,000 ambiguous strings that map to more than one concept in a thesaurus.

Nadkarni et al. (2001) reported that a complete automatic concept indexing in medical notes may not be achieved without addressing ambiguity issue in free text. A good example of the efforts in this area is Aronson $^{(}$2001) study. In 2001, Aronson reported that addressing ambiguity issues is important for enhancing the performance of MetaMap, a mapping program for UMLS concepts. Later in 2001, Weeber and Aronson with an intention to evaluate different available algorithms for WSD, developed a manually sense-tagged test collection of data (Weeber, M., Mork, J., & Aronson, A., 2001) suitable for this purpose. This test collection became a good resource for different researchers to evaluate their algorithms against a standard corpus like the study which has been done by Liu et al. (2002).

Most of the available approaches to word sense disambiguation use or combine different machine learning techniques and refer to characteristics of the ambiguity and its surrounding words relying on a collection of examples Schuemie, M. J., Kors, J. A., & Mons, B., 2005$^{;}$ Leroy, G., &. Rindflesch, T. C., 2003; Resnik, P., & Yarowsky, D., 2000; Dorow, B., & Widdows, D., 2003). In 2005 by Schuemie et al. performed a comprehensive study about WSD in biomedical domain in recent years. They classified the current available approaches into a 5 major branches namely, WSD using:

1. Established knowledge.
2. Bilingual corpora.
3. Supervised learning.
4. Feature vectors.
5. Unsupervised learning.

They concluded that the lack of adequate test sets is probably the most important obstacle to the development and evaluation of effective WSD methods in this field.

Negation

One of most extensive studies on negation was published by Mutalik et al. in 2001. They reported Negation of most concepts in medical narratives can be reliably detected by a simple strategy depending on several factors, the most important being the accuracy of concept matching. Later in the same year, Chapman et al. conducted a study about negation recognition algorithms and they concluded that to be robust a negation algorithm triggered by the negation phrases should apply syntactic and lexical knowledge.

In 2005, Elkin et al improved the Chapman and Mutalik findings by comparing the accuracy of an automated mechanism for assignment of negation to clinical concepts with human assigned negation. They performed a failure analysis to identify the causes of poorly identified negation. Based on their findings, they introduced a new strategy of association of the negative concept to other concept(s) to increase the accuracy.

While most of the negation identification approaches rely on either regular expression matching (Chapman, W. W., Bridewell, W., Hanbury, P., Cooper, G. F., & Buchanan, B., 2001) or grammatical parsing (Huang, Y., & Lowe, H. J., 2005). In 2007 **Huang** and his group introduced a new hybrid method combining regular expression matching with grammatical parsing. They reported the grammatical parser enabled them to detect negated concepts more accurately at a distance from the negation phrase.

It seems, negation identification in clinical notes cannot be done effectively without addressing special requirements of these types of text such as multiple negations and indirect negations are important sub-types of negation.

Mapping between Terminologies, Thesauri, Ontologies & Classifications (TTOCs)

There are a variety of lexical resources available for processing clinical texts. Bodenreider (2006) completed a study of many of them and concluded there are difficulties in differentiating between terminologies, thesauri, ontologies and classifications (TTOCs). Each however can be used solely as a lexical resource without considering its structural organisation. Nevertheless, a major issue in natural language processing is a lack of a truly comprehensive clinical vocabulary (Sun, J. Y., & Sun, Y., 2006). Several algorithms have been proposed to automate translation across the variety of TTOCs. Frames (Rocha, R. A., Rocha, B. H. S. C., & Huff, S. M., 1993), semantic definitions (Dolin, R. H., Huff, S. M., Rocha, R. A., Spackman, K. A., & Campbell, K. E., 1998) adopting diagrams [11], and a mix of lexical, logical and morphological methods (Rocha, R. A., & Huff, S. M., 1994) are examples of these algorithms.

In 2004 a comprehensive study was published by Sun (2004) about different techniques and approaches to finding a mapping between two different medical terminologies. He introduced an application, MEDIATE, which adopted semantic networks as an intermediary representation of the databases then an automated mapping algorithm can locate equivalent concepts in different TTOCs. The algorithms take advantage of the conceptual ‘‘context’’ implemented within a semantic network to populate a list of candidate concepts (Sun, Y., 2004). Later in 2006 he extended his work and introduced the LINC tool and listed some new obstacles that confront the data mapping efforts. (Sun, J. Y., & Sun, Y., 2006) This remains an unsolved problem with most practical solutions resorting to some degree of manual processing.

A MODEL OF NLP SERVICES FOR CLINICAL WORK

There are two classes of written materials relevant to studies of clinical narratives. The first class is published content for example, case studies, medical knowledge and clinical protocols/pathways, and standardized care plans. These have correct English prose, shifting contexts, and scientific background knowledge from many aspects of medicine: diseases, procedures, chemistry, pharmaceuticals, family history, and current care plans. The good prose strategy allows for the use of many of the traditional methods of NLP analysis.

The second class of materials is progress notes or clinical notes from the point-of-care. They are collected in acute care as ward notes and are very different (putting handwriting problems aside) in that they are written rapidly, have rapid shifts in context, extensive abbreviations, significant faulty and improvised orthography and grammar. Sources of some errors are LOTE background and poor typing skills. They make significant assumptions about context and in the limit are written in the highest order of assumptions about a priori knowledge being solely for the benefit and understanding of the writer without consideration of another reader.

Content analysis of published materials is about supporting IR to deliver general medical knowledge to the practitioner. Ward notes are multi-pronged and directed at supporting the attending physicians and their team for a much broader range of activities. We define physicians as needing to serve four roles in their working environment:

1. Point-of-care clinician
2. Researcher
3. Administrator
4. Auditor

In each of these roles the experienced physician has to constantly serve the modes of both the professional and the teacher. The use of progress notes and therefore the types of processing that they require varies between these roles.

The *point-of-care clinician* requires access to the narrative of the notes to determine their next act of care, hence the processing system needs to produce an extract of the current state of the patient and the issues that need to be addressed immediately about their ongoing care whether that is a short term decision as in the Emergency Department or the Intensive Care Unit, or for the longer term at the point of discharge from a hospital. The processing needs are essentially information extraction of particular items such as current diagnoses, care plans, current pathology results (taken from a narrative report) etc. These needs have a high requirement for precision of retrieval as errors of "fact" can lead to disastrous consequences, were as errors of omission are less likely to have such effect and more likely to lead to user discontent of the system.

The *researcher physician* has a somewhat different demand in that they are most interested in aggregation over sets of patient records in the process of performing analytics. Under these circumstances some errors in retrieval are likely to be tolerable as the conclusions one draws from aggregation are likely to be understood to have their own error behaviors. However as the research process is seeking associations between variables the nature of retrieval is intrinsically about the association of one phenomenon with another. This problem can be defined if one so wishes as two or more independent information extraction tasks, however it is likely to be more valuable and possibly more reliable to perform retrieval exploiting a supposed relationship between two variables of interest. For example a study of fractures and hips, would lead to a strategy to extract references to either collocated or anaphoric cross-references to hips and fractures with processing to assess their grammatical relationships (the x-ray showed a 20mm mass just above the hip which became fractured in a later fall") rather than a hunt for "fractured hip" and its string variants. This role and the language processing functions to be provided for it are fundamental to translational research both for retrospective studies and prospective studies.

The *administrator physician* has similar functions to that of the researcher physician in that they require aggregation of content across collections of patients. The difference is that the target variables will come from issues about usage and management of clinical resources.

The fourth role is that of *auditor physician*, that is, a person who audits the processes in the clinical unit to ensure they are maximized for patient safety as well as throughput. The auditor needs processing systems to support analysis of both single patient records and aggregation. When investigating an individual case the auditor will need tools to make ad hoc queries about a single case and at the same time seek to understand the performance of the unit over collections of cases to establish if single cases are out of the norm.

Understanding the roles of clinicians and their needs enables targeting the design and development of language technology to attend to those needs and so deliver productivity and patient safety gains in the workplace.

In summary, the processing requirements are to perform information retrieval on single records to find the precise location in the record for a precise piece of information. For example a staff member attending a patient might want to ask a specific question *"what medications were ordered by this morning ward rounds staff"* which most closely matches an information extraction or Q&A process. Nevertheless another question could be *"what is this patient's care plan and how far have we progressed with?"* This question requires extracting a set of information that has some intrinsic coherence which may well not be all in the one place, in particular the record of actions in executing the care plan will be distributed over pages of notes recorded across the whole time period the patient has been in hospital.

The role of the researcher physician has both different and overlapping needs to the point-of-care clinician. The researcher requires aggregation over records as they investigate the behaviors of staff/processes/drugs/procedures over a collection of specially defined patients. They also need to be able to frame their questions in a manner that is linguistically formal but in the terminology of the clinical setting. The language processing needs for this role are formidable as it requires a number of processing sub-systems to be delivered:

1. Support the common language in the clinical setting in use in the user interface.
2. Information extraction from the individual patient records.
3. Co-ordination of record retrieval based on language and non-language variables.
4. Descriptive statistics analytics using the two types of variables concurrently. An example question might be: "*what is the mean hospital bed occupancy of all males over the 5-year age groups of 40-90 with lung cancer?*"
5. Analytical Statistics comparing hypotheses, for example: "*is there a statistically significant difference in the age of admission for women compared to men for an upper respiratory tract cancers treated by chemotherapy compared to radiotherapy?*"

The processing systems required by the roles of administrator and auditing should be catered for by the systems needed for point-of-care clinician and the researchers if they are designed with sufficient generality.

Experienced staff will need to place themselves in all four of these roles, and their modes of practitioner and teacher, many times in the working week. The objective of NLP should be to develop systems to serve these roles and their modes. The following case study of a corpus analysis identifies many of the problems associated with the current quality of clinical documentation and the strategies we have to implement to overcome them, so that the contents can be used for retrospective clinical research. Moreover building new language technologies to eliminate or minimise these problems paves the way to doing prospective studies in situ in the clinical context and thereby support the enhancement and momentum of translational research.

A CORPUS OF NARRATIVE NOTES FROM AN INTENSIVE CARE UNIT

Building practical language processing systems to serve the roles of physicians and hence support the care and safety of patients and as well as the advancement of medical science requires learning from retrospective studies the limitations of already recorded information and then to design and build new technologies to overcome them. This has been achieved in the case of a study of intensive care notes from an Australian hospital.

The corpus of this study was drawn from 6 years of progress notes (2002-2006) consisting of 44,000,000 words written about 12,000 patients. The notes represent the recordings of all disciplines working in the Intensive Care Service of the Royal Prince Alfred Hospital, Sydney Australia, including intensivists, visiting medical officers (medical specialists), nurses and allied health workers (physiotherapists, psychologists, dietitians, etc.). The corpus is to be known as the RPAH-ICU corpus.

Stages of Processing

This paper deals with a range of issues important to processing these materials before they reach the stage of being usable for information extraction, plus some of the issues related to working as collaborators with clinicians pertinent to the privacy of the records.

Anonymisation

While anonymisation is not directly related to information extraction for use in the clinical wards, it is important in obtaining access to these records so that they can be removed off-site to our own installation for extensive analysis. Hence it is a matter that all researchers have to resolve early in their work. The simplest form of anonymisation is achieved by removing the names and address of patients from the header of the record and only use a Medical Record Number (MRN) to identify the record. This step provides surface anonymisation but there may be other personal information in the record that can enable reconstruction of the patient identity. This can happen especially with distinctive information such as rare disorders, rare locations (e.g. the location of a motor car accident), distinctive names of relatives or attending physicians when combined with information such as age and gender of the patient.

Deep anonymisation requires replacement of the names of all third parties in the narrative notes, including hospital staff and relatives, the names of organisations including other hospitals. It is not normally sensible to remove references to age and gender of a patient as this information tends to be important in many aspects of care and so for any future processing tasks, however reference to specific dates of birth should be removed.

An effective method for identifying names of entities not found in suitable gazetteers is to complete a process of lexical verification over the complete corpus and then manually search the list of unknown words for named entities. Whilst this does not guarantee all named entities will be identified it will capture a very large proportion. We have found that the only names we have not been able to recognise are those from languages with which we are unfamiliar. One confounding variable in this process is the names of medical entities which carry the name of a person. This

Table 2. Distribution of the known and unknown words in the RPAH-ICU corpus

Token Type	No. of token types	No. of tokens in corpus	Percentage
Alphabetic words	157,866	31,646,421	71.8%
Words in Moby	32,081	28,095,490	63.7%
Words in SNOMED	22,421	29,008,594	65.8%
Words in UMLS (excludes SNOMED words)	25,956	27,893,156	63.3%
Words in SNOMED but not in Moby	5,005	1,985,391	4.5%
Words in either SNOMED or Moby	37,086	30,080,881	68.3%
Words in neither SNOMED nor Moby (Unknown words)	120,780	1,565,540	3.6%

is a problem in two situations: when the word is miss-spelt and when the name is not recorded in the medical lexicon, e.g. Hudson mask.

Lexical Verification

Lexical verification is specifically separated from other lexical processing e.g. tagging, spelling correction, because there is a very significant problem in completing this task with narrative clinical notes. We have identified three phases to lexical verification. The first phase is compiling a set of lexica that can be used for verification. The second phase is separating out the unknown words and providing putative known words, and the third stage is capturing true words unknown to the current lexica in an automatic way that makes them readily re-usable.

Assembling Lexica

Lexica for medical NLP need to be assembled from a variety of locations. A lexicon of common English words was taken from the MOBY resource. Medical terminology was drawn from the UMLS and also SCT. SCT is not strictly a lexicon but an ontology consisting of a large collection of medical concepts (approx 360,000). In our work we stripped the individual words of each concept to make a lexicon. The concepts were used in a later processing stage. Many more lexical resources can be found on the Internet for single word processing but are not available for high volume batch throughput. The RPAH-ICU corpus was processed through each of these lexica with the results shown in Table 2.

Identifying and Correcting Unknown Words

Medicine has a highly productive use of language that is, it uses the rules of English word formation very regularly to produce new words, especially the combination of semantic fragments to form new clinical words. In our corpus we have discovered approximately 1000 words indicating medical anatomy and procedures that are not present in SNOMED CT, e.g. anteroseptoapicolateral, heparinise.

The former example shows the morphology of the concepts antero-, septo-, apico- and lateral. The later example has a range of forms that show multiple morphologoical transformations, its longest form so far discovered is “reheparinisation”, which demonstrates a process of taking a noun neologism, verbalizing it, nominalising the verb and then adding a prefix of repetition. Further cases are new forms of existing abbreviations, which might be treated as spelling errors, entirely new abbreviations, and new/proprietary drug names.

The RPAH-ICU corpus provided 120,780 unknown word types representing about 5% of the alphabetic words (Table 2) although they only constitute 3.6% of the total corpus. Whilst there is some temptation to treat this error rate as tolerable in a very large corpus it is not advisable. On an assumption of an average of 10 words per sentence then this error rate represents one unknown word in every second sentence which would produce a parsing error in 50% of the sentences, without allowing for errors from other sources.

The unknown word list was processed for putative corrections by computing the edit distances of 1 and 2 edits to known words. The results were divided into three classes: words that had only one candidate correct word (64,152), words that had multiple candidates (27,610), and words that had no candidates (29,018). The verification process involved inserting the words into a spreadsheet with their putative correct forms, manually checking the offered correction and accepting it or providing an alternative word. Checking was done by an experienced English speaker (JP) from personal knowledge and with support from use of dictionaries sources available from the Internet and Google searching. Unidentifiable words were referred to medical colleagues. Ever word type in the single candidate and no candidate classes have been manually corrected in this way. In the multiple candidate class all words down to a frequency of 4 (6312 types) have been manually verified, giving a total of about 100,000 corrected words.

Avenues of research created by having this material will be valuable for future work. Better automatic spell checking at the point of data entry of narrative notes will enhance the quality of the English and make post processing and especially semantic search and concomitant analytics more reliable. Further support at the point and time of data entry can be created and improved, e.g. automatic expansion of acronyms and abbreviations, verification of clinical terminology, autocompletion of difficult terminology for trainees and LOTE speakers.

Two other ICU corpora have been offered to us for similar analyses. This processing will significantly reduce the amount of effort we have to input into preparing these materials and providing analyses. Also we will be able to investigate the differences in lexicon and language usage from different instances of the same communities and thereby recognise the phenomena that are common to all and also triangulate on the level of differences that exist. The continuity of this work both within the community of Intensive Care Services and the potential to expand into other clinical disciplines makes it vitally important to effectively and automatically manage the collection of new language lexica and usage in the course of studying each corpus.

Capturing New Words

Identifying a "correct" form of a word is straight forward despite being very time consuming. However it is most important that the results of this work are captured whilst the work is progressing. Part of the process of manually verifying unknown words provide the opportunity to collect other information to attach to the word. In our case we have added semantic classes to words and descriptions of their morphological components where applicable. The morphology is useful in the future to recognise hyphenated and un-hyphenated version of words even though they have not been seen in the current corpus. The semantic class information we expect to assist us in later tasks of knowledge representation of the patient case, but we have no specific need for it at this stage.

New words need to be provided to subsequent lexical verification processes after they are initially captured. In principle this merely requires adding the word to the current word list used in the processing system. However if the full value of the process of acquiring new words is to be obtained a record needs to be kept of the source of the word and any other classificatory information that is collected at the time of verification, as described above. This approach demands the compilation of the history of the discovery and usage of the lexical item, which self evidently indicates the need to develop a lexical database to record the relevant content. The database should contain all the words identified from the corpus, which by implication includes the misspelt forms so that they can be readily used in later spell checking software. However, the primary function of the lexical database is to record the first source of the word (to the processing system) and then other classical lexicographical information. In a large production processing system the database itself would not be invoked but rather wordlists would be extracted from it for use in "in-memory" processing applications.

Spelling Correction

Automatic and semi-automatic spelling correction at the time of data entry can be based on two alternative premises. The first premise is that the true word can be found by searching a nearby space of letter configurations for the incorrect word – this is the edit distance model and it is effective if the true solution is truly close to the original word. The limitation is created by the fact that computing edit distance alternatives is expensive given real-time response is needed and it generates a large number of alternative answers. The second premise is that a mapping from the erroneous form to the true form is stored in a lexical database with perhaps better than 90% reliability. This approach is most limited when the true word is not stored. The alternative strategy is to build a statistical spell checker based on a supervised machine learner that estimates the type of mistake made by the user and offers alternatives based on the statistical characteristics of typical spelling errors. To develop such an approach requires the accumulation of the data we have collected by manually correcting the RPAH-ICU corpus.

Spell correcting as a post hoc process required for the analysis of a collected corpus requires some variations in these processes.

1. Word substitutions may sometimes be incorrect because the corrected word has not been identified in situ.
2. Some words cannot be corrected and remain "unknown".
3. The consequences of changing the text after the fact can be serious if any mark-up annotation has already been done to the text.

Appropriate planning for the acquisition of new words and their reuse in later processing needs to be carefully engineered. This is an on-going task for poorly composed materials which arises from the continual variation of content that is introduced in a large and busy hospital unit with diverse and ever-changing staff and patient populations.

The objective of the NLP research in this domain should be to draw an ever increasing amount of content from other clinical disciplines, where each new additional corpus will be better served with a continued accumulation of new terminology and new usages of it.

Entity and Concept Recognition

The recognition of medical entities is a vexed and thorny problem for a number of reasons, namely:

1. There are many knowledge resources in existence and a subset has to be chosen to do a particular piece of work, and any selected resources will have their own gaps in the knowledge one needs to give complete coverage for a given corpus.

2. Even with the use of a comprehensive resource like SNOMED CT when gaps are detected there is no ready mechanisms for inserting the nearly discovered content into the original resource.
3. Rich entity resources have concept entities written in linguistically idiosyncratic ways which create their own obstacles to being used for ready recognition in narrative notes. For example the SCT concept of "third degree burn of elbow with loss of limb" can be written in a myriad of other grammatical forms. In another classification it might have the form "burn, 3rd degree". The processing system needs to be able to reduce both the resource text and the narrative text into canonical forms so there is a better chance of matching the narrative with the concept definitional text.

The RPAH-ICU corpus was analysed for concepts using a methodology reported in Patrick et al. (2007) which indexes every SCT concept for its words (excluding stop words) and then reduces the target text to chunks which are in turn canonicalised. Matches with the SCT words are made and the highest ranked matching concept is accepted as the authentic concept representation of that chunk in the narrative notes. Figure 1 shows an example of a block of narrative text, the SCT concepts recognised and the locations they have in the SCT ontology. Apart from 6 true positives there are 4 false negatives: "Cholycystectomy" is "Cholecystectomy" in SCT, a spelling error in "hypogylcaemics", BSL is an unknown abbreviation in SCT, and cardiac failure is an incomplete expression in SCT used in a total of 27 different concepts. Manual inspection of concept identification suggests the error rate on false negatives is between 20-30% without allowing for all forms of orthographic variation. The amount of false of positives has not been estimated yet, as they require extensive manual analysis of the texts.

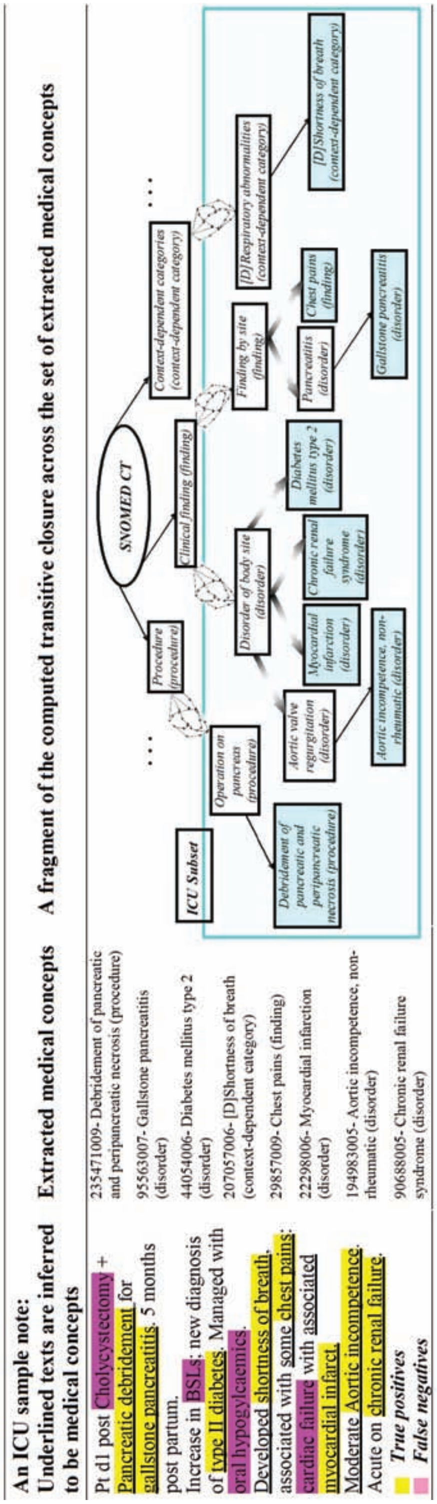
Terminology Server

An infrastructure for supporting the analysis of text requires an underpinning data repository that stores all the language resources and also supports a variety of processing tasks. Typically NLP projects have used a lexical database for this function however this is not sufficient for clinical NLP. In this field the medical knowledge is invariably stored in more complex knowledge schemata such as TTOCs, from which the terminology server has to deliver all their structure to an application as is necessary. Design issues of terminology servers have not been visited since the late 1990s (Chute, C., Elkin, P. L., Sheretz, D. D., & Tuttle, M. S., 1999) and require a review which we are undertaking. However the practical experience of this research indicates that a terminology server must serve at least the needs of concept identification, data analytics, Inter TTOC mapping, and decision support. It is within the terminology server that medical terminology that is acquired during processing a corpus is not only recorded but placed within a TTOC framework to maximize its potential re-use in knowledge modelling – not just language processing.

Research Objectives

A set of SCT concepts extracted from a large corpus brings the opportunity to inductively infer the most appropriate subset of SCT for Intensive Care services. There are 13,136,022 concept instances making up about 30,000 unique concept types detected in the corpus. Reducing the set of concepts to those of a frequency 100 and more yields the reduced set comprising 2718 codes, which covers 6,177,077 of the 6,428,597 codable item instances or 96.09% of all codable items. The remaining 3.91% of codable items (n=251,520) requires an additional 21,375 SCT codes. Restricting the set to only the top 1000 codes by usage would cover 89.25% of the codable items in the corpus.

Figure 1. *Example of clinical narrative notes annotated of SCT codes and illustration of their relationships in the SNOMED CT ontological structure*



Subsequent to computing the SCT subset evidenced in the corpus another stage of computing the minimal superset of the evidenced set and the local sub-trees around them has to be performed. This ensures coverage beyond what has been observed to what might reasonably be observed without allowing the subset to expand too greatly. The subset inferred from this strategy produced about 15,000 concepts and relationships or about 1% of the total SCT database.

The process has a number of advantages over recruiting a panel of experts to define a suitable SCT subset, namely:

1. It constitutes the evidence for the subset in an unchallengeable manner.
2. It is not susceptible the vagaries of human memory and preferences to compose the list.
3. It provides a small enough list for the subset to be manually reviewed and modified to create an improvement on "native" SCT.
4. Once the methodology is systematized it provides a strategy reusable for any and all clinical specialties.
5. It should prove to be both a highly economical and efficient method of deriving subsets that are more reliable.
6. It shrinks SCT enough so that description logic engines might perform queries for users in real-time.

PRACTICAL APPLICATIONS OF NLP IN THE HOSPITAL WARD

The use of entity and concept identification can assist in a number of fundamental tasks in the care process. In the two use cases described below (WRIS and CliniDAL) the SCT concept identification enables a semantic index to be created over the narrative notes and thereby provide a mechanism for fast retrieval and categorization of their contents. Much of the activities in processing narrative notes can be viewed as research for academic purposes and contributing to computational linguistics research in its own right. However, it is more valuable and rewarding to affix the research to objectives of providing improved processing for the medical care work of itself. Described below are two projects that require the use of our knowledge and research into the ICU corpus but where that knowledge has been put to use for practical benefit for our medical collaborators.

Ward Rounds Information System

The Ward Rounds Information System (WRIS) is a two part processing system aimed at gaining work productivity in carrying out ward rounds in the ICU (Ryan, A., Patrick, J., & Herkes, R., 2008). In the past the system for performing ward rounds entailed a junior doctor reading many pages of the clinical IS and compiling the most appropriate recent information into a report. This process was error prone, tedious and timely costly taking between 5-10 minutes per patient and needing to be repeated across a 50 bed ward. The first phase of WRIS was to build a complementary system that read the wanted data from the host IS and presented it on a web page. The second phase of the WRIS was for the medical staff to write their clinical notes into the web page and then submit them for conversion to SCT codes. These codes are presented to the staff along with the original text and they are asked to confirm or reject the computed codes. The accepted codes can then be written to the patient record and by being resident there they constitute an index of the record for later retrievals and analytics. The rejected codes form a body of knowledge that can be used to improve the text to SCT encoding process. This technology is now the basis of a wider project to produce a generic strategy for generating Handover reports based on natural language processing.

Clinical Data Analytics Language (CliniDAL)

The CliniDAL is a controlled language for expressing queries to perform retrievals and data analytics on the patient records held in the host clinical information system. It is especially designed to support the use of local clinical dialectal language to express queries, but also it executes those queries over the clinical notes as well as the structured parts of the database. CliniDAL contains a mapping table of every data field in the database relating it to a user interface term, SCT expression (where possible) and the community's clinical sociolect. Furthermore the SCT indices created in the WRIS process are used for retrievals across the clinical notes.

CONCLUSION

All medical imaging and measurement eventually becomes language so NLP is the most important innovation required to advance medical research using the information captured at the coalface of health care – the patient record. Using the patient record retrospectively requires solving serious problems in dealing with linguistically inferior content. Learning how to solve these problems for the retrospective material is fundamental to creating aids for current staff to create future records of a much better linguistic quality and thereby enhance the quality and purposefulness of future language processing systems. There are major problems in giving full coverage to a very broad range of terminologies and concepts needed to be recorded in acute care situations. Better language processing is needed but it is also important that mechanisms ensure knowledge is captured at its time of first recognition and passed back into the processing system for continual reuse. It is an important facet of language processing that any created resource is always reusable and never suffers from depreciation, although the technology that exploits it might.

The narrative of the clinical record constitutes the most important piece of evidence collected in the process of caring for sick and infirmed people. Efforts to relate the outcomes of care processes to their interventions and the medicines will only be achieved on a large scale by harnessing the contents of the patient record, and at the moment, most of the relevant content is locked in the written text. While some valuable content is available from the structured part of the clinical record substantial advances in translational research are dependent on retrieving content locked up in the narrative texts. The technology required to achieve this access has to move through two major phases. Firstly significant studies have to make use of retrospective content to establish the nature of the contents and the best methods for dealing with the processing problems intrinsic to the nature of the data. We have described examples of those problems in this paper with respect to materials from one intensive care service. The second phase is inferring from this knowledge the technologies we have to build to support and shape the behaviours of clinical staff in the future so that firstly they minimise the problems we currently encounter, but also that the technology supports improvement in the way they record the content relevant to not only patient needs at the point of care but also to the larger objectives of translational research. Once such objectives are attained then natural language processing will be able to serve the prospective needs of medical science in very significant ways.

ACKNOWLEDGMENT

We wish to acknowledge the contributions of our partners and collaborators: Dr Robert Herkes and Angela Ryan from the Royal Prince Alfred Hospital, Peter Budd, Yefeng Wang and Yitao Zhang from the University of Sydney, and Prof

Alan Rector, Dr. Sebastian Brandt and Jeremy Rogers from the University of Manchester,and Bahram Vazirnezhad, Tehran University of Technology, Iran.

Chapter 7.17

Multicriteria Models for E-Health Service Evaluation

Gulcin Buyukozkan

R. Ufuk Bilsel
The Pennsylvania State University, USA

ABSTRACT

The use of advanced telecommunications and information technologies has been investigated for several decades as an effort in improving healthcare services. Over the last ten years, in particular, efforts have been centered on telemedicine, which has become an increasingly attractive field of research in healthcare service delivery. This chapter discusses multiple criteria evaluation of electronic healthcare (e-health) services, a branch of telemedicine, with both users' and practitioners' (service provider) perspectives. The proposed approach integrates several analytical decision making techniques and can be helpful in increasing the flexibility and efficiency of e-health service planning. Several different discrete alternative methods, namely AHP, Borda Count, LINMAP, and PROMETHEE are utilized to prioritize different e-health services and to evaluate preferences of both users and practitioners.

INTRODUCTION

Quality of healthcare service delivery has been one of the major issues facing healthcare providers, employees, employers, and government agencies. Healthcare delivery is mainly constrained by geographical location and economic status of intended receovers and operational efficiency at service providers. As a result, the healthcare community has faced challenges in distributing healthcare resources, providing healthcare equally to all socio-economic segments of the population, and controlling healthcare costs. One way to efficiently handle these limitations is to incorporate innovative information technologies (IT) in healthcare service delivery. Telemedicine has been proposed as a multifaceted IT based response to solve the above mentioned problems (Bashshur, 1997). American Telemedicine Association (ATA) defines telemedicine as the use of medical information, exchanged from one location to another via means of electronic communication, to improve health status of patients (ATA, 2006). The objectives of telemedicine, and of electronic health (e-health) which is an implementation of telemedicine, are to enhance patients' equality in the availability of various medical services despite geographical and economic barriers (McConnochie et al., 2006), reduce direct and indirect costs (loss of production or income) to patients and to healthcare industry (de Toledo et al., 2006), save travel time for both practitioners and patients (Samii et al., 2006), reduce waiting time and cut lines in healthcare institutions (MacFarlane et al., 2006) and improve consultation and co-operation among geographically distributed healthcare units by bridging the distance between practitioners and specialists (Harrison et al., 1996).

Telemedicine continues to become a facilitator in healthcare delivery. A recent article by Samii et al. (2006) describes a telemedicine application in Parkinson treatment. They used telemedicine to conduct follow up controls of 34 patients at several regional centers located 67 to 2,400 kilometers away from a main healthcare facility. They report cost, time and travel savings amounting up to $37,000, 1,500 patient hours and 100,000 kilometers. McConnochie et al. (2006) comment on benefits of telemedicine in the treatment of childhood illnesses. They tested the effectiveness of two practices: patients actually visiting physicians and patients treated via telemedicine. They found out that about 85% of cases were suitable for treatment via telemedicine and that telemedicine provided the same service effectiveness as personal visits. de Toledo et al. (2006) report a telemedicine service that delivers home care to chronic obstructive pulmonary disease patients. They tested the service during a period of one year and reported the improvements through telemedicine implementation. One of their major findings was that the telemedicine services resulted in up to 51% increase in the number of patients that were not readmitted and required low implementation costs. MacFarlane et al. (2006) report telemedicine applications in Ireland and provide some comments from actual practitioners and users of these services. They argue that reducing patient traveling and removing isolation from professionals for people in rural areas are among the significant benefits of telemedicine. Several other publications report successful telemedicine applications worldwide, including in Canada (Jennett & Andruchuk, 2001), Europe (Lareng, 2002), Nigeria (Adewale, 2004) and eastern Asia (Chen et al., 2001; Kasitipradith, 2001).

Surprisingly, despite the increasing popularity of telemedicine, published work in telemedicine service assessment is limited. One reason behind this scarcity is the lack of extensions of well developed brick-and-mortar service quality models to electronic services (e-services). Particularly, most of the e-health service evaluation literature is at the level of conceptual work (e.g. Bedini et al. (2006) and Giansanti et al. (2007)). A few papers addressing the issue via analytical approaches also exist. For instance, Bilsel et al. (2006) proposed a ranking method to evaluate hospital websites and presented an application in Turkey. They argued that telemedicine service assessment should be based on several evaluation criteria and proposed a multicriteria decision making (MCDM) scheme. They teamed up with actual decision makers (DMs) in their study and modeled their verbal judgments as fuzzy numbers for integration in the MCDM framework.

This chapter fills the service assessment gap in research on telemedicine service delivery evaluation by proposing MCDM methods and applying them to evaluate e-health applications. We study e-health services with both users' and practitioners' perspectives. Our aim in this separation is to bring a broader view to e-health service evaluation by acknowledging potential differences between what users are looking for and what practitioners are seeking to offer. Criteria of the problem are grouped in two sets in a way to reflect expectations of both parties and their understanding of e-health services. The proposed approach integrates analytical decision making techniques and can be helpful in increasing efficiency of e-health service planning and delivery. Our methodology will affect e-health service providers in at least two ways. Firstly, our results are valuable in better understanding demands and needs of customers. Moreover, the evaluation framework presented here can be extended with additional criteria and alternatives and be used in professional pre implementation and feasibility analyses.

This chapter is organized as follows. The immediately following section presents the overall evaluation framework. The next section, introduces problem alternatives and evaluation criteria followed by descriptions of MCDM methods used in the application. The section that follows presents results of two studies we conducted; Study 1 which treats the problem from users' point of view and Study 2 which provides a practitioners' perspective. Discussion and conclusions section compares and contrasts the two studies and concludes the chapter with a future research agenda.

EVALUATION FRAMEWORK

This section provides an overview of the evaluation framework proposed in this chapter. The first step is identifying the alternatives to evaluate and criteria to be used in evaluation. The second step selects appropriate MCDM methods for use in the ranking of alternatives. The third step involves interactions with DMs and acquires their preference information. The final step is the application of the MCDM methods to determine the ranking of alternatives. The framework can be summarized as below,

- *Step 1:* Determine the alternatives to evaluate and appropriate criteria to use in evaluation. This step should be carried out through a literature survey and by consulting the practitioners and users.
- *Step 2:* Determine one or several MCDM methods. The selection of the MCDM method depends on the number and type of alternatives. In our study, both criteria and alternative sets are finite and discrete (see the next section); therefore, we use discrete alternative MCDM methods.
- *Step 3:* Determine the DMs and the preference data collection method. The selection of the preference collection method depends on the number of DMs. Nominal Group Technique or Delphi Method are suitable for relatively small sized groups. For large groups questionnaires or surveys may perform better.
- *Step 4:* Collect preference data and apply the selected MCDM methods to rank alternatives. This step processes gathered data and derives conclusions using the selected MCDM methods.

We shall follow the above sequence in detailing the proposed framework.

ALTERNATIVES AND CRITERIA

In this section we present the evaluation criteria and alternatives used in the e-health service assessment study. We analyze e-health services from two different perspectives. In our first study we approach the problem from the perspective of e-health service users. The second study treats the same problem from the practitioners' point of view. Alternatives compared in these two studies are the same but there are differences in the criteria sets to acknowledge that the two parties may approach the same problem in distinct ways and criteria appropriate for one group is not necessarily valid for the other. All evaluation criteria and alternatives are derived from published literature including Parasuraman et al, (1988), Jennett & Andruchuk (2001), Cox & Dale (2002), Richardson (2002), González & Palacios (2004), Kim & Stoel

(2004), Van Iwaarden et al. (2004), ATA (2006), de Toledo et al. (2006), EHNAC criteria report (2006) and Bilsel et al. (2006). We have also made several modifications in the criteria sets following the suggestions of DMs prior to preference data collection sessions.

Alternatives

We consider the following six e-health services as alternatives in our analysis. The alternatives are determined in coherence with published literature including Richardson (2002), ATA (2006), de Toledo et al. (2006), EHNAC (2006) and through communications with practitioners. Some of these alternatives have been widely implemented in healthcare institutions which provide e-health services (e.g. teleconsultation) while some others are in trial phases in very few institutions (e.g. remote patient monitoring). The alternatives are as follows:

Teleconsultation (A1): A teleconsultation system is an e-health application to be used by physicians to inspect the medical symptoms of patients at remote locations. Teleconsultation may be performed either in real-time or asynchronously. In real-time teleconsultation, specialized medical staff inspects vital signals and images of patients and makes a diagnosis at the end of the session. In the asynchronous case, on the other hand, physicians accesses medical data at a later convenient time.

O*nline appointment (A2)*: An online appointment application is a service that allows patients to schedule physician appointments on the Internet. This service potentially eliminates human errors such as mistyping the appointment time or entering patient data wrong and may simplify the scheduling procedure. Online appointment can also reduce costs and increase efficiency of bookkeeping at healthcare institutions.

Online pharmacy (A3): An online pharmacy service functions similar to electronic marketplaces like Amazon.com or Buy.com and allows patients to purchase drugs over the Internet. The online pharmacy service involves online money transactions and may require physician's prescriptions as well.

Remote patient monitoring service (A4): Electronic patient monitoring is an advanced service that collects data at patient's location and sends it to a monitoring station for interpretation. Also referred to as home telehealth applications, electronic patient monitoring services might include transmission of specific vital signs such as blood glucose, heart ECG or a variety of indicators for homebound patients. Such services are proposed as a replacement to visiting nurses.

Electronic medical library service (A5): Electronic medical libraries are healthcare databases; patients can use these online applications to access information on various diseases and relevant suggestions about how to get cured. An electronic library service requires a well formed database to keep and deliver requested information and an intelligently created website to attract patients.

Electronic medical record (EMR) access (A6): An EMR contains a patient's health history and is highly confidential. A patient that needs to access his or her record would be able to do so electronically if such a service is provided.

Criteria for Study 1

We present below six criteria used in Study 1, the evaluation of e-health services from users' perspective. Criteria are derived from published literature on service quality including Parasuraman et al., (1988), González & Palacios (2004), Kim & Stoel (2004) and Van Iwaarden et al. (2004). The criteria set is slightly modified after interactions with DMs: accessibility was previously the second criterion in this set but was modified to access speed following DMs suggestions. Criteria used in Study 1 are as follows,

Web design (C_u1): This criterion represents the quality of the web page through which the e-health service is delivered. An effective web design should be user oriented and customizable. Site layout, graphic animations and presentation are also important features. A sophisticated web design may attract more users; hence, web design criterion is to maximize.

Access speed (C_u2): Access speed emphasizes the importance of the time required to get information from the web server. This criterion was proposed by the DMs of Study 1. It is assumed that all users have the same bandwidth, so that the access speed would depend only on the size of the application and the upload rate of the e-health service server. The access speed criterion is to maximize.

Attractiveness (C_u3): Attractiveness measures the attitude of potential customers towards an e-health service. If the DMs think that a particular service would be useful they assign a high attractiveness score. Hence the attractiveness criterion is to maximize.

Safety threat (C_u4): This criterion is used to measure the users' attitude towards the level of exposure to threat while using a particular e-health service. If the DMs think there is a high possibility of personal information theft while using a particular service, the safety thereat for that service is high. Safety threat criterion is to minimize.

Quality of content (C_u5): Quality of content refers to the relevance of the content of an e-health service, level of detail of the information and frequency of updates. Quality of content criterion is to maximize.

Interactiveness (C_u6): Interactiveness is related to the degree of responsiveness of an e-service. It is an important feature for an e-service to be user friendly and practical. Interactiveness criterion is to maximize.

Criteria for Study 2

The second set of criteria is used in the evaluation of the e-health service alternatives from the practitioners' point of view. These criteria are denoted with a subscript *p* to distinguish them from the criteria used in Study 1. Except for the web design criterion, criteria for Study 2 are different from criteria used in Study 1. Criteria of Study 2 are derived mainly from the following references: Jennett & Andruchuk (2001), Cox & Dale (2002), Bilsel et al. (2006) and through interactions with the DMs of Study 2.

Web design (C_p1): The web design criterion in Study 2 represents the same concept as in C_u1 of Study 1. The web design criterion is to maximize.

Service readying time (C_p2): Service readying time represents time spent to prepare the content of the e-service to offer and to execute required operations before going online; such as testing and validating the web site operability. Some services might require acquiring special permissions or may be subject to some particular regulations that need to be satisfied and meeting these requirements might be time consuming. In the contemporary competitive business environment, institutions that can offer new services faster have better chance to gain competitive edge over their rivals; therefore, a shorter readying time should be preferred. Hence, the service readying time criterion is to minimize.

Customer potential (C_p3): The customer potential criterion represents the expected number of customers that would use the new e-health service. The estimated number of future users is vital to the success of the e-health service. The customer potential criterion is to maximize.

Setup difficulty (C_p4). Setup difficulty represents the complexity of the operations executed during the service readying period such as the complexity of the underlying software, synchronization of the new e-health service with the current hospital IT systems, etc. This criterion is to be minimized.

Staff training (C_p5). Current staff at a medical institution may require additional training to provide a new e-health service. For instance, in a teleconsultation service physicians should be familiar with setting and conducting video conferences and online data sharing. If practitioners do not have the required background, they have to receive training to be able to offer the new e-health service and may delay the implementation. These instruction sessions will also consume resources such as time and money. Hence, the staff training criterion is to be minimized.

Expected utility (C_p6). The expected utility criterion represents possible outcomes of offering a new e-health service. The expected utility criterion is proposed by the DMs who participated this study and is mostly perceived as financial benefits. The expected utility criterion is to be maximized.

EVALUATION METHODS

MCDM methods provide the flexibility of considering multiple measures in comparing and ranking a set of alternatives. These methods are especially useful in problems where analysts and DMs desire to treat the problem using more than one criterion. MCDM is one of the rare operations research techniques where DMs are involved in the solution process. This feature brings two significant advantages: the problem can be easily structured corresponding to DMs requests and the results are more easily adopted by DMs since they are actively involved in the solution procedure (Masud and Ravindran, 2007). We have determined four MCDM methods to be used in our framework. Following subsections detail these methods and justify our selection.

The PROMETHEE Method

PROMETHEE (Preference Ranking Order METHod for Enriched Evaluations), developed by Brans (1982) and further extended by Brans & Vincke (1985) and Brans & Mareschal (1994) is an effective ranking method which is accepted as one of the most intuitive of all discrete alternative MCDM methods (Pomerol & Barba Romero, 2000). PROMETHEE has found a large domain of application such as finance (Bouri et al., 2002), transportation (Ülengin et al., 2001), energy source selection (Topçu & Ülengin, 2004), information technology strategy selection (Albadvi, 2004), and hospital website evaluation (Bilsel et al., 2006).

The PROMETHEE approach is based on a preference function Ω which expresses the DM's preference for an alternative against other alternatives. For two alternatives α and β and a criterion j to be maximized, let the evaluation of the alternative α under criterion j be denoted as $C_j(\alpha)$ and let the difference of the evaluations of α and β as $d_j(\alpha, \beta)$ as in Equation (1).

$$d_j(\alpha, \beta) = C_j(\alpha) - C_j(\beta) \quad (1)$$

Two critical values, an indifference threshold q and a strict preference threshold p can be introduced to customize the preference function. Then, Ω can be presented as in Equation (2)

$$\Omega_j(\alpha,\beta) = \Omega_j\left[d_j(\alpha,\beta)\right] = \begin{cases} 0 \ if \ d_j < q \\ H_j(d_j) \ if \ q \le d_j \le p \\ 1 \ if \ d_j > p \end{cases} \quad (2)$$

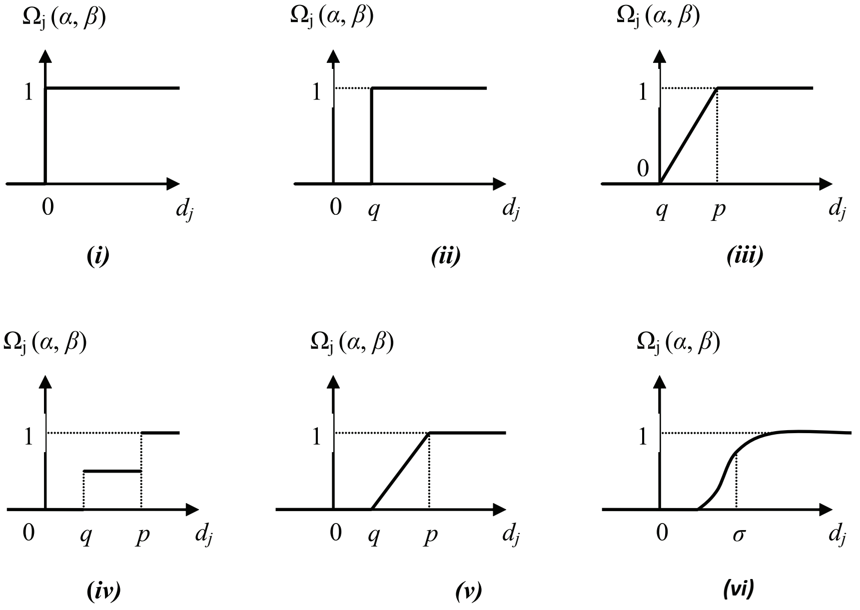
where H_j is a criterion function varying in the interval [0, 1]. Six different H_j functions have been proposed to be used in PROMETHEE. These functions are given in Figure 1. Note that the preference function Ω takes values in the interval [0, 1].

Once the type of the H_j function to be used for each criterion j is determined, the preference index $c(\alpha, \beta)$ can be calculated as follows,

$$c(\alpha,\beta) = \sum_j w_j \Omega_j(\alpha,\beta) \quad (3)$$

where w_j represents the weight of criterion j. For a proper application of the PROMETHEE method, weights should be strictly positive and

Figure 1. H_j functions. i: Simple criterion; ii: Jump with indifference threshold q; iii: Linear passage with indifference threshold 0 and strict preference threshold p; iv: Staircase; v: Linear passage with indifference threshold q and strict preference threshold p; vi: Gaussian. (Schärlig, 1996)



normalized. Several different methods can be used to calculate the w_j values. In this chapter PROMETHEE weights are calculated using the Analytic Hierarchy Process (AHP) detailed in the next subsection. Several other publications followed the same approach as here (see for example Macharis et al., 2004, Bilsel et al., 2006)

The next step calculates flow values of alternatives. PROMETHEE uses two types of flows: *leaving flow* and *entering flow*. The leaving flow of an alternative α is an indicator of preference of α over all other alternatives. It quantifies the relative "strength" of alternative α. The leaving flow is calculated as in Equation (4).

$$\Phi^{+}(\alpha) = \sum_{x \in A} c(\alpha, x) \tag{4}$$

where A is the set of alternatives. Entering flow of an alternative α, on the other hand, indicates the superiority of all other alternatives over α; that is, it quantifies the relative "weakness" of alternative α. The entering flow is calculated as in Equation (5)

$$\Phi^{-}(\alpha) = \sum_{x \in A} c(x, \alpha) \tag{5}$$

In PROMETHEE I, alternative α is declared superior to alternative β if the leaving flow of α is greater than that of β and the entering flow of α is smaller than that of β. Using our notation, α outranks β if $\Phi^{+}(\alpha) \geq \Phi^{+}(\beta)$ and $\Phi^{-}(\alpha) \leq \Phi^{-}(\beta)$. α and β cannot be compared if $\Phi^{+}(\alpha) > \Phi^{+}(\beta)$ and $\Phi^{-}(\alpha) > \Phi^{-}(\beta)$ or if $\Phi^{+}(\alpha) < \Phi^{+}(\beta)$ and $\Phi^{-}(\alpha) < \Phi^{-}(\beta)$. The PROMETHEE II method can be applied to overcome the issue of incomparability and to obtain a complete ranking. PROMETHEE II takes into consideration the net flow values, Φ^{net}, calculated as the difference of leaving and entering flows as in Equation (6). The alternative with a higher net flow value is better than the ones with smaller net flows.

$$\Phi^{net}(\alpha) = \Phi^{+}(\alpha) - \Phi^{-}(\alpha) \tag{6}$$

PROMETHEE provides an intuitive and tractable approach to treat MCDM problems. It poses relatively less burden on the DMs compared to other well known methods (AHP for instance); and therefore, it's more attractive. Finally, PROMETHEE is very flexible since it provides analysts with a wide range of criterion function shapes (see Figure 1).

The Analytic Hierarchy Process

Analytic Hierarchy Process (AHP), developed by Saaty (1980), is one of the most widely applied discrete alternative MCDM methods. It has been used in a wide area of applications including telecommunication systems selection (Tam & Tummala, 2001), supplier selection (Chan, 2003), new product development (Ayag, 2005) and flexible manufacturing systems (Bayazit, 2005). Moreover, AHP is also used as a means of generating weights to be used in other MCDM methods, e.g. PROMETHEE (see for instance Macharis et al., 2004)

AHP consists of constructing a problem hierarchy, defining priorities between the elements of the hierarchy and checking for overall consistency of DM´s evaluations. The first act when applying AHP is to recast the decision problem into a hierarchy with a goal at the top, criteria and sub-criteria at descending levels and sub-levels and decision alternatives at the bottom. Then, elements of the constructed hierarchy are compared in pairs in order to set their relative priority with respect to elements at the immediately upper level. The DM is suggested to use a fundamental 1-9 scale defined by Saaty (1980) to assess the priority scores. In this context, the assessment of score 1 for a pairwise comparison indicates equal importance of the compared criteria. A score of 3 indicates the first criterion is preferred moderately more, 5 strongly more, 7 very strongly more and 9 extremely more. The intermediate values 2, 4, 6, and 8 are allotted to indicate compromise between the scale values.

AHP requires pairwise comparisons of criteria among themselves to determine criteria weights. In a problem with *N* criteria, preference values are stored in an N-by-N pairwise comparison matrix $\mathbf{A}_{\mathbf{NxN}}$. Let the entry at the intersection of row *i* and column *j* of **A** be a_{ij}. A criteria weight vector $\boldsymbol{w}$ is obtained by normalizing the a_{ij} values first with respect to the columns of **A** using the L_1 norm as in Equation (7) and then with respect to rows as in Equation (8).

$$r_{ij} = a_{ij} \Big/ \sum_{i=1}^{N} a_{ij} \tag{7}$$

$$w_i = \frac{1}{N}\sum_{i=1}^{N} r_{ij} \tag{8}$$

AHP assumes that the weights calculated verify Equation (9) where λ_{max} is the largest eigenvalue of **A**.

$$\mathbf{A}.\boldsymbol{w} = \lambda_{\max}.\boldsymbol{w} \tag{9}$$

λ_{max} is used to evaluate the consistency of DM's pairwise comparison inputs. λ_{max} can be approximated as in Equation (10).

$$\lambda_{\max} \approx \frac{1}{N}\sum_{i=1}^{N} \frac{(Aw)_i}{w_i} \tag{10}$$

Consistency of DM's inputs is checked in two steps. First, the λ_{max} value is fed into Equation (11) to calculate a consistency index (CI) value.

$$CI = \frac{\lambda_{\max} - N}{N - 1} \tag{11}$$

Then, the CI value is divided by an empirical consistency value RI which depends on the problem size. Usually, the DM's inputs are assumed to be consistent if the final consistency ratio is smaller than 0.10. If the DM's inputs are inconsistent, then he needs to provide new pairwise comparison data until consistency is reached. The above process is repeated to get the pairwise comparison results of alternatives with respect to each criterion. The scores of alternatives are recorded in a matrix **B** and the final ranking is obtained through multiplying **B** by the criteria weight vector ***w*.** A more detailed description of AHP can be found in Masud and Ravindran (2007).

AHP provides a systematical way to structure a MCDM problem as a hierarchy, analyze the hierarchy using matrix calculations and check for consistency for assessing the overall quality of the analysis. It also provides criteria weights as a byproduct which can be used in other MCDM methods. For large problems however, AHP requires tedious calculations and may pose significant cognitive burden on the DMs.

Borda Count Method

Borda Count is a discrete alternative MCDM method where a DM ranks alternatives in order of preference. For an MCDM problem with P criteria, the criterion ranked first by the DM gets P points, the criterion ranked second gets $P - 1$ points, etc., where the last criterion gets 1 point. Let S denote the sum of all points. Then the first ranked criterion gets a score of P/S; the second ranked criterion gets a score of $(P - 1)/S$, etc. and the last criterion is assigned a score of $1/S$. The score of an alternative is calculated by multiplying the alternative´s evaluation for a criterion with the weight of that criterion. The overall score of an alternative is calculated by summing the scores of that alternative over all criteria.

Borda Count is less frequently applied compared to AHP and PROMETHEE. It has been used in engineering design (Dym et al., 2002) and pattern recognition (Nanni & Lumini, 2006). Borda Count is relatively easier to apply compared to other MCDM methods with less cognitive and computational burden.

The LINMAP Method

LINMAP is a discrete alternative method based on pairwise comparison of alternatives (Srinivasan and Shocker, 1973). Using these comparisons, a linear programming formulation is crated to minimize the inconsistency of DMs. Let **A** be the matrix of paired comparisons of alternatives with respect to P criteria and let $S_i = \sum_{j=1}^{P} a_{ij} w_j$ be the score of alternative i. Decision variables in LINMAP are the criteria weights denoted by w_j. If alternative i is superior to alternative k, then the score of alternative i should be greater than the score of alternative k; that is, $S_i > S_k$. However, this inequality may not be verified if the DM is not consistent. LINMAP accounts for DM´s inconsistency and introduces an error term x_{ik} for the comparison of alternatives i and k. The objective of LINMAP is to minimize the sum of the x_{ik} error terms. The generic form of a LINMAP model is as follows,

$$\begin{aligned}
&\min \sum_i \sum_k x_{ik} \\
&s.t. \\
&S_i - S_k + x_{ik} \geq 0 \quad \forall i, k \ni i \succ k \\
&w_j \geq 0 \quad \forall j
\end{aligned}$$

Note that the first set of constraints can be expanded as in Equation (12).

$$S_i - S_k + x_{ik} \equiv \sum_j a_{ij} w_j - \sum_j a_{kj} w_j + x_{ik} \tag{12}$$

LINMAP provides a structured way to calculate criteria weights and assess DM´s inconsistency. Like the Borda Count method, it has been less frequently applied compared to other MCDM techniques. Recently, Xia et al. (2006) proposed a fuzzy extension of LINMAP. Zhang and Lu (2006) applied LINMAP to solve a reverse logistics problem.

Table 1. PROMETHEE evaluation scores of alternatives with respect to study 1 criteria (scores represent consensus evaluations of DMs)

Alternative	Criterion						H_j	q	p
	C_u1	C_u2	C_u3	C_u4	C_u5	C_u6			
A1	6	9	6	4	2	9	*iii*	0	5
A2	8	5	9	5	2	3	*iii*	0	5
A3	9	5	6	9	5	3	*iii*	0	5
A4	4	9	4	7	1	8	*iii*	0	7
A5	6	5	4	1	7	1	*iii*	0	6
A6	8	3	3	5	7	3	*iii*	0	5

Preference Data Collection Method

There are several techniques that can be used to collect preference information from a group of DMs for later use in management improvement studies. In this study we use the Nominal Group Technique (NGT) in acquiring the inputs of DMs. First proposed by Delbecq and Van de Ven (1971), NGT is a structured brain storming technique to extract and aggregate multiple participants' opinions on a problem. NGT is suggested to be used with groups of up to 10 people, can be carried out in relatively short time; and therefore, fits very well with the constraints of our DM groups. An NGT session has the following steps:

Step 1: Silent generation of ideas in writing,
Step 2: Round-robin recording of ideas,
Step 3: First discussion,
Step 4: Preliminary voting,
Step 5: Second discussion,
Step 6: Final voting.

We followed these steps during interactions with DMs and recorded their preferences to use in our multi criteria ranking studies.

STUDY 1: EVALUATION OF E-HEALTH SERVICES FROM THE USER'S PERSPECTIVE

The first study aims to rank the e-health alternatives with respect to users' preferences. To demonstrate the methodology, we present a case study that involves four participants. The DMs were graduate students at the Pennsylvania State University, one PhD and one MSc student from Industrial and Manufacturing Engineering Department, one MSc student from Computer Science Department and one PhD Student from the Department of Learning Systems and Performance. All DMs were frequent Internet users and have previously used an e-health application. An NGT session was conducted in order to collect and aggregate the DMs' scores to obtain a consensus evaluation. The problem, alternatives, criteria and methods to be used were first presented. Then the DMs provided scores to be used in PROMETHEE, pairwise comparison results to be used in AHP and LINMAP and Borda Count rankings. During the execution of this step, the DMs were allowed to discuss about the importance of each criterion and were asked to provide a single final evaluation which represents their consensus on the evaluation. During the AHP data collection the evaluation scores were tested for consistency using the Expert Choice software and in any case of inconsistency, the DMs were asked to come up

Table 2. Summary of study 1 weight calculations

Method	*AHP*	*Borda Count*	*LINMAP*
Criterion	***Weight***	***Weight***	***Weight***
C_u1	0.118	0.190	0.000
C_u2	0.039	0.048	0.058
C_u3	0.154	0.143	0.256
C_u4	0.345	0.286	0.056
C_u5	0.278	0.238	0.331
C_u6	0.066	0.095	0.299

with a different evaluation. Various reasons of inconsistency were explained to the DMs before starting this final step. A sample output from the NGT session is given in Table 1. Columns C_u1 to C_u6 record the preference values assigned by the DMs to be used in PROMETHEE and LINMAP calculations. The last three columns show the type of criterion function and relevant threshold values for PROMETHEE application.

There are no strict rules for selecting H_j functions and threshold values. Threshold values are given by DMs and H_j functions are proposed by the author and DMs together. Note that type *iii* is the most widely used function type in PROMETHEE applications.

DMs provided the following ranking to calculate Borda Count weights. The criterion on the left side of the $\succ$ sign is superior to the criterion on the right.

$$C_u4 \succ C_u5 \succ C_u1 \succ C_u3 \succ C_u6 \succ C_u2$$

Finally, DMs provided the below pairwise comparisons to use in LINMAP calculations. Note that AHP pairwise preference inputs are not shown here due to space considerations.

$1 \succ 2 \quad 1 \succ 3 \quad 1 \succ 4 \quad 1 \prec 5 \quad 1 \succ 6$
$2 \prec 3 \quad 2 \prec 4 \quad 2 \succ 5 \quad 2 \succ 6$
$3 \prec 4 \quad 3 \prec 5 \quad 3 \succ 6$
$4 \prec 5 \quad 4 \succ 6$
$5 \prec 6$

Results of Study 1

Results obtained using the AHP method ranks A4 as the first alternative. A4 is followed by A1 and A3. PROMETHEE II yields a different ranking than AHP where A5 occupies the first spot and

Table 3. Summary of study 1 alternative rankings

Method	*LINMAP*		*Borda Count*		*AHP*		*PROMETHEE II*	
Alt.	**Score**	**Rank**	**Score**	**Rank**	**Score**	**Rank**	***$\Phi^{net}(\alpha)$***	***Rank***
A1	5.1871	1	2.619	3	0.344	2	0.352	3
A2	3.8768	4	2.381	4	0.062	4	0.153	4
A3	3.8770	3	1.715	5	0.080	3	-0.529	5
A4	3.8772	2	0.762	6	0.441	1	-1.640	6
A5	3.8766	6	3.429	1	0.045	5	1.247	1
A6	3.8768	4	2.619	2	0.029	6	0.418	2

is followed by A6 and A1. Borda Count gives the same ranking as PROMETHEE II.

The LINMAP model was coded and solved using the LINDO optimization software. The objective value was found to be 1.31, which indicates that there is a slight inconsistency with the DMs' pairwise comparisons. A close look at the solution revealed that the inconsistency resulted from the comparison $1 \prec 5$. To correct this problem we contacted the DMs and had their approval to change $1 \prec 5$ to $1 \succ 5$. The new objective value was very close to zero to indicate that the inconsistency issue has been resolved. A summary of criteria weights and alternative rankings for each method are given in Tables 2 and 3.

Table 2 indicates that different methods yield different weights. For instance AHP and Borda Count declare C_u4 as the most important criterion; whereas according to LINMAP, C_u4 is only the fifth most important criterion. Obviously, each method uses a different approach in calculating weights and treating alternatives; which explains the difference in the results. Rank reversals (different methods yielding different criteria and alternative rankings) is a common observation in MCDM problems (see for instance Wadhwa & Ravindran (2006) for a recent example in applications). On the other hand, all three techniques rank C_u5 as either as the most important or the second most important criterion. Overall, we can say that criteria C_u3 (attractiveness), C_u4 (safety threat) and C_u5 (quality of content) are the important criteria from users' perspective.

Rank reversals can also be observed in the alternative rankings (see Table 3). For instance alternative A4 comes in the first place in AHP and second place in LINMAP, but it is the least preferred alternative according to Borda Count and PORMETHEE II. On the other hand, all methods rank alternative A1 among top three alternatives. Overall, we can conclude that users are most interested in alternative A1 (teleconsultation). Furthermore, we can judge that alternatives A4 (remote patient monitoring), A5 (electronic medical library) and A6 (electronic medical record access) are also promising since they are ranked in top two by at least two evaluation methods. Therefore, according to our case study, installing one or more of these e-health services would increase the customer demand. However, the previous statement makes the assumption that the service installation is feasible and practical for the service provider; which might not always be true. To have a complete judgment on which e-health service might add value, one needs to consider the problem from the practitioners' point as well. Study 2 presented next addresses this issue.

STUDY 2: EVALUATION OF E-HEALTH SERVICES FROM PRACTITIONER'S PERSPECTIVE

The second study we present in this chapter focuses on the problem of e-health service evaluation from practitioners' perspective. Alternatives in Study 2 are the same as in Study 1 where we treated the problem from users' perspective. However, as opposed to Study 1, the evaluation criteria are different to reflect the preference of practitioners (see the section *Criteria for Study 2*). We present a case study to convey the application of our method. Practitioners (DMs) in our case were three IT professionals specialized in hospital IT systems and e- health services. They were interviewed during a hospital IT implementation project in Istanbul, Turkey. As in Study 1, the problem at hand, alternatives, criteria and methods to be used were first presented to the DMs. They then provided PROMETHEE scores, pairwise comparisons and Borda Count rankings. Note that DMs commented that availability of one or several e-healthcare services in an institution would have an impact on these judgments and provided scores for an institution that does not offer any e-healthcare services. These inputs are then used to calculate criteria weights and alternative rankings as in Study 1. Table 4 presents

Table 4. PROMETHEE evaluation scores of alternatives with respect to study 2 criteria (scores represent consensus evaluations of DMs)

Alternative	**Criterion**						H_j	q	p
	C_p1	C_p2	C_p3	C_p4	C_p5	C_p6			
A1	9	5	3	7	9	6	*iii*	0	5
A2	9	7	5	5	5	6	*iii*	0	5
A3	9	7	5	5	5	6	*iii*	0	5
A4	5	9	1	1	9	4	*iii*	0	7
A5	9	8	8	7	3	9	*iii*	0	6
A6	9	7	6	6	9	5	*iii*	0	5

performance scores of alternatives with respect to criteria of Study 2.

Similar to Table 1 in Study 1, in Table 4 above H_j denotes the type of function to be used in PROMETHEE and p and q are threshold values. These values can be modified whenever judged as appropriate in a particular implementation. Moreover, we asked DMs to provide a ranking of criteria for use in Borda Count weight calculations. The following ranking was obtained,

$$C_p3 \succ C_p1 \succ C_p6 \succ C_p4 \equiv C_p2 \succ C_p5$$

Finally, the DMs provided the below pairwise comparison of alternatives to be used in LINMAP programming,

$$1 \succ 2 \quad 1 \prec 3 \quad 1 \succ 4 \quad 1 \prec 5 \quad 1 \prec 6$$
$$2 \succ 3 \quad 2 \succ 4 \quad 2 \prec 5 \quad 2 \prec 6$$
$$3 \prec 4 \quad 3 \prec 5 \quad 3 \prec 6$$
$$4 \prec 5 \quad 4 \prec 6$$
$$5 \succ 6$$

Again, we skip the AHP pairwise inputs due to space considerations.

Study 2 Results

All of the weight calculation methods we tested put the largest weight on C_p3, the *customer potential* criterion. Furthermore, AHP and Borda Count weights follow a similar order but with different magnitudes. LINMAP weights on the other hand are substantially different than the weights provided by the former two methods. Note that

Table 5. Summary of study 2 weight calculations

Method	*AHP*	*Borda Count*	*LINMAP*
Criterion	***Weight***	***Weight***	***Weight***
C_p1	0.260	0.227	0.000
C_p2	0.117	0.136	0.333
C_p3	0.425	0.273	0.334
C_p4	0.118	0.136	0.333
C_p5	0.046	0.045	0.000
C_p6	0.268	0.182	0.000

LINMAP had an objective value of 0.67 which indicates a very slight inconsistency in DMs' pairwise comparisons. A full output of Study 2 criteria weights is given in Table 5.

Similar to the weight values, we have some consensus in alternative rankings, at least about the best alternative. All methods we used ranked A5, the *electronic library service* as the best alternative to implement. The rest of the rankings, however, varies from one method to the other. LINMAP ranks A4 as the second best and A6 as the third best alternative. According to Borda Count, the second and third best alternatives are A6 and A3 respectively. AHP reports A1 and A3 as the second and third best alternatives; and finally, PROMETHEE ranks A2 and A3 in the second and third spots in the alternative ranking. A summary of alternative Study 2 alternative rankings is given in Table 6.

As we discuss above the electronic library service is ranked as the most viable e-health service. It is hard to assess a runner-up using these data since rankings are very different from one method to the other. Nevertheless, we can argue that A2, A3 and A6 would occupy the second, third and fourth places. Furthermore, A1 and A4 seem to be the least attractive e-health services and should get the last two ranks. In order to have a more complete and well distinguished ranking, alternatives A2 - A3 - A6 and A1 - A4 might further be evaluated with respect to additional criteria.

DISCUSSION AND CONCLUSION

This chapter presents an MCDM framework for e-health service assessment. The problem falls under the domain of discrete alternative MCDM studies and is treated using four different methods; namely, PROMETHE, AHP, Borda Count and LINMAP. We approach the problem from two complementary sides in two Studies. Study 1 presents an evaluation from users' perspective and incorporates a set of criteria that reflects the users' preferences. Study 2 approaches the problem from practitioners' point of view and evaluates a different set of criteria. The alternatives on the other hand are the same for both Study 1 and Study 2.

Both Studies were conducted with the participation of actual DMs. For Study 1, we teamed up with a group of graduate students that previously used e-health services. Study 2 was conducted with IT professionals specialized in the area of hospital IT systems and e-services. Each group of DMs participated in separate NGT sessions, one for Study 1 and another for Study 2, and provided their performance evaluations to be used in the calculations of the MCDM methods. AHP evaluations and LINMAP programming use consistency measures that should be verified for

Table 6. Summary of study 2 alternative rankings

Method	**LINMAP**		**Borda Count**		**AHP**		*PROMETHEE II*	
Alt.	**Score**	**Rank**	**Score**	**Rank**	**Score**	**Rank**	$\Phi^{net}(\alpha)$	***Rank***
A1	0.336	6	4.087	5	0.160	2	-0.631	5
A2	2.336	4	4.997	3	0.146	4	0.495	2
A3	2.336	4	4.997	3	0.149	3	0.464	3
A4	2.998	2	3.629	6	0.140	5	-3.249	6
A5	3.005	1	6.136	1	0.327	1	2.469	1
A6	2.337	3	5.132	2	0.079	6	0.451	4

proper implementation. We contacted the DMs for revisions in cases where they were inconsistent with their judgments. After acquiring the evaluation results, we used Expert Choice to finalize the AHP study, and LINDO and MS EXCEL for the other methods.

We found that Study 1 results differ from one method to the other. However, we were able to conclude that overall, users are most attracted to alternative A1 (teleconsultation) according to all methods. Also, alternatives A4 (remote patient monitoring), A5 (electronic medical library) and A6 (electronic medical record access) were declared as promising e-health services since they were ranked in top two by at least two evaluation methods. Therefore, according to our case study, installing one or more of these e-health services is expected to increase the customer demand. The results of Study 2 showed better consensus in determining the winning alternative; but it was harder to interpret the runner-ups. Alternative A4 (electronic medical library) came in first and was followed by alternatives A2 (online appointment), A3 (online pharmacy) and A6 (electronic medical record access), not necessarily in this order.

Bridging the outcomes of Study 1 and Study 2 would provide valuable information for institutions aiming to deliver e-health services. Our results show that alternative A4 should be given priority because it holds high rankings in both studies. Furthermore, A6 appears in both rankings as a mid-valued alternative which can be considered as a second priority service. We found that neither users nor practitioners who took part in our study value the other alternatives as much as A4 and A6. We believe these results directly serve as beneficial guidelines for parties developing and implementing future e-health services and for current service providers in matching patient requests to services offered. Furthermore, institutions currently not focusing on e-health might use these results as directions towards new service offerings which would focus on patient demand and increase customer potential.

Practitioners considering using the conclusions presented in this chapter should note that the results reflect preferences of a rather small group of users and practitioners. A well diversified and larger group of participants would yield more accurate results; and therefore, is suggested for professional implementation of our methodology. Furthermore, the number of alternatives and evaluation criteria might change and increase in relation to the group size and institution. On the other hand, some methods we present here, AHP in particular, may not be practical to use in large scale implementations due to the heavy cognitive burden it poses on decision makers. In such cases, we suspect that PROMETHEE and Borda Count would be the better methods to use.

Future efforts include running the same studies with larger groups. Service alternatives and criteria that did not get high scores in our study may be replaced with others. Additionally, our study involves many qualitative criteria. Dealing with qualitative criteria in decision making applications has always been challenging since DMs are only able to provide vague linguistic assessments for these criteria. Fuzzy MCDM methods have been developed and used to account for DMs' vague assessments (see for instance Bilsel et. al 2006). We argue that solving the problem presented here using a fuzzy MCDM method may provide additional insights.

ACKNOWLEDGMENT

The authors appreciate Dr. A. Ravi Ravindran's comments and help in developing earlier drafts of this work.

KEY TERMS AND DEFINITIONS

AHP: An MCDM method.

E-Health: Application of advanced information technologies in healthcare delivery.

MCDM: Multicriteria Decision Making, a set of techniques involving multiple evaluation criteria facilitating in managerial decision making.

NGT: Nominal group technique, a method used to retrieve preference information from a group of decision makers.

PROMETHEE: An MCDM method.

Rank Reversal: Obtaining different rankings for a same problem using different MCDM methods.

This work was previously published in Handbook of Research on Information Technology Management and Clinical Data Administration in Healthcare, edited by A. Dwivedi, pp. 143-160, copyright 2009 by Medical Information Science Reference (an imprint of IGI Global).

Chapter 7.18

An Evidence-Based Health Information System Theory

Daniel Carbone
University of Melbourne, Australia

ABSTRACT

The aim of this chapter is to bridge the gap between what is known about IS theory and the specifics characteristics of health to develop an evidence based health information systems theory. An initial background first sets the significance for the need to have a solid information systems theory in health and then argues that neither the information systems literature nor the health sector have been able to provide any satisfactory pathway to facilitate the adoption of information systems in health settings. The chapter further continues by reviewing the common pathway to develop information systems theory and the knowledge foundations used in the process, and then proceeds to highlight how this theory was developed. Subsequently, the building blocks (constructs, premises, supporting evidence and conclusions) that underpins the constructs and a brief explanation of the relationships between them is included. A discussion and limitation section is then followed by a conclusion.

BACKGROUND

The importance of having information systems theories that will be conducive to the adoption of new technologies in health settings cannot be underestimated. To place it in context, the health-care sector is not only one of the world's most knowledge-intensive industries but also one of the largest employers; for example the National Health Service (NHS) in the UK is the largest employer of staff in Europe and third largest in the world (Herzlinger & Ricci, 2002; Leitch, 2008).

More important is the worldwide, current and urgent need to improve the uptake of technology in health settings to improve clinical care and associated costs through the use of technology, as clearly defined in the literature (AIHW, 2006; Department of Health and Aged Care, 2003; Grol et al, 1998; Gross et al., 2003; HealthConnectSA, 2007; Nader, 2007; Schuster et al., 2003; WHO, 2008). This is currently occurring despite mounting evidence suggesting positive clinical care improvements due to the introduction health information systems (Celler et al., 2003; WHO, 2008).

This current failure to adopt technology in health settings appears to point to gaps in the understanding of technology implementation and adoption in the health sector.

The current literature on health information systems implementation and adoption suggests that perhaps the health sector suffers from a fixation with 'technology driven implementations' to the detriment of other factors (Aarts et al., 2004; Bates, 2005; Chaudhry et al., 2006; Humber, 2004). That is, the focus of change management strategies to implement these technologies in health settings is seen almost exclusively as a technical (computer/technology system) issue. Moreover, most information technology applications have centered on administrative and financial transactions rather than on the core business of health: the delivery of clinical care (Audet et al., 2004). The concept of clinical care is the central principle associated with the field of health and known these days as Evidence-Based Medicine (EBM). The most important aspect associated with Evidence-Based Medicine is the measure of clinical improvement on patients or a term also known as health outcomes (Heckley, 2004).

In summary, the health sector appears to lack solid theoretical knowledge in organizational change, workflow redesign, human factors, and project management issues involved with realizing benefits from health information technology to tackle the clinical and financial burdens in current health systems (Chaudhry et al., 2006). Moreover, and central to this paper, the health specific literature on information systems implementations appears to fail to acknowledge the role of Evidence-Based Medicine (and health outcomes specifically) in the implementation process.

Perhaps, the solution is to consult the information systems literature in search for theoretical foundations that would support the adoption of technology in health settings.

The Information Systems (IS) literature on the other hand, mainly focused on the business sector and having left much of the 'technology-driven' approaches failures behind, has long benefited from a much more humanistic and contextualized appreciation of non-technological factors (i.e. Human, environmental, Social, etc) to improve adoption; However, in spite of the availability of more than fifty information systems theories and many others form other fields to inform practitioners, implementation failures in health settings still continue unabated to this day (HealthConnectSA, 2007; Schneberger & Wade, 2006). It would appear that even the existing broad knowledge in the IS sector is still not enough to affect effective technological uptake in health settings. What appears to be missing is 'specific' knowledge that would support the adoption of technology in health settings.

As a conclusion, the preceding and very brief literature review suggests that neither the health nor the information systems sectors have succeeded in developing solid theoretical knowledge that would lead to the successful implementation and adoption of information systems in health settings.

This chapter will advance some theoretical constructs regarding observed phenomena that might help bridge the gap between existing knowledge and new knowledge gained in the field and through relevant information systems research in health settings by the author. This examination leads the author to believe that perhaps there is a misalignment in the understanding of current information systems theories and health constructs; more specifically, that existing theories do not specifically focus on the 'core businesses of health' (Evidence-Based Medicine).

It must be also noted that this paper is not meant produce a definitive full-fledged theory, but contribute to the beginning of a theoretical discourse in information systems for health specific settings. Although initially built from an existing theoretical framework; it is intended to go above and beyond the founding theoretical frameworks as suggested recently by the editors of MIS Quarterly (Markus & Saunders, 2007).

THE KNOWLEDGE FOUNDATIONS OF INFORMATION SYSTEMS THEORY

The most common approach to developing or building on theory in the discipline of information systems is to use an established theory (authoritative knowledge) from a reference discipline, develop and adapt it to the information system context by 'trial and error'; this is also known as 'the logic of science' (Popper, 1979). In this approach, an established theory is used to categorize and classify information systems phenomena through a deductive approach (Lind & Goldkuhl, 2006).

Another approach is the inductive analysis of empirical data for the creation of a theory; Grounded theory is perhaps the most widely known methods of inductive theory building (Glaser & Strauss, 1967). This form of theory building was called 'logic of inquiry' by philosopher John Dewey in 1938 (Dewey, 1938), and involves the idea of 'application' grounding, including observational grounding to develop theory (Lind & Goldkuhl, 2006). This method has lead to the creation of concepts and theory useful for practical workplace change and is in line with the notion of a 'practical theory' (Cronen, 2001). However, the lack of relationship to other existing theories and unclear epistemological basis have been sited as criticism of this approach (Bryant, 2002; Charmaz, 2000).

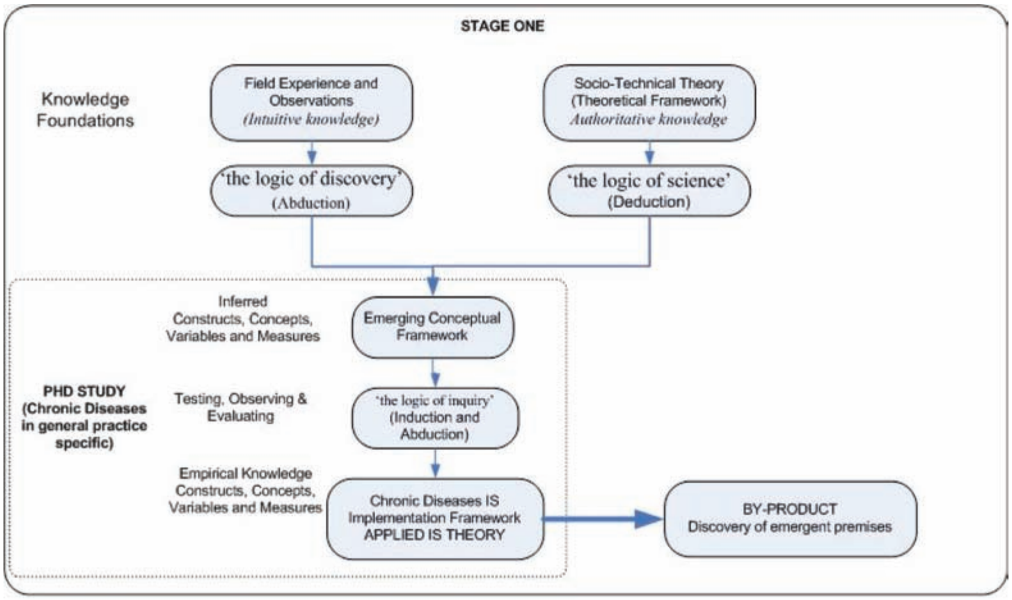
There is, yet another closely related logic called 'logic of discovery' and it seems to underpin abductive reasoning (Popper, 1979; Wirth, 2008). Wirth (1998) defines abduction as 'the process of adopting an explanatory hypothesis' and covers two operations: the selection and the formation of plausible hypotheses. He goes on further to explain that 'as a process of finding premises, it is the basis of interpretive reconstruction of causes and intentions, as well as of inventive construction of theories' (Wirth, 2008). It is motivated by the observation of a surprising fact or an anomaly that disappoints an expectation; abductive reasoning is a strategy of solving problems and discovering relevant premises. It is "inference to the best explanation". However, from a logical point of view, Pierce (1958) suggested that reasoning backwards is no valid form of inference. It is conjectural, or presumptive thinking, aiming at matching pragmatic standards of plausibility, guided by the reasoner´s guessing instinct (Peirce, 1958; Wirth, 1998).

Further epistemological and ontological strengths and weaknesses of every approach can be discerned in a number of other resources (Bryant, 2002; Charmaz, 2000; Urquhart, 2001; Wirth, 2008).

Bob Zmud (1998), ex editor-in-chief of MIS Quarterly, suggested that to truly contribute to theory building, it is necessary to develop and describe a rich conceptual understanding of an information systems phenomena so that it serves to enhance the field's collective understanding of the phenomena and as a basis for future empirical and theoretical work (Zmud, 1998).

More importantly—as the basis for the development of the particular theory to be examined in this chapter stands solely on the author understands of the phenomena, it is imperative that the phenomenon's constructs are augmented compellingly (Zmud, 1998). Arguments, for the purpose of this paper, are defined as set of one or more declarative sentences (or propositions) known as the premises along with another declarative sentence (or proposition) known as the conclusion. Premises are those statements that are taken to provide the support or evidence and the conclusion is that which the premises allegedly support (Fieser & Dowden, 2008). Furthermore, arguments can be deductive and inductive; according to Fieser and Dowden

Figure 1.



(2008), a deductive argument is an argument in which it is thought that the premises provide a guarantee of the truth of the conclusion. Conversely, an inductive argument is an argument in which it is thought that the premises provide reasons supporting the probable truth of the conclusion. In an inductive argument, the premises are intended only to be so strong that, if they are true, then it is unlikely that the conclusion is false. Moreover, Fieser and Dowden further clarify that even if the author of the argument does not think that the truth of the premises definitely establishes the truth of the conclusion, but nonetheless believes that their truth provides good reason to believe the conclusion true, then the argument is inductive (Fieser & Dowden, 2008).

Zmud (1998) further suggested a four step development pathway to developing sound theory including: (1) the description of the phenomenon, (2) the construct creation, development and explication, (3) the identification of key relationships and (4) the development, justification and articulation of these relationships. (Zmud, 1998). These headings will be used to develop the theoretical discourse.

The Context of the Emerging Phenomena

The first stage in this examination evolved as the observation of emerging facts and anomalies (abductive approach) as a result of the development of the author's PhD information system framework (Carbone, 2008); from where a set of new constructs or 'by-products' of the PhD emerged. The PhD study began its own development as a conceptual framework; a product of adapting existing theoretical constructs (authoritative knowledge) and the researcher's own field experience and observations (abductive reasoning). Socio-technical theory provided the theoretical framework to guide the research processes (Clegg, 2000; Land, 2000; Liehr & Smith, 2001; Mumford, 2003, 2006a, 2006b; Williamson, 2002). The testing process itself was inductive in nature (logic of inquiry), aiming at the empirically provable coherence between the premises and experience, in order to derive a probable generalization (Wirth, 2008).

The PhD research focussed specifically on developing an information systems framework to support the prevention and management of

chronic conditions (i.e. Asthma and Diabetes) in general practice following a pre-determined deduction/induction pathway. While this was satisfactory for the needs of the PhD study, it left a number of wider emergent constructs outside its limited scope. The limitation included the focus to just chronic conditions and to general practice settings only, even though the emergent premises observed were seen to be applicable to the wide clinical care continuum and other health settings as well.

The following graph in Figure 1 represents the knowledge foundations and research pathway just described above down to the emerging premises discovered in the study.

Phenomena Description

Successful implementation and adoption of information systems within the scope of chronic conditions and general practice were formally examined within the PhD study. Similar successful adoptions were observed by the author's own work role as an IS practitioner in a variety of other health settings like Hospitals and Community Health Centres. Furthermore, the practical implementation of information systems outside the realm chronic conditions provided additional opportunities to observe the same phenomenon in action.

This 'logic of discovery', based on abductive principals, requires a process of adopting an explanatory hypothesis covering the selection and the formation of plausible hypotheses (Wirth, 2008). To this effect a plausible hypothesis to explain the emerging phenomenon under examination here suggests broadly that:

Health settings will adopt information systems if a clear alignment of its core business with the proposed system outcomes is facilitated through the proper mechanisms.

More specifically, any implementation strategy must take into account the hierarchical socio-technical and clinical values exclusive to every health setting and the system development must be facilitated by catalyst that can clearly understands and align their value structures to the intended information systems.

Construct Creation, Development and Explication

Within this phenomenon, three distinct constructs are identified: The catalyst; the sub-system hierarchy and the evidence-based system. To strengthen the claim for each of these constructs, and avoid being based solely on the author's understanding of the phenomena, inductive arguments will provide reasons (premises) supporting (via varied sources of evidence) the probable truth of the conclusions.

Due to space limitations, and bearing in mind that, as suggested earlier, this examination is not meant to be exhaustive or conclusive (but is meant to begin dialog and further empirical work), premises (or propositions) will be reduced down to short list of declarative sentences and its supporting evidence will also be presented in succinct table format to further reduce the length of the explanations. The conclusions are also provided in short declarative sentences (propositions).

THE CATALYSTS CONSTRUCT

This construct relates directly to individuals (acting as change/external agents) that find and analyse the evidence and facilitate and support the whole implementation and optimization of subsystems in health settings. The specific catalyst functions are identified through the argumentation that follows:
Premises:

- The skills required to find (research), analyse and feed-back empirical evidence to clinicians (decision makers) are not readily available in health settings.
- Research and information management skills are needed to produce evidence to drive change and measure outcomes.
- Access to health seating electronic health records is necessary for local evidence.
- External agents specifically trained have the skills but not the access to clinicians and health setting databases.
- Most health settings have 'key' individuals (in health called referred to as 'champions') that have access to databases and the ears of the clinicians/decision makers.

Figure 4.

- External agents can work with champions produce local evidence and optimise sub-systems.
- External agents can train champions and other health setting members to become trainers of other members and improve monitoring and maintenance of the sub-systems.

Conclusions:

An external agent working in conjunction with health setting champions is an effective catalyst to drive change management strategies, development, maintenance and evaluation of health information systems.

THE SUB-SYSTEM HIERARCHY CONSTRUCT

The first phenomenon observed was perhaps not a new theoretical construct per se, but perhaps an extension of existing Socio-technical theory; nevertheless, the construct is seen as new in the sense that it exclusively applies to health context.

Socio-technical systems theory is theory about the social aspects of people and society and technical aspects of machines and technology. Socio-technical refers to the interrelatedness of social and technical aspects of an organisation. Socio-technical theory therefore is about joint optimization, with a shared emphasis on achievement of both excellence in technical performance and quality in people’s work lives (Ropohl, 1999).

The contribution by socio-technical theory should be self-evident albeit with some specific tweaks to reflect the ‘fit’ to health settings. The recognition of the need to harmonise all existing sub-systems has always been the cornerstone of the socio-technical approach (Schneberger & Wade, 2006). This authoritative knowledge was well supported during the testing phase in twenty eight case studies and well supported by the literature. The following premises were discerned during practice throughout the chronic diseases study further supporting the literature in informing the conclusions and augments in this construct:

Premises:

- All health settings are unique (i.e. structural and cultural complexity and variation)
- There are many subsystems in health settings.
- Sub-systems are interdependent in different measures to their own contexts
- All subsystems need attention to maximise optimization.
- Not all sub-systems are valued equally by everyone in health settings.
- There is a well defined hierarchy apparent in health settings.
- Patient Care is the most valued sub-system (a kind of health 'bottom-line').

Conclusions:

Every health setting possesses a number of interdependent sub-systems that need to be optimised; that are value laden and unique to their context; and the most important is the 'Patient Care' sub-system.

EVIDENCE BASED SYSTEM CONSTRUCT

The concept of evidence is not new to health settings; however in health the use is normally reserved for medico-clinical endeavours only. The findings from this examination and the relevant authoritative literature suggest evidence to be the key conduit or foundation pathways where information system implementation are quickly accepted and sustainably adopted. The arguments are drawn on the following premises and conclusions:

Premises:

- Health settings are owned and/or run by clinicians (decision makers).
- Patient care (sub-system) shortcomings are important motivating factors to clinicians.
- Other sub-systems (risk management, financial, etc) are also of concern to decision makers.
- Clinicians are trained in scientific thought (empirical-rational methods).
- Empirical-rational change management strategies exist.
- Empirical-rational methods influence clinical practice (behavioural change/motivational drive).
- Evidence of care deficit in clinical practice is found in the local (electronic) health records.
- Empirical-rational change management strategies using local data (evidence) affects behavioural change positively.
- Sustainability of change and further change depends on the evidence of success.
- Local empirical evidence and analyses is needed to measure success (patient health outcomes).

Conclusions:

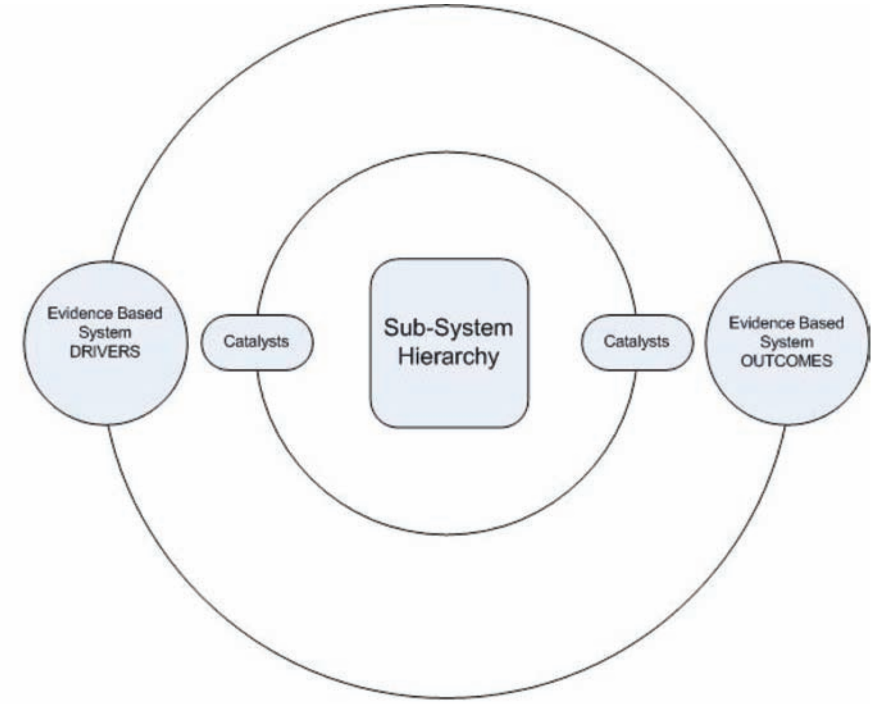
Clinicians need empirical evidence that highlights care gaps to affect behavioural change in their clinical practice. Clinicians also need concrete evidence that their efforts are benefiting their patients (health outcomes) and all other subsystems are working efficiently.

The Identification of Key Relationships

A sound theory must offer —besides arguments and conclusions for each construct, a compelling discussion on the phenomena resulting from the relationship between these constructs (Zmud, 1998). A complete discussion is in the scope of this paper is clearly limited; however a concise emergent dialog will follow:

The relationships between the three main constructs identified earlier can be readily represented as the analogy of a computer system: two concentric operating and application software

Figure 5.

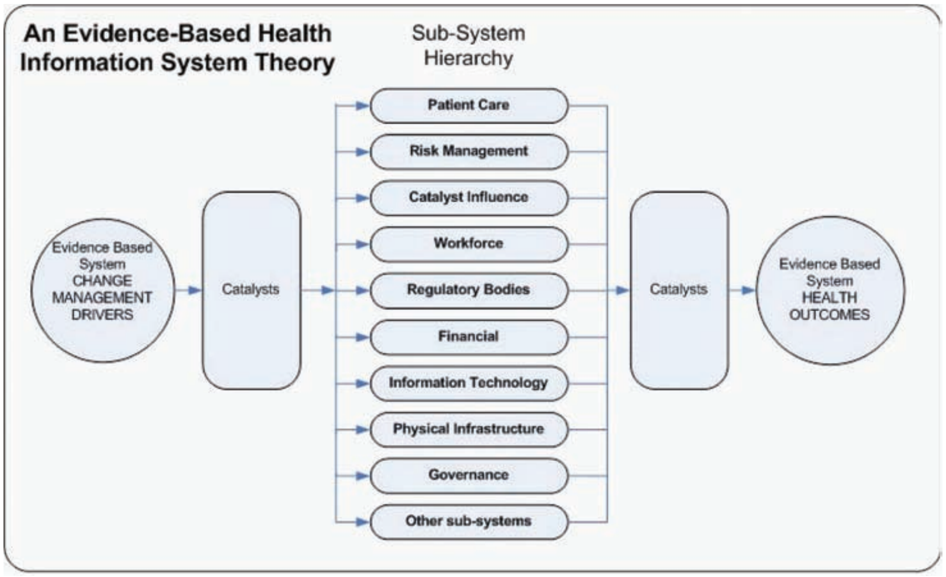


systems over a set of interconnected hardware. As per diagram shown in Figure 5.

Where the evidence based system construct represents the core business of health (patient care). Identifiable by its twin concerns: input task (drivers) and output task (outcomes). It can be thought of clinical task (business) that needs to be performed or improved (though the adoption of information systems) like the management, prevention or treatment of clinical problem in any health setting. As such it subsumes all other concerns in this theory. The bottom line, to borrow a business term is: 'the clinical improvement of patient care'.

The catalyst, as with an operating system is the enabler of that overall "clinical ncare" task. However, along the way (from input to output) the catalyst, like an operating system, must make sure that a set of circumstances or optimisation occurs to allow the clinical (input) task —driven by the expectation of improving the health of an individual or population is satisfactorily carried out (output), known in the health field as a clinical outcome. The tasks carried out by the catalyst (operating system) to enable the evidence-based system to succeed are multiple: for example, just to name a few of the potential sub-systems in health settings, it must allow members of the clinical team (Doctors, Nurses, staff, etc) to communicate with each other; it must make sure that risk management systems exist to follow up on patients that might miss out on clinical care; it must ensure that there is a sound financial systems underpinning the work being carried out and it must be capable of providing clinical information required on-time/every time to assist with clinical tasks. Perhaps the most important task that an operating system engages in a computer system is in "bootstrapping" (booting/starting) the system; this analogy essentially matches the first of the two principal role of the catalyst. The first task of this external (or internal if existing) change agent is to kick start the system by providing the initial "momentum" (data feedback) of what clinical business is at

Figure 6.



hand (what clinical care needs improving at the health setting by analysing gaps in care within its own patients). The second principal role is to measure the success in achieving that original task (improvement in health outcomes).

The hierarchical set of sub-systems construct represents in this analogy, the existing sub-systems that need to be optimized to allow for the core business (patient care) to be carried out successfully (outcomes). At this point in time, many of this sub-systems exist, however they can be paper-bases (in the case of financial records, recall and reminder letters, appointment books, to name but a few). It is important at this stage to recognize that any system being replaced must be "better", whatever the meaning for users (time efficient, error free, economical, etc) than existing ones. This also will include having the skills and broad knowledge to affect clinical, financial, legal and organisational systems including the provision of education and training. Many important sub-systems, in the author experience, do not exists and need to be developed from scratch. More importantly, every setting is completely unique in almost every aspect (governance, culture, workforce, etc), hence the catalysts must be always willing to adapt and customize solutions that might not optimize a system, but will make individuals feel in control of their setting and their culture.

A key aspect of this theory is the relationship between catalysts and the human/workforce sub-system. This relationship needs to be built around principles of mutual trust and purposeful action between individuals that appear to share a common 'end' goal (health outcomes improvements). This connection between the catalyst and health setting is not always evident as sometimes 'individual's short term goals' might no be the same; for example, the IS practitioner (catalyst) might be more concerned with training and technical processes while the practice champion might be more compelled to be financially and workforce savvy; each sharing their expertise to create a contextually customised and optimized health information system. This explanation is by no means comprehensive, but begins to discuss the basic assumptions behind the constructs' relationship.

Development, Justification and Articulation of these Relationships

Presenting a complete theoretical treatise in the space of single chapter is at best misguided. However an attempt will be made to succinctly summarise the main thrust of this emerging theory.

The simplest approach to do this to follow the suggestion made by one of the greatest mind of our century when he said:

…unless a theory has a simple underlying picture that the layman can understand, the theory is probably worthless...
Einstein (Pescovitz, 2005)

The following graphic in Figure 6 represents the main components in this emergent theory, including some of the sub-systems and potential hierarchy. Further explanation follows.

While a picture can paint a thousand words, a misinterpreted picture can lead future researchers down the wrong path. In "reading" this conceptual framework it is important to define the development and articulation of the relationships in this theory as it would apply to a "real world" situation. Let not forget that this theory is based on 'real' observed successful implementation and adoptions.

To start with, the intended implementation and consequent adoption of an information system in a health setting, according to this theoretical model, depends on the potential for that system to improve patient health. However, this position assumes that health settings are aware of their own deficiencies in patient care. In the author's experience, via a purposeful PhD study and everyday observations, there has never been a single case when a clinician has been aware of such deficiencies. In this circumstance, possessing a great solution to a problem that is not perceived to exist is next to useless.

The key to this model then does not start with "the solution", but finding "the problem". That is having access to or securing access to the health setting's medical records. This is in itself is a challenging task, particularly in countries like Australia where patient health data in well protected by law and clinician's own concerns for its use.

This has implications not just for being able to carryout further validating research in practice, but also for policy at the governmental level; as it suggests that health settings need to be supported by dedicated and well trained health information systems professionals to achieve any degree of success in implementing information systems in health settings. The amount of time resources needed by a well trained catalyst to support the health setting adopt information systems, including education and training and software support are considerable, although easily offset by the gains in health outcomes at the population level.

This is where the catalyst construct comes into its own, particularly as recognised earlier on, that there are no individuals in health settings that possess the multiplicity of skills needed to retrieve, review and analyse their own clinical data. This is further exacerbated when it is considered that there are financial, legal, communication and organisational skills still to be used in the optimization of all remaining sub-systems.

The catalyst would also have to build a high level of trust to be allowed impute (and optimization) in every sub-system; this is perhaps achieved in time as relationships develop. In my own experience it has taken me sometimes three to four years to develop enough rapport in some cases to truly affect the more sensitive sub-systems systems (i.e. financial and governance).

Perhaps the most important relationship a catalyst will make is with a "champion"; these individuals are more often than not the key to fully access every sub-system in health settings. These can be managers, nurses, doctors or staff members; they are the most valuable asset for a catalyst.

When looking at the sub-system hierarchical list on the diagram, it must be made clear that the hierarchy will change form setting to setting and country to country, and is probably time specific as certain development occurs (for example, laws might be passed that incline a health setting to value risk management more than patient care). In Australia for example general practices are private businesses, so there will be a lot more emphasis on financial sub-system outcomes compared to other countries where clinicians are paid a fixed fee.

DISCUSSION AND LIMITATIONS

There is a general awakening in the health sector that sustained behaviour change in clinical practice cannot be brought about solely by traditional dissemination methods (Peer-reviewed journals and re-education). Theoretical approaches to clinical change management require efficient and wide ranging change processes and implementation processes and procedures. These implementations must integrate the individual and existing inter-related human networks. These theoretical approaches must also acknowledge that organisations exist in unique contexts with unique structures and processes all supported by information systems of one type or another; all underpinning the 'core business' (clinical patient care) through evidence-based medicine.

The author sees in these developments an emergent opportunity for the field of information systems to take a leading role in the development and improvement of the health sector. However, to achieve this role, a solid theory of information systems in health is essential. This emergent theory is a small step towards a more empirically strong theory.

However, the limitations of this examination are many, the content of this chapter was never meant to be comprehensive or conclusive, what it does do however, is to begin a discourse in the hope that others join in its future development. Of the three constructs that were exposed here, only marginal coverage was provided with many premises (if not all) needing further research and critical appraisal; particularly over a broader population than originally studied (general practices). Although there is an emergent authoritative literature supporting some of the premises and conclusions in the constructs; the use of evidence to influence change and validate success and patient outcomes needs further investigation; as does the critical discussion of the extent and role and influence of the catalysts along the artisans-technician and internal-external consultant continuums. Furthermore, the proposition of hierarchical nature of socio-technical sub-systems in health settings needs further verification.

This theory would be better served by further purposeful quantitative and qualitative research that would test every construct down to every single premise. It should focus on a variety of health settings and across a number of countries and across a number of health conditions to better generalise its potential usefulness.

In summary, what was concisely offered here is the beginning of a unique discourse (Hassan, 2006); a theoretical introduction to a multidisciplinary fields not well understood by the information system discipline. In essence an evidence-based health information systems theory holds that: "an information system implementation approach in health setting must be guided, first and foremost by clinical evidence supporting the need for such change in that specific health setting. This evidence is predominantly focused on discovering gaps in local patient care populations to drive change management strategies. Secondly there is a hierarchical necessity to focus on the optimization of all contextual and interdependent subsystem. And thirdly, any measure of success must also be based on the evidence of specific patient health outcome and all other subsystems, keeping in mind their hierarchical importance to the health setting. The facilitation process for all this to happen is through the collaboration of an IS field expert and a site 'champion' that share common goals and objectives".

CONCLUSION

The chapter provided a succinct summary of the context, immediacy and significance for the need to successfully implement information systems in health settings. It briefly discussed the need to consider the core business of health (patient care). The chapter also pointed to the influence that evidence-based medicine (EBM) exerts on health settings and physicians. It suggested mainly a lack of theoretical understanding in the fit between EBM and how it interacts with prospective information systems that are used to research and analyse patient data to improve patient clinical care.

The chapter continued providing the context and foundations for the new constructs discovered in the author's own PhD study to then finally submitting the beginnings of a theoretical foundation to discuss the potentials for the further development of a new evidence-based health information theory. The emerging trends in the health literature suggest many opportunities for the information systems field if solid theories are developed. Future research needs to strengthen the findings that were outlined as well as the need to further expand on this exploratory chapter. It also suggested that a longer treatise with multiple and international contributors is perhaps a more desired approach for further development.

KEY TERMS AND DEFINITIONS

Abduction: Is the process of adopting an explanatory hypothesis (CP 5.145) and covers two operations: the selection and the formation of plausible hypotheses. As process of finding premises, it is the basis of interpretive reconstruction of causes and intentions, as well as of inventive construction of theories.

Concepts: A term or label to describe aspects of reality that can be consciously sensed or experienced; the term or description given to events, situations or processes. Evidenced that is sense-based or grouped together through thought connections.

Conceptual Framework: This is a structure of concepts and/or theories which are pulled together as a map for the study as opposed a ready made map (Theoretical Framework).

Constructs: Is a term or label invented by the researcher for a specific purpose to describe a phenomenon or group of phenomena. In other words, it is a summary of thoughts related to a phenomenon.

Deduction: Determines the necessary consequences, relying on logically provable coherence between premises and conclusion. Induction is aiming at empirical provable coherence between the premises and experience, in order to derive a probable generalization.

Empirical-Rational theory of Change Management: People are rational and will follow their self-interest - once it is revealed to them. Successful change is based on the communication of information and the offering of incentives. People can be persuaded AND 'bought' ('carrot' side of carrot-and-stick) (Chin & Benne, 1969).

Induction: Is aiming at empirical provable coherence between the premises and experience, in order to derive a probable generalization. Yet, induction only classifies the data.

Inductive Argument: Asserts that the truth of the conclusion is supported by the premises. (a deductive argument asserts that the truth of the conclusion is a logical consequence of the premises).

Theoretical Framework: This is the structure of concepts which exists in the literature, a ready-made map for the study; it provides the structure for examining a problem; serves as a guide to examine relationships between variables (Liehr & Smith, 2001).

Theory: A theory is an organized and systematic articulation of a set of statements related to questions in a discipline that are communicated in a meaningful whole. Its purpose is to describe (set forth what is -Descriptive), explain (account for how it functions - Explanative), predict (under what conditions it occurs), and prescribe (under what conditions it should occur) (Ingelse, 1997).

This work was previously published in Handbook of Research on Contemporary Theoretical Models in Information Systems, edited by Y. Dwivedi, B. Lal, M. Williams, S. Schneberger, and M. Wade, pp. 95-111, copyright 2009 by Information Science Reference (an imprint of IGI Global).

Section VIII

Emerging Trends

This section highlights research potential within the field of health information systems while exploring uncharted areas of study for the advancement of the discipline. Chapters within this section highlight new trends in the creation of personal health records, healthcare education, and coding and messaging systems for health informatics. These contributions, which conclude this exhaustive, multi-volume set, provide emerging trends and suggestions for future research within this rapidly expanding discipline.

Chapter 8.1

Toward a Better Understanding of the Assimilation of Telehealth Systems

Joachim Jean-Jules
Université de Sherbrooke, Canada

Alain O. Villeneuve
Université de Sherbrooke, Canada

ABSTRACT

A number of healthcare authorities are considering bringing telehealth systems out of experimental settings into mainstream clinical care. As most literature on telehealth systems to date has focused on their adoption and their evaluation, more work is warranted to understand how telehealth systems can be assimilated and to identify factors that may facilitate or impinge onto this assimilation. Borrowing from institutional, structuration and organizational learning theories, we propose a conceptual model of the determinants relevant for the assimilation of telehealth systems in healthcare organizations. The result is summarized in eight conjectures and a conceptual model. This work not only goes beyond the common methods of analyzing and discussing telehealth systems with user acceptance models, but it also draws a strong link between the assimilation of technological innovations and their institutional context. We hope it will contribute to guide research and managerial actions directed toward integrating telehealth systems in the workplace.

INTRODUCTION

Many western countries have undertaken telehealth projects for providing healthcare services to underserved populations living in remote regions and low-cost specialty services to areas where full-time staffing is uneconomical.

The term telehealth is presently used to describe all possible variations of healthcare services using information and communications technology (ICT) such as tele-education, teleconsultation, and teletraining, among others.

Given the centrality of information technology in telehealth, many studies in information systems (IS) research have been devoted to telehealth systems. A close examination of these studies revealed three salient streams, namely 1) user acceptance/adoption of telehealth systems (Mitchell, Mitchell and Disney, 1996; Hu and Chau, 1999; Cohn and Goodenough, 2002), 2) the characteristics of these systems (McKee et al., 1996), and 3) the effectiveness of telehealth systems compared to conventional face-to-face delivery in different medical specialties (Picolo et al., 2000; Nordal et al., 2001; Bishop et al., 2002). Although our knowledge has been enriched by such diversity, we need to go a step forward in order to consider the organizational assimilation of telehealth systems. The following reasons justify such an endeavor.

First, since telehealth programs have demonstrated clinical value and technical feasibility (Shore, Brooks and al., 2007; Duplantie, Gagnon and al., 2007; Putnam, 2007), they must move from experimental settings to the real world calling for adjustments to healthcare organization's administrative and clinical routines (Saga and Zmud, 1994; Zucker, 1977) as well as into its work systems and technological configuration to account for its assimilation as a technological innovation (Kwon, 1987; Cooper and Zmud, 1990; Chatterjee and Segars, 2001; Keen and McDonald, 2000).

Second, innovation adoption is not always accompanied by widespread deployment (Fichman and Kemerer, 1999). For instance, Eveland and Tornatzky (1990) and Cooper and Zmud (1990) reported that new technology enjoying widespread adoption may fail to be widely deployed.

To be truly valuable, a technological innovation must be routinized and infused in the adopting organization's operational or managerial work systems (Zmud and Apple, 1992). Consequently, to materialize the benefits of telehealth systems, we need to better understand the mechanisms through which their assimilation into administrative and clinical practices occurs. Little is known, however, about the process of telehealth systems assimilation and about assimilation enabling and impeding factors since most studies to date have focused on user acceptance and adoption little being said on what happens after the initial adoption decision has been taken.

This article attempts to add to our knowledge of assimilation of large-scale IS by developing a mixed determinants model of telehealth systems and is structured as follows. First, we explain the nature of telehealth systems, the concerns raised by their deployment and elicit on this basis the underlying mechanisms of their assimilation. Next, we develop the conceptual model by integrating insights from three influential theories: the sociocognitive theory of organizational learning, the institutional theory and the structuration theory. Then, we proceed with our contributions to both theory and practice. Finally, we conclude by indicating the future steps of this research.

THEORETICAL BACKGROUND

We first propose a conceptualization of telehealth system to identify its characteristics. We then cover the role and nature of the technological artifact and their articulation with the social and institutional contexts in which the systems and the adopting organization are embedded (Orlikowski and Iacono, 2001). Such a theorizing strategy ensures that the technological artifact is at the core of the model.

Understanding Telehealth Systems

Information technology systems for telehealth projects are large-scale systems linking two or more organizations and many categories of actors. Considerations about social context are essential to insure the success of systems deployment. An understanding of social relations, work structures, cultural factors and the organization's experience with IT are additional imperatives. Given the scope of telehealth information systems, decisions are far too numerous and technology is too diffuse and complex to be grasped by a single person's cognitive ability. Moreover, acquisition and deployment decisions of such systems are not generally situated within the discretionary power of a single member of the organization (Eveland and Tornatzky, 1990 p.

124). When deployment of an information system requires complex organizational arrangements regarding the location of individual decisions, its adoption and application are the product of numerous decisions dictated by economic and social forces that go beyond managerial logic. The organizations' institutional properties, their work politics as well as certain environmental characteristics (Orlikowski, 1992) can be included into the conceptual model by means of the use of relevant social theories to better understand participating organizations' IT assimilation. Most telehealth initiatives to date aimed at extending conventional health systems by overcoming their limitations such as the inability to provide proper and accessible care throughout large geographical areas. Telehealth projects, combining primary as well as specialized services, not only enable health care coverage beyond geographical boundaries, but also offer the organizational integration of entities with distinct vocations. The rationale for this type of integration goes beyond the logic specific to each organization. All these reasons suggest that assimilation of telehealth systems is influenced by institutional factors, if only to mobilize the necessary resources required to the system integration.

Further, since telehealth systems comprise a variety of technologies such as home healthcare monitoring, telemedicine and tele-education, the very nature of the technology must be accounted for in our conceptual model. Telehealth applications are diverse and are deployed based on numerous technologies such as teleconferencing, digital imaging, data storage and retrieval (sound, images, and alphanumeric data), robotic, two-way interactive television, etc. An appropriate infrastructure enabling data transmission and data entry, the creation of multimedia databases as well as communication between different partner organizations must be in place. Accordingly, telehealth information systems comprise different classes of technology. These vary from technologies that do not interact with users to more advanced technologies that require high interaction with professionals as they intrude into health care practices. Some technologies not only support clinical activities, they also provide reasoning behind medical evaluation and training (Grémy and Bonnin, 1995). Finally, they include infrastructure-type technologies, the purpose of which consists of managing large flows of information coming from numerous sources and going to numerous places, services or persons within the organization. These technologies have no reason for existence in and of themselves; they are an integral part of the telehealth organization (Grémy and Bonnin, 1995). When faced to such a broad range of technologies, individuals can feel threatened about partly losing control over their work schedule and professional autonomy. Moreover, given that the systems impose their own representations of the world, individuals' choices become limited. Feelings can range from fascination for some users to frustration for others. .

Telehealth systems combine several heterogeneous parts made up of numerous intrinsically complex components (Paré and Sicotte, 2004). Therefore, it appears more appropriate to conceptualize them as focal technological systems linked by a web of connections to its social, political, and institutional contexts (Kling and Scacchi, 1982). As such, despite the reality that the technological artifact is central to telehealth systems, it remains that it is an element of an ensemble that also comprises the necessary components to apply the technical artifact to a given socio-economic activity (Kling and Dutton, 1982; Illich, 1973). Among these components, we find commitment, additional resources such as training, qualified personnel, organizational agreements, the political and reward systems. In short, we find all that is necessary to promote the effective management of systems (Kling and Scacchi, 1982). The ensemble view of telehealth systems entails at least three things. First, the necessity to consider these systems as embedded in a dynamic and complex social context and the examination of the manner in which different social influences contribute to model its deployment along with how different user groups integrate them (Orlikowski and Iacono, 2001). Second, the structural potential of IT on the rules and resources and the spirit of these systems (Giddens, 1984; DeScantis and Poole, 1994). Finally, it is necessary to consider uncertainties and consequently the interpretation problems due to the diversity of the technologies involved, the organizational agreements they require and changes into organizational schemas and procedures for everyday action (Barley, 1986).

The previous developments lead us to understand that, not only does the assimilation of telehealth systems entail that we proceed with shared social representations of these systems but also that they are susceptible to become influenced by factors related to these systems' attributes, to characteristics of the institutional context, and to interactions between technological innovation and the organizational milieu.

Understanding Assimilation

Assimilation is often conceptualized as a learning process (Attewell, 1992; Fichman and Kemerer, 1997, 1999). Our conceptualization, though, differs slightly as we model assimilation as two processes: technological routinization and infusion. Routinization refers to the fact that as time goes by; the system ceases to be perceived as a novelty and becomes taken-for-granted (Saga and Zmud, 1994; Ritti and Silver, 1986; Zucker, 1977). Infusion refers to the system's embeddedness into organizational procedures and work architectures as it links different organizational elements such as roles, formal procedures, and emerging routines (Cooper and Zmud, 1990; Kwon, 1987). As telehealth systems combine diverse technologies their development and implementation, like that of complex systems, become a continual process (Weick, 1990).

Underlying Mechanisms of Assimilation

Making sense of telehealth systems is needed due to the nature of the system and because telehealth constitutes a new form of health services delivery.

Telehealth systems are complex, a reality that is not only due to the institutional agreements that their deployment requires but also to their technological constituents. For example, the Sores Care Tele Assistance Project (SCTAP) implemented by the Sherbrooke Integrated Health University Network deploys seventy three (73) information technologies within sixty five (65) points of care. The deployment comprises eight phases each including the organization of new clinical services and the elaboration of a deployment strategy of new virtual clinics, etc. (RUIS de Sherbrooke, 2007).

Given their complexity, systems in healthcare can create problems never-before seen by managers or by health care professionals (Weick, 1990). Given they are exogenous to the organization context, their introduction is likely to create a certain hiatus between existing meaning, legitimization and domination systems and the new exigencies related to the organization's daily actions (Barley, 1986). Therefore, these new technologies affect organizational members' capacity to reason on telehealth systems structures because technologies in general, and new technologies in particular, are interpretively flexible (Weick, 1990), they allow for different possible and plausible interpretations by diverse social groups and can be misunderstood, uncertain, and complex (Pinch and Bijker, 1987; Weick, 1990; Orlikowski and Gash, 1994).

This interpretive flexibility results from the presence of information technology artifacts as well as from cognitive schemas (Orlikowski and Iacono, 2001; Chae, 2002). While artifacts are made up of material resources like equipment, applications (Kling, 1987), non-material resources, networking capacity, programming languages (Chae, 2002) as well as structural elements built-into technology (DeSanctis and Poole, 1994), schemas point to generalizable procedures that take root in the context or pre-existing institutions (Chae, 2002). Within the context of implementation and utilization, procedures can be associated to the social organization of computerization (Kling and Iacono, 1989). Further, since telehealth systems often involve several organizations and individuals, this may even lead to equivocalities in meaning. For example, the SCTAP project regroups thirteen

(13) Health and Social Services Centers (Centres de Santé et des Services Sociaux, CSSS), spreading through three of Quebec's geographical regions and calling up ninety nurses. Consequently, schemas can be considered complex, numerous and embedded into multiple structures.

Precedent arguments stress both the participants' perception of ambiguity regarding the nature of telehealth systems and users' need to make sense of these technologies for using and integrating them in their daily practice. Following Orlikowski and Gash (1994), participants develop hypotheses and expectations to build their comprehension about what the technology is and what it is good for and their interpretation of the technology often dictates how he/she will use it. Hence, sensemaking is essential for assimilating the technology into work practice. Further, sensemaking clarifies the system's rationale and the development of its underlying philosophy or, in other words, its spirit (De Sanctis and Poole, 1994). It helps understanding the nature of the technology and its consequences within a given context (Orlikowski and Gash, 1994).

In our view, sensemaking is also a process that modifies the user's cognitive structure (mental models) which could be described as: "a built-up repertoire of tacit knowledge that is used to impose structure upon, and impart meaning to otherwise ambiguous social and structural information to facilitate understanding" (Gioia, 1986, p.56).

Technology Routinization and Infusion

In early research, IS implementation is viewed as a final step in which a new system is configured and installed. Since the work of Kwon and Zmud (1987), the process research stream in IS innovation implementation has instead focused its attention on post-implementation organizational behaviors (Saga and Zmud, 1994). Expanding the work of Kwon and Zmud (1987), Cooper and Zmud (1990) introduced a model of implementation that comprises the following stages: initiation, adoption, adaptation, acceptance, routinization, and infusion. This stream of research studies system implementation from a perspective inside the organization and conceptualizes implementation as a change effort to ensure successful implementation of a new system (Lucas, 1981). Indeed, Cooper and Zmud's model drew upon Lewin's (1952) planned change theory. As adaptation reflects the "changing state", acceptance, routinization, and infusion mirror the "refreezing state" (Saga and Zmud, 1994). Accordingly, inside this stream some scholars have later moved away from the planned change perspective. Their studies focused either on issues arising from implementation process or on how to manage the group along with the interpersonal process to make changes happen. IS implementation literature has later proposed a complementary view to the planned change perspective. According to this view, IS implementation is better thought of as a dynamic process of mutual adaptation between technology and organization (Leonard-Barton, 1988). Further contributing to this line of reasoning, Orlikowski (1992/1993) as well as Orlikowski and Gash (1994) proposed a situated change perspective. Central to this view is the subtle, smooth, and significant way through which organizational transformation is enacted. Such an organizational transformation is grounded in the organization's routines or work systems (Alter, 2003) and then in the ongoing work practices of organizational actors. These organizational changes are enacted as users accommodate to contingencies, exceptions opportunities, breakdowns, and even unintended consequences they face in their task (Barley, 1990). Scholars in this view widely acknowledge that new technologies always trigger changes in organizational routines (Barley, 1986; Tyre and Orlikowski, 1994) and this disruption in routines has been found to be largely associated with cognitive and interpersonal changes (Barley, 1986; Orlikowski, 1993).

Adopting this line of reasoning, moving away from studies that focus on the process through which managers alter routines, we take the perspective that when a new technology is implemented, the organizational actors engage in a sense making process and develop new frames about the technology. In so doing, they make cognitive, interpersonal, and organizational adjustments that allow the new technology and the corresponding new routines to become ongoing practice (Edmonson et al., 2001). Accordingly, routinization, in our view, follows Hall and Loucks' (1977) theory of cognitive adaptations. Individuals go through several understandings (meanings) of the technology as they first make sense of it before using it. Through their use of the technology, their sharing of their experiences with others and their coordinating of their activities with those of others, they refine their understandings (meanings) of it. Users confront their meanings with those of others and refine their understanding of the nature of the technology and of what it is good for though at times conflicts could arise that would lead to a new system's social representation (Lauriol, 1998).

Coordinating their activities with other users is an important means of assimilating the technology because it is the very nature of organizational learning, whose main outcomes are routinization and infusion. Coordination helps users build up new cognitive coordinations, to memorize them, to repeat them and to transpose them to new situations. Coordination also implies norms and rules and can promote the incorporation of technology into organizational routines. As long as the organization evolves in its understanding of the system and its possibilities, it tends to modify its workplace architecture to increase the extent of systems' use, to integrate the systems' usage and to accomplish activities not previously considered feasible (Saga and Zmud, 1994).

In summary, assimilation starts as an individual learning process through which participants later develop new schemas and scripts to represent the system. Afterwards, through interaction and coordination, an organizational learning process occurs by which individuals' schemas and scripts evolve leading to a shared understanding which initially blends into their routines but ends up being integrated into their daily practices and organizational beliefs, transcending the individuals who were at the beginning of the process.

DEVELOPMENT OF THE CONCEPTUAL MODEL

Figure 1 illustrates the conceptual model for this exploration of the factors that are likely to influence the assimilation of telehealth systems. Through this model we contend that systems innovation attributes, institutional environment properties, and interaction between technology and organizations are important determinants of telehealth systems assimilation. The different elements of the model are discussed below.

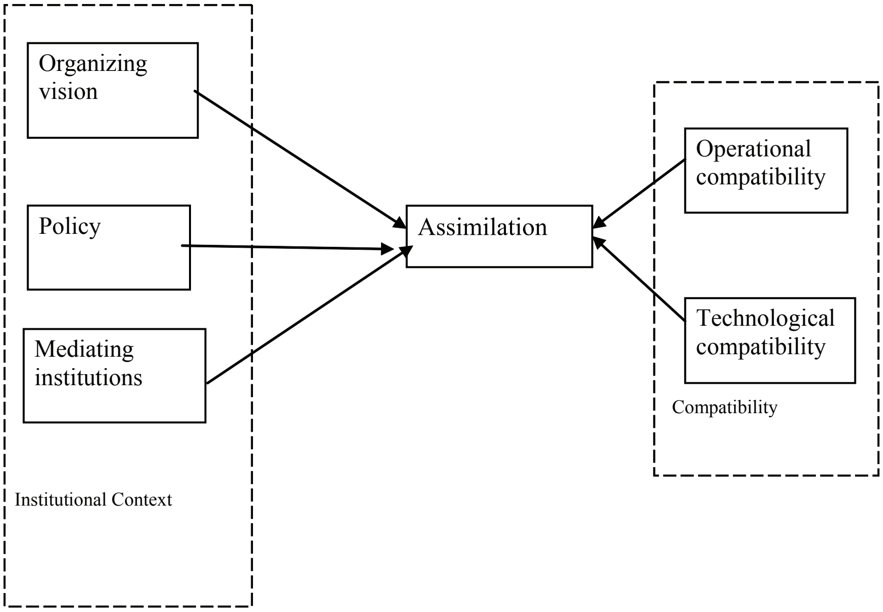
The Organizing Vision

In the case of technological innovations like telehealth systems, institutional processes come into play from the beginning of the diffusion process. A heterogeneous network of parties creates and employs an organizing vision that contributes to reduce uncertainties surrounding the systems along with their applications (Swanson and Ramiller, 1997). This organizing vision allows members of this network to make sense of the innovation. An organizing vision aims at making the spirit of the technology explicit, namely the underlying philosophies of the IT artifacts as well as the motives for its development (Chae, 2002)

Therefore, users do not rely exclusively on their own interpretations of the technology during the early phase of sensemaking as they can use the organizing vision as a starting point. From their original understanding, they will seek to search, probe and confirm meanings with others (Swanson and Ramiller, 1997). They will assess interpretations that exist within their own organization, yet consistent with those of partner organizations due the presence of an organizing vision. There are, however, some pitfalls and limitations that may arise during the process of sensemaking.

Telehealth projects vary in nature and objectives. They may vary in configuration (same technologies but configured differently). Sometimes, some of the system components are immature technologies or prototypes. Those system

Figure 1. Factors of organizational assimilation of telehealth systems



components are ill-defined and their applications are not well understood (Swanson and Ramiller, 1997). Meanings assigned to such technologies reflect incompleteness and instability (Rosemberg, 1994). An organizing vision is warranted to provide a structure that helps users understand the very nature of telehealth systems as well as their role given social, technical and economic contexts (Klecun-Dabrowska and Cornford, 2002). It also provides for reducing equivocalities and creating shared understandings of the system.

The sociocognitive theory of organizational learning, however, suggests that for a given technology, each group is likely to develop a specific set of shared understandings thus forming a technological frame. This frame emerges from interactions among group members through the coordination of their interdependent activities (Schein, 1985; Strauss, 1978) and also through the way the group's specific norms influence its members (Porac et al., 1989; Grégory, 1983; Van Maanen and Schein, 1979).

By formulating expectancies, assumptions and knowledge about key aspects of telehealth systems, the organizing vision contributes to make congruent the groups' technological frames. Therefore, organizations are likely to experience fewer difficulties or conflicts linked to systems' implementation and use (Orlikowski and Gash, 1994 p.180). Consequently, we make the following hypothesis:

Conjecture 1: *A compelling organizing vision is likely to positively influence the assimilation of telehealth systems.*

The organizing vision also provides a structure of legitimization that complements and reinforces the structure of interpretation by including in its discourse aspects directed toward justifying the technological innovation. Discourse pointing to the systems' legitimacy deals with technical and functional arguments with political, organizational and business arguments. This discourse is not just formulated in terms of the low-cost associated with electronically delivered services; it also includes dominant social values and principles like improving the quality of citizens' life (Klecun-Dabrowska and Cornford, 2002). This dimension of the organizing vision is dedicated to communicating not only the expected benefits of the innovation but also its spirit. To illustrate, by promoting telehealth as a means to bring specialized care services to remote regions and to recruit and maintain physicians in those regions, the organizing vision capitalizes on current norms and social values of our society. In so doing, it legitimates telehealth and mobilizes resources needed for its successful deployment (Orlikowski and Gash, 1994, Swanson and Ramiller, 1997). The preceding development suggests the following conjectures:

Conjecture 2: *An organizing vision that promotes telehealth on the basis of the health system's current values and social norms is likely to positively influence the assimilation of telehealth systems.*

Conjecture 3: *Perceived social benefits are likely to positively influence the assimilation of telehealth systems.*

Policy Making

Many barriers have been identified with respect to the diffusion of innovations, two of which are particularly relevant here: lack of reimbursement and legal liability. In the domain of reimbursement for instance, few public or private payers reimbursed healthcare services provided through advanced ICT in the USA during the early years of ICT. Some improvements have been made but are still deemed too restrictive. The Balance Budget Act expanded the coverage to telemedicine services but at the same time introduced new requirements that keep people from using telemedicine under current Medicare conditions (DHSS, 2001). Likewise, Gagnon et al. (2001) reported that the reimbursement system made some services less available and less accessible in the telehealth project implemented in Iles-de-la Madeleine one remote region in the Province of Québec, Canada.

Legal liability is an important issue in the diffusion of telehealth. Medical errors account for some 44000 to 98000 deaths every year in the US and errors are attributable in great part to the decentralized, fragmented, complex nature of the US healthcare delivery system (IOM, 1999). According to IOM, the relationship between the complexity of the healthcare system and medical errors can have serious adverse effects on the diffusion of telehealth. For instance, who is accountable for a medical error, the referent of the referring physician? There is no clear answer. Yet, specialists may be reluctant to give medical advice through ICT. We hence propose:

Conjecture 4: *Policy making directed toward facilitating the reimbursement of telehealth services is likely to positively influence the assimilation of telehealth systems.*

Conjecture 5: *Policy making directed toward establishing the liabilities of telehealth professionals when an error is reported is likely to positively influence the assimilation of telehealth systems.*

Mediating Institutions

Telehealth shares the properties of both technological and administrative innovations (Robinson et al., 2003). As such, deployment issues stem from their incorporation in the organizational and clinical routines (Paré and Sicotte, 2004). Partnerships with mediating institutions like knowledge generating organizations (consulting, universities) specialized in advanced technologies know-how could help lower knowledge barriers associated with technology integration (Attewell, 1992).

Conjecture 6: *Collaboration with some intermediating institutions is likely to positively influence the assimilation of telehealth systems.*

COMPATIBILITY

Operational Compatibility

Telehealth systems are deployed in healthcare organizations with well-defined values, norms and institutional practices. These institutional elements are instantiated in rules, work procedures, protocols and even current technologies which can influence their assimilation. It has been reported that social structures could serve either as constraints or as enablers to the implementation of systems (Kling and Iacono, 1989). Systems in turn have the capability to introduce a new organizational dynamic that modifies social and hierarchical relationships as well as the balance between institutional arrangements and the organization's daily life (Gosain, 2004). Then, telehealth systems not only trigger a structuration process, but also create the potential for misalignment between the incumbent institutional regime (installed social base) and the institutional logics embedded in telehealth systems. Indeed, telehealth systems are best conceptualized as complex social objects (Kling and Scacchi, 1982) embodying traces of human intentions that resurface as they are put in use (Chae and Poole, 2005). This raises a question of compatibility between telehealth systems and the adopting healthcare organization's work systems.

Conjecture 7: *compatibility between telehealth systems and the adopting healthcare organization's work systems is likely to positively influence their assimilation.*

Technological Compatibility

Information systems present a unique combination of human, material and disciplinary agency (Chae and Poole, 2005; Pickering, 1995). Agency refers to the capacity of a thing or person to act purposefully. While human agency involves self-reflexive monitoring and adjustment of action in order to achieve desired ends, material agency refers to the things the physical and biological world does (Chae and Poole, 2005 p.22). Disciplinary agency is the shaping and channeling of human action by conceptual and cultural systems. These differing agencies emerge when IS are put in use or when said differently through interactions with the adopting organizations. This raises a question of compatibility between telehealth systems and the adopting healthcare organization's work systems and technological infrastructure.

Conjecture 8: *compatibility between telehealth systems and the adopting healthcare organization's technological infrastructure is likely to positively influence their assimilation.*

CONTRIBUTIONS

This article developed a theoretical perspective for understanding the assimilation of telehealth systems on the grounds of their very nature and the issues raised by their deployment. In so doing, it contributes to research in pointing to the value of grounding the theorizing of assimilation of telehealth systems in the fundamental characteristics of the technological artifact like its interpretive flexibility as well as the complex organizational arrangements necessary to its deployment. Further, unlike in prior studies of assimilation of IS innovations (Chatterjee et al., 2002; Purvis et al., 2001; Gallivan, 2001; Meyer and Goes, 1988), assimilation is conceptualized as an organizational phenomenon that has its theoretical origins in individual interpretation. Second, the model uncovers the interplay between the institutional context and cognitive regulations. In so doing, it makes more salient the fact that assimilation of telehealth systems is essentially a multilevel phenomenon.

Our study also carries implications for practice. Particularly, it points to the importance of examining the assimilation process within the continuum of IS phenomena surrounding the deployment of telehealth systems. As such, it helps understand why managerial actions directed toward facilitating the assimilation process should be employed as early as the adoption phase. For instance, issues related to compatibility between the systems and the organization's work infrastructure should be managed during the development phase. Briefly, even though routinization and infusion are post-implementation behaviors, factors that are likely to influence them should be taken under consideration before systems acquisition.

FUTURE WORK

Given that the goal of this article is theory development, additional work is needed to fully operationalize the constructs and empirically test the model. Nevertheless, it builds a sound foundation for better understand assimilation of telehealth systems.

Our future work will focus on extending the current model of assimilation of IS and on addressing related open research issues. Indeed, despite the fact that we take individual sense making as the starting point of routinization, we focus on examining the assimilation of telehealth systems at the organizational level. As prior studies, our exclusive focus on the organizational level ignores more micro and meso explanation of the phenomenon (House et al., 1995). A more detailed account is then needed to explicit both the structure (Kozlowski and Klein, 2000) and the functional relationships of the phenomenon (Morgesson and Hofmann, 1999). In other words, it is necessary to account for how individual, group and organizational characteristics interact to structure the process of assimilation. Therefore, approaching this phenomenon from a socio-cognitive viewpoint will lead us to a multilevel perspective that will result in a more integrated understanding of how the assimilation process unfolds across levels in organizations and may add depth and richness to our theoretical model. In fact, the first reflections in this direction has already provided new insights and pointed to some key factors we would never supposedly think of.

This new research direction is likely to enhance the managerial significance of this work. Indeed, a more comprehensive and integrative multilevel model of assimilation, by making explicit the functional relationships at individual, group and organizational levels, will highlight the range of managerial interventions required to secure the IS assimilation and consequently the telehealth systems effectiveness. In addition, the model will provide, beyond policy, a better understanding of the locus of authority for each specific managerial intervention. In so doing, it will be helpful in enhancing the effectiveness of managerial actions and also in smoothing the IS governance aspects regarding telehealth systems. Finally, next in our agenda, we will test the model in an empirical, real-life, setting. This will provide for a test of the model and will allow us to identify additional contributing factors to better understand assimilation of telehealth systems into the workplace.

Chapter 8.2

Mobile Health Applications and New Home Telecare Systems:

Critical Engineering Issues

Žilbert Tafa
University of Montenegro, Montenegro

ABSTRACT

This chapter describes the very actual issues on mobile health (M-H) and home care (H-C) telecare systems, reviewing state of the art as well as theoretical and practical engineering issues crucial for designing these applications. The purpose, advantages and overall information and communication technology (ICT) architectures of M-H and H-C telecare systems are firstly presented. There are several engineering fields involved in the design of modern M-H and H-C applications. Making the optimal application-specific choice in each engineering aspect and achieving the right balance between complementary coupled technological requests are of crucial meaning so the main critical engineering issues (weighted at sensing node's design and the wireless communications) are presented in details as well. Systematic theoretical review and accentuation of the design and realization problems given in this chapter can contribute in better understanding of crucial engineering issues and challenges on this topic as well as in giving the proper direction lines to approaching the practical realization of M-H and H-C telecare systems.

FROM DESKTOP TELEMEDICINE TO THE NEW WIRELESS SOLUTIONS

For more than 30 years, the achievements in IT, electronics, telecommunications and biomedical engineering have been used to facilitate the quality of health care delivery. This kind of approach has provided great benefits in improving the health of population generally, especially by assuring the timely diagnostics and therapeutic treating of patients. Taking the historical view of the technologies that have been used in classical telemedicine applications, one can notice that these applications mainly were designed for fixed-based infrastructure remote monitoring, professional teleconsultations and in providing medical help to remote patients treatment. These applications were concentrated on transferring biomedical and video signals, as well as the medical images and sounds, with the main aim of providing the remote health care service. But, the main drawbacks of the early health delivery systems are contained in the fact that they were not designed to provide the mobility, autonomy of measured subject and health care delivery integrated into patient's everyday life.

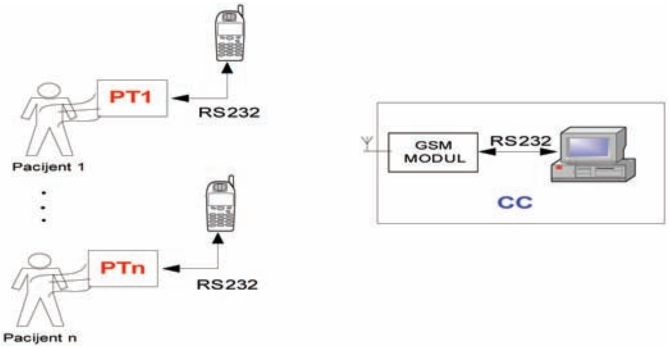
Current and emerging developments in microelectronics and wireless communications integrated with developments in pervasive and wearable technologies will have a radical impact on future health care delivery systems (Istepanian, Jovanov, and Zhang, 2004). The results of these developments make possible the realization of the wireless medical sensors with networking capability. Such medical sensor networks greatly enhance the ability of physicians to timely examine and treat complex biological systems at a distance and effectively reduce the infrastructure cost at hospital side and the travel expense at the patient side. The use of new wireless technologies in health delivery systems, offers many advantages, especially in continuous remote monitoring of patient vital signs. The most important improvements are achieved in earlier illness detection enabling timely medical intervention as well as in the treatment of chronic diseases . The integration of emerging wireless technologies in health delivery applications today is separated in two new engineering challenged disciplines – **mobile health** and **home care telecare** systems. Newer concepts represent M-H as a form of e-health evolution from traditional desktop telemedicine to wireless mobile configurations. M-H provides remote medical service delivery (especially the monitoring of biomedical signals) even while patient is in a move and regardless of geographical location of the patient. Home care systems, on the other hand, provide usually more functionality but these systems have the reduced range of mobility. In this case, the mobility range is usually limited to the level of the house, hospital or office. So, the main functional difference between M-H and H-C telecare systems is related to the mobility area. By using small-scale sensing and processing hardware attached to the patient's body or embedded into patient's everyday life ambience, both M-H and H-C systems make possible: more often or continuous inspection of patient's health condition generally, the monitoring of daily variable medical parameters (ECG, SpO2, blood pressure, glucose level, EEG etc.) which variations can point to specific medical conditions and illness etc. The advantages of using the modern m-health and home care applications can be summarized as follows:

- Medical treatment even when the patients are not situated in medical institution,
- Continuous, "real time" or store-and-forward insight into patient's health parameters
- Mobility and comfort of patients while medically treated
- Intelligent monitoring systems with the ability to generate alarms
- Multi-parameter and multi-user health care delivery
- Tele-consultations and flexibile access to expert opinion and advice at the point of care without delay
- Easy integration into greater telemedicine systems.

M-HEALTH AND HOME CARE APPLICATIONS

Applications related to the applying of wireless concept in medicine, usually have been realized for portable teletrauma systems (Chu & Gantz, 2004) and in systems designed for remote medical monitoring of mobile or "semi-mobile" patients (Lin et al, 2005, Anliker et al 2004, Fadlee et al 2005, Boquete, 2005). In the case of teletrauma systems, realized applications provide the transmission of medical parameters as: biomedical signals, images, video signals and voice assuring better understanding of the problem by medical professionals residing at remote location and, consequently, better assistance to the medical

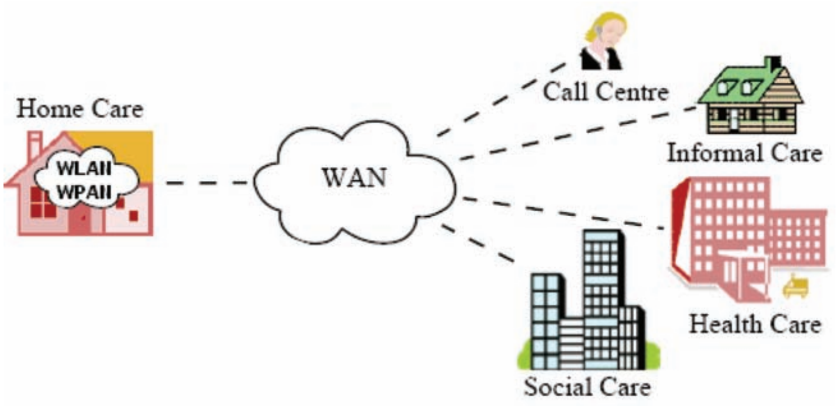
Figure 1. Example of a typical M-H application architecture



trauma team. On the other hand, systems designed for continuous remote monitoring of physiological parameters, usually are dedicated to the treatment of patients with chronicle disease as well as in case of post-hospital home care and also in cases when monitoring of some parameter's daily variability are of crucial meaning. Teletrauma and similar systems along with systems for remote continuous long term health monitoring are today known as M-H and H-C telecare systems, respectively. The first ones primarily aim to provide the ubiquitous health delivery while the second ones provide the home environment for patients while medically treated, which can be very impotant for the recovery process. Beside the main, medical advantages, the usage of these systems have economical meaning (especially when applied for longer patient-to-hospital distances) and social meaning too (in elderly population care). Health parameters which are often monitored using these systems are: ECG (electrocardiogram), HR (heart rate), SpO2 (arterial oxygen saturation), and blood pressure which are usually named as vital signs. But, signals as EEG (electroencephalograph), patient's physical activity, respiration, blood glucose etc. are also often included in these applications. Besides the basic meaning of these parameters, when monitored together, their inter-relational meaning can extend the range of the diseases that can be detected. For example, SpO2, heart beat, blood pressure, and respiration can form together an indicator of the oxygenation of the patient's brain in trauma care (Hailiang, 2006), or, when temperature and humidity sensors are used along with ECG sensor, the correlation between environment conditions with heart conditions can be derived. In all of these applications, the intention is to provide health care delivery not affecting significantly (or not affecting at all) the patient's everyday life and activities. For example, in home care applications, sensors can be embedded in bed and wrapper (Seo, J.Choi, B.Choi, Jeong, and Park, 2005), chair and computer mouse (Kim, J., Park, J., Kim, Chee, Lim, and Park, K., 2007) and so on. On the other hand, the main benefit of using M-H monitoring system is contained in fact that the patient can be medically monitored while being in car, office, or generally, anywhere else in the area of M-H network coverage. The patient's data can be send using mobile phone (GSM, GPRS, 3G etc). An example of a step-by-step application developing process is given in (Boquete, 2005). Functional modules of the system are shown in Figure 1.

In this figure, PTn is abbreviation for the *patient terminal n* (which does the sensing and signal conditioning tasks and transfers data to the mobile phone thought RS232 interface), and CC is the abbreviation for the *control center* (which does the data storing and screening). The transmission here is done in "RS232 over GSM" manner. Typical H-C system organization is given in Figure

Figure 2. A typical H-C telecare system



2 (Turner J. Kenneth, Gemma A., Campell and Feng Wang, 2007).

The main drawback of M-H system is the link capacity and the resource capacity fluctuation within the mobile environment while the main H-C system's limitation is contained in the mobility range. So, M-H and H-C systems overlap regarding the purpose – remote monitoring of human health parameters and remote health care delivery generally, but the mobility range and the wireless link capacity seems to make the main border on choosing between M-H and H-C systems in general.

ARCHITECTURAL ISSUES

The choice of the adequate technology for each sub module of the system for wireless remote medical monitoring and the way in which various technologies are implemented and integrated into these systems are still application-dependent. Some applications are designed for long term monitoring so they are limited to low power consumption technologies and design. Others are primarily constrained with the mobility range or link capacity, extended functionality etc. The view on typical M-H and H-C telecare system's position into a global Telemedicine system is shown in Figure 3.

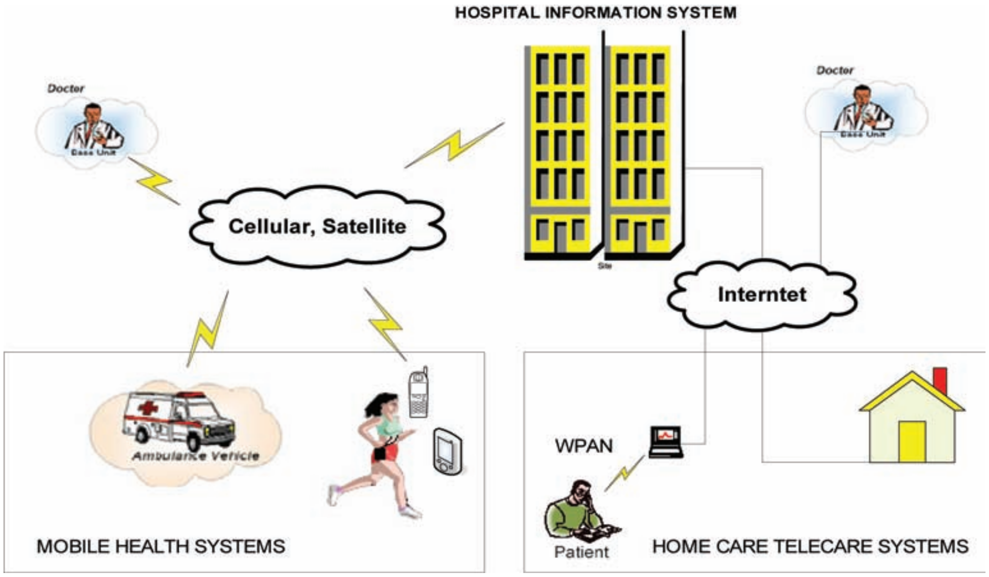
It becomes obvious that there are 3 main architectural parts either in M-H and H-C systems:

- Hospital core information system (servers, core network, database organization etc.)
- Communication infrastructure (wired and wireless)
- Mobile subsystem (hardware and software modules)

Hospital core Information system is the framework where different kind of applications are attached to and integrated into. Modern Telemedicine networks support various kind of data flow. M-H and H-C systems are just a part of these networks. Modern telemedicine IT system enables the hardware and software for storing the biomedical, financial and social data. It enables the distributed connectivity, offering various levels of authorized access to the patient's data. Patient and medical professionals can access needed information through secured Telemedicine network (or Internet) links.

Communication infrastructure depends on various factors as: the location and the level of access, the type of transferred data, etc. It is based on standardized networking devices and technologies and does not basically differ from ordinary general purpose computer network infrastructure. In architectural sense, the differences are only

Figure 3. The view on the position of the M-H and H-C modules in telemedicine architecture



noticeable at the level of the remote data upload, specific for M-H and H-C applications, and regarding the end-user networking devices.

A module specific to all wireless medical systems (as new M-H and H-C telecare systems are) is **mobile subsystem** or **personal server.** In case of H-C systems, mobile subsystem contains sensors (along with signal conditioning electronics), digital processing unit and the radio-device. In M-H systems, mobile subsystem contains the gateway device too, which is one additional difference in architectural sense between M-H and H-C systems. In modern wireless H-C applications data are sent through short range wireless links to the fixed wireless ADSL router or some other wireless / cable-based gateway device though Wireless wide area networking (WWAN) links are sometime used as well. Generally, sensing module, equiped with the wired or wireless interface, sends medical information to the gateway device. This module is attached to the monitored patient and is supposed to transmit medical data while the patient is on the move. M-H or H-C applications differ in the way the gateway device achieve the connection to the medical server. home care applications make WAN connections using fixed non-movable or semi-movable gateway devices while M-H applications use WWAN cellular links as GSM, GPRS, 3G, satellite communications etc. The information flows to the medical server which actually represents secure and authorized access point for accessing the data by medical expert from the remote locations (usually Internet).

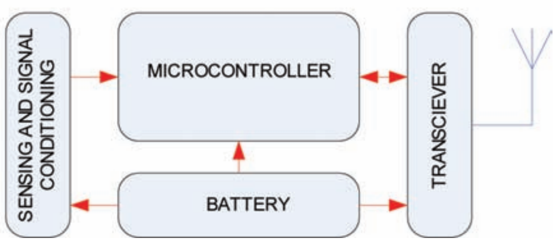
Sensors assure the conversion of biomedical signals into electrical equivalent and can be of various types (optoelectronic, ion-to-electronic, mechanical, magnetic, temperature sensors etc.). These signals are then conditioned (using analog front ends), converted into digital form and post-processed. The analog signal shaping and A/D conversion is realized in the so-called **acquisition / processing unit**. Some applications, as a part of this unit or the gateway device functionality, provide the possibility for directly viewing the data and generating alarms. Signals are further transferred to the communication module which is used to communicate with gateway device. **Gateway device**, if designed for only transferring the data, can be of miniature dimensions. In case of M-H applications, it is usually mobile phone, PDA or Laptop PC. In these cases, for communication with gateway, the processing unit uses wired connections or some of WPAN technologies (usually Bluetooth or some other widely used technology). In some applications the processing unit and gateway device can be integrated in one, in form of PDA or laptop computer. These systems usually have extended functionality (but greater physical dimensions and weight too). For example, sensors can directly be connected to laptop computer (as it is often case in emergency care applications) and the laptop computer can act as a processing and gateway device, offering direct data screening, data storage capabilities and providing expert system as well.

CRITICAL ENGINEERING ISSUES ON MODERN M-H AND H-C TELECARE SYSTEM'S DESIGN

Both M-h and H-C systems are considered to be multidisciplinary engineering areas. The design of wireless medical applications integrates sensing, processing, communications, computing and networking together into a reduced volume for wearable devices that reliably processes, transmits and represent medical parameters and data. In this sense, various aspects of design should be considered. It is very important to point that these technical issues and performances are often complementary coupled. For example, a longer range in wireless communication often means the higher output power of the transmitter, which implies the higher power consumption which further shortens the battery life or enlarges the overall system costs and the implementation complexity. As it can be concluded, main engineering aspects that are specific to the M-H and H-C application's design, can be summarized in:

- Electronic, electrophysiological, and electromechanical design of sensor nodes - sensing

Figure 4. Block diagram of a typical sensing node



- Wireless communications and networking
- Software engineering

Sensing in M-H and H-C Applications

To monitor human health constantly without disturbing the user's normal daily activities, the wearable sensors and devices for physiological data collection should be designed to be compact, durable, accurate, small, and noninvasive, to have a fast response time, and provide disturbance rejection capability. It is not always easy to meet all these requirements because, beside the accuracy, electrical, processing/software, mechanical, and practical aspects, communication aspect of these modules should be treated as well. Block diagram of typical sensing/acquisition unit is shown in Figure 4.

Because of the uniqueness of telemedical applications, non-invasive M-H and H-C measuring nodes should strictly follow some special limitations as in:

- Adequate sensing, signal shaping and digital signal processing capability, compared to the predefined medical standards
- Miniature physical dimensions
- Low power consumption
- Multi-functionality
- Resistance to various sources of noise (electrical, electromagnetic, chemical, mechanical, ambient noise etc.)

- Must be non-intrusive, acceptable for most patients, and have easy-to-use interface
- Must have the adequate wireless communication performances.

Medical signal recognition begins at **sensor's** end. Generally speaking, biomedical sensors are a subset of specialized sensors responsible for sensing physiological or biological measurands (Yeow, 2006). The biomedical measurands are used as indicators for clinical diagnosis or in therapeutic purposes. Most often, a biomedical sensor node is used as a diagnostic tool.

Many different kind of medical sensors are now available on the market, ranging from conventional sensors based on piezo-electrical materials for pressure measurements to infrared sensors for body temperature estimation and optoelectronic sensors monitoring SpO2, heart rate, HRV, and blood pressure.

In the sense of achieved measuring functionality, biomedical sensing is based on one of the three principles:

- Direct measuring of the electrical activities of organs (heart, brain, muscles, etc.) – bio potentials
- Measuring the influence of physiological processes on some external source of energy (light, ultrasound etc.)
- Injecting substances and detecting their flow by special detectors (as in case of the detection of injected radioisotopes by gamma cameras).

M-H and wireless H-C systems are typically dedicated to non invasively measuring of basic physiological signals (ECG, SPO2, heart rate, blood pressure, etc.). In some special cases, images and video signals are transmitted too (as, for example, in mobile emergency care diagnostic systems). So, It is very important for the designer to be aware of electrophysiological and other (electronics, mechanical) measurement aspects of sensor's node design.

ECG sensor's functionality is based on electrical activity of the heart. As a result of cell's depolarization and repolarization, ionic current is spread over human body. This current can be detected (and transformed into electronic current) using various types of sensors, so called electrodes. Very important issues when using these sensors are: good electrical contact with the body of the measured subject and mechanical stability, the number of used leads, and the position of the leads. The number and the position of the leads determine the range of measure sophistication – the number of the diseases that could be detected. Good electrical contact and mechanical stability directly influence the quality and accuracy of measurement. Bad contact means higher signal attenuation and noise while mechanical instability (vibrations and other mechanical movements) usually introduce so called artifact. An efficient low-noise transducer design can often reduce the need for extensive subsequent signal processing and still produce a better measurement (Semmlow, 2004).

Pulse rate, SPO2, HRV (heart rate variability), and blood pressure are usually derived from the measuring method called PPG (photoplethysmography). PPG is non-invasive method for the detection of cardiovascular pulse waves propagated around the human body based on the determination of optical properties of vascular tissue using light source and photo detector. It is also the mostly used sensing method to monitoring the physiological signals in M-H and H-C applications. There are two PPG approaches based on transmission or reflection of the light (**transmission mode** and **reflection mode**, respectively). Transmission mode is limited to areas such as finger, earlobe or toe, since the light emitter and receiver should be positioned on opposite side of tissue but should also be in close distance to each other. On the other side, reflective mode can be used virtually on any skin area, because the emitter and the receiver are positioned in parallel (and close) to each other. Experience in using PPG sensors in wearable sensor applications for wireless data transmission shows that the finger-base PPG may be most acceptable to users and provides excellent access to an arterial blood signal. PPG is based on the fact that, when directing the light on tissue, the light absorption (and consequently reflection) depends on the concentration of blood in vessels, which is generally given by Beer-Lambert law (Ward, 2001). Using this technique, usually pulsating current is measured and conditioned on the detector side and this pulsating current corresponds to pulse rate. PPG signal has two components: DC and AC component. DC component is relatively constant because it represents the absorption/reflection of the light by constant values as: skin, bones, venal blood, and a non-pulsating arterial blood. AC component represents pulsatile component of arterial blood and is usually 1 to 2% of the DC value. Beside the use in directly determining the pulse rate and shape (HRV), PPG signals are often used in deriving SpO2 – the level of oxygen saturation in hemoglobin. The measurement is based on the fact that deoxyhemoglobin (Hb) is more absorbed by red (R) then infrared (IR) light and on the other hand oxygenated hemoglobin (HbO2) is more absorbed by IR than by R light. Saturation of hemoglobin is estimated by the following formula:

$$S_pO_2 = 110 - 25R \tag{1}$$

where

$$R = \frac{AC_{RED} / DC_{RED}}{AC_{IR} / DC_{IR}} \tag{2}$$

where alternated current (AC) and direct current (DC) components are firstly calculated.

SpO2 is a very important physiological parameter which gives information about respiration. On healthy subjects, the SpO2 values should be above 96%. This parameter is often monitored during anesthesia but is also used in M-H and H-C applications alone or together with other parameter's monitoring.

Blood pressure is also one of the basic physiological parameters which are often monitored in typical M-H and H-C applications. There are few standard methods for blood pressure monitoring such as: invasive canola based monitoring (which is never used in M-H and home care systems), sphygmomanometer, oscilloscopic method, and lately some efforts are made in the direction of using pulse transit time (PTT) derived from PPG measuring sensors. Cuff -based method (oscilloscopic) is most popular for classical home but is also used in M-H and H-C applications (Anliker et al, 2004). The PTT based method measures the time distance between R or Q wave of the ECG and point of 50% of the pulse magnitude. Consequently, ECG and PPG sensors should be used together in order to derive the PTT value, but since most of M-H and H-C applications already monitor ECG and PPG signals, the PTT calculation may extend the application functionality without any additional hardware. It should be noted that PTT based measurement of blood pressure is not well correlated to the absolute value of blood pressure at the given moment. PTT actually enables the prediction of the blood pressure variations for short time intervals.

As can be concluded, PPG method offers the creation of multifunctional non invasive sensor nodes and as such is very suitable for use in M-H and H-C applications. Signal sampling is often based on so called chopper mode – when sampling is triggered by some external source (microcontroller, oscillator etc.), making the module low power consumer. The main drawback of PPG sensing method is noise: **ambient light and artifact**. In order to reduce ambient noise, instead of usually used LED-PIN (light emitting diode – P type intrinsic N type) configuration, a LEDs in reverse bias mode are lately being used as photo detectors. This measuring process assures greater immunity to ambient noise since LED detector operates as band-pass filter. In order to face the artifact, many methods are being proposed. They are usually based on mechanical modeling of sensor node (Booho Yang, Harry H. Asada, S. Rhee, 1999) or on using accelerometer which enables the use of active noise cancellation algorithms based on adaptive filtering (Shaltis P., Wood L., Reisner A. & Asada H., 2005).

Along with transducers, **signal conditioning sub module** is the most important part in achieving the needed quality of the signal for further processing and transmission. Output signal from sensor can be in digital or analogue form. In order to achieve the needed quality of the signal (satisfying magnitude level and low noise influence), it is always necessary to make some further signal conditioning as amplifying, filtering etc. The tradeoff is usually made between the complexity (the size and the price) of **front-end** and the accuracy. For example when using higher filtering degree, higher quality of output signal can be achieved but this implies bulkiest hardware and some more power consumption as well as greater overall physical dimensions. When designing this part of the system, it is important to do some quantitative observations, comparing the achieved results to some professional widely used instrument. It is crucial to know the all technical (electrical) characteristics of measured physiological parameters, and the most important ones being: the signal magnitude and the frequency range. Depending on these parameters and the way the physiological signals are electrically represented (as current, voltage or frequency), proper amplifying and filtering should be realized. For example, when conditioning ECG signal, designer should keep in mind that the voltage derived from electrodes is in range of 1-5 mV and that the frequency band of ECG signal is between 0.02 Hz and 150 Hz (though 1 KHz limit is often used at hospital devices). Although ECG is specified to have a wider frequency band, when monitored using low cost, low power wearable devices, usually only the band from 0.02 Hz to 50 Hz is treated and this quality is very satisfying since the main energy concentration of ECG spectrum belongs to this band.

Summarizing, in biomedical measurements and consequently in M-H and H-C applications, unwanted signal variability has four different origins: physiological variability, environmental noise or interference, transducer artifact, and electronic noise.

As mentioned previously, one of the main limiting factor to be considered in wireless sensor node's design is **power consumption**. In M-H and H-C applications, mobile subsystem is battery supplied. Bearing in mind that these systems are dedicated for long term continuous monitoring, it is obvious that this parameter directly affects most of the system's performances. Duty cycle reduction in conjunction with the so-called power save modes of the MCU and RF transceiver, are often used in order to reduce the power consumption. For example, when using CC1000 transceiver supplied by idealized AA batteries, with duty cycle of 2%, the autonomous battery supply is expected to last up to about a year. But this power consumption reducing method can be used only where the real time monitoring is not a primary limiting factor. In the sense of power consumption, most important sub module is radio device. As it will be described further, many telecommunication and architectural aspects affect the overall power consumption (such as operating frequency, modulation technique, output power, etc). Actually, radio device usually consumes more than 70% of overall power consumption of the sensing node. Processing units (microcontrollers) today are designed to be ultra low power devices. Their current consumption is expected to be in the range of 0,5 to few mA. Some other (but much lower) power consumption is expected from the rest of signal conditioning electronics (voltage regulators, etc.)

Processing unit enables A/D conversion, digital signal processing, and transmission of the signal to the communication module. In multifunctional applications where the data are needed to be screened from the sensing module directly, more powerful microcontrollers would be needed. Sometime this means some more external memory modules which, on the other hand, can enlarge the overall physical dimensions. Processing unit is not a critical part of the system because developments in today's microelectronic device's design offer very high performance products with: high processing speed, large memory space, low power consumption, high resolution, small physical dimensions, power saving modes, many I/O lines etc.

In the next section, special weight is given to the wireless communication's characteristics and performances since these communications make M-H and H-C applications differ from classical approaches in medical monitoring.

Wireless Communication Issues and the Emerging Wireless Technologies for M-H and H-C

Emerging wireless communications open new solution to health care delivery systems. The appliance of wireless communications in medical systems for remote monitoring such as M-health and home care telecare systems have the potential to transform the way health care is currently provided. Regarding the wireless communications, most important parameters that are considered when designing the M-H and H-C applications are:

- Range
- Data rate
- Resistance to the noise and disturbance
- Power consumption (of the radio-device)
- Physical dimensions (of the radio devices and antennas)
- Networking issues
- Security issues
- Easiness of implementation (the cost) and the ability to integrate smaller communication systems into larger systems (as larger networks or Internet) etc.

There is no actual wireless technology optimized on each of given parameters. These parameters depend on telecommunication aspects as well as the radio-technique architectures of used radio devices and usually are complementary coupled. In this sense, most important issues to be considered are:

- Operating frequency and the bandwidth
- Transmitter power, antenna gain, receiver sensitivity
- Modulation and multiplexing techniques
- Networking topology
- Higher networking protocols.

Although some wireless applications are based on using visible or near-visible optical spectrum, RF communications are mostly used (especially in wireless telemedicine systems). RF section of electromagnetic spectrum lies between the frequencies of 9 kHz and 300 GHz. The RF bands which are used for most wireless networking (including short range telemedicine modules) are the unlicensed ISM (instrument, scientific and medical) bands as: 314 MHz, 433 MHz, 868 MHz (for Europe), 915 MHz (for North America), 2,45 GHz and 5 GHz. Unlicensed in this sense means that the band is free for use and it is up to users to resolve any interference problems, while when dealing with licensed bands, the FCC and similar bodies have a role to play in resolving interference. The choice of **operating frequency** is directly correlated to some very important parameters as: range, power consumption of the radio device and (indirectly) the influence of electromagnetic noise and disturbance. Free space loss is the most important factor affecting the received signal strength. It depends on the signal frequency and transmission distance according to the formula:

$$Lfs = 20 \log (4\pi D \backslash \lambda) \tag{3}$$

Where D is the transmitter to receiver distance in meters and λ is the wavelength of the radio signal in meters which can also be expressed as:

$$\lambda = c / f \tag{4}$$

As can be noted from the given formulas (3) and (4), losses are larger when higher operating frequency is used. This is a very important conclusion, especially for the outdoor communications (as this calculation assumes the clear line-of sight between transmitting and receiving antennas). Lower frequencies better penetrate the walls but, in practical indoor situations, the differences in losses due to the difference between used frequencies are small compared to other environmental effects. The most important factor here is the material of the indoor construction and sometime the thickness of walls. Losses are in range from 2-4 dB for non tinted glass, wooden door, cinder block wall, or plaster to over 15 dB in case of metal and silvering (mirrors). Lower losses consequently imply typically lower energy consumption, so, generally, lower frequency transmissions mean lower consumption too. One drawback of using lower frequency is greater antenna length ($l \sim \lambda \backslash 4$). On the other hand, much higher operating frequencies (70 GHz) are sometime used as suitable for very short distances at the order of centimeters but they are not widely used in medical applications. When choosing the operating frequency, it is also important to choose the one which will not interfere with other networks at the same environment. This helps in preventing and minimizing the influence of the interference and noise.

Regarding the transmission frequency band, RF communications are often categorized as: **narrowband** and **wideband**. Data rate, as very important communication parameter, is directly correlated to the bandwidth: the greater the bandwidth, the higher capacity of the communication link. Narrowband devices generally have lower overall power consumption though some wideband systems can be highly effective in the sense of power consumption per transmitted bit (UWB). In order to avoid the interference and eavesdropping, today’s technologies often use some of the Spread Spectrum (SS) techniques. Most important spread spectrum techniques are DSSS (direct sequence spread spectrum) as used by ZigBee networks, and FHSS (frequency hopping spread spectrum) as used by Bluetooth technology. It is important to note generaly that the choise in **operating frequency** and the **bandwidth** directly influence data rate and the range. Higher data rates require more spectrum. But, more spectrum can only be found higher in the frequency band. Using higher frequency band, on the other hand means greater propagation losses, which implies the lower propagation range.

Beside telecomunication aspects of the wireless links, some radio-technique characteristics are also very important as: **output transmitter power, antenna gain, and the receiver sensitivity**. Along with losses, these factors make so-called **link budget** - the balance of power plus gain required to compensate for losses in the link so that sufficient signal strength is available at the receiver to allow data decoding at an acceptable error rate (Webb, 2007).

Output transmitter power is one of the most important characteristics of the radio device because, along with other parameters, it often directly determines the range of RF communications. For the radio devices operating at ISM bands, some strict regulations exists regarding the output signal strength. For example, in Europe, at frequency of 2,4 GHz, oputput power is limited to maximum 100 mW.

Antenna shape and the directivity can have great impact on strength and the quality of transmittet signal and sometime can influence the link security too. Directive antennas are more effective but in M-H and H-C applications they can not be used because the factor of mobility. In implementation process, in order to avoid losses and reflection, it is important to match antenna impedance with the output impedance of the radio device. The higher directivity of the antenna, the lower possibility to eavesdropping the data.

Receiver's sensitivity is the lowest limit of the signal strength that can be detected by the receiver. Typical values for receiver's sensitivity of the low power WPAN devices (which are usually used in H-C and M-H applications and in wireless sensor systems generally) are < - 85 dBm.

The bit stream must be **modulated** in order to be sent by the radio waves. It can be modualated onto either a single or multiple carrier frequencies but also can be modified regarding the position or shape of the signal. Right choice on modulation technique has impact on some important communication parameters as:

- Spectral efficiency (achieving the desired data rate within the available spectral bandwidth),
- BER (Bit Error Rate) performance – achieving the required error rate given the particular factors of the degradation (interference, multipath fading etc.),
- Power efficiency – particulary important in mobile health applications,
- Implementation complexity – wich direcly influences the cost of the hardware though some aspects of the modulation can be implemented in software (not influencing the cost of implementation).

On these parameters some tecniques can be more or less efficient and usually the choise depends on the purpose and on which parameter is application more limited to. For example, constant envelope of modulated signal, practically means higher efficiency of the output power amplifier (even to 50%) achieved by using nonlinear part of the transfer function in contrast to other types where efficiency can be up to 10%, so in the sense of power efficiency, these techniques can be more appropriate where power consumption is the primary limitation factor.

For combining multiple analog message signals or digital data streams into one signal, **multiplexing techniques** are used. These techniques define the way multiple users access the common medium and can be of types as: TDMA (time division multiple access), FDMA (frequency division multiple access) or OFDMA (orthogonal FDMA), SDMA (space DMA) and CDMA (code DMA). The combination of two techniques is used as well. For example, GSM uses FDMA/TDMA with eight time slots available in each 200 KHz radio channel.

Networking topology is one of the first issues that are considered in the process of M-H and H-C application's design. At the beginning of the project, the designer usually determines some basic architectural parameters as: wireless coverage, number of sensing nodes, redundancy, extendibility, connectivity to higher level Telemedicine networks etc. All these aspects more or less depend on the choice of the networking topology. For example, when designing simple typical home care application for only one user (e.g. in continuous monitoring of ECG, SpO2, blood pressure etc.), a simple **point-to-point** link can be used without the need for wireless networking in the sense of dealing with greater number of nodes and considering medium sharing and addressing. When dealing with smaller size network (for ex. in ambulatory monitoring of few patients), usually the simple **star topology** can be appropriate. The main advantage of star topology is the simplicity. The drawbacks are: a simple central node (which, in case of error, can break down the whole network), relatively small range and bandwidth sharing. Central node can be: PC, PDA, WiMAX base station, Wi-Fi access point, Bluetooth master, ZigBee PAN coordinator, embedded Web server etc. Typical indoor range of wireless short-range star topology networks (as in Home/Office/Hospital Care low power communications) is 30 m. **Tree topology** (extended star) is very popular and mostly used one because of: extended range (usually using wired infrastructure partially), simplicity and more efficient in using the overall bandwidth. **Mesh topology** enables greater functionality of the network. The main advantages are the redundancy and roaming. The data routing function is distributed throughout the entire mesh rather than being under the control of one or more dedicated devices. These networks are also known as mobile ad hoc networks (MANET) in which nodes are mobile and communicate directly with adjacent nodes not needing any central controlling devices. Distributed control and continuous reconfiguration allows for rapid re-routing around overloaded, unreliable or broken paths, allowing mesh networks to be self-healing and very reliable (Rackley, 2007). It is clear that for the network to be really meshed and mobile, routing protocols should be implemented in each node. This implies the increased node's complexity, since more processing power should be implemented also affecting the overall power consumption of the nodes which can be a critical factor in most Telemedicine applications. Wireless mesh networks are rarely used in typical M-H and H-C applications, mostly because of their complexity. When ubiquitous monitoring is needed (as in mobile health applications), cellular networks are used.

Higher communication and networking protocols are important in achieving wider network functionality and more reliable data transfer as well as in accomplishing better efficiency in sending different types of data. Generally, there are five categories of medical data that can be transferred: biological signals, live scene images, administrative data (e.g., access control, device configuration signals, etc.), control commands for remote devices, and warning signals (Polley, 2006). Because the telemedicine applications use different interconnected networks, protocols as TCP (transmission control protocol) and UDP (user datagram protocol) are usually used. TCP is connection-oriented reliable protocol with flow control and congestion control mechanism, whereas UDP uses a simple datagram with no congestion control. TCP is more suitable for transferring data which require small portion of bandwidth and high reliability. Very imprtant issue here is setting the various priorities for various data types. As an example, ECG, PPG and other vital signs, should be sent via high priority TCP link. On the other hand, bandwidth-hungry images transfer quality will satisfy the purpose by using low priority UDP protocol, since congestion control mechanism of the TCP protocol with retransmitting (especially in a wireless environment) would cause extra delays.

In M-H and H-C systems, security issues have to be considered as well. This factor should be treated as the priority one, since medical data are very sensitive so the data integrity is very important. Different technologies offer different mechanisms in this sense. Higher protocols (as encryption algorithms and others) are usually integrated into a technology-specific protocol stack. For example, Bluetooth technology uses integrity check system SAFER+ and the 128 bit E0 encryption. Some extension in security issues can be achieved by appropriate software development at the application level.

Engineering aspects mentioned previously are very important in choosing adequate technology which would be optimal for a given purpose. Some of standardized technologies are often used. Knowing their technical characteristics, the designer should be able to make the choice of the appropriate one.

Generally, today's wireless communication systems can be categorized as (Webb, 2007):

1. **Mobile:**
   - 2G
   - 3G
   - WiMax
   - 4G
2. **Private mobile radio (PMR):**
   - Analogue
   - Digital
   - Mobile mesh

  - Emerging technologies including cognitive radio and software defined radio (SDR)
3. **Fixed wireless:**
   - Point-to-Point
   - Point-to-multipoint
   - Fixed mesh
4. **Short range:**
   - WLANs (802.11)
   - WPANs (Bluetooth, ZigBee, UWB)
   - RFID (Passive and Active devices) – WBAN.
5. Conventional analogue and digital broadcasting

Since applications designed for continuous monitoring of physiological parameters mostly use some of standardized cellular or short range (WLAN and WPAN) technologies, these technologies will be described in some more details.

As mentioned, M-H application's primarily advantage is the network coverage which enables ubiquitous mobile health care delivery. Consequently, these systems use cellular networks as 2G (and the extensions as GPRS, MMS, HSCSD, WAP, EDGE etc.), 3G, and (in future) 4G networks. Beside the coverage, the advantage of these networks is contained in the fact that they are very much present in cellular phones, so their integration into telemedicine systems is easy. 2G systems, through EDGE for GSM, can provide (in "ideal" occasions) the data rate of up to 300 kb/s. In typical practical use, data rates are much lower. On the other hand, 3G systems were designed against criteria of delivering 2 Mb/s but they practically can achieve data rates up to 400 kb/s which open a wide range of opportunities for use as: video calls, video streaming, real time monitoring (with very satisfying data rate and coverage) etc. As such, they are very appropriate for use in M-H systems when sending medical data in real time manner such as video signal, images and other measured medical parameters. The problem with 3G is that this technology is still not widely deployed. 4G technology, beside cellular character, is expected to integrate other short range technologies as: Bluetooth, ZigBee, UWB etc. Very high data rates are expected to be achieved, even up to 100 Mbps.

Indoor data and voice traffic transmission, however, converge to short range communications systems because these systems generally have some important advantages over cellular (and other long-range) networks when integrated into telemedicine applications as: lower price, higher data rate, networking capabilities (supporting ad-hoc networking), longer battery life, smaller device's dimensions etc. New home care telecare systems are supposed to assure the mobility in range of ambulance, hospital sector, office or house. So, there is no need for the only advantage which mobile cellular networks offer over short range communications – the outdoor coverage. That's why, in these systems, short range communications are mostly deployed. On the other hand, in typical M-H applications, short range communications (for communication of sensor node with the gateway device) are often used too. For example, cellular phone can communicate with sensor node using Bluetooth technology and, at the same time, can act as a gateway device transferring data to some medical server or directly to some other mobile phone using cellular networks.

Almost all **WLAN** networks are covered with IEEE standard 802.11. Most popular versions are: "a", "b", and "g". Greatest advantage of 802.11 is data rate which can theoretically go up to 54 Mbps. Technically, IEEE 802.11 use ISM frequency 2,4 GHz (versions "b" and "g") and 5 GHz (version "a"). Version "a" is under the lower influence on disturbance because a small number of technologies use this frequency, but, on the other hand, this shortens the range, which can be up to 7 times shorter compared to standards "b" and "g". For collision avoidance, CSMA/CA (Carrier Sense Multiple Access / Collision Avoidance) is used and, on physical layer, techniques as DSSS (at version "b") and OFDM (at versions "a" and "g") are used too. Indoor range is typically 50 m while outdoor links can be in rage of km using special antennas. Another sdvantage of IEEE 802.11 devices is very good Internet connectivity which makes this networks suitable for use as backbone (in conjunction to UWB or other short range technology). On the other hand, typical WLAN devices are not suitable for the integration into wearable medical nodes, primarily because of their power consumption and physical dimensions. WLAN technology can be very appropriate in ambulatory/hospital monitoring where sensor node can be wired to Laptop PC or PDA or can be wirelessly connected using some WPAN link, while the transmission to the medical server can be accomplished by WLAN link.

UWB technology uses very wide frequency band, between 3.1 GHz and 10.6 GHz. Because of the bandwidth, power limitations are regulated and very strict. UWB is designed for short range communications (typically 10-20 m) of very high data rates (few hundred Mbps). This technology is most suitable for PC connectivity and wireless connection of home devices (DVD players and plasma screens etc). UWB transmission has the lowest consumption per bit but overall power consumption is typically higher than at Bluetooth or ZigBee devices. This technology could be a good choice when transferring larger medical data loads at short distances as when transferring medical images and video signal.

Bluetooth was initially designed to serve as cable replacement technology for data communications between mobile phones. When new improved versions appeared, it became clear that Bluetooth will do much more than that. Today, Bluetooth devices, beside their initial purpose, are used in creating wireless sensor networks and especially in forming WPAN (Wireless Personal Area Networks) for mobile health and home care telecare applications. From the technical point of view, Bluetooth works at frequency range 2,402 – 2,480 GHz using FHSS, GFSK modulation and TDMA multiplexing. Bluetooth defines 3 power classes: class 1 (maximum output power of 20 dBm), class 2 (maximum output power of 4 dBm), and class 3 (maximum output power of 0 dBm). Networking architecture is of type master/slave and usually forms star topology called **piconet**. Bluetooth network can be extended into **scatternet** – set of two or more piconets. Main characteristics of Bluetooth technology can be summarized as:

- Data and voice transfer at typical distances 1-100 m
- Various networking topology supported
- Data rates can be up to 723 Kbps (versions 1.x) and up to 3 Mbps (version 2.0)
- Small current load (typically from few mA to 30 mA) and usage of power saving modes as *sniff, hold*, and *park*.
- Robustness
- Miniature radio devices (typically 20mm x 20mm or smaller)
- Great presence in mobile telephone devices.

These characteristics make Bluetooth technology a good choice when simple short range star topology is needed, with solid data rate and small power consumption. As such, Bluetooth is often found in M-H applications as a communication method between wearable sensor and mobile phone, PDA or Laptop. At home care applications, fixed cable based gateway can be used and the communication between gateway and sensor node can be done using Bluetooth links.

ZigBee is another WPAN technology which works at 3 frequency ranges: 2,4-2,4835 GHz (with 16 channels and maximum data rate of 250 Kbps), 902-928 MHz in North America (with 10 channels and maximum data rate of 40 Kbps), and 868-868,6 MHz (only one channel and maximum data rate of 20 Kbps). The first one uses OQSK (Offset Quadrature Shift Keying) modulation technique and the other two use BPSK (Binary Phase Shift Keying). ZigBee uses DSSS and, for collision avoidance, CSMA/CA. Performances of ZigBee technology can be summarized as:

- Ultra low power consumption
- Miniature radio devices
- Capability of creating large ad hoc networks
- Ranges 10-75 m

Because of the mentioned characteristics, especially power consumption, ZigBee technology tends to become optimal choice in wireless sensor networks where power consumption is most critical parameter, while the high data rates and advanced capabilities of Bluetooth are not needed. In Telemedical applications, ZigBee would be an optimal solution in long term continuous monitoring of some slow changing signals (i.e. PPG) or in the case of implants and signal acquisition from different parts of human body (forming wireless body area network).

Critical Issues on Software Design

As mentioned before, the design of systems for remote monitoring of medical data belongs to so-called middleware engineering which, beside some physiological and electrophysiological aspects, includes the knowledge on hardware design, communications, and the software design. Most of the hardware and device's communications should be supported by appropriate software modules. Software design in M-H and H-C systems is related to the microprocessor / sensor unit programming, network programming, and the user graphical user interface (GUI). Also, some software integration into a hospital core information system are needed as transferred data need to be correlated to other patient's data. Sensor units for continuous monitoring of biomedical signals as used in M-H and H-C systems contain programmable units such as microcontrollers or microprocessors with the extensions (memory modules, etc.). There are different software platforms on which the functionality of these units is based. For example, C programming is often used as very efficient with high speed processing capabilities. Some sensors are programmed using the operating system called TinyOS, which is currently the industrial standard for wireless sensor network operating system. TinyOS also provide well-defined set of API's for programming the Motes and some on-board data processing. It supports the execution of multiple threads and provides a variety of additional extensions like virtual machine and the database (TinyDB). Typical software modules implemented into a microcontroller unit contain routines as: ports and timer's initialization, I/O initialization and communication routines, A/D routines, storage of digitized sampled data, interrupt routines, often CRC calculation routines etc. Beside this, some application-specific communication protocol is usually needed. For example, sensor initialization is usually made by the healthcare provider at the remote site. After that, the protocol might include some frames either for synchronization or for identification. To ensure the link security, some applications include special coding techniques. Into a software design, node control and administration often should be included in order to configure devices for various uses.

Generally, most important issues on remote health monitoring system software design can be summarized in following limitations:

- The ability for real time processing and (sometime) data compression
- User friendly GUI
- Security issues (authentication, authorization, encryption)
- Networking scalability and multi user platform
- Multi-functionality
- Database store and access for various types of patient's data as: medical, financial, insurance, etc.

The sensor node's software has to be able to efficiently capture and process data as well as to transmit them to the wireless radio device's interface. There are two ways of data processing storing and transferring at mobile subsystem's end*: real time* and *store and forward*. In order to achieve efficient and, for the purpose of the particular application, satisfying level of data processing and the transfer, it is very important to calculate and treat some parameters as: needed sampling period, duty cycle, etc. Depending on the fact if the data processing means buffering or not, some memory calculations sometimes are needed too. For example, if 4-Mb SRAM (static random access memory) is available and 10 min ECG signal buffering is needed, knowing the sampling rate (typical of 128 Hz or 250 Hz) and the resolution (typical 8-16 bit), leads to the calculations for the memory space. If the values are 14 bit resolution, 250 Hz sampling, and 10 minute recording of the ECG signal, then the amount of memory needed is *sampling rate x number of bits per sample x duration* = 250 x 14 x 10 x 60 = 2.1 Mb (Fadlee, 2005). This is about half of the SRAM capacity. Therefore there is a scope to alter the sampling rate, quantization level, and duration of the data according to the clinical need. It is also important to take into account the real transmission capacity of the system. For example, in order to transmit 2, 1 Mb of data through 32kb/s GPRS link, 66 seconds would be needed, so when programming the A/D conversion and buffering, it is important to make appropriate space between transmissions in order to avoid frame overlapping. In case when data are shown directly to user (as when using PDA or Laptop connection to the sensor node), the user friendly interface with easy and secure configurability should be designed. There is no practical limitation on which programming platform to use. The platform can be important mostly in the sense of portability.

At the core information system's end, software architecture is often comprised of a set of user-friendly software modules, which can receive data from the remote Telemedicine devices, transmit information back to it and store important data in local database. Authorized user (i.e. doctor) should be able to access patient's data either directly (while being logged on local hospital network), or through secured remote connection (i.e. using Virtual Private Network). These software modules should be flexible and integrated into the user-friendly GUI's functionality comprising together encircled software architecture for remote health care delivery.

CONCLUSION

M-H and H-C systems are new concepts that, beside classical integration of microelectronic design and computing in medical telecare application, include wireless communications as well. Biomedical signals are captured using sensors. They are further conditioned and processed using signal conditioning front-ends and the microprocessor unit, respectively. After digitally represented, medical data are sent to the medical server, partly or fully, using wireless communications. Medical server deals with remote connections, medical databases, networking etc. This approach assures continuous access to the patient's health parameters even when the patient is in move and usually regarding the geographical location. The benefits of this kind of health care delivery are shown in much aspects (medical, social, economical), but the essential one is facilitating the health condition of population which is already improved in countries and medical systems where these approaches are applied.

KEY TERM

Home Care: Home care is health care provided in the patient's home by healthcare professionals (often referred to as home health care or formal care; in the United States, it is known as skilled care) or by family and friends (also known as caregivers, primary caregiver, or voluntary caregivers who give informal care).

Mobile Health: M-health can be defined as emerging mobile communications and network technologies for healthcare. This emerging concept represents the evolution of e-health systems from traditional desktop telemedicine platforms to wireless and mobile configurations.

Physiological Signals: Physiological signals are acquired and processed to form psycho-physiological measures. These measures affect game play both through team understanding and altered game mechanics.

Sensor: A sensor is a device which measures a physical quantity and converts it into a signal which can be read by an observer or by an instrument. For accuracy, all sensors need to be calibrated against known standards. Sensors are used in everyday objects such as touch-sensitive elevator buttons and lamps which dim or brighten by touching the base. There are also innumerable applications for sensors of which most people are never aware. Applications include automobiles, machines, aerospace, medicine, industry, and robotics.

Telecare: Telecare is the term given to offering remote care of elderly and vulnerable people, providing care and reassurance needed to allow them to remain living in their own homes. Use of sensors allows the management of risk and as part of a package which can support people with dementia, people at risk of falling or at risk of violence and prevent hospital admission.

Vital Signs: Vital signs are measures of various physiological statistics often taken by health professionals in order to assess the most basic body functions. Vital signs are an essential part of a case presentation.

Wireless Communication: Is the transfer of *information* over a distance without the use of electrical conductors or "wires". The distances involved may be short (a few meters as in television remote control) or very long (thousands or even millions of kilometers for radio communications). When the context is clear the term is often simply shortened to "wireless". Wireless communications is generally considered to be a branch of telecommunications.

Chapter 8.3

Paediatric Telepsychiatry as Innovation in Healthcare Delivery

Katherine M. Boydell
University of Toronto, Canada

Tiziana Volpe
The Hospital for Sick Children, Canada

Antonio Pignatiello
University of Toronto, Canada

ABSTRACT

Although a great deal has been written about the potential for telemedicine to increase access to care, applications in paediatrics are sparse. This chapter details how one paediatric telepsychiatry program has facilitated the creation of integrated healthcare solutions in patient psychiatric care for children and youth in remote and rural communities. It demonstrates how the telepsychiatry model of healthcare service delivery has improved access, enhanced capacity, and promoted knowledge exchange in rural communities. A case study is used to highlight theoretical and empirical research on the value of televideo information technology in mental healthcare and its impact on the healthcare stakeholders who utilize this technology. An overview of the clinical, education, and evaluation components of the program is outlined, with a focus on knowledge translation and exchange as the underpinning foundation to the success of the program.

BACKGROUND

The recent proliferation of live interactive videoconferencing technology has made it possible for two or more individuals to interact in real time, sharing information through electronic media. Telepsychiatry is a specific term designating psychiatric applications employing live interactive televideo (ITV) communication (The Work Group on Quality Issues, 2008). In fact, telepsychiatry (Brown, 1998; Ruskin, Reed, Kumar, et al., 1998) is emerging as

DOI: 10.4018/978-1-60566-356-2.ch050

one of the most successful uses of this technology. Telepsychiatry has important implications for accessing paediatric subspecialty services, determining future health care workforce requirements and their distribution, improving communications with parents of sick and chronically ill children, and extending the boundaries of the medical home (Spooner & Gotlieb, 2004).

The Canadian Standing Senate Committee on Social Affairs, Science and Technology (Kirby & Keon, 2006) recommended that telepsychiatry be utilized in rural and remote communities for consultations, education and training of mental health practitioners. This is a prudent recommendation, because children and families in rural and remote areas may face more obstacles to obtaining services and support that those in urban areas (Cutrona, Halvorson & Russell, 1996; Starr, Campbell & Herrick, 2002). The problems of service access often result from geographic, economic and cultural factors (Kelleher, Taylor & Rickert, 1992; Letvak 2002). Canada is a vast, sparsely populated country, with a varied and sometimes harsh climate and geography. In thinly populated areas, travel expenses increase the costs of both providing and obtaining care. Furthermore, it is difficult to recruit and retain specialists and allied health care workers, who tend to concentrate in larger urban areas (McCabe & Macnee, 2002). The geographic and professional isolation makes rural communities less attractive to mental health workers. In addition, the shortage of resources and support services in rural communities means that children requiring urgent care often must be placed in residential care outside of their community (Sheldon-Keller, Koch, Watts, et al., 1996).

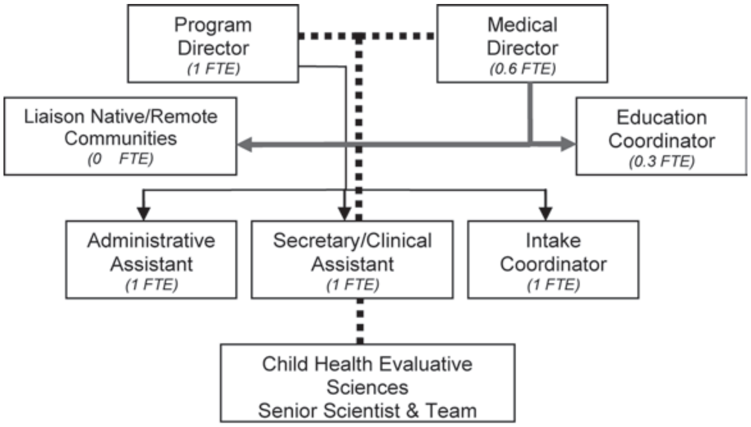
The problems associated with the mental health service system in rural areas (access, delivery, recruitment, retention) are exacerbated because, within the health research community, rural issues are often overlooked or dealt with generically. When rural perspectives are examined, it is frequently within the context of urban-rural differences, rather than as the sole focus of attention (Pong, Atkinson, Irvine, et al., 2000). Thus, providing psychiatric services to children and their families in rural and remote regions must address geographic barriers to access (Boydell, Pong, Volpe, et al., 2006) as well as the cultural context of individual communities, and the distribution, attraction and retention of psychiatrists and other mental health professionals.

THE TORONTO PAEDIATRIC TELEPSYCHIATRY PROGRAM (TPTP)

In the province of Ontario, Canada, the problem of access to specialty mental health care in rural communities is particularly problematic. In Canada, 20 percent of children and youth have a diagnosable mental health problem, yet only 1 in 6 receive any treatment (Offord et al., 1987). The ratio of child psychiatrists to children with mental health needs is approximately 1:6,148 (Steele & Wolfe, 1999). Furthermore, approximately 2% of child psychiatrists practice primarily in areas with populations of less than 20,000 while approximately 18% of the population resides in rural areas (Steele & Wolfe, 1999). Northern Ontario alone is the size of France and England combined.

To begin to address this need for service and support, in 2000 the Ontario Ministry of Community and Social Services (currently the Ministry of Children and Youth Services) (MCYS) funded the Division of Child Psychiatry, University of Toronto, operating through The Hospital for Sick Children (SickKids), in Toronto, to create The Toronto Paediatric Telepsychiatry Program (referred to as TPTP in the remainder of this chapter). The mandate of this program is to provide bilingual (English and French) psychiatric consultations and education to under-serviced children's mental health community agencies and their clients, utilizing ITV. As an academic site within the Division of Child Psychiatry at the University of Toronto,

Figure 1. Toronto Paediatric Telepsychiatry program hub site organization



SickKids is also required to fulfill clinical, teaching, and research mandates.

Funding by the MCYS compensates for capital and operating expenses, and remuneration of clinical and administrative staff at the SickKids "hub" site. TPTP functions under three distinct components: clinical (individual consultations, program consultations and special initiatives), education, and research.

The Clinical Component

Currently fifteen primary ("far") sites, along with their satellite locations[1] are connected to the SickKids hub site via an Integrated Service Digital Network (ISDN) carried on a maximum of three lines (maximum bandwidth 384 kbits/second) or via Internet Protocol (IP). Core hub site staff (as per Figure 1) and a designated telepsychiatry coordinator at far sites provide the necessary infrastructure. Seventy-five faculty members (almost exclusively child psychiatrists) within the Division of Child Psychiatry at the University of Toronto are available to provide consultations. Of those, approximately 40 participate with varying degrees of regularity.

TPTP is funded by the Ministry responsible for children's mental health (MCYS). Referrals are accepted from clinicians at community children's mental health agencies, who act as overall case managers, and not directly from physicians; however, participation from treating physicians is highly welcomed and encouraged. Agency clinicians are required to complete a mental health assessment prior to requesting the consultation. Consent is obtained for the youth and family to participate in the consultation and to release a copy of the report to the treating physician, with whom responsibility ultimately lies in facilitating any further medical/pharmacological interventions. Supporting documentation and referrals are triaged by presented urgency and matched to compatible consultants. It is a requirement that the child's case manager/primary clinician be present during the consultation to bridge culture, language, formulation, recommendations, and so forth between client and consultant, and for medical/legal prudence (Broder, Cheng, Cooke, et al., 2002). In the true spirit of a consultee-centred consultation (Lambert, 2004), the presence of the case manager and others involved in the care of the child/youth also serves to enhance capacity and facilitate collaborative care. Impressions and recommendations are provided verbally, immediately following the consultation, and a written report follows shortly thereafter. Follow-up consultations are not a mandate of the program and not routinely provided; however, are available if necessary and/

or requested. The program maintains a database derived from standard referral and summary sheets completed by all consultants.

From May 1, 2000 to March 31, 2007 a total of 4,382 clinical consultations were provided, of which close to one quarter (22.5%) were follow-ups. The most frequent diagnoses based on clinical impressions include Attention Deficit Hyperactivity Disorder (47%), Mood Disorders (21%), Anxiety Disorders (29%), Learning Disabilities (17.5%), Relational Problems (17%), Problems Related to Abuse/Neglect (12%), Conduct Disorder (11%), Attachment Disorder (8%), Pervasive Developmental Disorders (7%), and Psychosis (1%). These diagnostic categories are in keeping with other similar programs (Myers, Sulzbacher, & Melzer, 2004; Elford, White, Bowering, et al., 2000). Recommendations made, in decreasing order of frequency, have addressed (1) medication (2) counselling (3) focused assessment and testing (i.e. psychological/psychometric, neurological, etc.) (4) school-based interventions (5) day/residential treatment, and, (6) out of home placement.

In addition to individual consultations, program consultations are also offered. Of the 27 primary and satellite sites, 17 site-based programs (i.e. school-based day treatment programs, residential and foster homes, specialized programs working with children of military families, etc.) receive regular, monthly consultation where agency staff meet with a dedicated consultant(s) to discuss clinical, program-wide, and community issues. Topics for discussion have focused on individual youth and their behaviour, diagnosis, medication formulation and management, program, systems and community issues, transference and counter transference.

The clinical component of TPTP has created a variety of special initiatives to respond to the unique needs of the various partner communities: Native outreach, youthful fire setting, and military families. One of the early challenges recognized in TPTP was the difficulty engaging with Native communities. More active outreach and attention was clearly required to appreciate the cultural, spiritual, and traditional nuances of the Native populations. As a result, a core staff position, Liaison Native/Remote Communities, was created at the hub site to provide ongoing communication, education, and consultation between the hub site and remote site staff. The success of this position is evidenced by the increased referrals and participation by agencies dedicated to Native children and their families.

Another specialty area recognized as requiring attention was the problem of youthful fire setting. In response, TPTP introduced a specialized tertiary level consultation for youth involved in fire setting. Modelled after The Arson Prevention Program for Children (MacKay, Henderson, Root, et al., 2004), where fire setting behaviour is addressed within the context of a comprehensive mental health assessment, this service is offered conjointly by a specialist in the area of youthful fire setting and a generalist child psychiatrist.

A more recent special initiative has been the creation of ongoing program consultation to support and enhance the capacity of agency staff working with children whose military parent(s) are at various stages of deployment to the Canadian mission in Afghanistan. Dedicated staff specializing in war-related trauma issues, such as separation, loss, post-traumatic stress disorder, and grief, provide telepsychiatric consultations to children and youth living on military bases.

The Education Component

TPTP has used televideo technology for a wide variety of educational purposes, including continuing education and supervision (Broder, Manson, Boydell, et al., 2004; Hilty, Marks, Urness, et al., 2004). Seminars are delivered via ITV to multiple and diverse distant sites according to principles of effective continuing education. TPTP has primarily focused on providing exposure of telepsychiatry to trainees at the hub site and continuing education to professionals at the far sites. As part of their training at the University of Toronto, it is mandatory for psychiatry residents to attend two clinical consultations during their core six month rotation in child psychiatry. Evaluations completed by residents completing their core training in child psychiatry indicate that the experience is interesting and enjoyable, that their knowledge about providing psychiatric services to under serviced communities is increased, and that they would recommend the experience to others. Such exposure is ideal for residents wishing a diverse general child psychiatry community experience, and in particular for those who will be practicing in rural and remote regions. Research has shown that early exposure to telepsychiatry results in increased numbers of trainees who choose to locate their practice in rural communities (Hodges, Rubin, Cooke, et al., 2006). In such situations, efforts are made to connect the resident with the community in which they will likely be establishing professional practice upon graduation. This also allows for ongoing liaison and support for the resident in their future career. For example, child psychiatrists practicing in remote communities have the opportunity to connect into psychiatry Grand Rounds at SickKids via ITV on a regular basis.

The continuing education program for community mental health professionals at the far sites was developed on the basis of a detailed needs assessment completed by recipients of educational sessions. Continuing education is delivered in the format of multiple seminars in a series, using a range of interactive teaching methods. This format is based on evidence that suggests it is more likely to lead to changes in practice and patient outcomes (Davis, Thomson, Oxman, et al., 1995; Davis, O'Brien, Freemantle et al., 1999). Each seminar series is delivered to multiple sites at once, and cover a wide range of child mental health topics. In response to participants' requests, a calendar of educational events is prepared for six month blocks to facilitate planning for attendance. Feedback from attendees indicates that the content and teaching methods are valued by participants, and useful in their everyday practice. In addition, the seminars have had a noticeable impact on client understanding of mental health issues, resulting in increased confidence and competence. Providing continuing education in this way is very cost-effective: depending on the number of participants during any one session, the delivery cost is calculated to be as low as $21.66CDN per attendant, per session.

The Research Component

As TPTP represented a relatively new and evolving modality for the provision of psychiatric services, evaluative research was deemed critical to inform program delivery, clinical practice, and policy development. Consequently, within the first year of TPTP's establishment, an independent research team was engaged to devise and implement a comprehensive program of research. As a first step in the process, a critical review of the extant literature was conducted and an annotated bibliography generated. As well, the research team asked representatives from all the stakeholder groups (funder, hub site, and far site) to identify the key issues that the evaluation of TPTP should focus on, via a survey, focus group and individual interviews. An important finding from this design phase was that the resulting research evaluation must be inclusive of all stakeholders, and take into account the unique context (geographical, cultural, and social) of each telepsychiatry site and its community (Boydell, Greenberg & Volpe, 2004).

From this participatory process, a qualitative research program was developed to evaluate TPTP.

Various priority research areas were identified and to date four studies have been completed or are underway: (1) a study of the perspectives of service providers and family members (Greenberg, Boydell & Volpe, 2006); 2) a study of the opinions of consulting psychiatrists and community general practitioners and paediatricians; 3) a case study of recommendations made in a telepsychiatry consultation and whether or not they were successfully implemented (Boydell, Volpe, Kertes et al., 2007); and, 4) a study of the perspectives of young people who have received a telepsychiatry consultation (currently in progress).

Study 1: Service Provider and Caregiver Perspectives of a Paediatric Telepsychiatry Program

The study focused on the perspectives and experiences of family caregivers and service providers in rural children's mental health agencies. Focus groups with rural mental health service providers and interviews with family caregivers of children receiving a telepsychiatry consultation were conducted. The purpose of this research was to evaluate the benefits and limitations of providing pediatric psychiatric services via video-technology to inform future program development and health policy. While study participants indicated that their experiences with the telepsychiatry program had been overwhelmingly positive, they identified a number of barriers to accessing telepsychiatry services and implementing treatment recommendations.

The results of this study identified a fundamental need for follow-up consultations for particularly complex or unusual cases. Originally, the program's mandate did not allow for follow-up consultations. In response to the study's findings, the Ministry funder expanded the program's mandate to include and reimburse for follow-up consultations. Currently, follow-up consultations are viewed as an important element of the service, and consistently account for almost 25% of all referrals. Additionally, the research revealed the importance of program consultations that focus on discussion of specific challenges arising from individual cases or program-based issues. As with follow-ups, program consultations were not part of the program's original mandate but the policy was modified when research results revealed the multiplier effects of program consultations in rural communities, with service providers reporting increased comfort and confidence in dealing with complex mental health issues and competence in identifying future problems and potential solutions.

Research results also highlighted attention to cultural context as a key ingredient to the program's success, resulting in a number of program modifications and improvements. Originally, program funding did not provide for travel between the hub site and the various community agencies receiving telepsychiatry services. Following this study, the funder established a travel budget for Toronto-based staff to visit TPTP communities, build relationships with agency staff, and develop a knowledge base of each community's unique characteristics. In addition, telepsychiatry referral forms were scrutinized to ensure that they were user-friendly, culturally sensitive, and attentive to the nuances and heterogeneity of each community. For example, terminology specific to Native and military clients was incorporated.

Study 2: Physicians Weigh In - Medical Perspectives on Paediatric Telepsychiatry

This study focused on the perspectives of physicians (general practitioners and paediatricians) practicing in TPTP rural communities, as well as of child psychiatrists delivering consultations from the hub site. Physicians, selected from a random sample of TPTP sites, were interviewed via telephone. Many physicians were either unaware of the paediatric telepsychiatry program or lacked information about the ways that they could be involved. Recognizing that in over 60% of consultations a recommendation for further medical investigations and (or) intervention was made, requiring implementation by the local primary care physician, the telepsychiatry mandate was adjusted to allow physicians more direct involvement in the program as well as to make referrals. Physicians identified the factors that would facilitate their involvement in the program, including remuneration issues and education regarding the prescribing of newer psychotropic medications. To remedy the issue of the need for physician education, medication information sheets were created and widely distributed. Allowances are being made to the program's education component to expand the target audiences of professional development seminars, to include, for example, community physicians. Additionally, to allow physicians to benefit from the educational events at SickKids, an interactive link via videoconference was established between the hospital's weekly psychiatry Grand Rounds and the rural sites.

The interviews with hub-site psychiatrics were conducted face-to-face and provided direct feedback about the effectiveness and challenges of providing psychiatric consultations via televideo. In particular, psychiatrics appreciated their role of consultant as it meant that they were able to provide services without being burdened with an ongoing caseload. This clearly facilitated buy-in to the program and provided a strong directive to maintain a consultative model of service delivery. Research findings also revealed some difficulties in identifying non-verbal cues and facial nuances during telepsychiatry consultations. These results informed purchasing decisions by program managers regarding the type and quality of video equipment.

Study 3: Recommendations Made During Paediatric Telepsychiatry Consultations

Little is known about whether or not the recommendations resulting from telepsychiatry consultations are actually implemented, specifically, the barriers and facilitators associated with implementation. In study 3, 100 telepsychiatry consultations were selected randomly from TPTP program files and reviewed for information relating to the presenting problem, reason(s) for referral to the program, and treatment recommendations of the consulting psychiatrist. The majority of the recommendations revolved around monitoring, changing, starting, continuing and stopping medication. In addition to the case reviews, agency case managers assigned to each of the cases were interviewed to determine whether the recommendations had been implemented and examine the barriers and facilitators to implementation. Case managers indicated that the successful implementation of recommendations was often related to the value placed on the authority and expertise of consulting psychiatrists by case managers, family members, school personnel and physicians. Other facilitators to the implementation of recommendations included specific and clear treatment directives, the successful engagement of the young person and their family, the timeliness of scheduling a consultation following a referral request, and the availability of follow-up sessions for complex cases. Barriers to implementation of recommendations included the lack of cooperation or willingness on the part of family members and/or youth, the one time nature of the consultation, and the lack of community resources.

Study 4: TeleViews - Young People's Perspectives on Receiving Services via Televideo

The fourth study in the TPTP program of research, currently in progress, is focused on an important gap in our knowledge base of paediatric telepsychiatry: the views of young people themselves. Traditionally, the perspectives and experiences of young people are obtained by proxy, through the voice of parents, health care professionals, and other adults. This research seeks to hear the voice of young people themselves, and involves both focus groups and individual interviews. Preliminary results from the focus groups were shared with psychiatric consultants, who were easily able to incorporate some of the suggestions into their day-to-day televideo practices. For example, young people indicated that they would like to know something about the psychiatrist as a person. This was important to "break the ice" and enhance their comfort level before discussing sensitive and private information. The physical environment was also identified as being very important to young people. They highlighted many simple strategies that would improve the actual room in which the telepsychiatry consultation takes place. For example, youth noted that a table typically separates them from the television screen; this was seen as a barrier and its removal was recommended.

In the overall program of research, great efforts were made to ensure that all stakeholder groups were included in every aspect of the research, including design, participant recruitment, data collection and analysis, with a particular emphasis on knowledge translation and exchange. Research has demonstrated that interactions of clinicians and researchers are essential for successful knowledge generation and translation (Goering, Boydell & Pignatiello, in press; Golden-Biddle, Reay, Petz, et al., 2003). As a result, from the very beginning, members of the research team participated in monthly administration meetings with hub site staff and quarterly steering committee meetings with executive directors of the far site mental health agencies. The research team challenged commonly accepted views of health communication with their one-way transfer of information based on a one-sided relationship between communicator and receiver. Instead, information exchange based on a dialogue was highlighted (Lee & Garvin, 2003) and all members of the TPTP community encouraged to network, exchange ideas, and discuss priorities and issues. To facilitate this process, the bi-annual telepsychiatry newsletter, *Short Circuit*, originally created as a medium to communicate program news to psychiatric consultants was expanded to disseminate research findings to both hub site and far site staff. These initiatives ensured that regular input and feedback could be incorporated into the ongoing research. They also ensured the greatest buy-in to study results by all stakeholders, thus increasing the likelihood that the study findings would result in positive changes in clinical practice and service provision.

FUTURE DIRECTIONS

The Toronto Paediatric Telepsychiatry Program has moved far beyond the pilot phase, and is now an established program within the services and supports provided by the Ontario Ministry of Children and Youth Services. This solid base has allowed the TPTP group to think about expanding in a number of critical ways, in the clinical, education and research components.

In the clinical realm, multiple opportunities have presented themselves in terms of potential expansion. For example, in response to a demonstrated need for more input regarding specialized mental health care on the part of primary care physicians, the team is currently exploring the provision of support to this stakeholder group directly. The potential also exists to consider expanding the program to other service sectors that deal with children, youth and their families, such as recreation, health, criminal justice, education, and child protection.

Educational sessions are being planned for a service that is not currently offered by TPTP; education about key mental health issues targeted to the general public. This is particularly important as stigma and discrimination feature largely in help seeking efforts, and the general public - particularly in rural areas - has expressed a need for basic knowledge about mental health issues (Boydell, Stasiulis, Barwick, et al., in press). The scope and number of educational sessions offered to community mental health agencies in rural areas have also been targeted for future expansion.

With respect to research of telepsychiatry programs, the field needs to move beyond feasibility and pilot work and the tendency to focus on the technology itself and instead move toward examination of the impact and effectiveness of the intervention. The experience of using the technology for research purposes has also led the research team to begin to explore the methodological implications of conducting focus groups and individual interviews via televideo. Our early experiences using the technology in this way have proved successful, yet, it requires empirical study to enhance the knowledge base regarding the efficacy of qualitative research methodologies. The challenges of doing research with rural and remote communities must be acknowledged – especially the very real issue of lack of resources. The research team found that even when stipends were available to enable agencies to participate, it was difficult to engage rural service providers. Strategies that may facilitate research participation in meaningful ways without jeopardizing service delivery need to be examined further.

CONCLUSION

In a children's mental health system described as fragmented, under funded, and with a critical shortage of mental health professionals, telepsychiatry offers the promise of sharing existing limited resources. (Kirby & Keon, 2006). This must be viewed within a wider system of care that acknowledges that a basic level of mental health services should be in place, in order that recommendations made can be implemented. Telepsychiatry is well positioned to enhance the delivery of health care, reduce professional isolation and improve distribution of clinical expertise. The practice of psychiatry, which employs assessment via history taking, observation and collateral information gathering, lends itself well to the videoconferencing medium. Limitations imposed by catchment areas virtually disappear, and seamlessness and continuity of care are facilitated. Care can remain within the local communities of children and their families, critical masses can be achieved in communities which would otherwise be relatively isolated. The consultee-centred consultation model and the provision of continuing education, often to multiple sites simultaneously, contribute to the multiplier effect. This mode of service delivery offers solutions to some of the most difficult challenges to service access and utilization in rural areas due to geographic, economic and cultural factors.

The consultation model itself may pose its own challenges for those unfamiliar with it. The consultant is challenged to derive almost immediate formulation and recommendations. Once again, the importance of building relationships and exchanging information prior to the actual consultation assists with this challenge. Community and agency cultural issues and provision of recommendations that are feasible, locally relevant and available, require consideration.

The described program has facilitated the research and knowledge translation experience for researchers, policy makers, front line workers, community organizations and community members in rural and remote communities. Building local clinical and research capacity has increased by involving rural health care providers as collaborators in the clinical, education and the research components of TPTP.

The telepsychiatry program represents an important initiative to confront the serious challenge of shortage of specialized resources in rural and remote communities. It is an efficient, likely cost-effective (O'Reilly, Bishop, Maddox, et al., 2007; Elford, White, Bowering, et al., 2000; Mair, Haycox, May et al., 2000; Persaud, Jreige, Skedgel, et al., 2005) and user-friendly method (Ermer, 1999) providing increased paediatric mental health knowledge and training to distant and under-served areas. Early intervention through this program for children and youth and their families who are experiencing mental health problems can reduce the strain on family members, front line workers, physicians, community institutions, including schools, which will ultimately improve long term outcomes.

Mental health begins in childhood and investments in children's mental health are surely among the most important investments that any society can make. If we are to make a difference to the health of the population, new innovations in health care delivery such as TPTP to ensure optimal social and emotional development in children and to prevent mental disorders should have a prominent role. Integrated health care solutions provided by TPTP offers a comprehensive, critical initiative to confront the shortage of child and adolescent mental health resources in rural and remote Ontario.

KEY TERMS AND DEFINITIONS

Knowledge Exchange (formerly knowledge transfer): Knowledge exchange is collaborative problem-solving between researchers and decision makers that happens through linkage and exchange. Effective knowledge exchange involves interaction between decision makers and researchers and results in mutual learning through the process of planning, producing, disseminating, and applying existing or new research in decision making.

Paediatric Telepsychiatry: The use of electronic communications technology to provide and support health care for infants, children, adolescents, and young adults when distance separates the practitioner from the patient, parent, guardian, or referring practitioner. This definition specifically excludes from discussion the use of ordinary telephone communication between practitioners and patients and the use of communications technology for education of practitioners.

Stakeholders: Stakeholders refer to all individuals involved in/having an interest or stake in paediatric telepsychiatry. They include the funders of the program, the administrative staff, psychiatric consultants; mental health service providers in rural communities, and young people and their families.

Telepsychiatry: The use of electronic communications technology to eliminate or reduce geographic barriers to receiving psychiatric services.

ABSTRACT

It is essential that health information systems are easy to use, meet user information needs and are shown to be safe. However, there are currently a wide range of issues and problems with health information systems related to human-computer interaction. Indeed, the lack of ease of use of health information systems has been a major impediment to adoption of such systems. To address these issues, the authors have applied methods emerging from the field of usability engineering in order to improve the adoption of a wide range of health information systems in collaboration with hospitals and other healthcare organizations throughout the world. In this chapter we describe our work in conducting usability analyses that can be used to rapidly evaluate the usability and safety of healthcare information systems, both in artificial laboratory and real clinical settings. We then discuss how this work has evolved towards the development of software systems ("virtual usability laboratories") capable of remotely collecting, integrating and supporting analysis of a range of usability data.

DOI: 10.4018/978-1-59904-792-8.ch001

INTRODUCTION

A wide variety of health information systems have appeared in healthcare (Shortliffe & Cimino, 2006). Although, such innovation promises to revolutionize healthcare there are a number of critical problems and issues related to their development, deployment and acceptance by end users that are related to human-computer interaction (HCI). Usability of health information systems refers to the degree to which they are useful, effective, efficient and enjoyable (Sharp, Rogers, & Preece, 2007). Lack of system usability has been a major impediment to adoption of health information systems. Indeed, perhaps in no other field have issues related to HCI come more to the fore when attempting to introduce information technologies than in healthcare. It has been previously argued that issues of HCI may be the most serious barrier to successful implementation and adoption of information technologies in healthcare (Kushniruk & Patel, 2004). Strenuous demands are placed on healthcare professionals and end users of health information systems making the need for usable systems critical in healthcare. Health information systems must be designed to consider not only technical aspects but also the complex information needs, cognitive processing and limitations of human users of such systems.

One of the main areas of concern revolves around the following question: how can we ensure that the health information systems we develop are usable, meet user information, support work needs and are safe? The design of health information systems that are intuitive to use and that support human information processing is essential. This has become increasingly recognized as more and more complex software and hardware applications appear in healthcare. Furthermore, as the complexity and variety of healthcare situations in which this technology is deployed increases, issues related to ensuring that health information systems will support local work activities and practices in healthcare are becoming critical. Closely related to issues of usability are issues related to healthcare safety, with the need to ensure that new devices and information systems increase patient safety and facilitate healthcare work. In addition, applications targeted to health consumers (e.g., patients and lay people) are also being developed at an increasing rate. It is essential that these systems be usable and that the information and advice they provide is both understandable and safe. Improved understanding of issues related to human cognitive processes that are part of human-computer interaction in healthcare is needed so that we can develop more effective health information systems.

In order to be able to determine if systems developed in healthcare are usable and safe methods of analysis are needed that can be used to characterize the information needs and processing of users of these systems. A wide variety of techniques and methods have appeared from applied psychology that can be used in health information system evaluation. One powerful method involves application of "think aloud" protocols. This involves the recording of subjects as they verbalize their thoughts while interacting with computer systems (Ericsson & Simon, 1993). In addition, video recordings of user interactions with systems can also be collected to provide a more complete picture of the interaction between humans and health information systems, as will be described in this chapter (Kushniruk & Patel, 2004). In addition to assessing the interaction with systems such methods can also be applied to assess the information needs of healthcare workers in order to form the basis for design of systems that better match both information needs and human information processing capabilities.

This chapter describes the evolution of our work in the development of practical and efficient approaches to assessing of the use and usability of new and emerging health information systems. This chapter begins with a discussion of cognitive aspects of human interaction with health information systems. This is followed by a discussion of an approach to rapid low-cost usability engineering that can be applied in the field to conduct studies of users interacting with health information systems in real settings. The approach has been used to evaluate a variety of healthcare information systems ranging from electronic health records (EHR) to Web-based information resources designed for use by both healthcare professionals and lay persons. We then follow this with discussion of our most recent work in extending the concept of usability testing to conducting studies of system usage and usability over the World Wide Web (WWW) remotely.

BACKGROUND

The Study of Human-Computer Interaction

The study of human-computer interaction (HCI) is concerned with the human, social, organizational, and technical aspects of the interaction between human and machines. It is a broad area of study that deals with a broad range of phenomena, including the design, evaluation and social implications of computer systems (Sharp, Rogers, & Preece, 2007). Research in HCI lies at the intersection of a number of disciplines including: cognitive and social psychology, computer science, anthropology, sociology, design sciences, and engineering. In this chapter we will illustrate how interdisciplinary perspectives to designing and evaluating healthcare information systems are needed in order to lead to healthcare systems that will be more effective and acceptable to their users.

Cognitive Aspects of HCI in Healthcare

There are a wide range of aspects of health information systems that are related to cognition and human information processing. One may ask "why study cognitive aspects of health information systems?" In answering this we must consider that the user interface to healthcare information systems can be defined as being the component of the overall man-machine system responsible for communication with the user of the system. Thus, HCI can be considered to be largely cognitive in that it involves processing of information by humans, in close conjunction with computer systems. Therefore, the application of ideas, theories and methods emerging from the field of cognitive psychology are highly relevant to the design and implementation of more effective healthcare information systems from the perspective of human users, for whom systems are designed to support and serve. There are a number of ways in which knowledge of human cognitive processing is important for improving healthcare information systems. These include the following: (a) providing knowledge about what typical users of systems can and cannot be expected to do, (b) identifying and explaining the nature and causes of user problems, (c) characterizing the problem solving and decision making processes of healthcare workers, (d) assessing the cognitive needs of users in designing systems and user interfaces, (e) feeding input back into system re-design and improvement, and (f) providing models and frameworks for conducting HCI research in healthcare.

TOWARDS A FRAMEWORK FOR HCI IN HEALTHCARE

In this chapter we take a broad perspective on HCI which encompasses the first three levels of human, social, and organizational aspects of health information systems, as outlined in the preface of this book: (1) Level 1—the level of the individual user interacting with a system in isolation, (2) Level 2—the level of the user interacting with an information system in order to carry out real work tasks, and finally (3) Level 3—the social and organizational level, where the interaction with an information system is considered in the context of its impact and effect on the organization as a whole. This characterization of the use of new information technologies in healthcare builds on a multi-level model of HCI which provides a useful framework for considering the complex problem of understanding how to best design, test and deploy innovative healthcare information technologies (adapted from Eason, 1991). Using this model, we can consider problems in acceptance of new technology at each of the three levels. For example, the goal of successful adoption of a health information system may fail at Level 1 if the design of the computer screens and instructions are such that users cannot easily learn how to use the system to enter patient data. Even if a system is designed to work well at Level 1, problems may occur once the system is inserted into the complex day-to-day activities and workflow of healthcare work practices, which may involve a variety of team members, contexts, environments, levels of urgency and complexity of tasks. However, careful analysis and adjustments made to provide effective systems at Level 2 does not guarantee uptake and acceptance of a new healthcare information technology, since the effect and impact of deploying such a technology at the organizational level (i.e., Level 3) may be an issue. For example, in the context of a patient record system, privacy and confidentiality issues at an organizational or political level may restrict the deployment of this technology within an organization such as a hospital. Nowhere in healthcare may careful consideration of each of these three levels of HCI be more germane than in consideration of barriers to adoption of health information systems. Health information systems span the levels of individual users of systems, from application of new technology within complex work roles and activities to issues that emerge with the increased possibilities for widespread access and dissemination of patient information along with the resulting organizational concerns regarding privacy and confidentiality.

Another perspective from which to consider health information systems relates to the extent of interaction of human users with the system. Thus, we can consider user interaction with health information systems in healthcare along a continuum from applications which require continual focus of user attention on the information technology, to applications where the technology is "invisible" or interacts to a very limited extent with the user. For example, the user interfaces of many handheld applications typically represent an extension of conventional desktop user interfaces to mobile applications. With these types of applications, users must focus considerable attention on the user interface [e.g., to enter medical values into a PDA (personal digital assistant)] at particular periods in time and explicitly insert its use within their work activities. Thus, the introduction of the technology must be understood in how it changes the work activity of the user and many aspects of human factors from the study of conventional user interfaces are applicable. However, many new applications of health information systems, including remote monitoring devices and wearable computing, are designed to be used ubiquitously *while* the user carries on their work activities (i.e., without switching their focus of attention to interacting with the technology). The implications of this new type of user-system interaction include the following (Lukowicz, Kirstein, & Troster, 2004): (1) interaction of the system with the environment is through a variety of modes that are appropriate for different contexts of use (2) the system may need to be operated with minimal cognitive awareness and effort on the part of the user, and (3) a wide range of tasks may need to be performed by the system with varying degrees of human-system interaction.

USABILITY ENGINEERING METHODS FOR IMPROVEMENT OF HEALTH INFORMATION SYSTEMS

Usability engineering is a rapidly emerging area in the field of human-computer interaction and has provided a set of methodologies for analysis of complex human interactions with computer-based systems. In this section, we will describe some of the main methods that may be employed for gaining insight into detailed aspects of HCI in the study of health information systems (Nielsen, 1993). These approaches can be considered along a continuum from experimental laboratory-based studies to the study of use of systems in naturalistic real-world settings. There is also a category of study of HCI that falls between pure experimental approaches that involves use of realistic simulations of real settings and contexts where information technologies may be used. For example, the laboratory study of a handheld application for entering medical prescriptions might involve subjects coming to a usability laboratory where their interactions with the application are recorded as they respond to artificial medical cases (e.g., they might be asked to verbalize their thoughts as they enter prescriptions from paper into the device). A simulation-based study of the same application might involve subjects (e.g., physicians) interacting with a "simulated patient" (i.e., a research collaborator playing the role of a patient) while the subject conducts an interview of the "patient." A naturalistic study of the same application might involve remote logging and tracking of user interactions with a device as the users carry out actual day-to-day activities in a medical clinic (as will be described later in this chapter). It should be noted that in-depth analysis of HCI in healthcare may involve iteration from laboratory study of user interaction with a device or application, that then lead to testing under simulated conditions and then finally in naturalistic settings. Analysis of HCI aspects of health information systems may require initial testing in artificial settings, followed by analysis involving simulated conditions, where conditions may be controlled for evaluation purposes.

USABILITY INSPECTION

Usability inspection is a cost-effective methodology adapted from study of HCI to healthcare that has emerged for improving the usability of health information systems (Nielsen & Mack, 1994; Zhang, Johnson, Patel et al., 2003). Usability inspection involves a usability analyst or inspector stepping through or "walking through" use of an interface or system in the context of some real task or activity. For example, an approach known as the cognitive walkthrough, involves the analyst (or a team of analysts) stepping through the activities that might involve use of a new health information system while recording their goals, actions, system responses and potential problems (Kushniruk & Patel, 2004). To guide such analyses, sets of principles emerging from HCI are considered. As another example, the methodology known as heuristic evaluation involves the identification of violations of principles of human factors design when a system is used to carry out a task. Jacob Nielsen (1993) has outlined a set of principles or rules to consider when conducting such analysis which include the following: (1) visibility of system status—this principle states that the state of system's processing should visible to users of a system when they so desire that information, (2) matching the system to the real world—this principle states that real world language and conventions should be used in user interfaces, (3) user control and freedom—users should feel like they are in control, (4) consistency and standards—the user interface and system operations should be consistent, (5) error prevention—designers should design interfaces to prevent errors, (6) minimize memory load—systems should support recognition (e.g., using menus) rather than recall, (7) flexibility and efficiency of use—systems should allow for customization and adaptability, (8) aesthetic and minimalist design—often the simplest and most minimal designs are the best, (9) help users recognize, diagnose and recover from errors, and (10) help and documentation—help should be available to users when needed.

These principles can be extended when considering health information systems, in particular system designed to be integrated into complex healthcare work activities. In our current work, we have developed the following heuristics for evaluation of such pervasive health information system applications: (1) unobtrusiveness—direct interaction of a user with a health information system should be limited to only parts of the task where such interaction is necessary (i.e., allowance for visibility when required), (2) privacy and security—use of a health information system must not violate privacy and security restrictions under normal conditions of use, (3) ability to provide emergency override capability—under exceptional conditions, security and access restrictions may need to be overridden, however such exceptional cases need to be identified and logged for subsequent audit, (4) appropriate context-awareness—health information systems must be able to track the context of use and respond to differing contexts in an appropriate manner, (5) failure backup—failure of a health information system or its supporting network should be made apparent to the user through some form of notification, (6) allowance for recovery and alternative modes of user interaction during failure periods, (7) information and altering prioritization—the system should appropriately prioritize and display alerting or remaindering information only at essential points in user workflow to avoid cognitive overload, (8) user control in the absence of traditional interface cues, (9) Selection of appropriate mode for system-user interaction, (10) consistency across modes of interaction, and (11) allowance for seamless modal switching.

Heuristics, such as those presented previously can be applied in a principled manner in both designing and evaluating health information systems. For example, analysts may step through the use of an information system, recording violations of any of the heuristics mentioned during such testing. In addition, the same heuristics can be used to guide the analysis of data collected from study of subjects interacting with systems under artificial conditions, simulations or naturalistic settings. These types of heuristics essentially form the basis for coding and quantifying problems observed by analysts and investigators in reviewing video data obtained from recordings of user interactions. Used in this way, the heuristics provide categories for identifying interaction problems in coding the resultant video recordings of user interactions, as will be illustrated later in this chapter.

USABILITY TESTING IN HEALTHCARE

One of the most powerful methods for understanding and analyzing usability of health information systems is known as usability testing (Nielsen, 1993). Usability testing refers to the evaluation of information systems through the in-depth analysis of user interactions with the system (under artificial or realistic conditions). Subjects in such studies are asked to carry out tasks for which the system or device was designed to support. For example, physicians may be observed while they carry out tasks that may use of a system to remotely access patient records. Typically this may involve video recording the entire interaction of users with the system (e.g., the screens of a computer application, or logs of the system's behavior as well as the physical and verbal behavior of subjects as they interact with others in their work environment and with a health information system). Usability testing may be conducted under artificial laboratory conditions, simulations, or in real-life settings. Under artificial conditions, subjects may be asked to "think aloud" while interacting with a device or carrying out a task that involves the use of an information system (e.g., interacting with a EHR system remotely while carrying out emergency procedures), while under simulated conditions use of the device might be recorded while the subject interacts with patients in a simulated clinical environment. In either case, the resultant audio and video recordings of the interaction can then be analyzed using methods involving the coding and classification of user problems, as will be described in a subsequent section.

Usability testing is closely related to on an approach to analysis of HCI known as cognitive task analysis (CTA). Cognitive task analysis emerged from the fields of cognitive science and psychology and involves the detailed analysis of humans as they carry out complex reasoning and decision making tasks (Gordon & Gill, 1997). In healthcare, CTA is concerned with characterizing the decision making, reasoning skills, and information processing needs of users (e.g., doctors, nurses, patients) of health information systems. An essential part of conducting a cognitive task analysis is to initially identify the essential tasks, or work activities, that an information system under study has been designed to support. For example, tasks might include entering a medication order into a health information system or accessing patient information about drug allergies from a health information system. Once tasks of interest have been identified, CTA typically involves observing subjects of varying levels of expertise as they carry out the tasks, identifying the skills, knowledge and problems encountered by subjects.

Our approach to usability testing, which we term "rapid low-cost usability engineering" (Kushniruk & Borycki, 2006) builds on CTA as well as usability testing and involves the following stages (Kushniruk & Patel, 2004; Kushniruk, Patel, & Cimino, 1997):

- **Stage 1.** Identification of testing objectives: As a first step the objectives of the usability test must be identified. The objectives might for example consist of testing a new health information system in order to determine what specific aspects of the user interface design might be adversely affecting its adoption by physician users.
- **Stage 2.** Selection of test subjects and computer application: Data is typically collected from a representative sample of users (e.g., physicians, nurses, patients) of the system under study. This often involves testing 10-20 representative users of a system (Kushniruk & Patel, 2004). It is important that subjects selected for the testing are representative of real users of the system under study (e.g., physician users of a patient record system).
- **Stage 3.** Selection of representative experimental tasks: Usability testing of healthcare information systems typically involves selection of several key representative tasks (that the system under study is designed to support) that will be used in the testing. For example, in analyzing the interaction of physicians with a medication order entry system, representative tasks might include the entry of specific medications into the system by physicians.
- **Stage 4.** Selection of an evaluation environment: The actual environments where usability testing will take place may vary from a fixed usability laboratory (under artificial laboratory conditions) to the recording of users interacting with real systems under real conditions (e.g., evaluation of users interacting with a health information system in an operating room or hospital ward). The approach described in this chapter is based on a portable and low-cost approach to usability engineering, where the equipment required can be brought into any healthcare environment.
- **Stage 5.** Observation and recording of users' interaction with the health information system under study: This is the stage where the users' interaction with the system under

study are observed and recorded. For example, physicians may be instructed to interact with a new patient record system while "thinking aloud." The resulting interaction is typically recorded in its entirety, for example, all computer screens are typically recorded using screen recording software, the users' physical interactions are video recorded and all verbalizations are also audio recorded (using methods that will be detailed following).

- **Stage 6.** Analysis of usability data: The data collected in Stage 5 can be analyzed using a variety of methods. In our consulting work this has often involved simply "playing back" the recordings of users interacting in order to visually illustrate type of issues and problems that users of their systems may be encountering. From our experience this can often provide extremely useful to designers of healthcare systems that will suggest improvements and modifications that might greatly improve adoption. More detailed forms of analysis (which will be described) can also be conducted. Typically, this involves coding the resultant data (which may consist of screen recordings, video recordings and transcripts of any audio recordings) to precisely identify the occurrence, type and frequency of user problems encountered. This type of in-depth analysis can also be used to characterize the cognitive processes of users of health information systems (e.g., reasoning and decision making strategies of healthcare professionals as they interact with computer technologies).
- **Stage 7.** Interpretation of findings and feedback into system improvement redesign: The ultimate objective of our work in conducting usability testing of health information systems is to understand the complex interaction between healthcare workers and computer systems in order to improve the usability of health information systems. This typically involves feeding back results obtained from the analysis of usability data (as described in Stage 6) to designers and implementers of such systems in the form of recommendations for system improvement. In general we have found that the earlier in the development cycle of health information systems that results from usability can be fed back into design, the better (Kushniruk, 2002).

We have used the approach to analyze a wide range of healthcare information systems. For example, in a recent study of a medication order entry system, subjects were asked to enter prescriptions as accurately as possible into the system. By recording their activities in doing so, we were able to identify aspects of the user interface ranging from content issues that needed to be changed to allow for accurate data entry (e.g., changing the default dosages provided to users to match dosages actually used in their hospital) to issues related to lack of consistency in the user interface (e.g., multiple ways to exit a screen leading to confusion for new users).

RAPID LOW-COST USABILITY ENGINEERING IN HEALTHCARE

In this section of the chapter we will describe our approach to usability engineering that can be applied in any type of setting (ranging from hospital rooms to the home setting) to study the use of health information systems by end users (e.g., healthcare professionals or patients). This approach to rapid usability engineering has so far been used for a number of projects, ranging from the study of nurse's information needs to the evaluation of a range of new and emerging health information systems including medication administration record systems, which are designed to allow for electronic ordering of medications

Figure 1. User interacting with a health information system while being video-recorded

(Borycki & Kushniruk, 2005; Kushniruk & Borycki, 2006).

Figure 1 shows an example of a typical user (a nurse) interacting with a health information system under study during usability testing. In this example, the subject is interacting with the system within a hospital, obtaining information about a specific patient. The subject is being video recorded while doing so. Our typical studies carried out in naturalistic clinical settings involve asking subjects (e.g., nurses or physicians) to interact with systems to carry out real tasks (e.g., to enter medications for patients or access patient reports). In many of our studies, we also ask subjects to "think aloud" while carrying out the task (which is audio recorded). The recordings of subject's "thinking aloud" while using a system can be analyzed using methods from protocol analysis (Ericsson & Simon, 1993; Kushniruk & Patel, 2004). The subject's overt physical activities are recorded using a video camera (i.e., a mini-DVD camcorder) as shown in Figure 1. In addition to recording physical activities and audio of think aloud, the actual computer screens are also recorded as digital movies (with the audio portion of each movie corresponding to subject's verbalizations). In order to do this we are currently using a screen recording program called Hypercam© which allows one to record all the computer screens (and verbalizations) as a user interacts with the system under study, and stores the resultant digital movie for later playback and in-depth analysis of the interaction.

The equipment we are currently using for many of our usability studies of health information systems is both low-cost and portable. In summary, this typically includes: (1) a computer to run the system under study on, (2) screen recording software which allows the computer screens to be recorded as movie files (with audio input of subject's "thinking aloud" captured using a standard microphone plugged into the computer), and (3) a digital DVD camcorder on a tripod or a ceiling mounted camera to video record user's physical interactions.

ANALYSIS OF USABILITY DATA

As previously mentioned, the analysis of the data collected varies from informal analysis (which consists of simply playing back the recordings of user interactions) to identifying specific usability problems and issues. The analysis can involve systematically annotating the recordings of interactions using software such as Transana© (a video annotation program that allows analysts to "mark up" and time stamp movies of user interactions with a system) as described in Kushniruk and Patel (2004). The typical result of carrying out such analyses includes identification of specific usability problems (often in a meeting setting with system developers, customers, and hospital or management staff present). For example, our work in the analysis of use of electronic health record systems has identified the following categories of problems with many health information systems we have studied: problems with lack of consistency in the user interface, lack of feedback provided by the system to the user about the status of the system, user problems in understanding information or terms displayed by the system, as well as user problems in entering information into the system in a timely and effective manner (Kushniruk, 2002).

As noted, the intent of our work is to provide feedback to system designers and implementers about system usability in order to provide useful information to improve systems. Our most recent projects have involved applying usability engineering methods to identify potential errors that may be caused by a system (e.g., inappropriate medication defaults in an order entry system), or "induced" by poor design of a user interface *prior* to release of the system in real clinical settings (Borycki & Kushniruk, 2005). This has involved conducting simulations of user interactions with systems under study as will be described below. We have also employed a similar approach to detecting and correcting potential user problems and preventing medical error in a range of systems. This has included analysis of handheld prescription writing software designed to run on handheld devices to allow physicians to record medications and obtain recommended guidelines about their use (Kushniruk, Triola, Borycki et al., 2005). More recently, we have employed a methodology based on rapid usability engineering and use of simulations of clinical activities to determine how medical workflow may be inadvertently affected by introduction of a medication order entry system, described in the case study below (Borycki, Kushniruk, Kuwata, & Kannry, 2006).

In the early stages of our work and early experimentation with usability engineering in healthcare, we employed a number of different approaches to conducting usability testing including setting up a considerably more expensive "fixed" usability laboratory (where users would interact with systems in a fixed "wired" room while being observed through one-way mirrors). However, our experience has indicated that this approach does not allow us to easily and rapidly collect data at the site where the software under study is actually installed—which often ends up being at a location that is not readily accessible (e.g., due to security restrictions) from a fixed usability laboratory. In addition, for many of our studies it is essential that we test information systems in the actual environment in which the system under study is being used (i.e., in order to determine how aspects of a particular environment may be affected and how users interact with a system) which is not realistically possible without employing a portable approach. With the advent of inexpensive screen recording software and high quality portable digital video cameras, the costs have decreased for conducting such studies along with an increase in the portability of the equipment that can be taken into any hospital or clinical environment, which also simplifies the entire process.

Based on our experiences, the approach to rapid usability engineering in healthcare typically involves the following steps: (1) familiarizing oneself with the techniques and approaches that are possible (see Kushniruk & Patel, 2004, for details) in healthcare, (2) setting up a low-cost portable usability laboratory, (3) choosing a project area that is of significance (e.g., to identify the major usability problems that users of a patient record system may be encountering), (4) working closely with clinical informatics staff, designers and management to show how system usability can be improved in an effective and cost-beneficial manner, and (5) making alterations to the information system based on feedback.

EXAMPLE: EVALUATING THE UNINTENDED CONSEQUENCES OF A MEDICATION ADMINISTRATION RECORD SYSTEM

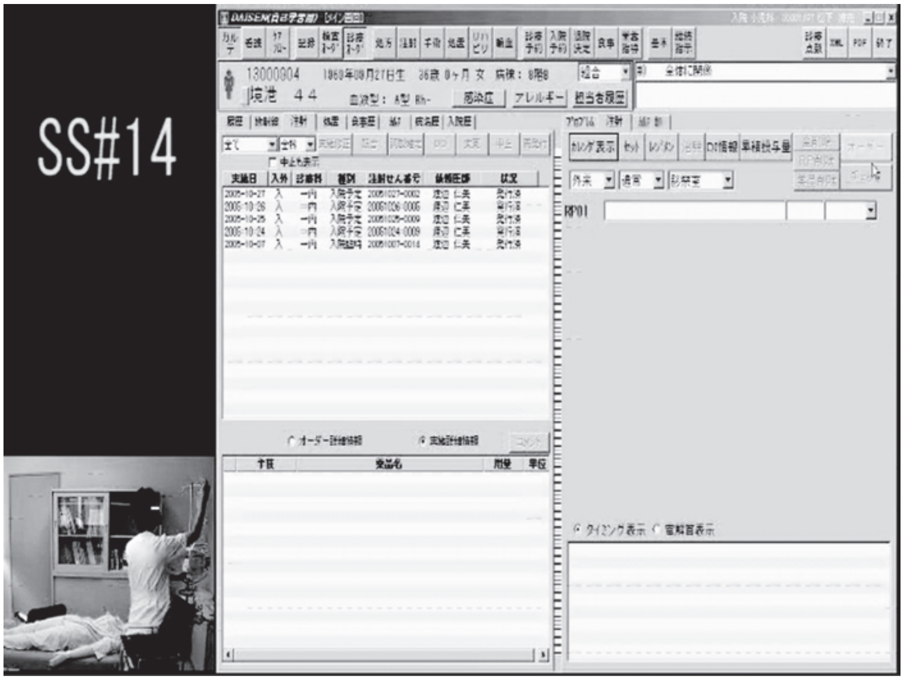
In the example described in the following, a rapid usability engineering approach (employing simulations of realistic healthcare situations) was used to assess the impact of a new medication administration system about to be deployed in a teaching hospital in Japan. The system was designed to allow users (e.g., physicians and nurses) to obtain information and instructions about medications to give to patients and to record the administration of the medication in a computer system. Thus the system is similar to many systems currently being deployed in hospitals around the world. The computer component of the medication administration system was also integrated with bar-coding technology that allows the doctor or nurse to scan the wrist band of the patient to identify the patient and to also scan the labels on medication bags. The study set up involved asking subjects to obtain information from the medication order entry system and administer medications while being video recorded (physical activities were recorded using a camcorder on a tripod, while all computer screens were automatically recorded using screen recording software).

Sixteen subjects, consisting of doctors and nurses were given written instructions for entering medications for a list of simulated patients. The subjects interacted with both the computer system as well as the "patient," which consisted of a dummy (i.e., a mannequin) with a bar coded wrist band (as shown in the bottom left-hand side of Figure 2). A typical computer screen from the system is shown on the right-hand side of Figure 2. Figure 2 shows the two video views from subject #14—the video of the subject's interaction with the patient in one window while the screen recordings of interactions with the computer system are shown in another window (supporting analysis of both "views" to identify subject actions both on and off the computer). In the study, subjects were specifically instructed to interact with the computer system and the dummy patient (e.g., to hang intravenous medication bags) just as they would be doing in a real situation. In order to record the use of the system in the study, we employed a digital video camera on a tripod to record the interactions of the subject with both the computer system and the patient.

In summary, the study design included full video recording of the subjects' interaction with the system while subjects were asked to use the computer application to enter the patient's name, obtain the list of medications to give the patient, to administer the medication (to the dummy patient) and to then record the administration in the computer application. All computer screens were recorded while subjects interactions with a dummy patient (a mannequin) were recorded using the portable camcorder. At the end of the session the subjects were also interviewed about their experience in using the system (and the interviews audio recorded).

In order to analyze the data collected, first the audio portion of the recorded sessions were transcribed in their entirety (including the interviews at the end of each session—see Figure 3 for the transcripts from one nurse subject) and then annotated by the experimenters by reviewing the video recordings of the computer screens and subjects' physical activities (e.g., actually hanging medication bags). In Figure 3 the numbers on the left hand side refer to the video counter corresponding to the actual actions of the subject. The latter portion of Figure 3 also contains the transcript of the interview with the subject (a nurse)

Figure 2. Video playback of 2 recorded views: the subject's physical interactions (lower left window) and the computer screens (right window)



conducted immediately following completion of the simulation task

From analysis of this data a range of usability problems were identified including the following: difficulty in physically scanning the medication bags and scanning the patient's wrist band, inability to record administration of a medication when the patient's record is "locked out" by other users of the system (who are accessing the system at the same time as the nurse or doctor is attempting to administer medication), and issues related to the slow speed of the system particularly when there were many medications to be administered. In addition to identifying potential sources of specific problems that would arise from implementation of the new system, it was also observed that introduction of the computer actually generally led to a major change in the *process* of medication administration. This was characterized by a serialization of the workflow process that could not be deviated from, for example, as shown in the annotated transcript in Figure 3, the physician or nurse would have to administer one medication at a time, first accessing the computer, physically moving to the patient, scanning the patient identification band on their wrist, moving back to the computer for details, then back to the patient to administer that drug and finally back to the computer to record the administration prior to administering the next medication (which is repeated each time for each medication). As compared to the previous workflow (i.e., the workflow before the system involving paper records), it was discovered that the new system imposed a relatively rigid order of activities for medication entry that could not be deviated from. Under normal conditions, this could lead to increased safety in medication entry by providing a structured and standardized procedure for medication entry. However, from our simulations it was also clear that under certain conditions (e.g., need to administer a number of medications under time-

POST-TASK INTERVIEW:

Experimenter: Did you find any difficulty with the task ?

Subject: I’m used to this operation, but sometimes it is hard to use the barcode reader when the barcode is not clearly printed.

Experimenter: What difficulties did you have with the barcode reader?

Subject: There are no problems when we have both a printed order and a label on the bottle (we can use either of them, because there are the same barcodes on both). But if the barcode is only on the bottle with its rough surface, I have often pushed its surface to flatten it, and scan it many times until I can read the barcode correctly.

Experimenter: Do you find any difficulty during the workflow process?

Subject: Sometimes I could not open the record of the patient whom I was giving a medication to because another nurse or doctor was opening the record at the same time

constrained conditions) the new computer-based system could also potentially result in cognitive overload leading to the need for complete bypass of the system by users under emergency or stressful situations. It should be noted that such potential unintended consequences of implementation of the system were not anticipated by the designers of the medication order entry system and that applying an approach to usability testing where users of health information systems are recorded as they participate in simulations of real clinical activity we were able to anticipate user problems prior to implementation of the system (Borycki & Kushniruk, 2005).

TOWARDS REMOTE USABILITY ANALYSIS OF WEB-BASED INFORMATION SYSTEMS

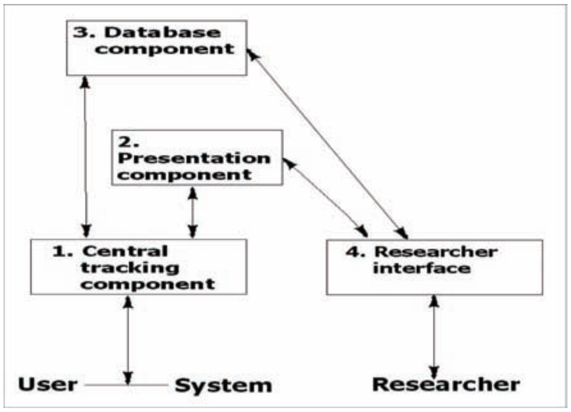
This section describes our most recent work in extending rapid usability engineering to the development of methods and approaches that will allow for remote usability testing of health information systems. The remote evaluation of the use and usability of Web-based healthcare information systems and resources is becoming recognized as being a critical area within health informatics. Many new health information system applications are being targeted towards use by not only health professionals but also by patients and lay people in an ever increasing variety of physical locations. Web sites containing digital libraries of on-line clinical information and guidelines, which provide health professionals with guidance and current evidence about the treatment and management patient cases, have appeared widely over the World Wide Web (WWW). In addition, many reputable healthcare organizations are providing similar type of information adapted to patients and lay people over the WWW. For example, the Canadian Medical Association provides guidelines on the treatment of Breast Cancer which are publicly accessible through their Web site. The assessment of such applications by varied end users (patients, physicians, nurses, etc.) from varied locations is challenging and has led us to a complementary line of work in developing and extending portable usability testing to the remote distance analysis of large numbers of users (e.g., healthcare providers or patients) interacting with health information system applications from any number of physical locations over the WWW.

As noted above, the evaluation of the use, usability and effectiveness of Web-based health information systems by end users who may vary greatly in terms of education, computer expertise and motivation, has become a major issue (Nielsen, 2000). However, the distributed nature of these systems leads to a number of challenges for system designers and evaluators. As a result in recent years an attempt has been made to conduct remote usability evaluations over the WWW. Such evaluation can involve collection of a variety of data, including remotely collecting on-line recordings of patients' and physicians' use of systems, telephone interviews, and in-depth video analysis of users interacting with systems. An example of this is a distance evaluation approach we have termed "televaluation" (Kushniruk, Patel, Patel, & Cimino, 2001). Cimino et al. (2002) describe the application of this approach to assess the use of a patient clinical information system (that allowed patients to access their own patient data from home over the WWW) based on remote logging of all user interactions with the system. This work built on and extended the work of Felciano and Altman (1996) in development of methods for remote tracking of Web users (using a program known as 'Lamprey'). By employing such a remote Web-based tracking component at the core of an evaluation system (Kushniruk et al., 2001; Kushniruk & Ho, 2004; Owston, Kushniruk, Pitts & Wideman, 2005; Kushniruk, Owston, Pitts et al., 2007) this line of work went on to extend the data collection to include results from online questionnaires and other sources of data (including remote recordings of computer screens), in an attempt to relate detailed usage logs from Web tracking with other types of data, such as user demographics, patient records etc. In the following, we describe experiences in extending the approach for evaluating a range of Web-based systems and information resources. The objective of this most recent work has been to develop an automated system to support the collection, integration and analysis of a range of remotely collected data and more specifically to extend the approach to the evaluation of Web-based information resources and health information systems targeted to both healthcare providers and patients.

METHODOLOGICAL APPROACH

Our approach to developing an evaluation tool for conducting remote usability evaluations has to involved the creation and integration of the following interacting system components (see Figure 4) to form the basis for an evaluation tool known

Figure 4. Overall VuLab architecture



as the virtual usability laboratory or "VULab":

1. A central tracking component, residing on an evaluation server (i.e., a computer located in our facilities), was designed for remotely tracking and analyzing use of Web-based information systems located at remote sites. This component can provide a customized record of all accesses by users to a system under study. For example, it can provide a log file of what Web pages within a site are accessed, the order of browsing and a time-stamped record of the users' activities in accessing a remote site. In addition, this component has recently been extended to allow for remote recording of users' computer screens (and audio) as digital movies stored on a central evaluation server allowing usability data (similar to the type of data collected described in the first part of this chapter) to be collected remotely.
2. A second component was designed for controlling the automatic presentation of online forms and questionnaires to users in order to assess the usability of Web sites remotely at point of use. The triggering of such online questionnaires can be based on a user profile created for each user of a site being evaluated. By redirecting requests for access to a Web site under evaluation through our evaluation server we are able to write programs that can trigger prompts for user information (e.g., about user satisfaction with information provided or usability) to appear at points when users enter or leave parts of a Web site of interest. For example, on first entry into a system under study a demographic questionnaire can be triggered to appear and later, when the user accesses a page of interest, e.g., a Web page containing clinical guidelines in a health Web site, an online questionnaire can also be triggered to appear automatically to query the user (e.g., about why the page is being accessed, satisfaction with information provided, perceived educational value of the content provided, etc.).
3. A database component was designed for collecting and integrating the results of remotely tracking users, screen recordings and questionnaires in an integrated database containing other information about users including demographic and illness information (using relational database tables to store and interrelate data). For example, a database table can be created containing the results of logging of users' interactions with a Web site. This type of information can be linked to other data including information about user demographics, results of pre and post test online questionnaires (that may be triggered to appear just before or after a user enters a Web page being analyzed).
4. A researcher user interface component was designed that allows evaluators of a health Web site to easily set up a remote evaluation. For example, a researcher may specify what site will be evaluated, what type of questions should appear to users (by adapting or editing questions contained in a questionnaire bank) and indicating when questionnaires/logging is to be triggered. To facilitate this process, the researcher

can choose from and modify questionnaires and prompts contained in a template bank, or alternatively choose to create their own. Finally, the researcher is prompted to indicate what type of data analysis they would like by selecting from a list of built-in types of statistical analyses. In addition, we are currently working on making a variety of data mining and knowledge discovery algorithms available to the researcher to select from in order to support computer-based automated analysis of use and usability data collected from many system users remotely (Han & Kamber, 2001).

REMOTE USABILTIY ANALYSES: EXPERIENCES TO DATE

The VULab is currently being tested and deployed for a number of projects examining the use of innovative health information resources and information systems. This has included the evaluation of a Web site designed to filter patient and provider requests for health information, as well as on-going application of the approach for a project involving remote analysis of use of advanced simulation software for health education purposes. We have found that the collection of varied forms of usage data remotely is not only feasible, but additionally by storing data in consistent database format the integration and querying of varied forms of usage data can be supported for practical purposes.

A current application of the VULab is in the area of assessing the use and usability of Web-based applications and clinical guidelines designed to support physician decision making about cancer. To illustrate its use, a researcher studying use and usability of Web-based breast cancer guidelines might wish to set up a series of questions that are triggered to appear whenever a user of a system (e.g., a physician browsing through the guidelines) enters a particular part of a Web site or information system (including specifying what type of questions will be asked of users as they enter specific sections of a system under study, for example, “why are you interested in breast cancer guidelines?”). Specifically, the researcher may wish to understand when and why physicians access the breast cancer guidelines. To do this, the VULab can be set up by the investigators to automatically trigger presentation of a pop-up questionnaire to users whenever they click on the page containing the guideline (in this case the user would be queried as to why she is interested in breast cancer guidelines—see the pop-up question in Figure 5). It should be noted that this type of subjective information at point of user (regarding use, usability or usefulness of information presented) can be integrated with the logging data which records all Web pages the user had browsed through during his/her interaction with the site. Therefore we can interrelate logging data to subjective user data collected right at point of use (this combination of different types of data can be fed into data mining and knowledge discovery methods—see Han & Kamber, 2001).

In summary, the researcher interface allows the researcher/investigator to specify: (1) when and where in a remote web site questions should be automatically presented to the user, (2) what the question should be (e.g., in the example, “Why are you interested in breast cancer guidelines?”), and (3) in what format they would like user logging data to be stored. The results from the questionnaires are automatically stored in the database component of the VULab and collated with results from other users, to create a statistical summary of system usage. In addition, this information can be merged with results from other forms of data collection, such as responses from users to online demographic questions regarding their health status, as well as remotely collected screen recordings.

Another current application of the VULab is its use as a central component for evaluation in a cross Canadian network of researchers studying

advanced gaming and simulation software for educational purposes—the SAGE project (Wideman, Owston, Brown et al., 2007). The objective of this line of research is to identify and assess key aspects of games and simulations that could be incorporated in educational software, evaluate learning as a result of use of such software, and analyze use and usability of emerging gaming and simulation components being developed as part of the SAGE project. Specifically, the VULab is being used to automatically collect and collate data on usage of Web-based collaborative, and other forms of educational games and simulations aimed at improving awareness and understanding of health issues. Data being collected includes what parts of games are accessed, how often along with information about specific user impressions and results from on-line questionnaires and quizzes presented to users. In one study of users of an educational simulation, the approach was able to identify and tease apart a variety of usability problems with the software under study, ranging from technical problems with scripting to problems of usability and understandability of user instructions.

CONCLUSION

In this chapter, we discussed our work in the development and evolution of methods for the analysis of health information systems by end users. As we have described, this work has evolved from development of low-cost rapid usability engineering approaches for conducting usability testing in both laboratory and real settings (which we continue to employ to study a wide range of health information systems) to the design and development of a "virtual" usability laboratory for the analysis of use and usability of health related Web-based information systems, resources and sites. Our work has been employed for improving healthcare information systems in Canada, the United States and internationally. Using these approaches we have been able to feed valuable information back to both designers and implementers of health information systems about what aspects of the system work from the end user's perspective and what aspects need to be modified to ensure usability. From our work we have found that is essential for dissemination of these approaches that we strive to develop methods that are both practical and cost-effective. The argument for the need for such analyses extends not only to providing input to improve and refine usability of health information systems and Web applications but also to ensuring patient safety. Indeed, based on studies indicating that poorly designed healthcare systems may actually facilitate medical error we must ensure not only system usability but also equally as important we must ensure the safety of healthcare information systems. In this context, we have successfully used the approach to predict errors and problems that will occur from human-computer interaction *prior* to releasing the system for general use (Kushniruk et al., 2005). With the rapid increase in deployment of health information systems, continual development and refinement of new methods for conducting such analyses of human-computer interaction in healthcare will become even more critical.

FUTURE RESEARCH DIRECTIONS

There are a variety of future research directions in the area of usability engineering in healthcare. These include: (a) research into application of methods described in this chapter throughout the development cycle of health information systems, from system selection through to design, implementation and system testing, (b) further extension of usability engineering methods to data collection and analyses conducted remotely over the WWW, (c) development of experimental study designs that can be used to assess use of systems and cognitive issues involved in using system in real clinical conditions, (d) extension to use in the study of new and emerging health information systems, including mobile applications, (e) extension of approaches from usability engineering to include advanced simulation methods, and (f) automated analysis of usability data and application of data mining and knowledge discovery methods.

The application of scientific methods for analysis of health information system usability have been shown to be usefully applied throughout the entire process of developing health information systems. Kushniruk (2002) describes how the approach can applied from the earliest stages of system development, even including applying usability testing to assess different health information systems prior to selecting them, to the analysis of early system prototypes to provide early feedback to designers about features of systems that may enhance or decrease usability. As described in this chapter work in developing methods for remote analysis of a large number of users of systems is another area where ongoing research is being conducted, including work on tools such as the VULab. Also, the application of new study designs, incorporating aspects of ethnography and portable recording techniques, will be important to move usability engineering from being conducted in only a few fixed usability laboratories to widespread application throughout the healthcare industry. This will lead to study of new and emerging applications, including pervasive healthcare information systems, such as wearable computing and hand-held computing devices (Kushniruk & Borycki, 2007). Further work will also include incorporation of methods of simulation from other domains such as aviation and nuclear power to improve the identification and prediction of usability errors before systems are released for real use in healthcare (Borycki & Kushniruk, 2005). Finally, the application of methods from the field of data warehousing and mining will provide designers, implementers and health decision makers with improved knowledge about use and usability of health information systems.

ABSTRACT

Sentient computing can provide ambient intelligence environments with devices capable of inferring and interpreting context, while ambient displays allow for natural and subtle interactions with such environment. In this paper we propose to combine sentient devices and ambient displays to augment everyday objects. These sentient displays are aware of their surroundings while providing continuous information in a peripheral, subtle, and expressive manner. To seamlessly convey information to multiple sentient displays in the environment, we also propose an approach based on abstract interfaces which use contextual information to decide which display to use and how the information in the display changes in response to the environment. Our approach is illustrated through a hospital monitoring application. We present the design of two sentient displays that provide awareness of patient's urine outputs to hospital workers, and how contextual information is used to integrate the functionality of both displays.

INTRODUCTION

Sentient computing is an approach that allows users to naturally interact with the physical environment by becoming aware of their surroundings and by reacting upon them (López de Ipiña & Lai Lo, 2001). Awareness is achieved by means of a sensor infrastructure that helps to maintain a model of the world which is shared between users and applications – referred as Sentient artifacts (Hopper, 1999). Indeed, sentient artifacts have the ability to perceive the state of the surrounding environment, through the fusion and interpretation of information from possibly diverse sensors (Addlesee et al., 2001). However, it is not sufficient to make Ambient Intelligence (AmI) environments aware of the user's context, they must be able to find a way to communicate this information to users while becoming a natural interface to the environment (Shadbolt, 2003).

Ambient displays could be embedded in everyday objects already known and used, thus becoming the user interface of the AmI environment. This vision assumes that physical interaction between humans and computational devices will be less like the current keyboard, mouse, and display paradigm and more like the way humans interact with the physical world. For instance, a mirror augmented with infrared sensors and an acrylic panel could detect human presence and act as a message board to display relevant information when a user faces the mirror. Hence, AmI environments could be augmented with such displays that unobtrusively convey information to users without requiring their full attention, while at the same time, allowing an implicit and natural interaction. Indeed, the notion of what constitutes a computer display is changing. No longer is a display confined to the typical CRT monitor with a single user paying focused attention while interacting with virtual objects on the screen (Lund & Wilberg, 2007). Rather, computer displays are found in such diverse forms as small screens in mobile phones or handheld computers, to ambient displays that provide peripheral awareness to the presence and status of people, objects or information.

In this article, by binding the ideas of sentient computing and ambient displays we propose the concept of sentient displays to define a new and appropriate physical interaction experience with an AmI environment. Such sentient displays will be capable of monitoring users' context, promptly notify relevant events and provide users with continuous information in a subtle, peripheral and expressive manner without intruding on our focal activity. Moreover, multiple such displays could be integrated in an AmI environment, with a decision of which one to use dependent on contextual circumstances, such as the user's location, the presence of other people or the activity being performed by the user. Thus, we also discuss an approach to develop contextual interfaces for a variety of sentient displays located throughout the intelligent environment. Our approach is based on the use of abstract interfaces that are specialized to specific devices once a decision is made as to which sentient display(s) should be used. This approach facilitates the progressive integration of new sentient displays.

To illustrate the concept of sentient displays we draw upon scenarios related to hospital work. Mobility and frequent task switching cause hospital workers to occasionally miss important events, such as a catheter being disconnected due to the patient movement or the need to change a urine bag that has been filled-up (Moran et al., 2006). Consequently, hospital workers have been held liable for their failure to monitor and promptly respond to patients needs (Smith & Ziel, 1997). Sentient displays located throughout hospital premises could be used for a diverse number of hospital applications, such as notifying hospital workers of a crisis or just provide continuous awareness of the health status of patients.

SENTIENT DISPLAYS: AUGMENTING NATURAL OBJECTS WITH AMBIENT DISPLAYS AND SENTIENT TECHNOLOGIES

Research in pervasive computing has included the development of ambient devices that can become part of the background while acting as a digital interface to ambient information. As stated by Mankoff: "Ambient displays are aesthetically pleasing displays of information which sit on the periphery of a user's attention. They generally support the monitor of information and have the ambitious goal of presenting information without distracting or burdening the user" (Mankoff et al., 2003). For instance, the artist Natalie Jermijenko at Xerox Parc augmented a string with a motor and spin to convey the traffic's status to a user –the Dangling String (Weiser & Brown, 1995). The device rotates at a speed that depends on the amount of traffic in the highway captured through analog sensors. During periods of intense traffic, the string's movements are slightly audible as well. Thus, ambient displays are, unlike ordinary computer displays, designed not to distract people from their tasks at hand, but to be subtle reminders that can be occasionally noticed. In addition to presenting information, the displays also frequently contribute to the aesthetics of the locale where they are deployed (Lund & Wilberg, 2007). For instance, as part of the AmbientRoom project, several displays using light, sound or motion have been developed to augment a user's office (Ishii et al., 1998). Undeniably, ambient displays need computing devices capable of perceiving our surroundings by seeing or hearing the entities in the environment, what these entities are doing and where they are. To this aim, research in sentient computing has focused on the development of sensors that attached to today's computing and communication technology are capable of perceiving a range of contextual information such as location, traffic status, user's presence and so on (Abowd & Mynatt, 2002). The most popular sentient devices are indoor location systems (Addlesee et al., 2001; Werb & Lanzl, 1998).

While ambient displays provide a different notion of what constitutes an interface to the AmI environment, sentient technologies allow such displays to be reactive and perceptive to dynamic changes in the environment. In this article we propose the concept of sentient displays combining the ideas of ambient displays and sentient computing. Sentient displays are our everyday artifacts augmented with digital services capable of perceiving information from the environment and then using this information to extend the capabilities of such artifact. We envision a sentient artifact as an object that encapsulates the information perceived and then provides users with a new form of interaction with the environment. This interaction could be either by offering continuous, subtle and peripheral awareness or by allowing users to change the status of such object in order to affect an AmI environment.

OPPORTUNITIES FOR THE DEPLOYMENT OF SENTIENT DISPLAYS IN HOSPITALS: A CASE STUDY

For nine months, we conducted a field study in a public hospital's internal-medicine unit, observing the practices of the hospital staff, who attended patients with chronic or terminal diseases (Moran et al., 2006). Such patients are often immobile and incapable of performing the activities of daily living (ADL) by themselves. The study was conducted to understand: (1) the type of patients' information being monitored by hospital workers and (2) the problems faced by hospital workers when monitoring patients.

Hospital workers are responsible for providing integral and specialized care for patients. As part of this, nurses monitor patient's activities of daily living (ADL), such as, if a patient has taken his medicine, if he has walked, eaten, felt from the bed, evacuated, etcetera. As a part of specialized care, nurses need to monitor the behavioral patterns in the activities that put at risk the patients' health or that indicate an internal failure which might evolve into a more serious disease (e.g., pneumonia, an apoplexy or a stroke), such as, if a patient is agitated, if a patient is bleeding or if the patient has respiratory insufficiency. These behavioral patterns associated to risk activities (RA) are monitored through the vital signs. To illustrate the problems faced by hospital workers when monitoring patients we present a real-scenario that was observed in the hospital:

Nurse Rita is informed, at the beginning of her working shift, that the attending physician has changed Pedro's medication to include cyclosporine. Pedro is a 56 years old man, who has a chronic renal failure and just had a renal transplant. So, to monitor Pedro's reaction to the new kidney and to the medicine being administered to him, Rita needs to supervise the frequency and quantity of Pedro's urine. Nurse Rita starts her shift by taking care of Juan –the patient in bed 226. While she is inserting a catheter to Juan, Pedro's urine bag fills up. Unaware of Pedro's status, Rita continues taking care of Juan. After several minutes another nurse informs Rita that Pedro's urine bag spilled up. Rita moves to Pedro's room to clean him.

The problem illustrated in the scenario could be avoided if Rita knows when Pedro's urine bag is almost full. This, and similar examples, helped us identify major issues faced by hospital workers when monitoring patients. In particular, issues related to hospital workers being on the move include maintaining awareness of their patients' status, being easily accessible when an emergency occurs, and prioritizing patient care on the basis of the patient's health condition. In addition, nurses must manage the tradeoff between having expressive versus silent awareness. While nurses want to be aware of the status of all the patients they are taking care off, they don't want this awareness to intrude in their focal activity. Finally, nurses need to interpret ambient information over time and at different levels of detail. This poses interesting challenges related to how contextual information influences the importance of the information presented. For instance, while to monitor Pedro's health it is significant for Rita to know the frequency and quantity of his urine outputs, for those patients with other diseases this information might not be relevant for her. This need to monitor the status of patients in an environment already saturated with information and with hospital workers constantly on the move and switching from one task to another, inspired us to design sentient displays for the hospital.

THE ADL MONITOR: A MOBILE SENTIENT DISPLAY

The ADL Monitor is a sentient display aimed at creating a wearable ambient connection between patients and nurses (Tentori & Favela, 2008). The ADL Monitor is composed of one sentient artifact and two ambient displays. The first ambient display is a two-layered vinyl bracelet containing five buttons with embedded lights (see figure 1a). Each button represents a patient under the nurse's care. The lights turn on when a patient is executing an activity, when particular actions occur, or after a series of events take place. Nurses can press the button to consult information associated to the activity a particular patient is executing. This information is shown by the ADL assistant that runs on the nurse's smartphone (see figure 1b) –the second ambient display. Nurses can also use the ADL assistant to assign priorities by selecting colors (figure 1c) or to set contextual information to act as a trigger for the activities being monitored (figure 1d). To notify patient's urine habits the mobile ADL Monitor uses the WeightScale. The WeightScale is a sentient artifact attached to the urine bag and measures its weight.

Figure 1. The mobile ADL Monitor. (a) A nurse uses the bracelet; (b) the mobile ADL assistant shows information related to an activity being executed by a patient; (c) a nurse uses her smartphone to configure the bracelet; and (d) a nurse associates contextual information with an activity.

Going back to our scenario: Rita uses ADL assistant in her smart phone to specify that the light representing Pedro in her bracelet should turn yellow when Pedro evacuates, and red if he evacuates more than five times in six hours (Figure 1d).

Later, while Rita is preparing medicines, Pedro's light turns yellow. Rita presses the button, and her smart phone indicates what Pedro is doing (Figure 1b). Rita learns that Pedro has urinated approximately 10 milliliters (this information is calculated though the weight sensor attached to Pedro's urine bag). Rita goes to Pedro's room to update his liquid balance.

Throughout the night, Pedro's light in Rita's bracelet constantly turns yellow. A couple of hours later, while Rita is talking to Dr. Perez, her bracelet turns red. Rita consults her smart phone and realizes that Pedro has urinated seven times in six hours. She discusses this with Dr. Perez, who then decides to change Pedro's medication to avoid damaging the new kidney.

The system uses a client-server architecture as a basis for its implementation. When a nurse presses a button on the bracelet, a message is sent back to the server, specifying a patient and bracelet ID. This ID is used by the server to determine which patients' status should be displayed on which smart phone. We developed our own components to communicate the bracelet with the server. A transmitter is responsible for sending and receiving messages from the bracelet at frequencies under 27 Mhz. This transmitter is internally connected to the CPU and embeds a receptor circuit that manages the radioelectrical signals from the bracelet and translates them into pulses. In contrast, the bracelet has embedded a receptor circuit that converts radioelectrical signals into electrical pulses. In the following lines we described how the components work to support the services just described.

Providing Perceptible and Silent Awareness

The idea of this service is to adequately manage how the information will be presented to the user. An ambient display that changes too fast can distract the user whiles a display that changes too slowly can pass unnoticed (Johan et al., 2000). To balance this tradeoff, the mobile ADL Monitor modulates the information shown to the user. While the bracelet only displays the status of a patient and his identity, the smartphone shows more information, such as the quantity and frequency of urine outputs. This will allow a nurse to explicitly extend the information shown by the bracelet with the one shown in the smartphone binding both displays while unrestricting their usefulness by presenting just enough information –how much a patient has urinated.

Enabling Simple, Effortless and Seamless Interaction

Users should be able to interact with the display implicitly and naturally. Users do not have previous experience interacting with ambient displays; hence they should be intuitive. The mobile ADL Monitor uses colors analogous to a traffic light adapted from the medical model used in the emergency unit. This allows nurses to naturally discover the emergency state of a patient. In addition, nurses can press the button that represents each patient to consult more information of the state of a patient. Therefore, by embedding a light in each button of the bracelet we are extending the capabilities of an artifact without altering the traditional means of interaction with it. This will result in a reduction of the cognitive load by learning how displays work and increasing the amount of attention on content (Gross, 2003).

Enabling Unobtrusive Information Sensing

The mobile ADL Monitor requires to monitor the weight of a urine bag wore by a patient. For this, we developed a sentient artifact that measures the amount of urine in a bag and communicates this information wirelessly through a mote –the weightScale. This weightScale is attached to a urine bag wore by a patient allowing thus an unnoticeable sensing. The weightScale is made of two acrylic pieces which are separated through a spring and a push button. We calibrated the required separation between both pieces. When the urine reaches a threshold (i.e., when the urine has filled 80% of the urine bag) the button is pressed. Once the button gets pressed, the sensor generates an electronic pulse. This pulse is read by the mote that is responsible for the transmission of this information wirelessly. When the bag is replaced the button goes back to its normal position. We use motes to avoid saturating the rooms with wires that could be obtrusive to nurses and patients.

To evaluate the ADL Monitor we interviewed seven nurses, each for 30 to 60 minutes, to evaluate the bracelet's design, the system's core characteristics, the nurses' intention to use the system, and their perception of system utility. All seven nurses indicated that the bracelet will help them save time, avoid errors, and increase the quality of attention given to patients. One nurse commented,

> *this bracelet will improve the quality of attention. The work will be the same, but I will do [it] faster. ... For instance, if a patient has evacuated ... I would promptly know the patient needs and I [could] take with me the things that I would need.*

In addition, nurses noticed that the system will help them prioritize events and patients:

> *Something that we currently cannot do is identify which patient has to be attended first; a system like this one [would] help me identify the urgency with which each of my patients needs to be attended.*

Overall, the staff viewed the application as useful, efficient, and generally appealing. Nurses repeatedly expressed that this system would solve many of the problems they face and improve their work, saying that it directly assists with "patient care" rather than merely supporting "secondary tasks," as they say current systems do. Nurses validated both scenarios and provided us with additional insights and opportunities for applying our technology. For instance, nurses explained that they are used to have the technology directly attached to the patient to avoid problems and errors. Nurses explained that having the information in the smart phone might cause problems, because they might confuse the patient they are attending with another one. For instance a nurse explained:

I prefer for the bracelet to only function as an indicator, rather than consulting the information of the patient in my cell phone I would prefer to consult this information in the room of the patient. In this case I would be sure that the problem I am handling corresponds to such patient.

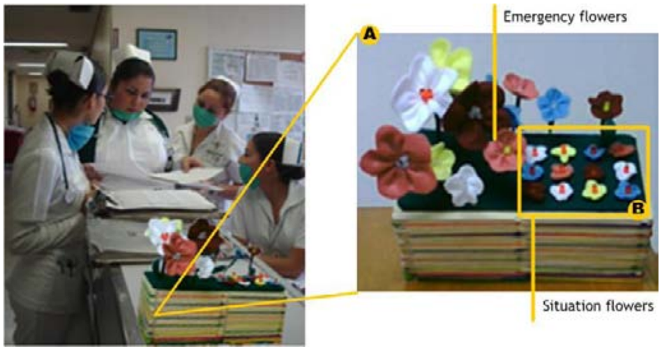
Indeed, fixed monitoring systems that allow patients to place a call to a nurse at the nurse pavilion have been successfully adopted in hospitals. What we need is to allow our sentient display to be seamlessly integrated with fixed monitoring systems.

THE FLOWERBLINK: A FIXED SENTIENT DISPLAY

In this section we describe a fixed sentient display that notifies nurses the patients' urine outputs and the status of their urine bag to be integrated with the ADL Monitor–the Flower Blink (Segura et al., 2008). The FlowerBlink is a wooden box containing twenty four artificial flowers: twelve emergency flowers with stems and twelve situation stemless flowers (Figure 2). The flowers are composed of a two-layered felt that enclose pistils covered with insulating tape. In each pistil a red or yellow led is embedded. The emergency flowers have stems with an embedded yellow light in their pistils (Figure 2a). All emergency flowers blink whenever an event or an emergency occur with a urine bag wore by a patient –if a urine bag is full. In contrast, situation flowers are flowers without stems that have a red light embedded in their pistils. These situation flowers are arranged in a matrix to represent patients' location in the unit. Each column in the matrix represents a room while a row represents a patient's bed (Figure 2b) –each room has three beds for patients. This arrangement allows nurses to quickly discover which patients' bag is about to spill. Situation flowers turn on whenever a nurse approaches the FlowerBlink or if the emergency flowers are blinking. While emergency flowers are blinking a situation flower turns on, indicating to a nurse the location of the patient related to that event.

The FlowerBlink includes two sentient artifacts and one ambient display. The first sentient artifact is the WeightScale, described in section 4. The other sentient artifact is the PrescenceDetector that is a card carried out by a nurse that detects her presence when she is in front of the FlowerBlink. The ambient display is the flower vase with a set of flowers that display the status

Figure 2. The FlowerBlink placed in the nurse pavilion. (a) The flowers that notify of emergency events (b) The flowers that personalized their color based on the nurse's presence



of the urine bag of the patient. We embedded in the box of the ambient display a communication interface which directly controls the flowers light. When the base station receives the information, it identifies the sensor that sent it, thereby identifying the location of the patient, and then turning on the red light of the corresponding flower. We use the phidgets toolkit (Greenberg & Fitchett, 2001) to implement the FlowerBlink.

One of the main challenges in integrating the FlowerBlink and the ADL Monitor is content adaptation. Binding both sentient displays will involve choosing on which device to display the information. This decision must take into account the device capabilities and its user's context. For instance, while the FlowerBlink can show patients' status, their location, their urine bag status and their frequency of urine outputs; the bracelet is only capable of displaying patients' identity and their status. Moreover, the smartphone can show a more complex representation of content because a complex interface can be displayed in such device. Adding more information in the FlowerBlink or in the bracelet could cramp both displays confusing the user on how to use them. This mismatch between rich content and constrained devices capabilities presents a main challenge in integrating multiple sentient displays (Lum & Lau, 2002).

SUPPORTING MULTIPLE SENTIENT DISPLAYS TO MONITOR PATIENT STATUS

In this section we describe our approach to seamlessly convey patient status information to multiple sentient displays. Based on contextual information our approach: (1) selects the sentient display to be responsible for showing ambient information, (2); defines a concrete interface for the selected display; and, (3) finally, adapts the information in the target display. The concrete interface is derived from an abstract, generic user interface (Braun & Mühlhäuser, 2004; Souchon & Vanderdonckt, 2003).

This is illustrated through the following version of our scenario:

Rita uses the FlowerBlink and the ADL Monitor to supervise the frequency and quantity of Pedro's urine outputs. A sensor in the urine bag detects the presence of new liquid. At this time, Rita, the nurse responsible for monitoring the patient, approaches the nurse pavilion. Thus, the system decides to notify her through the FlowerBlink sentient display located in this area. The description of the abstract notification interface is sent to the agent that acts as a proxy for the sentient display. The agent calls its interpreter to transform the abstract interface to a concrete interface that it then sends to the FlowerBlink. Rita notices that the flower base is blinking and realizes that the information relates to one of her patients. She consults her smartphone to learn that Pedro has urinated for the third time this morning and his urine bag might soon need to be replaced. The interface in the FlowerBlink will turn all lights off as its proxy agent becomes aware that Rita has consulted the information in her smartphone.

As the scenario shows, contextual information is used by the system in two stages. First, location information is used to decide which sentient display will be the most suitable to use. Since Rita is in the nurse pavilion the FlowerBlink located there would be the best display to notify the status of her patients. Once the concrete interface is executing on the sentient display it will be adapted when it is informed that the users notices the information. In the example when the sentient display realizes that Rita has become aware of the patient status it adapts its interface by turning off the lights. The presence of another person for which the information is relevant, for instance, the head nurse, might turn the lights on again.

Figure 3 and Figure 4 show the sequence diagram of the scenario. These show the main com-

Figure 3. Sequence diagram of the scenario, showing how the notification is sent through the FlowerBlink

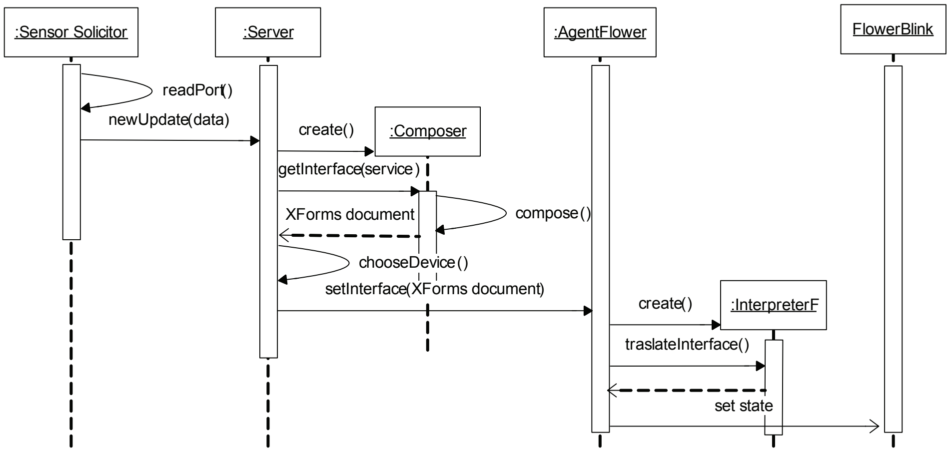


Figure 4. Sequence diagram of the scenario, showing how the FlowerBlink is turned off when its Agent becomes aware that the nurse has consulted the information in her smartphone

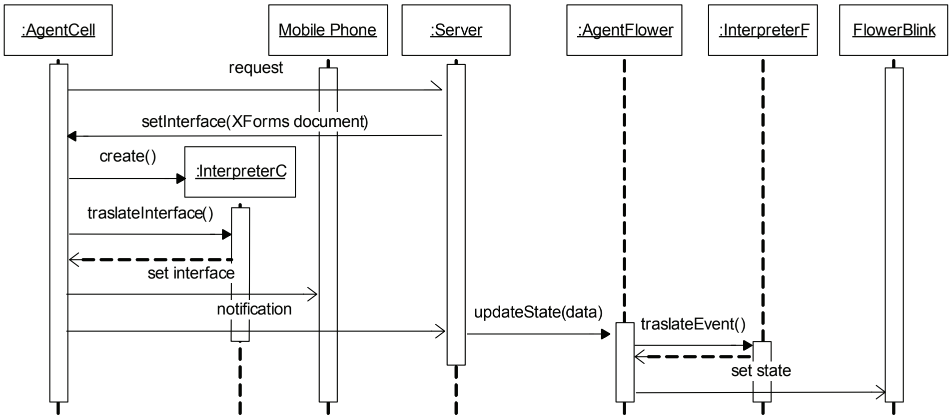

ponents of the architecture, which are described next. In the architecture a Server application communicates to the different sentient displays, trough their Proxy Agents, the changes notified by the Sensor Solicitor. The Sensor Solicitor is connected to a set of sensors which update the information about the state of patients' urine bags. When a notification is about to be sent the Server requests the Composer for the generic user interface to be used to inform the patient's status (patient, disease, time, urine bag level, and so on). This interface will be interpreted for each sentient display depending of its own resources. The Server decides to notify the nurse through the FlowerBlink because she is at the nurse pavilion, thus the generic user interface is sent to the FlowerBlink Proxy Agent. This agent updates the FlowerBlink state in response to the interpretation of the generic interface given by the Proxy Agent's Interpreter. In this case, the lights are turned on, to inform that the urine bag is almost full.

When the nurse notices that the FlowerBlink is blinking, she consults her smartphone for detailed information about her patient. The smartphone's Proxy Agent requests the information to the Server. This information is delivered using the same generic interface sent to the FlowerBlink. Then, the Proxy Agent invoques its interpreter to translate it to the capabilities of the smartphone, so the Agent can render the information in the smartphone using text and images. This acts as a trigger to notify the FlowerBlink that the nurse has become aware of the patient's status, so it must turn off the lights. The Server is responsible for sending to the FlowerBlink Agent the event, which in turn is passed to the Interpreter to adapt the information in the user interface. The interpreter indicates to the FlowerBlink Proxy Agent the adaptation to be performed in the display, in this case, to turn the lights off.

The generic user interface is described using a User Interface Declarative Language because it does not assume any specific interaction modality or presentation. It captures the purpose of the interface, defining what it must do and not how. Such an approach is followed by XForms (Boyer, 2007), which can separately declare the data model, the presentation, the way of binding the data model to the display elements, as well as the actions and events.

User interface elements in XForms are abstract, so that different platforms can choose to implement them in different ways, however the purpose of the tags remains the same (Rivera & Len, 2002). Inputs and outputs, events and actions that modify data element must be translated to appropriate representations for the platform. For example, an input for FlowerBlink could be given by a sensor sensitive to the light, another example is when the data model is changed and in response the output related to this data could be represented by turning off or turning on the lights through an electric pulse. In the smartphone the output could be rendered using text and images.

The XForms document is the same for each device, in consequence an XForms interpreter is required for each platform, which must implement the XForms specification, but for the purpose of the application it only needs to implement the elements of XForms that are used. In addition, the interpreter for the FlowerBlink needs to consider two cases, first it must select just the output related to the data element needed to display, in this case the amount of urine in the bag, and in the second case the amount of urine in the bag at three state alerts depending on a predefined threshold. This kind of consideration goes beyond the XForms specification, since this is specific to the application and platform. For the cell phone it is possible to display all the data in the model.

The XForms composer defines the abstract user interface in an XForms document, it contains the information related to the patient defined in the data model, an XML structure, the generic outputs bind to the data model, and the actions to perform adaptations in the data model and the user interface. All possible adaptations that data model or interface may suffer in function of the context must be considered, so the events and actions related to these adaptations must be defined in the abstract user interface. The Server must notify updates on relevant contextual information so the adaptation defined for these updates could be realized in the concrete user interface.

CONCLUSION AND FUTURE WORK

In this article, we discuss the concept of sentient displays in support of hospital work and a context-aware approach for content adaptation. We show that sentient displays are capable of becoming aware of users' context and then present continuous and expressive information in a subtle and unobtrusive way. We show that a combination of mobile and fixed displays enables a hospital smart environment to provide the type of awareness hospital workers need to promptly identify patient' needs, save time and avoid errors. We discuss that contextual information allows an

AmI environment to automatically choose the adequate sentient artifact to display information according to users' needs.

We plan to conduct an in situ evaluation of the displays developed to assess their impact within the hospital. In addition, we plan to explore a new setting where this type of technology could be useful –in particular, in nursing homes. Workers at nursing homes specialized in the care of elders with cognitive disabilities face working conditions that are similar to those in hospitals. Such workers also use common strategies to monitor patients' status. This monitoring is done manually, making it time consuming and error prone. This is another healthcare scenario in which sentient displays can prove useful.

ABSTRACT

The rapid pace of new medications introduced to the market and the trend of modern healthcare towards specialization complicates doctors' prescribing process and patients' management of medications, resulting in an increase in the likelihood of unsafe prescriptions. The severity of this problem is magnified when patients require multiple medications or have cognitive impairments. The Medicine Information Support System (MISS) is designed to integrate related information systems from doctor offices, pharmacies and patients' smart homes with a universal database of medication conflicts to enable safety checks for adverse reactions among prescribed medications. MISS enhances the quality of patients' healthcare by monitoring and promoting the compliance of patients' medication intake. It also ensures patients' medical records remain private by following the privacy guidelines and regulations such as the Health Information Portability and Accountability Act (HIPAA) law in the United States.

INTRODUCTION

A Smart Home (SH) integrates and networks different technologies to provide assistance with activities of daily living. SHs, especially those designed for the elderly and persons with special needs, have gained importance as a research subject in the last few years as the baby boomer generation reaches the retirement age and begins to experience the need for assistance (Noury et al., 2003). One of the primary needs of this population is assistance in managing medications, which can be challenging due to complicated medication names, multiple simultaneous medications, or medications with differing types of dosing instructions. Two extremely important facets of medication management are the detection of possible conflicts among medications and compliance with prescriptions.

The Medicine Information Support System (MISS) presents a smart home-based solution to integrating doctor offices, pharmacies and a patient's home to assist patients in managing their medications (Reyes Álamo et al., 2008). It supports the safety of prescriptions by checking at multiple times for conflicts between medications, health conditions and foods that a patient may consume. It forwards prescription data from doctors, pharmacies, and smart home if no conflict in found and provides the mechanism for enhancing compliance with medication intake. More details of this process will be described in the following sections.

MISS is designed to transparently wrap around existing computer systems in doctors' offices, pharmacies and smart homes using Web Services (WS) to provide interoperability via standard communication interfaces. The section on system requirements and design architecture provides a detailed view of the interactions between different subsystems, as well as the data they exchange.

Additionally, because proper medication management is critical to patients' well being, a medication management system must be error free and capable of detecting various types of medication conflicts. The section on system model demonstrates the correctness of MISS. Additionally, since prescriptions and health conditions are personal health information, using telemedicine for the storage, use, and disclosure of this information between systems presents potential threats to patient privacy. As a result, privacy regulations such as the Office for Civil Rights (OCR) HIPAA (OCR, 2009) must be incorporated into the requirements and design of MISS to provide proper privacy protection for patients.

The rest of the paper is organized as follows:- the requirements, design, and detailed architecture of MISS are presented after a discussion of related work. We then describe a system model for conflict checking and compliance monitoring and illustrate MISS's prototype implementation. The last section of the paper summarizes the contributions of MISS and states future work.

RELATED WORK

Some previous efforts have been made to help individuals manage their prescriptions. For example, the Magic Medicine Cabinet (MMC) (Wan, 1999) is an Internet-enabled medication manager equipped with facial recognition software, Radio Frequency Identification (RFID) smart labels, and vital signs monitor and voice synthesis. The MMC generates personalized reminders, detects when a wrong medication is taken, and measures vital signs. However, no details are provided on the authors' claim that their system interacts with the patient's pharmacy, doctors and health care providers, and no safety checks are made for conflicts among medications. Our work bridges this gap by using WS to connect the patient's SH with the patient's visited doctors and pharmacies and to conduct multiple checks for medication conflicts. In New Zealand the ePharmacy system ("ePharmacy," 2009), connects the doctors and the pharmacies to facilitate medicine prescribing process and dispensing information among these parties. However, there is no mention if this information is shared with a Smart Home System.

The Smart Medicine Cabinet (SMC) (Brusey, Harrison, Floerkemeier, & Fletcher, 2003), and the Smart Box (Floerkemeier, M. Lampe, & Schoch, 2003; Siegemund & Floerkemeier, 2003) extend the Magic Medicine Cabinet by using passive RFID tags to identify medication containers and Bluetooth technology to synchronize the MMC with a patient's cellular phone. The SMC is automatically updated when the cell phone is brought within range. The major drawback of these two systems is that the patient must remember to carry the cell phone to the pharmacy as well as near the MMC. Our system presents a more user-friendly solution, especially for those with cognitive impairments, in that it does not require special user interaction or a cell phone.

Technology for automatic dispensing of pills also exists ("e-pill Medication Reminders: Pill Dispenser, Vibrating Watch, Pill Box Timer & Alarms," n.d.; Testa & Pollard, 2007), typically, manual configuration is needed to set notifications and dispensation schedules. Also, the medications have to be manually removed after a reminder is generated.

These proposed solutions certainly facilitate the task of taking medications by assisting with prescription compliance (Floerkemeier et al., 2003; Matthias Lampe & Flörkemeier, 2004), generating reminders to the patient (Szeto & Giles, 1997; Denis Vergnes, Sylvian Giroux, & Daniel Chamberland-Tremblay, 2005), and detecting missed doses. However, they do not provide a solution integrated with a patient's home system and still require significant manual input, which would be difficult for patients with cognitive impairments. This limitation is addressed in Fook et al. (2007) where a system for patients with dementia is presented. Our system is similar in making use of related technology to help patients with prescription compliance, but our work is more comprehensive as it transparently networks the smart home with existing systems in doctor offices and pharmacies thus require no manual data entry from the patients.

In addition to these systems, several software applications have been developed to assist with the medication prescribing process and the management of patients' medical records. For example the Computerized Physician Order Entry (CPOE) (Koppel et al., 2005) allows a physician to enter instructions for the treatment and communicate them to other parties such as nurses, pharmacies and laboratories. CPOE can significantly reduce medication errors and delays in process and treatments since instructions are communicated over a computer network, but this application is more targeted to health specialists. Other applications target mobile devices such as cell phones, smart phones, and PDAs ("WebMD Mobile for Apple iPhone," 2009). Nevertheless, they are intended for people familiar with these devices and do not always provide support for safety checks for conflicting medications or assistance in monitoring compliance with a prescription. Recently, many solutions have been proposed by the industry to provide electronic medical records (EMR),, such as Google Health ("Google Health," 2009), Microsoft Health Vault ("HealthVault: Home," 2009), and MediConnect (IT Strategic Projects, 2009). However, it remains to be seen if patients will be comfortable storing personal information in remote enterprise or government environments. The crucial added values provided by MISS, such as safety checking and compliance monitoring, are equally applicable whether data is stored in distributed subsystems or a centralized EMR database. Pervasive spaces like SHs can be used to assist patients in performing activities of daily living (ADL) (Helal, 2005), including the management of their medications (Reyes Álamo et al., 2008; Nugent et al., 2005; Noury et al., 2003). A well integrated system should integrate all these independent solutions to provide a comprehensive management of medications.

SYSTEM REQUIREMENTS, DESIGN AND ARCHITECTURE

A successful medication management system must have a set of well defined requirements and a well planned design. The requirements and design of MISS are discussed below.

System Requirements

A step-by-step description of how a patient acquires a prescription and takes a medication reveals important system requirements. Based on our observations, obtaining a prescription usually involves the following steps:

1. The patient visits the doctor.
2. The doctor prescribes medications.
3. The patient visits the pharmacy and gets the medications.
4. The patient intakes the medications at home.

Medication intake can be further broken down into the following steps:

4.1 Wait for the next dosage time
4.2 Locate the medication container
4.3 Open the container
4.4 Extract the appropriate amount of medication
4.5 Intake the medication
4.6 Close the prescription container
4.7 Return the container to the medication cabinet

The aforementioned related work helps to automate some of these steps. For instance, the Smart Box or Smart Cabinet can automate steps 4.1 and 4.2, while automatic pill dispensers address steps 4.3 and 4.4. Cognitive impaired patients might forget when the next dosage time is (Fook et al., 2007), hence a system that automatically sets up the dosing schedule using the prescription's data, generates the reminders and notifies if a dosage is missed, will help to improve the compliance with medication intake (Nugent et al., 2005). SH can also help to locate the medications container by incorporating unique identifiers using RFID tags (Ni et al., 2004).

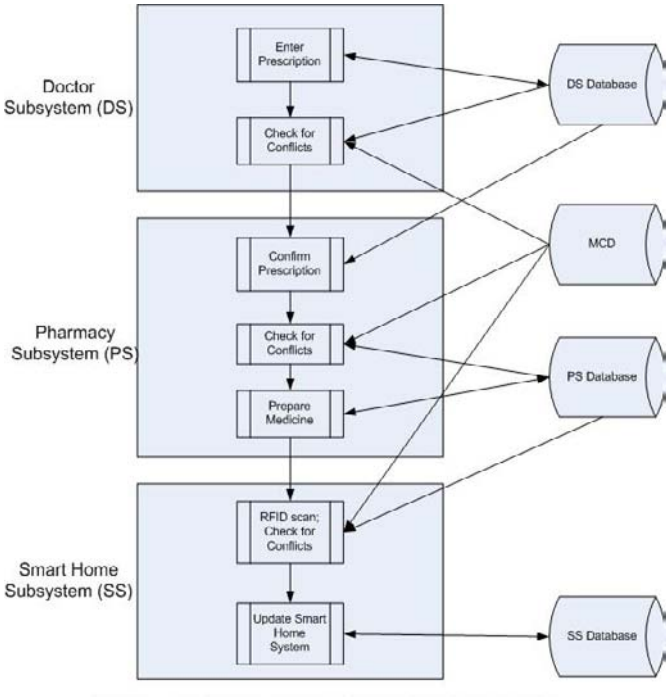
Manual entering of prescription information is often unreliable due to inexperience and frequent human error, therefore the prescription information should be entered by an expert and automatically forwarded without repeated manual entries at various locations. In MISS, prescription information is automatically forwarded between doctors, pharmacies, and homes.

Human behavior can be unpredictable, and there might be variations to the aforementioned steps when obtaining or intaking medications. The design of MISS assumes these steps are followed by most patients, and the variations will be considered as exceptions, which would likely trigger unwarranted reminders or warnings to patients, doctors or pharmacists. The next section presents the system design and operation of MISS in greater detail.

MISS Design and Architecture

MISS consists of three main subsystems: the Doctor Subsystem (DS), the Pharmacy Subsystem (PS) and the Smart Home Subsystem (SS) and four main actors: the doctor, the pharmacist, the patient, and the SH. Each subsystem is assumed to have a local database that stores information about the patient medications and medical conditions. A global medication conflict database (MCD) exists that defines all conflicts between medications, conditions, and foods. The MCD is maintained by a knowledgeable and trusted third party, and is accessed remotely by MISS without replicating the data locally. The conflict checking is executed locally at each subsystem using the data retrieved from MCD and the local patient's data. The MCD and the local databases use the same database schema and medication's data for maintaining

Figure 1. Medicine information support system diagram



consistency. Figure 1 illustrates the interactions between these actors and subsystems.

The most important use cases and actors for MISS are shown in Figure 2. The UpdateSmartHome action will be responsible for updating any subsystem that might use the medication data such as medication inventory and notifications.

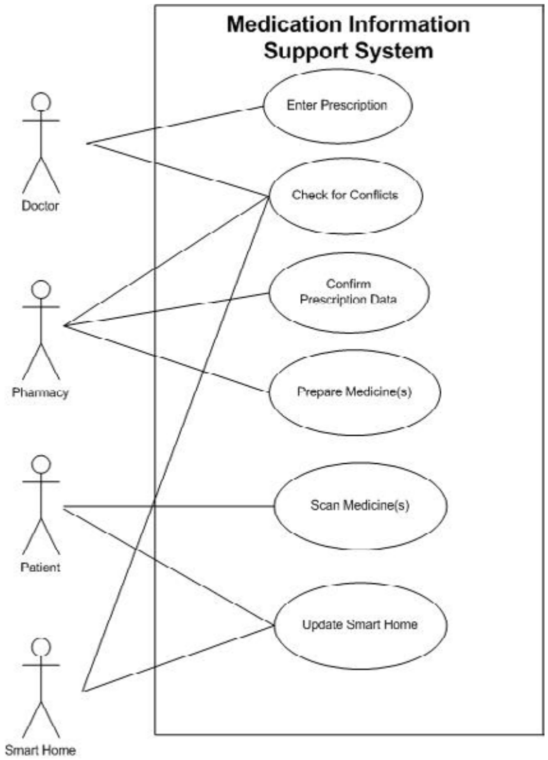
The architecture of MISS can be best presented in two tiers. The higher tier deals with the inter-subsystem communication that mimics the actual actions and interactions among patients, doctors and pharmacists. The lower tier describes the detailed structural make-up and inner operations of each subsystem.

The higher tier overview, as illustrated in Figure 3, shows that MISS includes three subsystems, DS, PS and SS which utilize the external MCD system. Each subsystem provides a human computer interface that allows interactions with users in certain role, and a system interface implemented as a WS that allows communications between subsystems.

Doctor's Subsystem (DS)

The primary owner and user of DS (Figure 4) is the doctor who after each medical examination enters any new condition c and any newly prescribed medication m into the system as needed. MISS assists the prescribing process by identifying the conflicts among new conditions and medications, helping the doctor to make better decisions. The DS uses the patient's local medical record of previous prescriptions M and the current health conditions C to determine possible conflicts and adverse side effects. The list of side effects and possible conflicts for a given medication can be retrieved from the common database, known here as the MCD, maintained by a trusted third party such as the Food and Drug Administration (FDA) ("U.S. Food and Drug Administration (FDA)," 2009), or the Physician's Desk Reference (PDR) ("The Physicians' Desk Reference (PDR)," 2009). To check for conflicts the system sends anonymized c, m, from DS to MCD, receives the conflict

Figure 2. Use cases and actors



information and checks that against the patient's M and C. If no conflicts with the new prescription are found, the prescription information is then stored into the local database. This conflict-free prescription will then, depending on the patient's preference, either be pushed immediately to the patient's selected pharmacy or pulled by the pharmacy the patient visits later. If conflicts are found, a notification is sent to the doctor, along with suggestions on alternatives.

If the data is forwarded to a preferred pharmacy, each patient must be associated with a unique ID that's shared between the DS and the PS. Using the ID, DS will check its local database for conflicts with the new prescription. If no conflict is found, the prescription's data is forwarded to the patient's preferred pharmacy through a secure channel. The doctor's office will also issue a customized printed-RFID prescription which will be used later by the pharmacy subsystem.

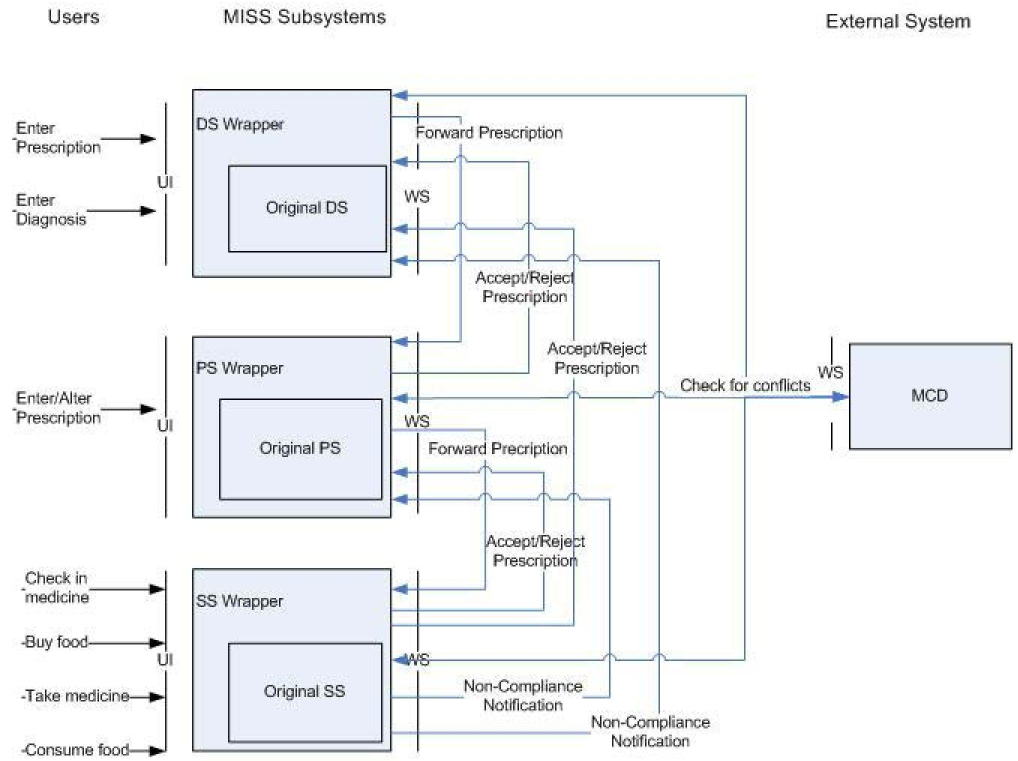
If the patient chooses a pharmacy later, the process is almost identical except the timing of when the data arrives at the pharmacy. Instead of arriving immediately, the data will be transferred only after the patient arrives at the pharmacy and the pharmacist requests the prescription information from the doctor's office.

The Pharmacy Subsystem (PS)

There are two possible starting scenarios for the PS: when the patient specifies the preferred pharmacy at the doctor's office or when the patient chooses the pharmacy later. In either case, once the new prescription information arrives at the pharmacy (Figure 5), the PS retrieves the patient's locally stored prescriptions and conditions, and checks for possible conflicts with the MCD.

In the first scenario, the pharmacy receives the prescription's data over a secure channel when the patient is still at the doctor's office, allowing

Figure 3. Communications between ISS subsystems and MCD

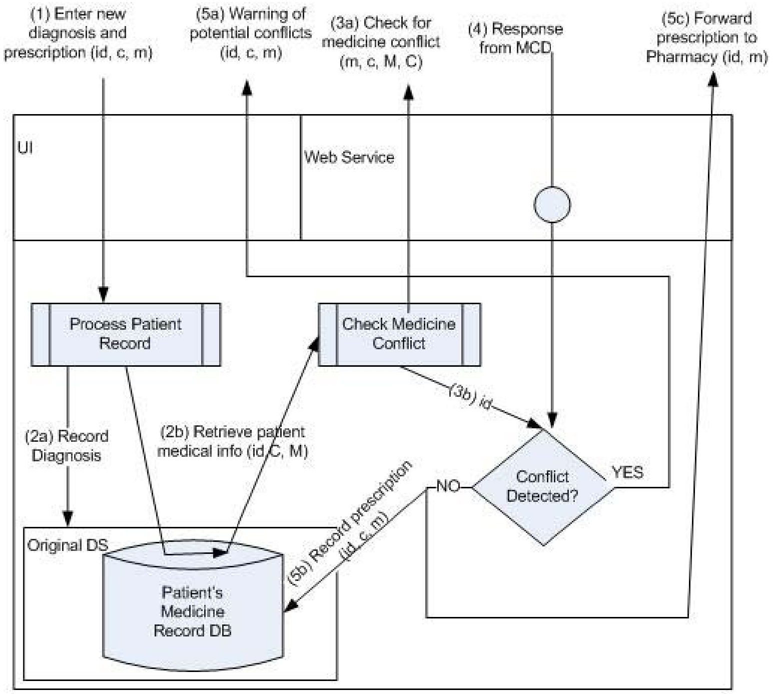


the pharmacist to start preparing the prescription before the patient arrives. The prescription is checked for conflicts with other medications that have been recently filled for the patient, similar to the check performed at the DS. However, this additional check is necessary since the patient might be receiving prescriptions from different doctors and filling them in the same pharmacy. Once the new prescription is cleared of conflicts, the pharmacist would prepare the drugs, while PS returns with a confirmation to DS and forwards the prescription's data to SS. If a conflict is found, a notification is sent to the pharmacist who might contact the doctor or take other appropriate measures. If no conflicts are found, the medication will be issued in special RFID-enabled containers that will allow the system to uniquely identify the medication in them.

In the second scenario, the patient arrives at a pharmacy with a printed-RFID prescription. The RFID prescription is given to the pharmacist as if it is a regular prescription. It is scanned and the prescription data is pulled at that moment from the doctor's office. A check for conflicts is performed between this new prescription and previous medication picked up at the pharmacy. If no conflict is found with the new prescription, the medication is dispatched into an RFID-enabled container; otherwise, both the pharmacist and doctor are notified.

The waiting time at the pharmacy can be reduced if the prescription data is forwarded ahead of the patient's arrival. This is very important to the seniors who might need their medications urgently or want to avoid long lines or repetitive trips to the pharmacy. Another benefit of our system is the extra layer of safety by checking for conflicting medications using the pharmacy's local data.

Figure 4. Doctor subsystems

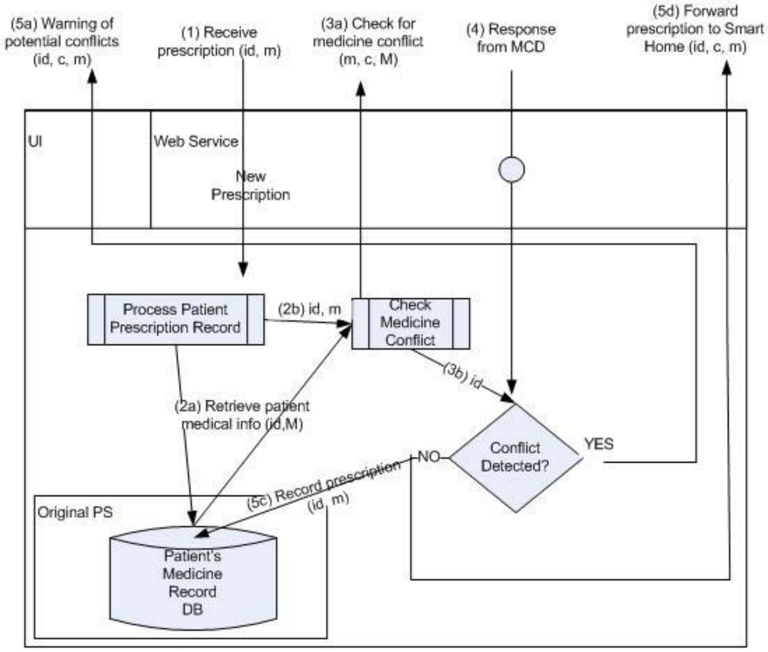


The Smart Home Subsystem (SS)

When the patient returns to the SH with the RFID-enabled prescription in hand, the local SS database is updated by scanning the prescription container with the RFID reader. A long range RFID reader, will allow the RFID tags be read automatically once the patient is within range, requiring no manual effort (Want, 2004). After scanning, prescription's data can be retrieved from the pharmacy via a secure communication channel. After the data is received, a final check for conflicts between the new prescription and current medications, health conditions, and foods in the home will take place. This third checking is necessary to detect conflicts of prescriptions filled at different pharmacies. Also, we assume the SS maintains a food inventory. Since this information is available only at home, this checking has to take place at home. If a medication conflict or health condition conflict is found, the appropriate parties are notified. Otherwise, the medications are placed in a SMC or loaded into an automatic medication dispenser and the patient will be notified of any potential food conflicts. Figures 6-8 describe the interactions within the SS. Figure 8 also describes the conflict triggered when a food item is consumed or brought into the Smart Home.

In addition to checking for the safety of a new prescription, we want ensure that the patients comply with the doctor's instructions by taking the proper dosage of each medication at the designated time. A patient's compliance with a given prescription can be evaluated based on two factors: timeliness and completeness. Timeliness determines whether the medications are taken at the correct time, and completeness defines whether the correct dosage is taken. Formal definitions of the timeliness and completeness are presented later with the system model, which is followed with a description of how the context information

Figure 5. Pharmacy subsystem



(Gu, Pung, & Zhang, 2004) and the notification services (Reyes Álamo, Sarkar, & Wong, 2008) in a smart home can be used to assist with prescription compliance.

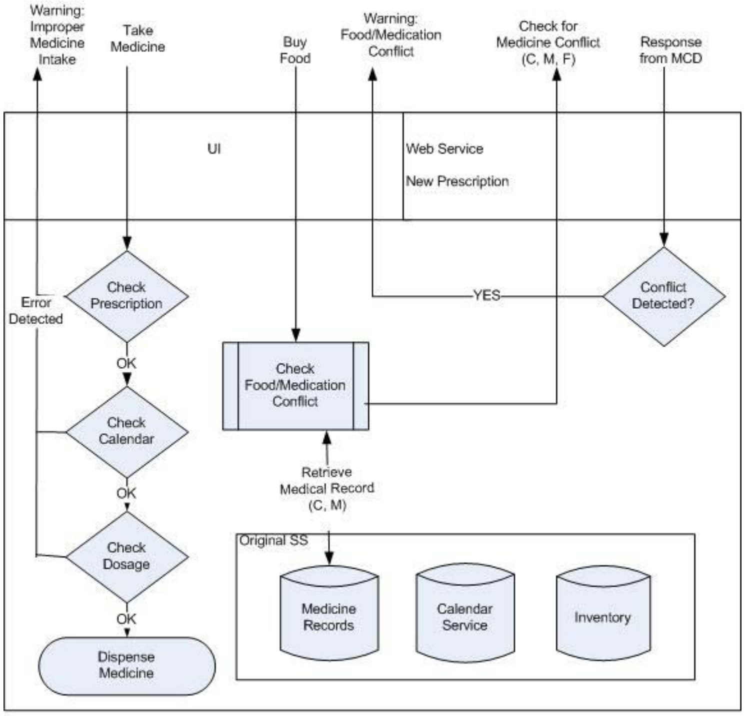
Interoperability by Using Web Services

MISS is intended to be an extension of the existing DS and PS, not a replacement, and one of our primary goals is to maximize the interoperability between existing systems. Since most doctors' offices and pharmacies already have some kind of computer systems to perform their daily functions and their respective employees are comfortable and accustomed to using these systems, it is essential that MISS works with different existing systems. Also the prescription information is sensitive data which should be shared only among doctors or pharmacies with proper authorization from the patient (OCR, 2009). It is necessary to use secure communication mechanism among subsystems for data transfer. WS can provide this secure communication as well as interoperability, since they are platform and language independent and network friendly and secure (Papazoglou & Dubray, 2004). Each subsystem will provide secure WS to allow communication with other subsystems in an efficient and secure way. Our system architecture achieves interoperability by encompassing existing systems with wrappers, and uses WS as the universal interface for secure communication between subsystems.

Designing for Privacy

Because MISS stores, uses, and discloses personal health information, it is mandatory that patients' concerns about the privacy of their data as well as related privacy legislation such as the Health Information Portability and Accountability Act (HIPAA) (Hodge, Gostin, & Jacobson, 1999; OCR, 2009) should govern its design and operation. To demonstrate how this is the case, we identify the potentially problematic aspects of MISS from a privacy perspective and show case by case that our design is in line with the

Figure 6 Smart home subsystem



corresponding HIPAA requirements. There are essentially four high-level problem areas (PA) that HIPAA addresses:

- **PA1:** The access and use of Protected Health Information (PHI) by employees within a health system or health information database
- **PA2:** The disclosure of PHI to other systems and health service providers
- **PA3:** The ability of the individual to access and amend PHI
- **PA4:** The ability of the individual (or a governing body) to audit the uses and disclosure of PHI including the management of individual consent

Since MISS essentially wraps WS around existing doctor, pharmacy, and smart home systems and uses a MCD, it is the disclosure of PHI among these systems (PA2) that is of primary concern. Implementing appropriate access control policies and other data security safeguards (PA1) are the responsibilities of each individual doctor and pharmacy systems and not of the MISS framework proper. If these systems correctly provide these mechanisms, then we can assume that only authenticated and authorized doctors and pharmacists can access PHI in their respective systems. Similarly, it is the responsibility of the original systems to provide access, amendment, and audit mechanisms that individuals can use to check, correct, and challenge the uses and disclosures of their PHI (PA3 and PA4). If these mechanisms are in place, then MISS can also wrap them with WS in a way that preserves the functionality of the original mechanisms but provides the interoperability and universal access of WS. The cases in which health information is sent between subsystems are 1) the transfer of information from doctor to pharmacy, 2) from pharmacy to doctor, 3) from doctor to home, and 4) from three systems to the conflict detection service.

Figure 7. Smart home subsystem 2

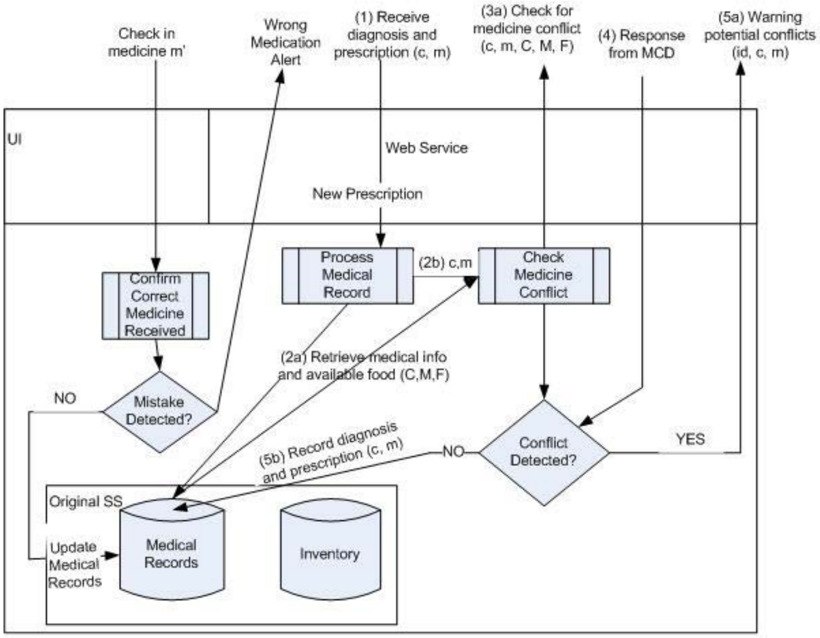


Figure 8. Smart home subsystem 3

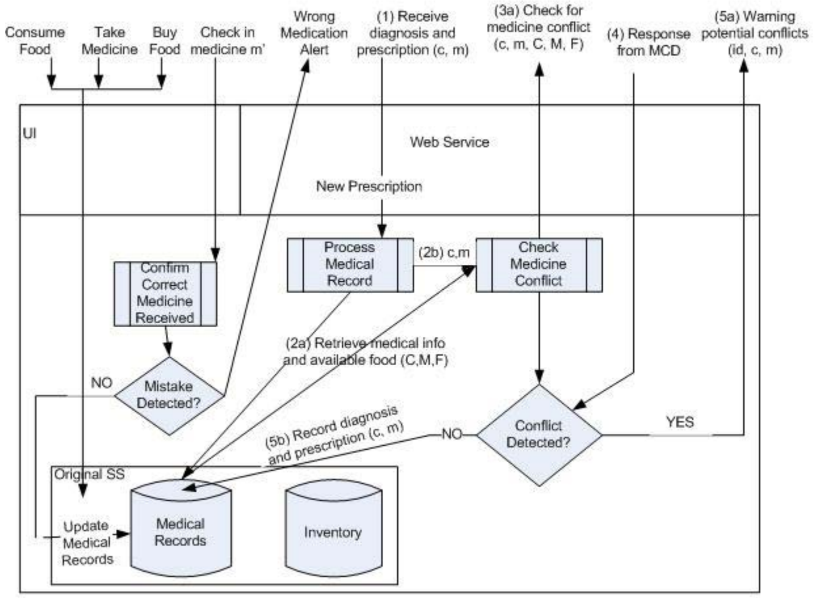


Case 1: DS Disclosure to PS

HIPAA permits the disclosure of PHI to other health care services providers if they have a previously established relationship with the individual and the disclosed information is necessary to that relationship. This rule applies to the transfer of prescription information from a doctor system to a pharmacy system as an identifier is transferred along with the prescription information. However, since the individual has chosen the pharmacy to which the identifier and prescription are routed, it follows that the necessary relationship between pharmacy and individual must exist. Also, the use of secure WS as a communication channel will protect this information in transit.

Case 2: PS Disclosure to DS

The reply from the PS to the DS when a conflict is found also leaks some information back to the DS because the presence of a conflict allows doctors at the DS to infer what the medication causing the conflict may be. Of course, the strength of this inference depends on the number medicines the patient has been prescribed by that doctor and the number of potentially conflicting medicines. However, this information flows between healthcare providers that have an existing relationship with the patient, and secure WS protects this information in transit.

Case 3: DS/PS Disclosure to the SS

The third case in which PHI is disclosed is from either the doctor or pharmacy subsystem to the home subsystem following the diagnosis of a new condition. However, because the home subsystem is viewed as a trusted representative for the individual, it follows that the doctor subsystem should be permitted to disclose this information to the home. Moreover, this information does not contain personal identifiers. On the other hand, since the doctor subsystem is communicating with an individual home subsystem (i.e. the home of a particular patient), the communication could be reasonably used to identify the individual if the destination of the messages were known. Therefore, secure WS is also required here to prevent information from leaking to eavesdroppers.

Case 4: DS/PS/SS to MCD

The fact that the doctor, pharmacy, and home subsystems submit medical information to the global conflict detection service also pertains to privacy. However, because both the doctor and pharmacy submit completely de-identified health information (only medication and health conditions) for conflict detection and de-identified information is returned by this service, there is no privacy risk inherent to these communications. On the other hand, the invocation of the conflict detection service by the home system does pose a privacy threat according to HIPAA. The fact that the request is coming from a system operating on behalf of an individual could allow the owners of the conflict checking service to identify on whose behalf the service request was made, thus linking the medication or condition to the individual. The MISS framework mitigates this situation with two security mechanisms. First, encrypted communication is done between the home system and conflict detection service, preventing eavesdropping. Secondly, a trusted anonymizing proxy is used by the home system to aggregate web traffic from multiple sources, sufficiently decreasing the likelihood that such information can be attributed to the originating individual.

SYSTEM MODELING

This section contains a model of the medication management system to further define and examine conflict detection and prescription compliance with different types of prescriptions.

Model the MCD

A medication management system must be accurate, reliable and provide safety by detecting conflicts that a new prescription may cause because of the interaction with other medications, health conditions, or foods. The trusted MCD defines the conflicts over the set of medications M, a set of food F, and the set of health conditions C using several functions over the set of medications. We define the Medication System Model as follows:

Definition

We define the Medication System Model as follows:

- M, the set of medications
- C, the set of medical conditions
- F, the set of foods
- D, the set of doctors, hospitals or clinics the patient may visit
- P, the set of pharmacies where the patient may get prescriptions filled
- H, the patient's Smart Home

Denoting the power set of X as P(X), we define the following functions maintained at the MCD:

- conflicting_medications: $M \rightarrow P(M)$
- conflicting_conditions: $M \rightarrow P(C)$
- conflicting_food: $M \rightarrow P(F)$

Where the function conflicting_medications: $M \rightarrow P(M)$ returns the set of medications that conflict with a given medication, the function conflicting_conditions: $M \rightarrow P(C)$ returns the set of health conditions that conflict with a given medication, and the function conflicting_food: $M \rightarrow P(F)$ returns the set of foods that conflict with a given medication.

A patient p is represented by a tuple p = (id, Mp, Cp, Fp, CMp, CFp, CCp). The id field uniquely identifies the patient, and $Mp \subseteq M$, $Cp \subseteq C$, $Fp \subseteq F$ be the subset of medications currently prescribed to patient p, the health conditions diagnosed to patient p, and the foods patient p has available in the smart house, respectively. The sets of medicines, conditions, and foods that are unsafe for patient p can be defined as follows:

$CMp = \bigcup_{m \in Mp}$ conflicting_medications(m)

represents the set of medications that conflicts with the medications prescribed to patient p,

- $CCp = \bigcup_{m \in Mp}$ conflicting_conditions(m) be the set of medical conditions that conflicts with the patient's medications.
- $CFp = \bigcup_{m \in Mp}$ conflicting_food(m) be the set of food that conflicts with the patient's medications.

These sets provide information to doctors when prescribing medications for a new or existing health condition. Given a newly prescribed medication m to patient p, the MCD is queried to determine what conflicts with m, and returns the results of applying the three conflict functions to m. If we let the sets of potential conflicts of the new medication m be

CM = conflicting_medications(m),
CC = conflicting_conditions(m),
and CF = conflicting_food(m),
respectively, m can be determined to be a safe medication if

1. $CM \cap Mp = \emptyset$ and $m \cap CMp = \emptyset$
    - None of p's current medications conflict with the new medication and the new medication does not conflict with any of p's current medications and

2. $CC \cap Cp = ø$
   - The new medication does not conflict with any of the conditions that patient p has) and
3. $CF \cap Fp = ø$
   - The new medication does not conflict with any of patient p's food

Conflict Checking

Each MISS subsystem (DS, PS, or SS) checks for conflicts with almost the same algorithm, but each subsystem is expected to capture a different set of conflicts because of differences in the data stored in the local databases. For example, the doctor and pharmacy subsystems focus on detecting conflicts among medicines and health conditions while the Smart Home focuses on conflicts among medications and foods. The generalized conflict checking algorithm and supporting functions are defined as follows:

Definition: Get_Data (GD)

```
Input: Prescription $r = (p, m)$

//Get patient's p data from the local database
Query Mp, Cp, Fp, CMp, CCp, CFp

//Get medication m conflicting data from the global database
Compute CM, CF, CC
```

Definition: Conflict_Checking (CC)

```
Input: Prescription $r = (p, m)$

Call Get_Data (r)
If ($CM \cap Mp = ø$ and $m \cap CMp = ø$)
    If ($CC \cap Cp = ø$)
        If ($CF \cap Fp = ø$)
            //No conflict found
            $CMp = CMp \cup CM$
            $CCp = CCp \cup CC$
            $CFp = CFp \cup CF$
        Else
            Medication m creates food conflict
    Else
        Medication m creates a health condition conflict
Else
    Medication m creates a medications conflict
```

Conflict Checking at Doctor, Pharmacy and Smart Home Subsystem

In this model the DS provides a new prescription r = (p, m) that r contains the id of the patient p and the id of medication m. The DS has a local database with patient's p record. The DS does not to store information related to food, therefore the checking at DS focuses on identifying conflicts between medications and health conditions. To perform this checking, we invoke the function CC with input r. If no conflict is found then the prescription r is forwarded to the PS.

At the PS, it is assumed that the prescription r has already been checked and cleared at the DS. The PS matches the new prescription r with the patient's local record of previous prescriptions and over-the-counter medications to check for possible conflicts. This second check is necessary as the patient might have prescriptions filled from multiple doctors. Over-the-counter medications may also be obtained at pharmacies and may also cause conflicts. The checking at the PS is performed by calling function CC with input r using the pharmacy's dataset. If no conflict is detected, the prescription r is cleared and forwarded to the SS.

Once the SS receives the prescription r, SS performs a final check for conflicts using its local inventory of medications, food and records of medical conditions. This check is necessary as the patient might be having prescriptions from different doctors filled at different pharmacies. Ultimately, SS will be responsible for detecting all the conflicts not identified during previous safety checks. Figure 9 shows an example of these multiple paths of conflicts. It illustrates how a patient might be visiting different doctors and pharmacies in which case some conflicts might go undetected, but the SH can detect them. It also illustrates how conflicts can be detected early in the process as each subsystem performs a safety check.

If all three stages of safety checks are passed, then all local databases involved are updated as necessary with p's new medication and new potential conflicts.

Compliance Monitoring

There are two aspects in determining if a patient is complying with a given prescription: if the right medication is being taken in the right dose and if it is being taken at the right time (Sarriff et al., 1992). We call the former requirement completeness and the latter as timeliness. For completeness monitoring, we currently make the assumption that the smart home has the capability to determine if a correct dose of medication was taken. This is not an unreasonable assumption if automatic dispensers are used to distribute the correct dose of medication and patients can be trusted to take all of the medication given to them. On the other hand, timeliness proves to be a much more complicated issue.

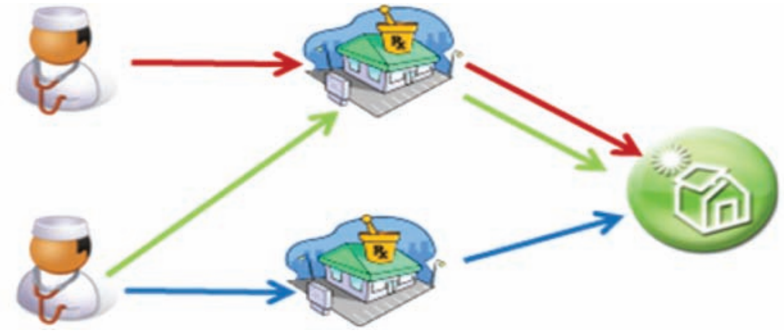
Different medications often come with different types of intake instructions requiring a medication management system to keep track of which medicines should be taken and when. For this paper, we study the three common categories of prescription instructions (Mazzullo, Lasagna, & Griner, 1974) listed below:

1. Do not take more than dosage d within time interval t
2. Take dosage d every time interval t
3. Take dosage d before (or after) activity a

In the following discussions on timeliness, it is assumed that the system has the capability to detect when medications are taken and deduce related context information about the patient such as if the patient has recently had a meal or is in the process of going to bed. It is also assumed that the system is able to dispense medications and is able to notify patients and doctors based on prescription instructions and a patient's intake actions.

For the first category of prescription instructions ("do not take more than dosage d within time interval t"), we need to keep track of the amount and time of medication intake. To monitor this condition, we use the common concept of a sliding window to create a Prescription Sliding Window (PSW) that continuously tracks the amount of the given medication taken in a given time period as follows. When a patient intakes a medication, the system generates an intake event e that consists of

Figure 9. Multiple paths of conflicts



the medication taken m, the dosage de of m, and a timestamp te. Each time an intake event occurs, MISS looks into the PSW, which covers the events from te-t to te. If the accumulated dosage ∑de'| ∀e' such that te-t ≤ te' < te exceeds permitted dosage d, an overdose exception xod is generated and the appropriate healthcare professional notified. In the actual implementation, the SS subsystem keeps a separate PSW queue for each medication, and when an intake event occurs, the dose amount is inserted to the corresponding queue and the accumulated dosage updated. The queues are maintained in a lazy fashion, meaning that MISS does not proactively remove intake events prior to te' - t but only purges events when a new intake event occurs and the recorded events fall outside of the PSW (i.e. they are outdated).

For the second category of prescription instructions ("take dosage d every time interval t"), the patient is required to space out the medication intake by a certain interval of time. These intervals are setup when the patient intakes the medication for the first time, which we label t0. Using t0 as the starting point, the subsequent intake events tn should occur at tn = t0 + nt for n=1 to the size of the prescription. However, instead of requiring the patient to take the dose at exactly some time tn, we allow a patient to take a dose at approximately time tn, providing a little bit of flexibility for the patient. To accommodate this flexibility, we introduce the concept of timing tolerance. We define tolerance tol as, given a scheduled time te for administering a dosage, the patient should take the medication at within some time interval which deviates from te by at most tol. In other words, only medications taken within the time interval [te –tol, te + tol] would satisfy this timeliness requirement. Any medication intake outside of [tn –tol, tn + tol] would be considered a violation to the prescription instruction. For most medications, this tolerance is in the order of minutes. However, should the patient miss a medication intake in a given tolerance time interval, both the patient and the doctor are notified. When the patient then intakes the medicine the system will adjust the schedule of medication, that is, establish a new set of time intervals, based on a new time t0' when the patient takes the first dosage after missing the previous dose. When the patient takes the medication, the system monitors if the dosage dtn at time tn corresponds to the prescribed dosage d. Figure 10 shows a visual representation of these intervals.

For the third category of prescriptions ("take dosage d before (or after) activity a"), the scheduled time for a patient to take the medication

Figure 10. Timeliness intervals: Take dosage d every time interval t

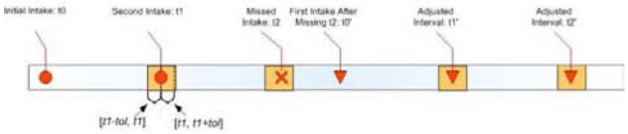


Figure 11. Timeliness intervals: Take m before activity a, take m' after activity a'

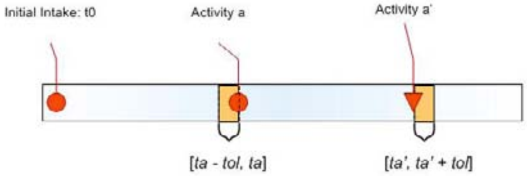

is relative to a certain activity that the patient performs, such as eating a meal or preparing for bed. We will use the same notation as in the previous discussion, assuming the patient takes the medication at time te, and the timing tolerance is tol. If the prescription instruction dictates "taking medication with dosage d before activity a," the system checks back at te + tol to see if activity a has occurred since te. On the other hand, if the medication is supposed to be taken after an activity a, the system first check if the time of occurrence ta of activity a falls into the time interval te - tol. In the former case, the system notifies the patient to take medicine if the activity of interest is detected as starting, and in the latter case, the system dispenses the medication and reminds the patient to take medication at the completion of the activity a. If the medication intake event e does not occur within the tolerance period, the patient would have violated the prescription instruction which would trigger notifications to the patient as well as the doctor. Figure 11 shows a visual representation of these intervals. In all three cases if the patient attempts to take more medicine than prescribed, takes a dosage out of schedule or miss it, the appropriate parties will be notified. The system can further impose compliance and safety by taking actions such as locking the pill dispenser to prevent an overdose.

PROTOTYPE IMPLEMENTATION

A prototype implementation of DS, PS and SS has been implemented in our SH Lab to demonstrate the feasibility of MISS. Our prototype of DS is an application that supports entering the prescription details, checks for conflicts and stores patients' record. This node forwards the data to another node that implements the basic pharmacy functionalities. The pharmacy receives the data, prepares the prescription and assigns an RFID tag to the prescription. Another node acting as the SH, queries the pharmacy using the RFID tag as the key and downloads the specific information about the prescription. A Phidget RFID reader is used to read RFID tags and identify the medications ("Phidgets Inc. - Unique and Easy to Use USB Interfaces," 2009). Different RFIDs assigned to several containers were tested to simulate a patient taking different medications. SH stores this data in its database to enable other services such as the reminder, notification and medication inventory. When a conflict is detected, the corresponding warning message is displayed and notifications are given (Reyes Álamo et al., 2008). The SS was developed as a bundle that runs in OSGi, a framework particularly suitable for SH applications (Gu et al., 2004). Our prototype implementation successfully transfers the relevant data from the DS all the way to the SS and captures all the conflicts presented in the experimentation scenarios.

To provide interoperability, WS are used to communicate among subsystems. The DS uses WS to access the third-party MCD. It also uses WS to communicate and send the data to the pharmacy. A WS is also provided so that a patient can have access to his or her record at any time with the appropriate authentication mechanism. Likewise the pharmacy makes a similar use of the WS technology. It accesses the third-party conflicts definition database via WS. It also provides a WS for the doctors to establish a connection and forward prescription data.

The SS makes use of the WS provided by the DS and the PS in order to keep a more complete record of the resident's medications and health conditions so that a final and more thorough check for conflicts can be performed at the house. The SH also has a mechanism to check for compliance with the prescription instructions. Timeliness and compliance requirements are enforced by using the prescription's data to define what to monitor, and the context information provided by the SH. When the patient is at home it is notified by giving voice reminder and pop-up windows. Text messages and emails are used to communicate with family and health care provider. Because public acceptance of RFID remains to be seen, we have also developed another version using barcodes and barcode readers.

CONCLUSION AND FUTURE WORK

Smart Homes are equipped with technology to help the elderly and persons with special needs to perform their activities of daily living, live more independently, and stay home longer. One vitally important activity of daily living is the management of medications. Several solutions have been proposed to help with medication management, but they tend to be non-networked and neglect the safety problems that arise from taking multiple medications, such as having medications interact with each other and knowing when to take each medication. This paper presents MISS, a comprehensive solution for successful medicine management that uses web services to provide interoperability among independent and existing medical systems and can detect conflicts among a patient's medications, health conditions and food intake. Because patient's preferred doctors and preferred pharmacies may vary, safety checking is enforced at multiple levels to catch more types of conflicts. We also investigate compliance with several types of prescription dosing instructions by monitoring intake actions with respect to the timeliness and completeness of each dose. Lastly, we use modeling techniques for the analysis of both the safety checking and the compliance monitoring.

This system can definitely help the patients with the management of their medication but certain limitations remain, including the need to follow the recommended steps for getting the prescriptions, the need for a universal standard medicine and food database and a more active role in error prevention. Our future work attempts to address some of these issues. A more complete integration between OSGi and WS as well as the implementation of the compliance checking routine is also in the work. We are currently applying formal techniques to further model and verify the compliance and safety of the entire system and are looking to perform a case study with medical experts to validate the usefulness of our design.

Chapter 8.7

Personal Health Records:

Patients in Control

Ebrahim Randeree
Florida State University, USA

Melinda Whetstone
Florida State University, USA

ABSTRACT

An increasing focus on e-health and a governmental push to improve healthcare quality while giving patients more control of their health data have combined to promote the emergence of the personal health record (PHR). The PHR addresses timeliness, patient safety, and equity, goals that the Institute of Medicine has identified as integral to improving healthcare. The PHR is vital to the National Health Information Network (NHIN) that is being developed to give all Americans access to electronic health records by 2014. Despite increasing public access to PHRs via employers, insurance companies, healthcare providers, and independent entities, it is unclear whether the PHR will be successfully implemented and adopted by the public. This chapter looks at how PHRs address the needs, desires, and expectations of patients, explores the data quality concerns regarding patient-generated information (data capture, sharing and integration with other systems), discusses social implications of adoption, and concludes with a discussion of the evolving role that PHRs play in the growth of patient-centered e-health.

DOI: 10.4018/978-1-60566-016-5.ch004

INTRODUCTION

The ongoing transition toward the electronic medical record (EMR), initially referred to as computerized patient record or electronic patient chart (Tang & McDonald, 2001), was spurred by concerns over medical errors and rising costs in healthcare. As EMR systems became more robust, they proved themselves to be beneficial to healthcare providers in many ways. The EMR reduced information duplication (Ewing & Cusick, 2004), improved utilization of lab and radiology results (Ewing & Cusick, 2004; Wang, Middleton, Prosser, Bardon, Spurr, Carchidi, et al., 2003), increased the efficiency of coding and billing (Menachemi & Brooks, 2006; Schmitt & Wofford, 2002), and provided healthcare personnel with quicker access to patient records (Sandrick, 1998; Wang et al., 2003).

Yet, patients and their caregivers share EMR benefits only indirectly. Patients continue to be viewed by EMR developers as passive participants who should not have direct access to or control of health data that are contained within the EMR. At the same time, patients want to be more engaged in their own healthcare and are seeking information online (Ball, Smith, & Bakalar, 2007). Use of the Internet to gather information about healthcare has increased substantially in recent years (Clark, Williams, Clark, & Clark, 2002; Gerber & Eiser, 2001; Lenhart, Horrigan, & Fallows, 2004), and the Pew Internet & American Life Project estimates the number of Americans searching for online health information at 113 million (Fox, 2006). As a result, patients have been undergoing a role change that is facilitated by Internet technology. The traditional paradigm of the patient as a passive recipient of physician diagnosis and instruction is evolving toward the patient becoming the driver of healthcare relationships. Patients have more options for receiving care, such as newly-created "store front" clinics being offered by major retailers to provide basic care (Wal-Mart, 2007). In addition, the Internet has greatly improved access to health information (Greenberg, D'Andrea, & Lorence, 2004), allowing patients to explore new treatments, to access current research journals, and to utilize increasingly sophisticated interactive and individually tailored programs through the Internet and Internet-enabled devices for health behavior change and chronic disease management (Ahern, 2007).

The personal health record (PHR) has emerged as a mechanism for patients to participate directly in the benefits of electronic records and integrated e-health delivery. Proposed benefits of the PHR include secure online access, comprehensive personal health history, means to become one's own health advocate, benchmarks and prompts for health maintenance, fluid communication between patient and provider, and automatic data entry (Morrissey, 2005). As patients manage their own personal health records using a PHR, it is hoped that this will help them make more informed choices about available options and give them the ability to exercise greater control over their own healthcare (Tsiknakis, Katehakis, & Orphanoudakis, 2002), in effect converting patients from passive information recipients to proactive consumers and generators of health information.

Leading health informatics groups in the U.S.—the American Health Information Management Association (AHIMA) and the American Medical Informatics Association (AMIA)—note that PHRs empower patients by providing a means for collecting, tracking, and sharing important, up-to-date health information for them or those in their care (AHIMA, 2006). Additionally, PHRs can promote patients' health management by providing cues for health issues (e.g., weight control or diabetes management), delivering reminders for medical test scheduling, and supporting entry of information—such as blood pressure or blood glucose levels—that may increase compliance to treatment protocols.

Patients have increasing opportunities to use a PHR, but many current initiatives offer only a partial PHR solution, are difficult to use, or raise privacy concerns. Typical offerings by employers and national insurers implement partially complete PHR designs that are limited in the scope of information that is readily included. For example, the PHR offered by Aetna, Inc. primarily provides information that is found in insurance records, such as billing and coding (Havenstein, 2007), and Kaiser's PHR contains only limited types of medical information (Hines, 2007). Although third-party PHRs have the potential to contain more complete healthcare documentation, the amount of manual data entry that users are required to perform and concerns over unauthorized secondary usage and privacy have dampened interest.

Despite positive news coverage of PHRs and their proposed benefits, nearly half of all Americans are still unaware of PHRs (Sprague, 2006). Adoption has been encouraged via legislation, with the premise that empowered consumers will help to decrease healthcare costs. However, the implications of further adoption—financial, social, and health-wise—are unknown. This chapter looks at how PHRs address the needs, desires, and expectations of patients, explores the data quality concerns regarding patient-generated information (data capture, sharing and integration with other systems), discusses social implications of adoption, and concludes with a discussion of the evolving role that PHRs play in the growth of patient-centered e-health.

BACKGROUND

PHRs have emerged as a new option for patients to become active participants in the federal push towards widespread digitized healthcare in the U.S. National Committee on Vital and Health Statistics (NCVHS, 2001) has identified the individual (personal health) as a key stakeholder in a technological National Health Information infrastructure, along with communities (population health) and healthcare providers. PHRs are seen as a critical component of an effective healthcare system, as they promote the patient-centeredness aspect of the six aims for improving healthcare called for by the Institute of Medicine, including safety, effectiveness, patient-centeredness, timeliness, efficiency, and equity (IOM, 1999, 2001).

The drive toward PHRs gained momentum in 2004 when the U.S. President signed Executive Order 13335, calling for "the development and nationwide implementation of an interoperable health information technology infrastructure to improve efficiency, reduce medical errors, raise the quality of care, and provide better information for patients, physicians, and other healthcare providers" (Brailer, 2005). This momentum is continuing in the U.S. with a steady flow of bills promoting a National Health Information Network (NHIN), overall health information technology adoption (S.1408, 2007; S.1455, 2007; S.1693, 2007), physician grants for EMR purchases (HR 2377, 2007), and physician reimbursement for each PHR that is provided to a patient.

Privacy and Security

As the push for PHRs increases and more companies provide access to them, the federal government will need to consider implications for health information privacy and security. Currently, personal health information is protected under the Health Insurance Portability and Accountability Act (HIPAA) of 1996, Public Law 104-191 (HIPAA, 1996). In addition to protecting personal health information, HIPAA ensures portability of medical records while governing the ability to disclose information contained within the records. HIPAA provides for sharing personal health information when "covered entities" have "reasonable safeguards and minimum necessary policies and procedures" in place (HHS OCR, 2003). A covered entity as defined by HIPAA is a health plan, healthcare clearinghouse, or healthcare provider who transmits protected health information in electronic form in connection with a transaction covered by the HIPAA transactions regulation (HIPAA PL 104-191, Sec 1172(a)). Under HIPAA, covered entities are expected to "maintain reasonable and appropriate administrative, technical, and physical safeguards" in order to "ensure the integrity and confidentiality of the information; to protect against" data or disclosure breaches and "ensure compliance with this part by the officers and employees of such person." Many security issues relating to the transmission and storage of PHR data have yet to be worked out, especially in the context of online PHRs, and this could slow the progress of PHR initiatives.

The concept of the PHR continues to evolve; its purpose and definition is still changing in step with technology advances and consumer demands (NCVHS, 2006). However, it is envisioned as an integral health resource that will promote informed health decisions as a consequence of increased health literacy, improved knowledge of healthcare practices, and expanded healthcare choices (AHIC, 2007). Optimally, the PHR will interrelate with other types of medical records, primarily the electronic medical record (EMR) and the electronic health record (EHR).

Electronic Medical Records and Electronic Health Records

The EMR is considered to be the legal record created in hospitals and ambulatory environments (Garets & Davis, 2006), and is the encompassing concept for health information (Stead, Kelly, & Kolodner, 2005). The EHR is a subset of the EMR that spans episodes of care across multiple healthcare providers and is designed specifically to be a resource for patients (Garets & Davis, 2006). Both records are generated as by-products of the healthcare provider's EMR system (Stead et al., 2005), the computerized system used by a healthcare provider to collect and manage detailed medical information (Connecting for Health, 2003; Garets & Davis, 2006). In effect, the EMR encompasses the various pieces of information collected and managed by the EMR system, and the EHR represents portions of the EMR that are most relevant to patients, potentially integrating documentation of care that is received from multiple providers. Although much of this information is only useful for administrative, financial, and billing parts of a healthcare practice, the EMR and EHR also contain patient encounter information which is highly relevant to the PHR.

Personal Health Information Management

Patients are not new to searching, retrieving, and storing health information. They have historically gathered personal medical information, including stacks of receipts, journal clippings, and lab results which are then organized to support ongoing management of health conditions or according to personal conceptions of future need. Moen and Brennan (2005) report that individuals use a wide range of media to manage health information for themselves and their families, including calendars, phonebooks, medical histories, and independent paper documents containing information about procedures, medication side effects, and medical instructions. These nondigital "personal health records" often are stored under refrigerator magnets, in shoeboxes, or simply piled in a drawer (Moen & Brennan, 2005). Only infrequently is a personal computer or personal digital assistant (PDA) used to manage personal health information at the present time.

Approaches to the PHR

Vendors of new PHR products strive to provide an efficient cataloging and health information management system that can replace *ad hoc* methods which patients have come to use. These new PHRs are intended to provide affordable, easy to use, life-long health and medical histories that are complete and accurate and can be generated and maintained effectively by patients or their caregivers (AHIC, 2007; AHIMA, 2005). Specific contents of PHRs vary, but these typically include the information that is normally filled out on a standard new patient questionnaire, such as personal identification, emergency contacts, prior healthcare providers, and insurance documentation. PHRs also frequently include documentation relating to immunizations, allergies and adverse drug reactions, prescribed medications (including dose and how often taken), over-the-counter medications and herbal remedies, incidents of illness and hospitalization, surgeries and other medical procedures, laboratory test results, and family histories. Additional information that may be encompassed by the PHR includes living wills and advance directives, organ donor authorization, physical examination results, physician opinions, eye and dental records, permission forms, and lifestyle information (AHIMA, 2005; Connecting for Health, 2004). As a complete and life-long record, the PHR should be designed to contain health information from all organizations and providers that serve patients (Connecting for Health, 2003). Additionally, the PHR should be maintained within a private, secure, and confidential environment (Connecting for Health, 2003).

Standards for data transfer and interoperability are supported by America's Health Insurance Plans (AHIP), a national association representing 1300 health insurers, and the Blue Cross and Blue Shield Association (BCBSA), a national federation of health coverage providers (MNT, 2006). Current standards primarily support data-driven PHRs, as described below. However, new standards have been proposed that will apply to all PHRs (Health Level Seven, 2007).

The three primary approaches to creating a PHR are as independent and personal applications, as transaction data-driven applications, and as EHR-integrated applications. Creation methods and security characteristics vary substantially among these approaches:

- **Independent and personal:** These PHRs are created manually by the individual user using commercially available applications and are unbound from any specific healthcare provider. They are categorized as standalone (independent) or Web-based types. When these PHRs are used as standalone systems, they offer high levels of security and privacy. However, they also require the most time to create and maintain, and standalone PHRs may not offer the level of "anyplace-anytime" access that is available with Web-based PHRs.
- **Transaction data-driven:** These PHRs are automatically created and typically maintained using transaction data from sources such as a healthcare provider, a health plan, or a pharmacy. As a result, they will typically be limited to automatically providing only information that is specific to the source, for example, an insurance company may only provide information pertaining to office visit dates, diagnoses, and costs related to covered providers. This type of PHR is sometimes referred to as "tethered" due to linkage with and control by a specific source entity. At least 70 million Americans have some form of access to a transaction data-driven PHR (Sprague, 2006), yet actual usage is estimated to be low, based on overall PHR use patterns (Denton, 2001).
- **EHR-integrated:** These are considered to be the "holy grail" among PHRs, as they are automatically populated with data from a healthcare provider's EHR, potentially providing the most complete collection of relevant patient information that can be made available (Tang & Lansky, 2005, pp. 1292). EHR-integrated PHRs often include additional functionality, such as secure email messaging, prescription renewal, appointment scheduling, and the ability for the user to add supplemental information (Sprague, 2006; Tang, Ash, Bates, Overhage, & Sands, 2006). Limited versions of the EHR-integrated PHR simply provide a view of the provider's EHR data. Several large organizations, such as the Pal Alto Medical Foundation (PAMF) (Tang, Black, Buchanan, Young, Hooper, & Lane, et al., 2003), Kaiser Permanente and the Veterans Health Administration

(Sprague, 2006) currently provide this type of limited access. Until a greater proportion of healthcare providers adopt EHRs, however, availability of EHR-integrated PHRs will be constrained.

Each approach described above presents tradeoffs. For example, the standalone PHR ensures high levels of privacy, but requires a high personal labor cost for creation and maintenance. While PHRs that are automatically populated with data from healthcare provider systems may appear to be optimal in that they require the patient to invest less startup effort, there are higher costs associated with this PHR approach as it requires the healthcare provider to use an EHR and to pay for the PHR to be integrated with it.

DATA QUALITY CONCERNS

We have discussed the importance of ease of use and interoperability in gaining patients' acceptance of PHRs. Ensuring data quality and relieving patients' concerns in this area are also important. High quality health information can reduce medical errors, avoid duplicating services, and give patients and their providers reliable information on which to base decisions. Quality issues are inherently multifaceted, and attention must be given to a number of dimensions in order to comprehensively address data quality issues and mitigate patients' concerns for data quality in PHRs:

- **Relevant content:** The most important criteria of a PHR is content (i.e., its informational and transactional capabilities) (Agarwal & Venkatesh, 2002). Relevant content promotes usage, especially where the content fosters self-education (Walter & Tung, 2002). This makes it important for PHR designers to learn which types of content are essential to patients and develop interfaces that allow quick access to this content while minimizing distractions. This is not a trivial exercise, as the relevance of content can be affected by numerous variables, including motivation, reading level, culture, primary language, technical knowledge, and background experiences of software users (Calongne, 2001).
- **Accuracy:** Accuracy (including completeness) of health information is very important for PHR users and their healthcare providers, as inaccurate information can lead to medical errors and practitioner liability. As the volume of electronic data increases, there is always the potential to overlook or aggregate relevant information. Of the various types of data entry methods employed by PHRs, approaches that rely on guided or automated entry of data elements abstracted from primary source documents may promote more accurate entry (Kim & Johnson, 2004). An additional concern for information that is provided to patients is the need to avoid descriptions that patients are likely to misinterpret. It is not in the best interests of patients or their physicians to provide health information with insufficient structure, patient education, or guidance to make it understandable to them (Walter & Tung, 2002).
- **Privacy/Security:** Security and privacy issues are of concern to both PHR users and developers. Patients using Web-based PHRs must be aware of the potential for misuse, unauthorized secondary usage, and other dangers that come with online transmission and remote data storage. Striking a balance between privacy concerns and the need for access can be difficult (Kelly & Unsal, 2002). Web-based data must be secured by the PHR provider, and patients should be confident that their data is secured and encrypted during online transmission. PHR providers should

attempt to meet all HIPAA standards for protection of patient health information, even where these are not directed explicitly toward online operations. Currently, many providers of Web-based PHRs operate outside of HIPAA rules, as they are not covered entities as defined by HIPAA and are not regulated by HIPAA privacy rules (Conn, 2006). Nevertheless, health records contain information that is highly sensitive, and patients have a strong expectation that such information will be used only in the context of providing effective care (Rindfleisch, 1997). Privacy and confidentiality issues are primary concerns underscoring the reluctance of administrators, physicians, and patients to completely embrace Internet technologies (Kerwin & Madison, 2002).

- **Authority:** Qualification of the author is crucial in determining the credibility of health information in PHRs. Physicians receive and process large amounts of data. If they allow patients to bring in PHR data, there must be checks and balances to support its interpretation. Similarly, patients who import EHR data into a PHR database must be able to verify who has provided the information. Authority has been recognized as the underlying theme in source credibility (Rieh & Belkin, 1998), and trust is established when the information is presented by a recognized author (Lin & Umoh, 2002). Authority criteria should include author identification (physician identification if the information is collected from an EHR). Identification of the author promotes perceptions of legitimacy and accountability of the information.
- **Timeliness:** Availability of timely health information is essential to improving the quality of healthcare. In addition, it is important that medical decisions be based upon correctly sequenced health information. For this reason, PHR entries should be accompanied by the dates and times the information was created, modified, and added to the PHR in order to inform judgments as to the value and relevance of the information. In addition, the PHR should be updated following medical encounters or to reflect changes in the patient's health status.
- **Usability:** Ease of use has been extensively researched across the IT domain (Agarwal & Venkatesh, 2002), and the general IT findings suggest usability is a key driver of PHR usage. Presence of design elements that support usability is an important determinant of whether visitors are likely to return to Web sites (Klein, 1998). A recent study of health records reports that attention to navigation, context, and information design is critical to the usability of a system (Rose, Schnipper, Park, Poon, Li, & Middleton, 2005). PHR developers should conduct usability testing to support patients in obtaining quality access to health data.
- **Information audits:** Given the critical nature of health information contained in the PHR, patients must have the ability to audit the information in order to identify and correct any discrepancies or to update information. Where the PHR is integrated with a provider's EHR, giving patients a moderated ability to review and update data could make both health records more robust. Auditing capabilities give patients control over the information dissemination and, by providing access histories, may help allay patients' concerns for privacy and security.

SOCIAL CONCERNS

Historically, one unfortunate side effect of the diffusion of new technology has been increased disparity for the socioeconomically disadvantaged (Rogers, 2003). The PHR is multifaceted in that it can operate as a data repository, a health information management tool, or an educational dissemination portal. The PHR is also a developing technology, and vendors generally have objectives toward using PHRs to support equitable and patient-centered healthcare. However, if efforts are not made ensure equitable access and to develop the appropriate levels of health literacy and technology competence for all potential users, the PHR may further alienate populations that have the most to gain from using it, such as chronically ill patients who have difficulty affording healthcare. Despite developers' intentions, PHRs may act to highlight and even exacerbate social inequities in healthcare. These social concerns can be broadly represented by the digital divide phenomenon with a secondary focus on literacy:

- **Digital divide:** Focusing on those with access to technology and those without will be a challenge for any PHR developer to overcome. The traditional racial and socioeconomic disparities of access to financial means, to computers, and to the healthcare system in general become more apparent in a PHR designed for Web access. While some may see public Internet access, at the library, for example, as a means to overcome barriers, a challenge still remains in how to provide PHR access to those who do not have medical insurance. Although "free" PHR access is available, these products typically offer limited functionality and still require extensive access to a computer.
- **Literacy:** Concerns of literacy relating to PHRs can be subdivided into three distinct areas: technology literacy (ability to understand and use the technology such as Web portals, Web forms, and so on), information literacy (ability to understand the information presented and the instructions provided), and health literacy (ability to understand the medical content provided sufficient o make basic health decisions). Use of PHRs is hindered by a range of barriers including lacking access to computers or devices, cognitive disabilities, physical disabilities, low computer skills or reading literacy, and low health literacy (Lober, Zierler, Herbaugh, Shinstrom, Stolyar, Kim, & Kim, 2006).

CONCLUSION

The national focus on applying health information technologies to improve healthcare delivery quality and lower costs has created momentum for patient-centered solutions. Increasing patient demand and a changing healthcare market now make it likely that Internet-based communication between providers and patients could soon be an everyday part of healthcare throughout the Internet-connected world (Wilson, 2003). The true benefits of PHRs become apparent when they are fully integrated with the healthcare provider's EHR or EMR. Using integrated PHRs, patients will not only gain access to their medical records but also will have the ability to update, correct, or add to the records. This will allow patients to become more engaged with their medical histories, plans of care, and options for treatment. While issues of data quality exist, inclusion of the patients will allow for these primary stakeholders in the healthcare process to be active participants in their own care. Potential benefits include better compliance with care protocols (translating to lower costs for insurers and patients), increased patient literacy, increased convenience for patients and their providers (translating to service improvements and better coordination of care), and better quality outcomes.

The monitoring of chronic conditions is an ideal fit for PHRs. The movement to involve patients stems to a large degree from the desire to engage patients in managing chronic diseases, along with selecting care based on quality characteristics, improving the quality of the care delivery system, and making healthcare more market-driven by increasing patients' share of costs (Fowles, Kind, Craft, Kind, Mandel, & Adlis, 2004). Chronic conditions require long term treatment plans and provide an opportunity for cost reduction if the care is coordinated effectively between the physician and the patient. Incorporating home monitoring and self-reporting features offers some of the most interesting opportunities for PHRs (Heubusch, 2007).

PHRs have potential to transform the healthcare setting: they can replace or augment existing care processes, provide interactive communication, support information exchange, initiate consumer activity, and increase convenience and efficiency of healthcare services (Hartman, 2006). In order for PHR benefits to be realized, however, several criteria must be addressed in the areas of PHR standards, interoperability, and system functionality:

- **Standards:** Current PHR systems are either linked to an EMR/EHR or are standalone systems that lack national standards. These heterogeneous systems will need to coalesce towards a shared standard that allows for simplified data transfer among systems. Records must be of sufficient size and scope to include both clinical and nonclinical data. Data standards should also determine the sources of information that is allowed to flow into and out of the PHR.
- **Interoperability with Privacy/Security:** The current focus in health information exchange initiatives is to connect electronic medical records among healthcare providers to allow sharing of data among physicians and healthcare facilities. The proprietary nature of health information systems presents a barrier to health information exchange in its current form. As patients interact with multiple providers and multiple systems, the creation of a national standard for electronic records will facilitate the exchange. The Certification Commission for Healthcare Information Technology (CCHIT) is a recognized certification body for electronic health records and their networks, and an independent, voluntary, private-sector initiative (www.cchit.org). CCHIT is working to accelerate the adoption of health information technology by creating an efficient, credible and sustainable certification program. The certification allows for development of interoperability standards among vendors that market electronic medical records.
- **Functionality:** Use of PHRs will be directly related to the benefits that patients perceive from usage. In this case, the functionality of the PHR and its ability to reduce costs increase the likelihood of quality outcomes. The ability to easily view and enter health information will help to increase use, as will automated integration of information between the PHR and the healthcare provider's EHR or EMR. Additional benefits of reduced insurance premiums for chronic condition management as well as participation in the management of care decisions could incentivize PHR usage.

As PHR vendors compete for market share, new models will need to be developed. PHR vendors must move toward providing more complete integration and access to medical records for patients to become fully empowered. PHR vendors must also integrate their services with traditional EMR and EHR vendors. For physicians to support these efforts, the PHR must not interfere with the workflow of the office and must be interoperable with existing systems so data can move seamlessly among systems, assuming adequate privacy and security protections are in place.

The growth of patient empowerment initiatives will continue to drive the direction of healthcare. Studies on how the Internet affects patients' experience of empowerment within the clinical encounter have shown mixed outcomes. While patients' desire to use the Internet for health information is increasing generally, many patients are reluctant to discuss information from the Internet in the clinical encounter for fear of challenging the physician's authority, and some physicians express frustration in dealing with patients who arrive with health information they obtain online (Jacobson, 2007). In contrast, PHRs tend to empower patients in their personal healthcare and in interactions with healthcare providers. In a comparison of effects of computer-generated medical record summaries and written PHRs on patients' attitudes, knowledge and behavior concerning health promotion, researchers found that patients receiving summaries as part of mail recruitment were significantly more likely to attend for a health check; those receiving both PHR and summaries were more likely to keep and use the record; and those receiving PHR improved their knowledge of health promotion, became more aware of lifestyle issues, and were more likely to change their lifestyle (Liaw, Lawrence, & Rendell, 1996).

The growth of patient self-management tools for remote monitoring will fuel PHR adoption, if tools and standards are developed that make clinical information understandable to and usable by patients (Ball et al., 2007). As a caveat, it must be recognized that not all patients will be excited to adopt PHRs. The use of a PHR to empower patients with their medical records will be beneficial to early adopters and those with chronic conditions. However, some patients, such as those who experience a rare acute incident, may not be attracted to PHRs. Patients also exist at varying levels of literacy, and not all will be eager to delve into their medical records without support.

For PHRs to have a future, the healthcare industry must determine the public's needs and interests and provide flexible tools that offer a range of data and resources that can be used to satisfy these needs and interests (Heubusch, 2007). In addition, physicians must be willing to share information with their patients through PHRs. In many cases, physicians concerns for negative impacts of information sharing are overblown and based on anecdotal sources, as empirical research in this area is limited and dated (Fowles et al., 2004). Much of the value of PHRs lies in shared information and shared decision-making in support of the continuity of care (Ball et al., 2007).

ABSTRACT

The e-learning 2.0 transformation of continuing education of healthcare professionals (CE/CME) will be characterized by a fundamental shift from the delivery of static information online to a seamless, digital operation in which all users have the ability to access, create, and share knowledge in a multidimensional, instantaneous, collaborative, and interactive manner. This transformation will be disruptive, blurring existing boundaries between CE/CME professionals, content experts, and student learners, and modifying the traditional structured learning process to a more informal one. While the opportunities are unlimited, the transformation will present not only technology challenges but also social and educational challenges. Recent experiences with similar disruptive technologies show that a meaningful transformation can be achieved only if the application of technology is accompanied by strategic operational changes. This chapter offers a conceptual framework to guide CE/CME professionals interested in transforming their operations with new e-learning 2.0 technologies. Employing several usage scenarios, a new e-learning 2.0-based model of CE/CME operation is introduced. We also present several examples of approaches adopted by our academic group to address the various challenges discussed in this chapter.

DOI: 10.4018/978-1-60566-788-1.ch019

INTRODUCTION

The threats of disruptive approaches to management education, CME, and probably to higher education as a whole are real. But so are the opportunities. Disruptive innovations – such as personal computers, photocopiers, helical scan video recorders, and microwave ovens – generally have brought useful technologies to much larger groups of people than previously had enjoyed access to them. Disruptive approaches to continuing education are likely to have a similar impact. Based on new models for learning, they are likely to be increasingly effective in delivering relevant knowledge to larger audiences than are reached by current programs. The lessons learned by private sector companies that have succeeded and failed in the face of disruptive technologies can provide useful models for directors of CME as they formulate strategies for the future (Clayton M. Christensen & Armstrong, 1998).

E-learning 2.0 technologies have the potential to profoundly impact continuing education for healthcare professionals (CE/CME). The evolution of CE/CME over the years can be characterized as a move from old-fashioned didactic lectures over coffee and donuts to online instruction closely resembling the traditional counterparts to a digital enterprise of high-tech, interactive, global, instantaneous, and collaborative exchange of information. For years, the tradition and culture of continuing medical education (CME) assumed that physician learning and performance improvement would result from a simple one-way delivery of information. Over the last decade, as it did with other learning groups, the Internet has stimulated significant changes. Healthcare educators now are able to leverage the Internet to overcome healthcare professionals' lack of time for traditional learning activities and to reach a broader audience, such as those working in more remote and underserved areas.

E-learning 2.0 technologies, such as Web services, semantic Web, social networks, and rich Internet technologies, have the potential to bring continuing healthcare education into a new era as a digital enterprise. However, like so many other disruptive technologies, they also can lead to significant failures. Building on several e-learning experiences (Casebeer, Allison, & Spettell, 2002; Casebeer, Bennett, Kristofco, Carillo, & Centor, 2002; Wall et al., 2005; Casebeer et al., 2006; Houston et al., 2007; Houston & Ford, 2008; Houston et al., 2008), our goal in this chapter is to provide a conceptual guide for early adopters of e-learning 2.0 technologies in CE/CME. While we discuss many opportunities presented by e-learning 2.0, we also recognize the need to modify current operations to facilitate the new opportunities. The chapter goes on to discuss two categories of barriers to adopting e-learning 2.0, and we describe several approaches in use by our academic CME group to develop best practices approaches for e-learning 2.0 adoptions in CE/CME operations.

E-LEARNING 2.0 OPPORTUNITIES FOR CONTINUING EDUCATION OF HEALTHCARE PROFESSIONALS

Defining E-learning 2.0

Before adopting e-learning 2.0, it is important to understand that it involves much more than technology (Downes, 2005; Ebner, 2007; Toub & Kostic, 2008). E-learning 2.0 is a cultural change, and it also has been referred to as social learning (Hart, 2008). This represents a key shift over e-learning 1.0. In e-learning 1.0, information flows "unidirectionally" from content creators to content consumers with the roles of the content creator and consumer generally fixed. In contrast, in e-learning 2.0 paradigms, information is socially and dynamically generated, meaning that a content creator in one instance becomes a content consumer in another instance involving the same learning activity. Accordingly, Ferretti et al. note

Table 1. Types of E-Learning 2.0 Technologies Beneficial to Continuing Education of Healthcare Professionals

Technology	Description
Web services	Web services provide standardized technology for integration and composition of infrastructure applications such as databases, tools, software, etc. (Brown, Johnston, & Kelly, 2002; Channabasavaiah, Holley, & Tuggle Jr., 2003). Web services are a critical piece to be considered for integration of disparate sources of information in an e-learning 2.0 infrastructure. Example Web services technology include SOAP, Web Services Description Language, and Business Process Execution Language (Newcomer & Lomow, 2005; Sadasivam, Tanik, & Kristofco, 2006; Sadasivam, 2008).
Semantic Web	The semantic Web is an extension of the current web to give information well-defined meaning, better enabling computers and people to work in cooperation (Berners-Lee, Hendler, & Lassila, 2001). The semantic Web builds upon Web services with the addition of semantics and ontologies to enhance the search for and access of information. The major efforts in the semantic Web are the development of new content markup languages, which finally has led to the W3C specifications of the Web Ontology Language (OWL) and the revised Resource Description Format (RDF) (Martin et al., 2004; World Wide Web Consortium, 2004).
Course development and management systems	Course development and management systems facilitate the easy, collaborative, and asynchronous creation of courses by different users. Examples of course development systems are Blackboard WebCT, Moodle, and Sakai.
Web 2.0, Rich Internet Applications (RIA), and social networking technologies	Web 2.0 features a new approach of presenting and developing content on the web (O'Reilly, 2005). Web 2.0 is very user-centric, enabling personal publishing where users can create their own data (Lin, 2007). Web 2.0 features include RIAs and social networking technologies. RIAs such as AJAX (Asynchronous JavaScript and XML) and Flex facilitate the enhanced presentation of content on websites. Social networking technologies such as Wiki, forums, blogs, and instant messaging facilitate the synchronous and asynchronous creation of new content. A discussion of the use of these Web 2.0 technologies in healthcare education is provided in (Kamel Boulos & Wheeler, 2007).
Video and audio technologies	Video and audio technologies provide an alternative way of presenting content. Video and audio can be presented in Real streaming, QuickTime, or Windows Media format.
Gaming and simulation technology	Gaming and simulation technology are gaining popularity as a means of e-learning. Gaming can provide a fun and engaging way of learning. Simulation technology can be used to develop models representing real world entities, which then can be used as a basis for learning.
Push technologies	Push technologies are used to enhance the e-learning experience. While pull technologies such as websites or forums expect users to come and interact with the learning medium, push technologies such as RSS, text messaging, and podcast can push content to the users. RSS (Really Simple Syndication, Rich Site Summary or RDF Site Summary) facilitates the quick publishing and syndication of new content. Podcasts allow the syndication of audio and video files. Text messaging can be used to send content to users' mobile devices.

that e-learning 2.0 has cast a new light over processes and roles in acquiring knowledge (Ferretti, Mirri, Muratori, Roccetti, & Salomoni, 2008). A broad definition of e-learning 2.0 is the ability to access socially and dynamically, create, and share knowledge in a multidimensional, instantaneous, collaborative, and interactive manner.

E-Learning 2.0 Technologies

Table 1 lists several e-learning 2.0 technologies that have played significant roles in the transformation of continuing education of healthcare professionals. The features and primary characteristics of each technology are described briefly, and references are provided for those readers interested in further study.

E-learning 2.0 and Current CE/CME Practices

Most physicians spend the majority of their active professional careers engaged in informal, self-directed learning activities. The goal of CE/CME is to provide effective, evidence-based programming to help health professionals with these identified needs, ultimately leading to better health care and improved patient health. In addition, adult learning principles (Merriam & Caffarella, 1999) are commonly used in the design of continuing education programs for healthcare professionals to increase their effectiveness for these audiences. While e-learning 2.0 presents many opportunities to enhance online learning, current CE/CME practices have not successfully integrated the use of e-learning 2.0. Despite overwhelming evidence suggesting that interactive resources are more effective than static information (Zeiger, 2005), a review of online CME practices shows that the majority of these online resources closely resemble their traditional counterparts (Zimitat, 2001). This lack of interactivity has resulted in reduced effectiveness of many online programs. For example, many physicians have reported concerns including lack of specific information, too much information, and poor formatting of resources (Andrews, Pearce, Ireson, & Love, 2005). In an age of instantaneous information, the web-based CME content development process also continues to be time-consuming and laborious. It takes too long for healthcare experts to find relevant information, coordinate their activities with CME professionals, apply necessary quality criteria, format the content into appropriate web delivery, and upload the content to web servers. Contrary to new synergistic learning models that emphasize interaction, current web-based professional continuing education is still primarily a one-way transaction between content experts and participant learners. The two following case scenarios illustrate opportunities as well as several critical challenges when using e-learning 2.0 in CE/CME activities.

The course development activity described in Case #1 is not uncommon and illustrates several critical limitations that can be addressed with e-learning 2.0.

Lack of Integrated Users and Collaboration

The organization of responsibilities in the development of the activity was distributed among a relatively large number of people in sequential fashion, contributing to a lack of efficiency. By using e-learning 2.0 collaboration software, the course can be developed asynchronously in a very efficient fashion.

Case #1. Course Development Activity

Dr. Allgood, a health expert, is interested in increasing the knowledge and skills of primary care physicians, and he assumes that with the development of an appropriate education program, this can be accomplished.

Ms. Bates, a CME professional, agrees to collaborate with Dr. Allgood to develop an online CME activity to address identified learning needs. Dr. Allgood enthusiastically agrees to prepare some educational content for the proposed course and return it to her when he thinks it is ready for distribution.

Dr. Allgood decides to contact Dr. Cook, a new junior faculty member, and asks her for help in developing up-to-date instructional content. To ensure that she includes all the important and relevant information, Dr. Cook conducts a thorough literature review of high blood pressure on the Internet by searching several databases such as PubMed, Medscape, Medline, and Science Citation Index. She synthesizes her findings and prepares a detailed Microsoft Word document. Dr. Cook forwards the document to a colleague, Dr. Doyle, to review the document's accuracy and thoroughness. Dr. Doyle agrees, and inserts his comments before sending it back to Dr. Cook, who makes some final changes and forwards the document to Dr. Allgood. Dr. Allgood makes only minor modifications before sending the document on to Ms. Bates.

Ms. Bates then makes a decision about the online instructional strategy to use and then develops a set of questions to assess participants' self-report of the impact and effectiveness of the new online module. Ms. Bates calls upon an in-house IT expert, Mr. Errez, to program and disseminate the activity through their website. Mr. Errez converts the document to an online format and configures the evaluation and instructions on the course website for earning credit for participation. Finally, the activity is released to a public audience of practicing physicians.

Lack of Integrated Information

Dr. Cook spent a large amount of time conducting a thorough literature review, which involves searches in several online databases. Instead of that, an e-learning 2.0 tool that integrates information from these different sources could be of great value to Dr. Cook and could accelerate the course content development process.

Lack of Enhanced Interaction

When the course is finally uploaded to the website, the information is presented in a static fashion. Learners have limited ability to interact with the course, the course developers, or their peers. As a result, the module is very non-interactive, reduces the effectiveness of the course, and fails to integrate critical components of adult learning theory (Knowles, 1990).

The learner experience described in Case #2 is unfortunately quite common and ultimately fails to provide a meaningful educational experience that will improve this physician's clinical performance. So what are some key issues and barriers that can be addressed using e-learning 2.0?

Lack of Integrated Information

Internet search strategies can be difficult, and locating specific, information related to complex issues involving multiple conditions and different treatment options can be time-consuming. Dr. Ferrini could have used an e-learning 2.0 tool that provided access to the various sources of information and saved both time and aggravation.

Lack of Integrated Users and Collaboration

Dr. Ferrini also discovered that once information is located, it is challenging to verify the credibility of its sources. If the accuracy of the information is questionable, physicians run the risk of using it to their patients' potential detriment. Dr. Ferrini could have benefited from the ability to debate the authenticity of the information with other professionals.

Lack of Enhanced Interaction

Dr. Ferrini's interaction with the information is limited in several ways. Dr. Ferrini was restricted to searching for static information on the Internet.

Case #2. Participation in Traditional E-learning CME Activity

Dr. Ferrini works as a primary care physician in small town. While reviewing his charts, he notices a large percentage of his patients suffer from the same chronic condition. Dr. Ferrini is uncertain about the steps he should take to improve their health. Should he investigate more about his patients' medication adherence? Should he increase their medication? Should he be more aggressive in helping them pursue healthy lifestyle modifications?

Dr. Ferrini decides to conduct on online search to see if he can find some relevant information to provide him with some direction and options. First, he sifts through abstracts he finds in literature databases. Even though he finds several relevant studies, Dr. Ferrini does not find straightforward, easy answers to his specific questions. He then looks for clinical guidelines, but he discovers that they are too lengthy and difficult to translate into concrete next steps that would apply to his specific patient population.

Fortunately, Dr. Ferrini discovers several interesting CME opportunities on new medical advances, but most are live events such as conferences and seminars and would require too much time away from the office. He also worries that the print materials he finds available for order might be out of date by the time they arrive and he gets a chance to review them. The online courses he finds force him to scroll through lines and lines of text, and several are not from recognizable providers, which makes him a little nervous and creates a question of credibility in his mind.

After about an hour on the Internet, Dr. Ferrini has found a great deal of information and has acquired some knowledge he did not have before. Unfortunately, he does not have any way to earn CME credit for the time spent searching, and he still has not found exactly what he needs.

Many of the websites that contained medical information consisted of simple presentations of best practices in managing chronic conditions. As a result, Dr. Ferrini was restricted to scrolling through several pages of text on several sites, information that was for the most part already familiar, to find relevant answers. Dr. Ferrini also could not discuss the information he found with peers to clarify some of his existing doubts. Since CME professionals have no way of monitoring Dr. Ferrini's activity, he also could not receive appropriate credit for his learning efforts.

TRANSFORMING CONTINUING EDUCATION OF HEALTHCARE PROFESSIONALS WITH E-LEARNING 2.0 TECHNOLOGIES

An E-learning 2.0-based Digital Enterprise Model for CE/CME

An E-learning 2.0 approach presents a number of new opportunities for CE/CME professionals. With e-learning 2.0 technologies, CE/CME educators have the capability to streamline needs assessment and content development processes by connecting CME facilitators, content experts, and learners to promote the exchange of information and ideas. Figure 1 depicts an e-learning 2.0-based conceptual model for CE/CME. The model shows the gradual transformation of CE/CME operations from a traditional face-face operation to a new transformed model of CE/CME that can operate as a digital enterprise. Using E-learning 2.0 technologies, all CE/CME users can be interconnected, information can flow freely between participants, access to internal and external resources such as databases and Web services can be seamless, and the interaction between participants and information can be enhanced. Successful transformation will require those adopting e-learning 2.0 technologies to focus their time and attention on three important and interdependent challenges:

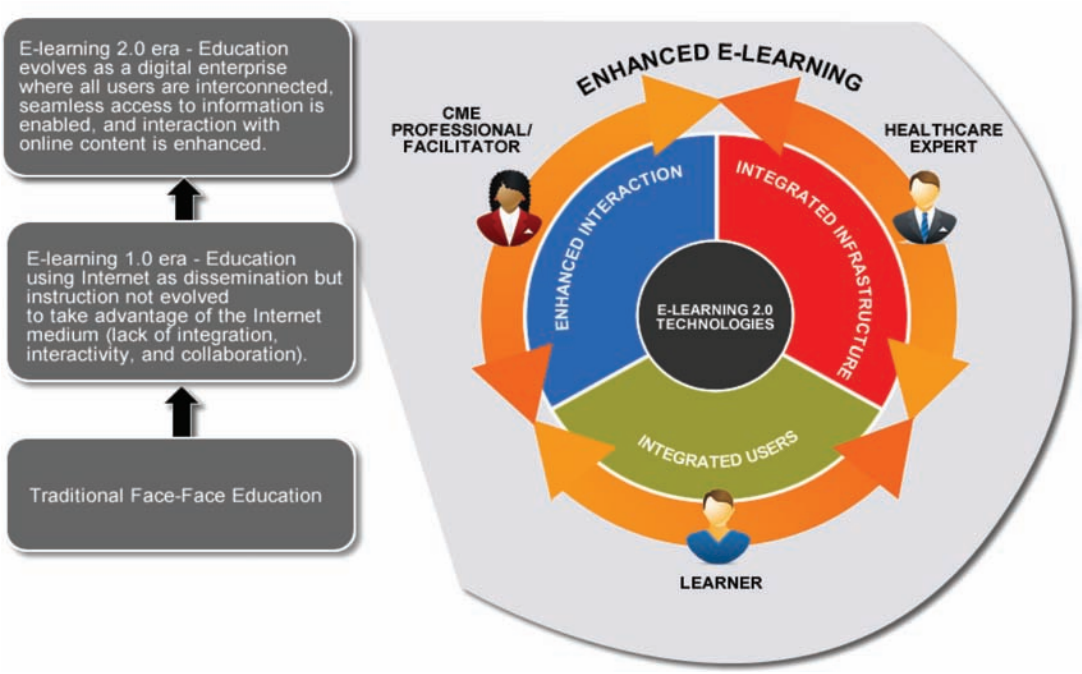
Integrating Users

Our conceptual model includes three sets of users: the CME professional/facilitator, the health care expert, and the learner. In traditional CE/CME models the roles of the three sets of users are clearly defined, but in e-learning 2.0 users are constantly moving between and among roles. A user might be a health care expert providing education to others in one instance, while in another scenario the same user could be in the role of learner. In traditional CME programs, course information typically flows in a unidirectional manner from the health care experts or facilitators to learners. In most current programs, an instructor (with help from CME professionals) designs a course with a designated amount of CME credit based on perceived level of difficulty of that course. In contrast, using e-learning 2.0 technologies, learners can initiate an educational activity by posing questions to facilitators, or healthcare experts can become learners in interactive discussion forums. Since learning happens in a very informal setting, it becomes more difficult or complicated to assign credit for a learning activity. Integrating users will allow CE/CME professionals to track user participation and assign credits in a new and improved way that reflects time and effort accurately. In addition, integration of all users contributing to a continuing educational activity creates a collaborative work process that yields the greatest efficiency in terms of time and effort. Only after all users are fully integrated can information flow in a multidirectional manner. Integrated users will be able to participate in a vast array of CE/CME activities, collaborate with each other, and actively participate in discussions while changing roles easily.

Integrating Information

In our conceptual model, information flows seamlessly between different user groups in a multidirectional manner. This is in contrast to

Figure 1. E-learning 2.0-based Digital Enterprise Model for Continuing Education for Healthcare Professionals



traditional CE/CME models, where information typically flows from health care expert or CE/CME professionals to the learners. Integration of information across diverse and disparate sources such as databases, web sites, documents, etc. is critical to the e-learning 2.0 educational process. Integrated information allows users to have an enhanced ability to search, access, and create new knowledge.

Enhancing Dynamic Interaction

Figure 1 also illustrates enhanced interaction between users involving information. Enhanced interaction means that users can access information from anywhere, using any devices. For instance, a user who is traveling will have access to information through his or her mobile device. The same user while sitting in his office will have access to information through his desktop. This transformative change implies that the information must be customized depending on the users' environment. E-learning 2.0 technologies have the capacity to build tools that allow users to interact with each other and information in a humanized, customized, and personalized way (Ramamoorthy, 2000). These technologies also can significantly enhance the way users access a particular educational activity. Activity formats can be personalized, based on educational appropriateness and learner preference, via deployment through web applications, mobile applications, audio or video activities, or even computer games and simulations. Tools that allow for this kind of personalization allow facilitators to address differences in adult learning styles.

To demonstrate application of this conceptual model, let us take another look at Cases 1 and 2 in which we now apply an e-learning 2.0-based digital operation model for each CE/CME scenario.

Case #3:*Continuing Medical Education E-learning 2.0 Activity*

During an Internet search on new medical advances, Dr. Ferrini discovers a web blog sponsored by Dr. Allgood at a university medical center. After joining the blog, he learns that Dr. Allgood and other experts at the academic medical center are conducting an interesting and lively discussion on the challenges they face in caring for patients.

The e-learning 2.0 system developed by Ms. Bates and Mr. Errez in the continuing medical education office allows the CME professional staff to monitor the content of the discussion blogs and reveals that many of the participants have very similar questions about the same set of issues. Based on this observation, Ms. Bates and Dr. Allgood decide to develop a web-based course activity anchored on the important content themes appearing in the blog, which they believe accurately reflect gaps between best practice established at the academic medical center and current practice out in the community.

Dr. Allgood then uses a literature integration software program to pull together related information from various scientific literature databases to create a strong evidence base for the CME course content. Dr. Allgood asynchronously works with several of his colleagues to revise the course information with an eye towards the potential (learner) audience. Ms. Bates (who provides instructional design expertise), manages the entire process to ensure that the revised course meets the appropriate quality guidelines. This expanded, evidence-based course content is then securely posted to the CME course website.

Dr. Ferrini is delayed at the airport late one night when he receives a text message from the CME office to his mobile phone announcing the release of a new online educational activity. Dr. Ferrini then accesses and completes the interactive, case-based module on his mobile phone. Dr. Ferrini also starts a forum thread to discuss with others application of the key elements of the case to his practice. Reflecting on this activity, Dr. Ferrini concludes that his educational experience was more meaningful than what he has experienced in the past, and he is particularly pleased that the course addressed several of his specific patient concerns. The e-learning 2.0 system developed by the CME office tracks Dr. Ferrini's course usage and awards the appropriate amount of CME credit to him.

Integrated Users

This case richly illustrates the benefits of having an integrated set of users and collaboration tools. Dr. Allgood and Ms. Bates were able to identify a key education need of the community based on the blog discussion. Dr. Allgood and his colleagues also were able to develop the course efficiently by working asynchronously with each other, and the system is aware of Dr. Ferrini's time and effort and is able to track and reward his learning activity.

Integrated Information

Using literature integration software, Dr. Allgood is able to pull together relevant information quickly from a large number of scientific literature databases to create a strong evidence base for the course content.

Enhanced Interaction

In this example, interaction is enhanced in multiple ways. First, Dr. Allgood is able to pull together quickly information from different databases. Then he is able to develop his course rapidly by working with others asynchronously. Ms. Bates is able to identify a key education need by monitoring the blog and can manage the course development activity asynchronously to ensure quality. Dr. Ferrini is able to participate in a discussion that enhances his educational experience, interact with the course from his mobile phone, and obtain the benefit of a course developed based on his specific clinical questions in the online discussion. The CME professionals are able to track Dr. Ferrini's leaning activity and assign appropriate CME credits to Dr. Ferrini.

Socio-Technological Barriers to Adoption of E-Learning 2.0 in CE/CME

Despite the exciting potential e-learning 2.0 technologies have for continuing educational of healthcare professionals, significant barriers exist that could interfere with their successful adoption. For purposes of discussion, these barriers will be categorized as either socio-technological or educational. In practice, however, the barriers are intertwined and sometimes difficult to untangle. If left unchecked, these barriers can create inefficiency and reduce adoption of e-learning 2.0 technologies. A useful framework for identifying these barriers is the interaction model (IM) of digital enterprises, which describes three types of interactions in a digital enterprise (Ramamoorthy, 2000). The first category of interactions is described as mechanistic or computer-to-computer interactions. An example of this type of interaction is website software interacting with a database for data access. The second category is mechanistic-individual or interactions between computer processes and individuals. An example would be a learner interacting with a website to complete an online course. The third category is mechanistic-team interactions, or those between computer processes and teams. An example of this interaction type would be a healthcare expert team working with facilitators or CME professionals to develop an online course. Using the IM model as a framework, we propose that the full scope of CE/CME transformation to a digital operation involves integration of a range of human interaction processes (Harrison-Broninski, 2005). Inability of organizations to address social, technological, and behavioral factors of the human interaction processes will lead to problems such as integration confusion. Integration confusion (Yeh, Pearlson, & Kozmetsky, 2000) occurs when incompatible e-learning 2.0 technologies are adopted (no sharing of information or users) and no organizational changes are made to accommodate these technologies. Consequently, organizations will find that the users and information linked with each e-learning 2.0 technology exist in functional silos, implying a lack of integration.

To avoid such problems as integration confusion, organizations should carefully and systematically modify existing policies and procedures to accommodate new e-learning 2.0 technologies. Enhanced interactions between CME professional staff, content experts and learners may require new skills for all participants who may be more used to traditional roles and educational models. Accurately identifying the new skills and behaviors needed to implement e-learning 2.0 technologies will require an additional level of analysis. For that purpose, we have classified socio-technological factors into three categories: (1) settings, which includes geographic and economic considerations; (2) people, which includes familiarity with and acceptance of such technologies in health care; and (3) technology, which includes challenges such as lack of a variety of infrastructure resources, data standards, proprietary issues, security, integrity, and privacy.

Settings

The specific work settings where users are found play an important role in the adoption and success of e-learning 2.0 applications. For example, e-learning 2.0 applications that are successful in an urban location may not work effectively in a rural location due to technology limitations and economic constraints. Questions about whether the available technological resources are able to support an application deployment platform will need to be answered before selecting the deployment approach.

People

Users' comfort level with technology and computer knowledge also plays a decisive role in the selection of an appropriate application. Studies have shown that lack of computer or information-seeking skills and lack of time often prevent physicians from engaging in Internet-based educational activities (Bennett, Casebeer, Zheng, & Kristofco, 2006). Sophisticated applications with complex interfaces are more likely to be accepted by technologically savvy users, while less sophisticated users are more likely to adopt simpler applications with easy-to-use interfaces. For some educators, the lack of technical know-how makes it difficult to design and deploy educational programs on the Internet. In other cases where collaboration technologies such as discussion forums have been tested, participation rates of healthcare professionals sometimes have been negligible, which may reduce the motivation level of educators who may otherwise employ them. People also must be open to the idea of granting access to information and sharing in ways that they may not be used to doing.

Technology

Technology factors, including lack of infrastructure resources, data availability, data standards, proprietary issues, security, integrity, and privacy play a key role in determining the complexity level of educational applications. For some educators, the lack of technical infrastructure is simply too overwhelming or burdensome to develop interactive applications. Integration of data and services must overcome issues such as legacy applications, incompatible interfaces, and proprietary limitations in order to provide effective continuing education. Integration of users overcoming issues such as diversity of locations, time factors, and technology access level also is a key factor in providing effective continuing medical education. The security, integrity, and privacy of data must be considered in determining the type of applications that can be deployed so that users can trust that their contributions, and in some cases their educational records, are safe and valued.

Educational Challenges to Adoption of E-Learning 2.0 Technologies to Continuing Education of Healthcare Professionals

While e-learning 2.0 presents many opportunities to enhance CE/CME education, it also introduces a number of educational challenges. Consider a web-based blog learning activity as an example. A user blogs on a health topic of interest. Another user finds the blog and comments on it. The first user synthesizes the comments, conducts some research on the topic, and responds to the comment on the blog. The discussion goes back and forth, with many other users joining in. Questions that could be asked on the activity include: 1) Does learning happen on the blog? 2) Is the learning happening in a structured format as in e-learning 1.0? While the answer to the first question is yes, learning happens, the answer to the second question is that it is not a structured activity. This dynamic and unstructured format of learning presents a number of challenges to CE/CME educators. We list a number of key questions below:

How Do We Measure Learning Needs and Outcomes?

Continuing education programs for healthcare professionals should be learner-centered, responsive to learner needs, and have meaningful and measurable outcomes (Davis et al., 1999). Use of e-learning 2.0 technologies provides educators with more sophisticated options in the design of educational content, based on the results of needs assessment. Traditional barriers to identifying learner needs through needs assessment have involved lack of time and difficult access to learners prior to program planning and design (Mazmanian, 1980; Moore & Cordes, 1992). However, most of these are based on the e-learning 1.0 paradigm (Grant, 2002; Norman, Shannon, & Marrin, 2004). The dynamic nature of learning with e-learning 2.0 presents new challenges in measuring learning needs and outcomes.

How Do We Maintain Quality Standards for Course Content?

A digital learning environment can lead to the rapid development of course content in response to identified learners needs. Maintaining rigorous quality standards for course content provides both a challenge and an opportunity for the continuing education professional. As the number of e-learning opportunities has increased dramatically in the last 5 years, the need for standards has become more clear (Ruiz, Mintzer, & Leipzig, 2006). A number of organizations have published standards for the development of e-learning, including the United Stated Department of Defense SCORM specifications (Fallon & Brown, 2003). Since e-learning 2.0 also occurs in places such as blogs and discussion forums, how do we ensure the quality of the course content?

How Do We Award CME Credit?

Continuing medical education credit is currently (and traditionally) awarded based on number of participant hours, with different states mandating various amounts of hours per year for re-licensure (Zeiger, 2005). When physicians participate in online learning for CME credit, most CME providers translate the number of hours the participant reports having spent on the activity into CME credit earned. This approach to translating learner activity into CME credits becomes problematic when e-learning 2.0 continuing education activities expand the range of learner behaviors to include time spent on internet searches and other self-directed learning activities. One example of an approach to address this challenge is the American Medical Association's Self-Directed/Self-Initiated (SDSI) Internet CME Pilot Project (American Medical Association, 2004). While professional associations recognize that this takes place, they have not yet been able to create a credit system that rewards the activity or behavior of facilitating the learning of others. In other words, continuing education accreditation standards have not yet caught up to technology as it relates to new models of learning.

How Do We Integrate E-Learning 2.0 with Other Traditional CME Offerings?

A question for researchers and program developers involves whether programs designed using e-learning 2.0 technologies can replace completely the need for more traditional CME activities. Are all learning needs effectively addressed with e-learning? Are all areas of the CME curriculum effectively taught by e-learning approaches? Can "e-conferences", for example, replace the need for live conferences, grand rounds lectures, journal clubs and other live events? Clearly, one advantage of e-learning approaches is their ability to create options for learners who may prefer live events but have real barriers involving time and place (Zeiger, 2005).

These educational challenges, like the socio-technological barriers described earlier, need to be addressed appropriately in order for e-learning to complete the transformation of continuing education of healthcare professionals to a digital enterprise.

Technology Framework: Service-Oriented Approach for Deployment of E-Learning 2.0 Technologies

Service-oriented-architecture (SOA)-based deployment may provide an effective technical framework for addressing barriers and adopting e-learning 2.0 technologies (Sadasivam, 2008; Sadasivam & Tanik, 2008). SOA provides a flexible, scalable, common, and convenient platform for integrating and consuming disparate data sources (users and infrastructure) (Newcomer & Lomow, 2005; Sadasivam, Tanik, & Kristofco, 2006). SOA also provides a pluggable framework for incorporation of organizational policies and procedures. Many commercial entities lead in the adoption of SOA-style deployment for transforming infrastructure into digital enterprises. Transformation with SOA is typically performed in phases, in which organizations first develop a consistent global strategy of deployment and then proceed with implementation in small, digestible chunks (Channabasavaiah, Holley, & Tuggle Jr., 2003). This development paradigm parallels our model of transforming continuing education, which involves building a seamless digital enterprise that advances in a gradual fashion.

SOA addresses socio-technological challenges of applying e-learning 2.0 technologies at three levels (Willig, Sadasivam, & Tanik, 2008). First, SOA provides a standard approach to the integration of heterogeneous data sources (sources with users and learning activity data). It also provides a flexible solution to configure and integrate the policies and procedures that are necessary to address the different socio-technological challenges. Finally, SOA provides a business-process-oriented approach to deploying targeted applications that address user needs. As business processes form a key lifeline for all organizations, deploying applications with a business-process-oriented approach allows the needs of an organization to be addressed in a systematic manner.

Two parts of SOA application development are the creation of services and the consumption of services.

Creation of Services

A service is defined technically as a location on the network that has a machine readable description of the messages it receives and returns (Newcomer & Lomow, 2005). A service provides uniform access to data sources. In this initial phase, services are developed for accessing the infrastructure resources by wrapping each heterogeneous resource with a service interface. The service interfaces describe the method of invocation, operations to be performed, the input format of the request, and the output format of the response. Other implementation details of the sources, including the type of data source and programming language of the data source, are hidden behind the service interface. Once the service is created, the data sources can be accessed and consumed through the service interface. Application developers are not concerned with the heterogeneity of the infrastructure resources. Instead, they deal with a homogenous service interface with well-defined rules for consumption.

Consumption of Services (Process-Oriented-Composition)

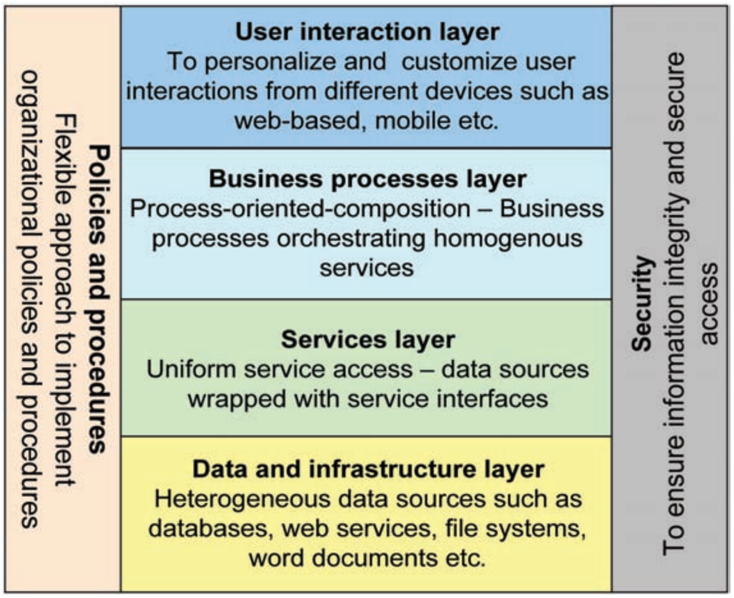
Once the services are created, application developers then build applications to request and consume the services. To avoid problems such as integration confusion, SOA recommends a business-process-oriented style of application development, with an emphasis on the consumption of services using business processes. Business processes can be implemented programmatically, as we are doing in our CME infrastructure, or using specialized business process languages, such as Business Process Execution Language or Business Process Modeling (Juric, Mathew, & Sarang, 2004; Pasley, 2005).

Figure 2 illustrates the layers of enterprise development with SOA. The base layer represents the heterogeneous infrastructure of an enterprise, such as databases, software, tools, and technology that a user would need to complete the task. The services layer represents a uniform layer of service interfaces that can be used to consume the infrastructure resources. The third layer is the business process layer or application layer. It represents the various applications of the enterprise that correspond to different needs. Finally, the top layer is the interaction support layer, which represents web-based or interaction tools that allow users to interact with the enterprise applications. On the left side is the policy and procedures layer, which represents a flexible layer to configure organizational policies across the layers. On the right side is the security layer to ensure secure access and storage of the organizations' information.

Towards E-Learning 2.0 Adoption: Example Implementation Approach

Our academic medical center has been developing and deploying e-learning applications for more than a decade. However, as with many other e-learning organizations, our infrastructure has often grown in response to the disparate needs

Figure 2. Layers of Enterprise Development with Service-Oriented Approach



of each new project. Over time, this sequence of non-strategic changes has made us inadvertently less efficient in achieving our long-term academic goals. Consequently, we recently have begun strategic development of several e-learning 2.0 initiatives that we predict will transform our unit into a more efficient, seamless digital enterprise. Two projects that illustrate our new approach to content development and delivery (or service creation and consumption) will be reviewed in this section. We begin by outlining and evaluating our efforts to address the infrastructure needs for deploying e-learning programs. The point-of-care CME program described next illustrates our efforts to identify specific challenges in the application of e-learning 2.0 technologies with an innovative point-of-care pilot study.

Example service-oriented approach for e-leaning 2.0 adoption: Reconstruction of CME infrastructure:
The CME infrastructure project addresses integration of our resources (users and information). The steps in the project follow the SOA approach closely.

Creation of CME Services

The first step in creation of CME services was to develop a data model to capture our users and course information. This step required that we analyze our existing projects, including the e-learning materials offered, the users list, the users' responses, and assessment protocol. Based on these results, we designed and implemented a data model that captures all the necessary information. A SQL database was used to implement the data model. We also created a service layer using Microsoft .Net technology to perform operations on the SQL database in a systematic manner. The creation of CME services enables us to deploy e-learning 2.0 activities integrating the existing users in our database. For users, this means the ability to traverse from one e-learning 2.0 application to another seamlessly without having to re-register or re-login. For CME professionals, this means being able to monitor the users' learning activities and award them appropriate credit.

Consumption of CME Services

In order to facilitate consumption of these services, we then created an online LMS system using Microsoft .Net technology. This gave us the capacity to develop new courses quickly and easily and deploy them through our three primary websites – the online continuing medical education site, the Alabama practice-based network, and the Mississippi practice-based network. The LMS has two parts. The first is an administrative interface that provides features to create courses collaboratively and asynchronously, and the second is a business process layer that makes it easy to consume the course. We are currently working on the development of a user-interaction layer to present the course on all the sites using the data from the business process layer. The user-interaction layer also will customize the course to other mediums, such as mobile phones or other portable devices. We also are working on adding discussion forums to the CME website to allow users to participate and discuss their questions with their peers and health experts.

While we have only started the work on reconstruction of the CME infrastructure, we will have an integrated and interconnected infrastructure on which to deploy new e-learning 2.0 programs once it is finished. We anticipate that it will be relatively easy to deploy new programs, leveraging the integrated infrastructure and not having to redevelop specific structures such as the database model and data access programs from scratch. The integrated infrastructure also will make it easier to personalize the learners' interaction with the education program. For instance, learners can interact using web-based or mobile devices depending on their preferences. In addition, we will be able to access a learner's data from one source instead of from several sources. A learner's data will provide a rich source to estimate the effectiveness of the CME programs and for data that is usable for program improvement.

Example modifications to educational policies: Point-of-care CME program

In point-of-care (POC) activities, physicians engage in an active search for specific information at the point of the patient encounter when a new condition or a clinical question arises(American Academy of Family Physicians). The significance of POC as a CME activity is the direct impact it can have on the quality of patient care (Ebell, 2003; Berkenstadt et al., 2006; Doran et al., 2007; King et al., 2007). Similar to other e-learning 2.0 scenarios, point-of-care learning represents a striking change in the way continuing education for health professionals is traditionally conducted and raises a number of challenging questions from an educational viewpoint. Some of these include questions about factors that motivate learners to access resources at the point-of-care, as well as questions concerning the quality of point-of-care learning encounters.

The learning activity website was designed for use during a five week period from July 16, 2007, until Aug 21, 2007, and contained resources for delivering effective clinical care for participating physicians (or the physicians' staff). Participants for this pilot study were primary care physicians from two practice-based networks that serve Alabama and Mississippi. The primary goal of the study was to identify a means of providing CME credit that would encourage physicians to participate in e-learning 2.0 activities and overcome barriers to such participation.

The pilot study was conducted in two phases of two weeks duration each, with physicians needing to complete a short questionnaire at the end of each phase in order to receive CME credit. Phase 1 awarded 4 CME credits for a minimum of 8 logins to the site and completion of the questionnaire by the user. During phase 2, users were awarded 0.5 CME credit every time they logged on, up to a maximum of 6 CME credits. A final questionnaire was required at the end of phase 2 to print the CME certificate carrying the CME credits that were awarded for usage of the website. All participants were eligible for the same incentives, which were advertised during the initial recruitment invitation. Benefits of participation included 24-hour access to the website and links to a collection of publicly available resources; a potential total of 10 CME credits for complete participation; a search feature for available topics within the site; and online access to an electronic therapeutics update subscription service. E-mail reminders were sent out weekly to registered participants, encouraging them to participate in the study and use the website in their practice.

The primary content area on the website was a list of 63 keywords and 188 links to the most common topics (Cancer, AIDS, women's health, etc), alphabetically ordered and linked to external websites that were either "framed" within the website or were placed as external links (in compliance with their web policies). The website was developed using the Content Management System DotNetNuke ("DotNetNuke Web Portal System") and included an SQL server database in the backend for capturing user data related to website usage.

A total of 24 CME credits was awarded in phase 1 of the study, and 24.5 credits were awarded for phase 2. The number of CME credit hours that could be claimed in phase 2 was higher by 2 credit hours, for a greater number of logons per learner, assuming that total time spent would be higher. While no conclusive data were found to suggest the relative effectiveness of one type of CME credit (partial or complete) over the other, the availability of credit appeared to be a highly effective incentive for participants.

Learners were asked about the factors influencing their decision to participate in the project. Results revealed an overwhelming majority of participants reported "free CME credits" and "convenience of on-line CME" as the major factors for participation in the study. The participant base was not completely new to on-line CME courses, with at least 7 of 9 users having had prior experience of 5 or more on-line CME courses. This might indicate that the participant base understands the advantages and convenience of on-line CME. Most of the learners suggested that they found the quality of the resources provided was 'excellent' or 'good.'

This pilot study clearly demonstrated that awarding CME credit was a motivating factor for health care providers to engage in point of patient care learning activities, although the amount of CME credit offered did not appear to be influential. Physicians were generally satisfied with the quality of the resources provided and reported that participation had an impact on their professional effectiveness. Lack of time surfaced as the largest barrier to participation, suggesting that e-learning 2.0 designers need to focus attention on displaying important information efficiently to make it salient to busy health care professionals.

CONCLUSION AND FUTURE TRENDS

This chapter has advanced the argument that e-learning 2.0 technologies have tremendous potential to dramatically change the landscape of continuing education programs for healthcare professionals. E-learning 2.0 technologies can be viewed as a type of disruptive innovation that will change fundamentally the way professional health education programs function, by adopting a user-centered approach that emphasizes interactivity among all participants. As the examples in this chapter illustrated, e-learning 2.0 cannot be applied successfully without carefully modifying existing continuing healthcare education learning and business models to accommodate the transformative changes. We have described a futuristic model of continuing education for health professionals following a transformation into a digital enterprise. While it is clear that e-learning 2.0 technologies have the power to simplify the process of interactive knowledge creation, management, and dissemination, they need to be deployed based on sound strategies to enhance the educational experience of the participants. A service-oriented approach of technology adoption has been presented, along with a discussion of the need for educational changes to address the manner in which e-learning 2.0 programs can be assessed and credited.

ACKNOWLEDMENT

We would like to thank Gayathri Sundar (Software Engineer, Infinity Insurance) for her assistance with creating Figure 1. We thank Dr. Murat Tanik (Professor, Electrical and Computer Engineering, UAB) for his thoughtful review of the chapter. We also thank Dr. Chittoor V. Ramamoothy (Professor Emeritus, University of California at Berkeley) for his overall guidance with digital enterprises. Finally, we are appreciative of the support and encouragement we received from Jeroan Allison (Assistant Dean and Director, CME, UAB) throughout the duration of this project. We would like to thank Susan Chandler Walker and Laura Gallitz (Administrative Assistants, Division of Preventive Medicine) for proofreading our chapter.

KEY TERMS AND DEFINITIONS

Adult learning: A relatively new area of study, the term "Andragogy" initially popularized by the original work of Malcolm S. Knowles. Knowles postulated that adults are autonomous and self-directed learners, practical, goal-oriented, and are guided in their learning by previous life experiences and prior knowledge

CME or Continuing Medical Education: Continuing professional development of physicians that is required by each state for keeping up with advances in medicine and with changes in the delivery of care. A variety of CME providers exist, including the American Medical Association, state medical associations, medical specialty societies, most academic medical centers, etc. CME formats vary depending on provider, audience and special needs of the physicians

Disruptive technology or disruptive innovation: A technological innovation that improves a product or service in ways that the market does not expect, typically by being lower priced or designed for a different set of consumers. The term was first coined by Clayton M. Christensen in his 1995 article Disruptive Technologies: Catching the Wave

Digital enterprises: Enterprises whose operations are predominantly electronic. Can also be referred to as Service enterprises or electronic enterprises.

E-learning 2.0: The ability to access socially and dynamically, create, and share knowledge in a multidimensional, instantaneous, collaborative, and interactive manner

SOA or Service-Oriented-Architecture: A style of design that guides all aspects of creating and using business services throughout the development life cycle. The SOA lifecycle runs from the conception of the business service to its retirement. A service is defined technically as a location on the network that has a machine readable description of the messages it receives and returns.

Human interaction processes: Are business processes that are human driven rather than machine driven. Humans participate in and influence the execution of the processes. Keith Harrison-Broiniski describes the unique characteristics of human interaction processes in detail in his book "human interactions: The heart and soul of business process management."

Point-of-care access: Situations in which physicians engage in an active search for specific information at the point of the patient encounter when a new condition or a clinical question arises.

This work was previously published in Handbook of Research on Practices and Outcomes in E-Learning: Issues and Trends, edited by H. Yang and S. Yuen, pp. 308-328, copyright 2010 by Information Science Reference (an imprint of IGI Global).

ABSTRACT

This chapter presents an abstract view of the regional health information networks (RHN). A presentation of the architecture and structures of the RHN is included. It also reveals the need for integration of information in the framework of a RHN and key issues for the applicability of health information standards to achieve interoperable health care organizations which are the stakeholders of the RHN are presented. Furthermore, a list of case studies for the implementation of RHN in health systems in European, as well as non-European countries, such as the U.S., Canada, New Zealand, and Australia are demonstrated. Finally, important areas to focus when evaluating RHN are described. The authors hope that the abstract view of RHN would assist in the understanding of the key areas when building regional health networks.

DOI: 10.4018/978-1-60566-356-2.ch008

DEFINITION OF RHN

Since 1990s, the regional innovation systems gain the focus of researchers and policy makers as the framework for financial development in regional level and generally for innovation policy making. The territorial dimension of regional systems remains ambiguous, along with the role of actors in those systems. The regional health network offers health care services in a region through efficient administrative organization of health care providers in region and by means of regional innovation systems like the information systems, eHealth tools and services.

The definition of regional systems should start with the definition of the region. The literature is ambiguous on the nature and characteristics of the regional innovation systems (Doloreux & Parto, 2005). The term region has sometime the same meaning with the administrative regions or divisions of country. However a regional health network does not always correspond to administrative regions. The regional structure is also ambiguous, where the providers can be public or private companies and their collaboration is diverse depending mainly on the scope of the collaboration.

According to Oates & Jensen in (Oates & Jensen, 2000) "A health region is the geographical area where most health services are provided to the inhabitants in the area, and in which area the patient typically receives almost all of the health services they need." Following this definition in many healthcare regions the population may reach the 0,5 million or more.

Additionally, according to Grinten & Jarvis in (Grinten & Jarvis, 2007) "a Regional Health Information Organization is a multi-stakeholder organisation that enables the secure exchange and use of patient health information among clinicians and caregivers to improve the delivery, efficiency, quality, and safety of patient care."

Generally the new area for development of regional health networks follows the need for active involvement of patients in the decision making process regarding the health services or knowledge about health and quality of life. The eHealth tools and services, the World Wide Web and other information system and communication tools facilitate these needs.

The healthcare providers in region are mostly the following (Oates & Jensen, 2000): (1) Primary care providers, (2) Secondary, Tertiary and specialised hospitals, (3) Pharmacies, (4) Laboratories and diagnostic centers, (5) Specialists, (6) Other healthcare providers, and (7) Home care providers and midwife services

The aim of the regional health networks is the sharing of health care information among the healthcare providers in regional, national or cross-border level. The factors that define the degree of development of those networks are the organizational structure of health system, the need for information flows according to the organizational structure and the penetration of ICT in health.

HEALTH INFORMATION NETWORKS: ARCHITECTURE AND ORGANIZATIONAL STRUCTURE

There is a wide variation on how the ICT facilitate the organizational structure of RHN and the sharing of information either patient information or administrative and financial information. The organizational structure of a RHN provided by the health policy makers, determines the possible data owners and the ability to achieve interoperability among the stakeholders of a RHN determines the architecture of the information system that supports the RHN. The models for the architecture of RHN can be an abstraction of the architecture models of the Health Units. The systems that support the health units can be categorized in three models: transactional, federated, centralized depending to their ability for health information exchange with other health care providers, individuals, patients etc.

The participation of stakeholders in a regional system depends on the implementation of an interoperable health information infrastructure. The main barriers to achieve the interoperable infrastructure and facilitate the information sharing are the patient matching and legal data sharing agreements.

According to Wilcox et. Al. in (Wilcox et al., 2006) and the experience from the case studies of Health Information Networks, the architecture approaches for an interoperable health information infrastructure in an organization are (Thielst & Jones, 2007):

Transactional Model

The transactional model is characterized by the fact that the architectures supporting the stakeholders are separated systems. The communication among those systems is achieved through telephone, fax and other means especially facilitating the personal communication. This type of health information exchange is the most common even nowadays and especially for clinicians. However this approach requires little changes in the healthcare provider to participate in the healthcare exchange environment. The patient is often the "carrier" of this information.

Centralized Model

In this case, the systems supporting the healthcare enterprises are centralized. The model implied systems supporting the RHN to be centralized or even monolithic. Their implementation is based on a central data repository for the health information that is exchanged. This approach requires having shared data among disparate systems using tools and methodologies for interoperability among those systems. Interoperability issues that are key factor in achieving data sharing through this model include the common data vocabulary, standards for technical, semantic and functional/business integration, legal issues regarding the ownership of data, cost investment on integration solution's provider and coding and classification.

Federated Model

The model includes systems that are integrated through several mechanisms like notification of information exchange, context synchronization on multiple data sources according to the user selections etc. The model is characterized by data sharing environments that healthcare providers can exchange information without having a central data repository. According to this model the users, like clinicians, of the health information systems, like clinical information systems, may view several systems and access several data sources in a RHN when technology enables interoperability among several data sources. This model is convenient in use for the providers that are already familiar with systems that are already functioning. Additional the cost of change to build an integrated RHN environment may be less than that of a centralized one as it is not required to build central data warehouses or replace applications from the health care providers, which the users are already familiar with. Moreover legal issues regarding keeping a central data warehouse with sensitive patient data are not raised as each participating organization can keep his own datasources.

Many case studies implement the federated model, while other the centralized one. In both cases a key issue is the patient identification and matching algorithm, as the patient data are the information that most RHN aim to share among its stakeholders.

Organization and Industrial Impact

The organizational models of RHN are several depending mainly on the stakeholders for their financial investment. The most common models are the following:

- *Non-profit public model:* the public organizations are characterized by the RHN authority which is under its director. The director can be either elected by the RHN authority members or is assigned by the government or the Ministry of Health. The income for the RHN can be benefit from taxes, or grants from hospitals or Ministry of Health or grants from other stakeholders of the RHN.
- *For-profit corporations' model:* For-profit organizations may serve the region with medical services, IT services, or other. The for-profit-organizations may receive a return of their investment through payment for the health care services in region. Examples could be insurance companies or other companies that outsource services for the region for example the e-procurement for the hospitals, educational services

Table 1. The 18 services in a RHN as mentioned in Oates J. & Jensen H. (Oates & Jensen, 2000)

Clinical Services	**Health Services**	**Administrative Service**
Clinical Messages	Surveillance information	Reimbursement
Clinical E-mail	Yellow Pages	*Electronic commerce*
Clinical booking	Professional guidelines	Patient id
Shared Records	Disease quality management	Resource management
Care protocols	Public health management	
Mobile and emergency	Continuing professional development	
Home-care monitorin		
Telemedicine		

in ehealth portal, home services etc. The stakeholders that participate to the non-profit corporation elect their directors.

- *Governmental district or authorities:* local governmental agencies that are settled with the government district authorities and are mostly governed by public officers or local board of advisors. The organizations' rules and services are described by state laws. The financial investments come from taxes or state's general fund.

The IT companies support with eHealth application and tools the model described above. The challenge is to provide reliable solutions for the eHealth services of any kind of RHN organizational model.

THE NEED FOR INTEGRATION

Information flows and Services in RHN

The information flows in a RHN can be divided into:

a. Clinical/patient information
b. Health information
c. Administrative information

Sharing information is the key concept for every RHN. The information flow in a RHN depends on health policy of a country, which also determines the structure of the RHN. In most of the cases the basic information flow is the patient and the clinical/patient information. In such cases the participants of the RHN need to share the patient information in the region. Examples of such cases can be the Integrated Electronic Health Patient Record (implementations are described in the paragraph "Case Studies"). In other cases the scope is to share the administrative information. In many of such cases the participants need to share the financial data to succeed reduction of costs of health services in region. Examples of such cases can be the e-Procurement projects in Germany etc (implementations are described in the paragraph "Case Studies").

The services provided in a RHN, according to Oates J. & Jensen H. in (Oates & Jensen, 2000), are those described in Table 1. This clarification of services is hardly the first attempt to record the services that could be provided by a RHN in 1990-2000. Based on those services, important project for regional networks has been developed like the PICNIC project (Saranummi, Piggot, Katehakis, Tsiknakis, & Bernstein, 2005) and other.

Based on the services described in Table 1 are built most of the Regional Health Networks. The only important advancement concerns the services in italic which are the clinical messages/

clinical email and the electronic commerce. The services for providing the clinical messages/clinical email among the healthcare providers has evolved in many cases to services provided clinical information through shared data sources and are facilitating by tools offered by the world wide web for the healthcare providers and the patient as well.

The services for electronic commerce has enriched with the services of e-procurement to facilitate the material management in the healthcare organizations.

Patient Identification & Matching

The implementation of clinical/patient information flow to provided services in a RHN is a key issue to succeed the scope of sharing information and ultimately improve the provided services. To succeed clinical/patient information flow, accurate patient identification and matching in the data sources of the RHN is required. In Hospitals or health units, patient identification is accomplished with the Master Person Index (MPI). In RHN, where several data sources often from many enterprises with patient information have to be integrated, the patient identification is accomplished with the Enterprise Master Patient Index (EMPI). There is great difficulty to achieve patient identification and matching with the MPI in unit level as well as to achieve patient identification and matching with the EMPI in regional level. There are several techniques that implement algorithms to patient identification and matching, the most common used are the deterministic matching, ad hoc scoring/ matching, probabilistic algorithm. According to the model of the structure RHN and subsequently to the data model used in the RHN the appropriate algorithm is used.

The model of data storage can be centralized, federated or hybrid:

- **Centralized data model:** Patient information is kept in a clinical data repository/data warehouse centrally. The data warehouse may contain clinical as well as other information like administrative. Legal issues may rise when the patient data are kept elsewhere from the data sources that are created from.
- **Decentralized/federated data model:** The data is physically stored in the participating organization in a RHN and the health information exchange among them ensures the sharing of information. The data may adhere to a standard of data representation to enable sharing information. The original data sources are kept intact in the hospitals.
- **Hybrid data model:** It is an aggregation between a centralized and decentralised architecture. The data may be physically stored and managed in a central location but the data is logically separated into data sources for each organization that contributes data. On the opposite the data may be physically stored in the organization, and managed centrally as a virtual data warehouse.

The ultimate scope is the accurate patient matching.

Health Information Standards: Key Issues in RHN

The implementation plan for an RHN has to accommodate also integration techniques with the usage of interoperability methodologies and standards.

According to the European Interoperability Framework for Pan-European eGovernment Services the definition for interoperability is as follows (IDABC_EIF, 2004), "Interoperability means the ability of information and communication technology (ICT) systems and of business processes they support to exchange data and to enable the sharing of information and knowledge."

The levels of interoperability for building integrated systems are:

- **Organizational interoperability:** This level aims in the determination of business objectives and the conformity of business processes so that the collaboration of services and administrations is achieved even when they have different internal structures and processes. It concerns the interoperability of business processes inside an organization or among organizations that collaborate.
- **Semantic interoperability:** Interoperability at this level aims that the information that is exchanged and has the same meaning from every recipient. In order to achieve interoperability in this level it is important to implement: (1) data integration, (2) functional integration and (3) presentation integration.
- **Integration at technical level:** This level includes all the technical matters for the exchange of information and the interoperability of information systems and services.

In order to achieve integration in RHN, integration techniques should apply to all levels to have interoperable stakeholders within the RHN. The integration in regional systems for all levels can be further analyzed as follows:

- **Organizational level:** Synchronization of business processes for the communication of organizations/stakeholders at regional level.
- **Semantic level:** Common Information model for the region that contains the meta-data needed for communication.
- **Technical level:** Customizations of systems and adherence to standards for the communication and the common services at organizational level.

On the other hand, the standards for interoperability are several. There are no rules or methodologies regarding the appliance of standards along with the needs for integrating systems.

The standards can be distinguished in the following categories:

- Standards for the communication (e.g. EDI, HL7, IEEE MEDIX, DICOM)
- Standards for the representation of clinical and other data (e.g. *open*EHR technology, CEN ENV 13606-2, HL7 version 2.x messaging standard, HL7 v3 Reference Information Model, HL7 Clinical Document Architecture (CDA), Good European Health Record (GEHR), coding standards: ICD, ICPC-2, Read Codes, SNOMED, DRG, ATC, LOINC)
- Standards for the identification
- Standards for data safety and safety for medical data

The structures of Regional Health Networks are building following one of the model centralized, federated, and transactional as mentioned in previous paragraphs. The centralized, federated and hybrid data model and the EMPI for accurate patient matching along with the models for RHN structure can be aggregated in Table 2. In the cells of this table there are the most important standards that have to be adapted in order to achieve interoperability among organizations e.g. for a RHN with centralized structure and centralized data repository the most important standards are those for communication and data safety.

Studying the experiences of RHN (National_EHealth_Transition_Authority, 2006), (S. Spyrou et al., 2005), (S. Spyrou, Bamidis, Maglaveras, & Vartzopoulos, 2006; S. Spyrou, Bamidis, Maglavera, Pangalos, & Pappas, 2008) some key requirements were identified for the applicability of standards for integration especially the standards for data representation. The requirements are listed in Table 3.

Table 2. RHN structure, data model and standards for interoperability development

Data Model				
		Centralized	***Federated***	***Hybrid***
RHN Structure	***Transactional***	NA	NA	NA
	Federated	Standards for Communication Standards for data safety	Standards for Communication Standards for data safety Standards for data representation Standard for the identification	Standards for Communication Standards for data safety Standards for data representation Standard for the identification
	Centralized			

Table 3. Key requirements for applicability of standards for data representation

1.	**Comprehensive support for representing full range of data content, especially for medical documents**
2.	Vendor and Technology infrastructure independence
3.	Compatibility with well known other standards for communication, safety and security etc
4.	Supports of the incorporation of existing coding sets and standard terminologies
5.	Supports of structured and non-structured data content
6.	Supports versioning of data content
7.	Communication based on established service/message formats
8.	Ability for content management and content enrichment
9.	Translated content to several languages
10.	Supports for the evaluation of data quality metrics especially for processes including data flow
11.	Acceptability by communities / alignment to national standards
12.	Cost of implementation based on existing infrastructure
13.	Cost of implementation when existing systems are legacy systems
14.	Supports safety and privacy rules especially in data flow processes
15.	Supports access control management
16.	Supports requirements risen from other legal issues

On the other hand, the risks encountered developing interoperability projects to build RHN structure are listed in Table 4 (as described in (S. S. Spyrou, Berler, & Bamidis, 2003))

CASE STUDIES OF HEALTH INFORMATION NETWORKS

The examples that are reported in the next paragraphs are mainly good practices of work of last five-year period as well as work that is reported in various studies of eHealth projects. The trend nowadays is about the provision of integrated health care services to the citizens. The ehealth applications that are implemented for this purpose are the use of Electronic Health Record (EHR), the clinical databases, electronic referrals, electronic orders, eBooking, ePrescribing, the home care systems and other networks for the provision of health services or telemedicine.

Table 4. Risks in RHN's interoperability projects (as described in (S. S. Spyrou, Berler, & Bamidis, 2003))

Risk	Description
Annotated database schema missing	Lack of a comprehensive database schema significantly reduces the successfully reverse engineering of the database schema
Database schema contents not interpretable	The names and consequently the relations used in the schema are unclear or ambiguous
Database tables not used as described in the database schema	Database table usage has drifted away from the logical or semantic design.
Free text fields used for structured data in an ad hoc fashion	Free text fields are using to store structured data.
Inconsistent use of enumerable data types	Strict adherence to the reference tables
Required data not present	Data required according to the database schema but are found to be null in the tables. The database schema does not reflect the current structure of the database
Semantic analysis of data	Data fields does not contain semantically valid data
Character set encoding problems	There are problems with the character set encoding in the database.
Technical risks	
General Interface to access database system	Open interfaces to access the Information Systems' databases are not available.
Proprietary operating system	The database system runs on operating systems that are not open or widely known (e.g. Not Windows, Linux, Unix, or VMS)
Database not accessible	It is impossible to logon to the database.
Exotic communication protocol	The platform on which the database runs requires can only be connected through a non-TCP/IP communication protocol.
LAN not reachable	The LAN on which the pilot system is connected to cannot be reached from outside the LAN due to security matters and other reason.
Instable or failing computing environment	The computing environment is instable or failing causing the pilot system to malfunction
Organisational risks	
Not enough competent staff	IT staff is not qualified or inadequate in quantity.
Lack of individual co-operation	Individuals in the organisation are reluctant to co-operate.
Rules and procedures	Rules and procedures are becoming an obstacle or slow down progress especially in public services
Lack of decision making	There are no decision makers that can put the project in progress.
Lack of software vender support	Software vendors that need to assist do not do this.
Software vendor sabotage	Software vendors are actually sabotaging the project out of commercial interests.

In the **United States America**, the National and Regional Structures of Information of Health (National and Regional Health Infrastructure: NHII) (Dykes & Bakken, 2004), (Poon et al., 2006) has the objective to facilitate the exchange of information and improve the provided health care services and public health through the use of technologies, tools, models and applications. Programs for the exchange of health information and the implementation of Health Networks in the USA, can be mentioned such as: the network of information of health of Delaware (Delaware Health Information Network - DHIN), the Network Veterans Health Information Systems and Technology Architecture, the incident reporting system NYPORTS and other.

In **Canada**, the Canada Health Infoway is a federally-funded, independent, not-for-profit organization which invests with other collaborators of public sector to accelerate the use of Electronic Health Records across the country. From 2001, Infoway has run over 100 programs, delivering solutions of electronic health records (EHR) in the Canadians. The main objective of work is the encouragement and acceleration of growth and adoption of electronic health information systems with the compatible models and the technologies of in pan-Canadian base. The initiative for the growth of interoperable, safe pan-Canadian Electronic Health Record (Giokas, 2005), constitutes a septennial program aiming by the end of 2009 to provide to the 50% of Canada with the basic elements of the EHR.

In Australia the National Health Information Agreement (NHIA)[1] is an agreement between the Australian Government and state/territory government health authorities, the Australian Bureau of Statistics, the Australian Institute of Health and Welfare (AIHW), the Health Insurance Commission, and the Department of Veterans' Affairs. The NHIA constitutes the framework for the coordination, collection and distribution of health information technology in Australia as well as the maintance of national health data standards. The National E-Health Transition Authority[2] (NEHTA) a not-for-profit governmental company to develop better ways of electronically collecting and securely exchanging health information. NEHTA proposed a framework for the identification of health care providers (HPI) and patients (IHI). Since 1987 the AIMS and AIMS-2 systems (Stroetmann, Thierry, Stroetmann, & Dobrev, 2007) have been developed and are incident reporting systems. Up to 2002, 2000 accidents have been examined. The penetration of health information systems in the society of Australia incorporated very early. About the 90% of general doctors of Australia use software for the medical information of patients, while most Australians have access via internet in various health services.

In the New Zealand the establishment of national strategies Hospital Act 1957 and Cancer Registry Act 1993 aimed at the collection of health information in national level. The team that constitute the New Zealand Health Information Service (NZHIS)[3], that functions under the Ministry of Health, is responsible for the collection and distribution of health information at national level. Some of the databases that are maintained at national level are: (1) National Booking Reporting System that contains information for the the waiting of patients for care and treatment (2) Primary Health Organization Enrolment Collection which is the national collection with the data of Primary Health Care Units and (3) National Health Index that is a database of unique Patient Identifiers that is the National Health Index Number.

In the United Kingdom, from 1998 the NHS recognized the important role of Information and Communication Technologies in the health and "Information for Health" (IFH) (The_Department_of_Health, 11 June 2002) determined the strategic planning for the use. In the frame of National Health System the NHS Direct has been built. The NHS Direct has two departments the NHS Direct Call Centers and the NHS Direct Online (NHSDO).

The NHSDO was developed in 1998 in order to provide the citizens information on the health via internet. It is a web portal that provides information of health like diets, way of life and health, health services etc. For further information the portal[4] is connected to a telephone citizen contact center the NHS Direct Call. The two systems, the NHSDO and the telephone centre NHS Direct Call, function on a twenty-four hour base. The visitors of the web portal have been about 1.5 millions in 2000 and, according to forecasts, will be about 24 millions by 2008.

An important application in the Hospital Wirral of NHS Trust (Stroetmann, Thierry, Stroetmann, & Dobrev, 2007) includes the application of CPOE in the medicine prescribing process. Another important projects are the IHE - Integrated Healthcare

Enterprise initiative, the Chelsea and Westminster Hospital NHS Trust - ePharmacy, the National Reporting and Learning System and other.

An important project that was developed in Scotland was the CHIN - Community Healthcare Information Network. In this project a regional health network for the geographic regions of the Scotland. In this network several organizations participate and provide their services under a common frame for communication and common data structures. Each organization maintains is independent, is responsible for the maintenance of information but the data structures are indicated by the organization SHOW - the Information and Statistics Division of the National Health Service.

In Denmark, the health care system is decentralised. The central vision is the development of a common model for shared clinical data. The Danish Health Network Medcom[5] aims at the electronic communication among the health care providers ensuring the collaboration of organizations of the private and public sector. The Medcom network began in 1995 aiming at the electronic collaboration among the health care providers in national and regional level. The network that was developed allows the exchange of information via the reliable exchange of data with EDIFACT or other XML-based messages. The electronic exchange of messages is implemented in the following cases: patient referrals from general doctors to Hospitals, prescriptions for diagnostic examinations, reports of examinations, discharge letters, and refundings. More than 3.500 hospitals, pharmacies, providers of home health services, general and special doctors are connected in the network, while in 2001 more than 2.5 millions electronic documents are exchanged per month, which is more than half of the prescriptions in Denmark (Lippert & Kverneland, 2003).

Denmark has also participated in projects that are best practices for Regional and National Networks like the Baltic eHealth network, the networks Health Optimum and Sundhed.dk - The Danish eHealth Portal and other (Stroetmann, Thierry, Stroetmann, & Dobrev, 2007).

In Holland the BAZIS project (Kuhn & Giuse, 2001), (Bakker, 1990) began as an experimental governmental program and has developed in a not-profit organization for Hospital Information Systems (HIS) in the Netherlands. The development began, experimentally, in Leiden University Hospital from the Dutch government in 1972. Till now, it is a well developed HIS that is used by more than 45 Hospitals in the country which cover the 35% of beds of intensive treatment. It is remarkable that so that in order to give priority in the service of patients, the system initially did not support the processes of the economic and administrative department that was, however, added later. The system supports completely the processes in clinical department.

In France the project that was selected between the 10 best practices in the study of eHealth impact (Stroetmann, Thierry, Stroetmann, & Dobrev, 2007) is the "ELIOS-a comprehensive EPR system, and Prométhée, a sophisticated search meta-engine", which was developed in the hospital centre Institute Curie. ELIOS is an electronic patient record system (EPR), in which all that provide health services to the patient can gain access. Moreover, with the ELIOS functions and the system Prométhée that is a meta-search engine for the ELIOS and a meta-search engine in the databases of Hospitals that belong in the Institute Curie or in other clinical databases.

Also the project Bioserveur, is a centralized platform for the management and exchange of laboratory examinations and reports that concern the general doctors. Till today 45 general doctors participate and roughly 250.000 files are exchanged monthly, while this solution is used widely in the region Rhône Alpes of France. France has developed many projects including the use of e-health tools in regional health networks such as the COHERENCE, Teleif, Oncolor, RIPAM, the network REIN and other.

In Finland, the project Healthnet (Stroetmann, Thierry, Stroetmann, & Dobrev, 2007) was developed for the implementation of regional health network in the region of North Karelia in Finland. The network includes e-health solutions for integration of health units of the Primary and Secondary Health System. 15 Health Centres are connected to the network and 1340 stations in the region. It allows the storage and exchange of patient information safely and facilitates the communication of the personnel and the patient. It also includes the electronic referral of patients and the teleconference among health care providers regarding patient information and specifically the radiographs. The project contributes to the reduction of costs be means of electronic storage and electronic signature of medical documents.

Many other important ehealth projects implemented in Finland like the UUMA (Stroetmann, Thierry, Stroetmann, & Dobrev, 2007) project, which implements the electronic patient referrals and interactive teleconference in region, and constitutes one of the biggest regional networks of images and examinations of PACS in the world as well as a system for the follow-up of patients with chronic diseases via the internet or other mobile units.

Finland has participated in the implementation of other successful projects for the regional health information networks such as Baltic eHealth, the PICNIC (Saranummi, Piggot, Katehakis, Tsiknakis, & Bernstein, 2005) and other.

In Germany the project which is included in the best practices according to the study in (Stroetmann, Thierry, Stroetmann, & Dobrev, 2007) is the "MedicalOrder®Center Ahlen (MOC) – supply chain optimisation". The MedicalOrder®Center provides to the Hospitals and to other health units logistics services in a region in a range of 300 km. The center provides administrative and financial services in order to support the procurement supply chain. It includes a prototype information system for the storage of hospital materials and the supply chain in Hospital in order to reduce costs. The MOC center supports the intensive units of St. Franziskus Hospital Munich and actually is the e-procurement system.

The work, also, "GesundheitsCard Europa (GCE), access to healthcare abroad D/NL/B", concerns the national card of insurance of health that circulated from the AOK Reinland in 2003. The card of social insurance concerns the electronic form of paper form E111 that the citizens use when they travel outside from their country. The application that supports the GCE service is the multilanguage web site: http://europa.aok-tk.de. Through the access to this site the personnel of 14 hospital in the Netherlands can simultaneously confirm the actuarial situation of patients as long as they have the GCE card. Also the compensations can be completed at about 3 months in collaboration with the insurance companies in the Netherlands.

The project MuM - Δrztenetz Medizin und Mehr is a network of about 60 general and specialized doctors in the Bónde Hospital, North Rhine Westphalia.

The network supports a surgery for treatments that are not covered by the established policies of insurance companies, a central surgery and a telephone centre of service. It has also been imported the card of health of patient for the storage of elements of electronic file of patient and the direct access of doctors in the elements of patient.

In Greece many eHealth projects have been implemented. It is important to mention the implementation of European work PICNIC (Professionals and Citizens Network for Integrated Care)(Saranummi, Piggot, Katehakis, Tsiknakis, & Bernstein, 2005) . The project began in 2001 with participating countries Denmark, Finland, France, Greece, Germany, Iceland, Ireland, Holland, Spain, Sweden and United Kingdom. The objective was the preparation of the regional health services' providers to a new, friendly and secure regional network for the patient care and the continuity of care in all European territory.

The information flow within the network can be distinguished in three categories: (1) information for the administrative services and electronic trade, (2) for the public health services and (3) for the clinical services and the services of telemedicine. The architecture of project was supported by the use of systems of open architectures.

Greece has also participated in the implementation of other important eHealth projects as the CHS (Maglaveras et al., 2005) - for the health home care services -, the PANACEIA iTV (Maglaveras et al., 2003) - with application of interactive TV for the home care services and other.

EVALUATION OF RHN

Evaluation of RHN has the purpose to define and measure quality dimensions of the provided health services. There are not many implementations of projects evaluating quality of regional health care systems. Additionally, it is a complex task, as the goal of the RHN and consequently its structure and its characteristics are not standardized and different among the various implementations.

Along with the scope of building a "virtual" environment for sharing data and knowledge through the use of IT tools and techniques, evaluation on the quality of data and information that is exchanged should be planned.

Additionally a list of other issues besides the IT technologies should be examined in an evaluation plan of a RHN (S. Spyrou, Bamidis, Maglavera, Pangalos, & Pappas, 2008). The main areas for evaluation could be:

- **Financial management:** The measurements aim at the financial benefits in a regional structure of the health system such as reduction of costs (administrative and operational), reduction of hospitalization times, and management of waiting list in tertiary hospitals and exploitation of resources in primary health care system.
- **Human resource management:** Evaluation on the number of staff needs to support the health units and organization in a regional environment which may lead to reassignment and reorganization of personnel or even business processes and organizations workflow.
- **Workflow management:** Evaluation of the structures and business processes of a RHN may lead to decisions for changes in business process and consequently to workflow changes in the region e.g. reorganization of processes in laboratories for resource and cost management, paperless communication and elimination of bureaucracy etc
- **Clinical care measures:** Quality measurements for clinical care can include reducing admissions/transfer of patients, reducing adverse drug events (ADEs), disease surveillance and other.
- **Utilization/facilities management:** Evaluation of the utilization of services and structures is also of great importance such as average inpatient length-of-stay, laboratory, radiology costs and structures and other.
- **User satisfaction:** This area for evaluation is very important for the development or regional networks and especially for the acceptance of health care IT systems. The user satisfaction evaluation dimension can lead to results for usability and usefulness of IT systems supporting the RHN.
- **IT management:** Quality evaluation for the IT tools and services that supports the new age of regional healthcare systems should be developed. Metrics like safety, reliability and other are important for the IT structures and the user acceptance of the new systems.

CONCLUSION AND FURTHER RESEARCH

In the previous paragraphs, the key areas when building regional health networks were presented. The Regional Health Networks constitute the new area of organizational structure in health care domain with the main aim to lead the collaboration among several stakeholders in the healthcare regional networks and make the patient health information electronically available. These organizational and structural developments of the health care domain can help to the following:

- Improvement of quality of patient care with the involvement of patient as a user to the health services and with ensuring the patient care continuity. Examples of the improvement of quality include the assessment of medical errors, shorter clinical workflow processes and patient pathways and other.
- Control and reduction of operational and administrative costs in the health services in the region with for example fewer duplicate and unnecessary tests.
- Interoperability among the stakeholders to facilitate operability and develop the framework for real-time access to health information and medical record.

The weakness of the development of RHN so far can be distinguished to the following:

- There is no standardized patient identification and matching algorithm across multiple systems.
- The effort to achieve interoperability has as a prerequisite the continuing funding of the IT services. Additionally the implementation of interoperability framework may cause changes for the users of the Health Information Systems, which may cause frustration.
- Privacy and security mechanisms for the shared health/patient information are still developing in the several RHNs (L. O. Gostin, 1993).
- Funding of the newly introduced RHN's services should be consistent.

Further research in the area could include the expansion of the Patient Health Record following the implementation of Enterprise Master Patient Index (EMPI) in the region (Mandl, Kohane, & Brandt, 1998). The refinement of clinical workflows along with the administrative workflows in the several stakeholders can lead to the continuity of patient care and the refinement of the consultation system for the professionals in the area. The collaboration of physicians with the use of eHealth services can improve the services. The home care health services seem to expand rapidly especially in the health regions. At last the implementation of a National Patient Information Network can be built over the Regional Health Networks.

The Regional Health Networks are the new area of organizational structure in health care domain. The eHealth tools and services are actually the implementation mechanisms of the structures of RHN. The eHealth is actually connected with the notion of integration. The ultimate scope of RHN, through the sharing of information among several organizations, is the improvement of quality provided health services and the control of expenditures for the health system.

Chapter 8.10

Introducing E-Procurement in a Local Healthcare Agency

Tommaso Federici
University of Tuscia, Italy

ABSTRACT

This chapter deals with the introduction of electronic procurement in the public healthcare domain. After a brief discussion on the healthcare spending characteristics and on the suitability of e-procurement tools in the public sector, the long-lasting experience of e-procurement implementation promoted by an Italian Local Healthcare Public Agency is described. This initiative included some pilot projects and applied many different solutions, always involving both a new ICT tool and a thorough process redesign. The development of the innovation introductions is discussed, together with their organizational and managerial background, the description of the new processes, and the analysis of the most relevant results. The chapter provides a fairly comprehensive illustration of available solutions, opportunities, and challenges in this still neglected topic.

DOI: 10.4018/978-1-60566-064-6.ch015

BACKGROUND

The spending for goods and services on public healthcare, significant for many years, is still growing at a fast rate, both in absolute terms and in percent of total spending, worrying many European governments that are engaged in identifying rationalization initiatives. In parallel, e-procurement solutions widened their range of application from business-to-business (B2B) transactions among companies to business-to-government (B2G) ones, introducing innovative processes in public administrations (PAs), based on information and communication technologies (ICTs). According to the i2010 eGovernment Action Plan, two recent European directives (2004/18/EC and 2004/17/EC) committed member states to give the *capability* of carrying out 100% of procurement electronically to all their PAs with the *obligation* of managing electronically at least 50% of spending.

E-procurement should enable significant efficiency improvements in the public healthcare sector, with the reduction of purchasing and administrative costs. Until now, however, most e-procurement initiatives at the country, regional, and local levels met difficulties and did not fully deliver the expected benefits. This is mainly due to the healthcare procurement complexity in terms of variety of goods and number of suppliers and to the resistances of public institutions to technology-based process innovation. Moreover, a different approach to the e-procurement opportunities is required in healthcare to take into account the specific characteristics and peculiar needs of particular supplies.

Following the initial statements, and according to many scholars (Berardi, Calvanese, De Giacomo, Lenzerini, & Mecella, 2003; De Meo, Quattrone, Terracina, & Ursino, 2006) and definitions (e.g., listen to the voice on A.dict.it, 2007) e-procurement should be included in the e-services domain, since:

- it is entirely based on the use of computers and electronic information exchanges (Internet/extranet);
- it involves the cooperation of various organizations, which integrate their services (functionalities) through these means.

It must be noticed, however, that the semantics of many "e" terms is still not universally shared and their meaning is continuously shifting and often incoherent; for instance, the term "e-service" is also applied to the public sector in the narrower sense of a service provided on the Web by an administration to their citizens.

E-procurement-related innovations in technology and organization have been considered mostly for private operators (Kim & Shunk, 2004), particularly marketplaces (Rossignoli, 2004). Fewer works deal with the public sector (Anderson, Juul, & Pedersen, 2003; Devadoss, Pan, & Huang, 2002; Zulfiqar, Pan, Lee, & Huang, 2001); they mainly discuss policies and behaviour of central PAs and central procurement authorities (Hardy & Williams, 2005; Panayioutou, Gayialis, & Tatsiopoulos, 2004; Somasundaram & Damsgaard, 2005). Even fewer are the studies on the public healthcare sector, particularly at the local operating level, where e-procurement solutions must be actually implemented, giving rise to changes on structures and knowledge already acting within each organization, thereby requesting different approaches.

Here, a case is presented that deals with an experience of e-procurement implementation promoted by the Italian Local Healthcare Public Agency (LHA) of Viterbo. This case is particularly interesting for the comprehensive design of the e-procurement system, the differentiation of the adopted tools, the long-lasting experimentations (since 2000), and the multiple solutions implemented or in progress. The decision to examine this case is also due to the following facts: the use of e-procurement tools is seen just as one aspect of a deep reorganization of the entire supply process; most performed initiatives were followed by a detailed assessment of their outcomes.

The history and key features of this experience will be examined in detail up to the ongoing project aimed at a wide e-procurement implementation. A framework of healthcare spending characteristics is also introduced in the beginning, together with a taxonomy of e-procurement tools in public healthcare sector.

HEALTH CARE SPENDING AND E-PROCUREMENT

Health Care Spending

About 27% of the public healthcare spending in Italy is for the "purchasing of goods and services," frequently named "intermediate healthcare consumptions" (Regional Healthcare Services Agency, 2005). When referring to the whole Italian *National Healthcare System,* this component reaches a huge absolute dimension—23.8 €b in the year 2005—with an increasing trend both in absolute terms (it more than doubled from 1997 to 2005) and in percent on the total spending (in 1997 spending for goods and services was lower than 10 €b and it weighted a little more than 20% of the total).

This part of spending varies largely among the Italian regions and the market is further influenced by some complexity factors: the presence of about 350 diverse healthcare structures and about 500,000 highly differentiated suppliers (multinationals, mid-size national companies, and local SMEs).

The main issue, however, is the composite structure of the spending in healthcare, which includes standard supplies for the whole PA, together with highly specific purchases. The spending for goods and services in such sector is highly differentiated and, according to the former aggregations used by the Italian Economic Ministry (very useful to single out the most suitable e-procurement tools), can be classified into three sections:

- *common spending* for the whole PA (about 25% of total healthcare spending for goods and services); the nature of this spending (e.g., phone services, office materials) is the same for all the buying administrations;
- *common-but-differentiated spending* (25% of total); it exists for all the administrations, but it is highly differentiated through the buying sector (e.g., in healthcare: maintenance and cleaning of hospital buildings);
- *healthcare-specific spending* (more than 50% of total), composed by medical devices, drugs, and materials used in case of injury, disease, handicap, physiological application, or surgical operation.

A fundamental concern is that, while healthcare *specific* goods require high quality level of each item, together with rapid and controlled logistics, the same aspects—although important—are clearly less critical for *common* goods. Furthermore, healthcare *specific* goods and healthcare *common-but-differentiated* spending often have peculiar characteristics, with limited offering standardization. This diversity must be taken into account when devising innovative ways to manage procurement before choosing the most appropriate solutions, in order to improve quality and efficiency of supplies, while rationalizing and reducing spending.

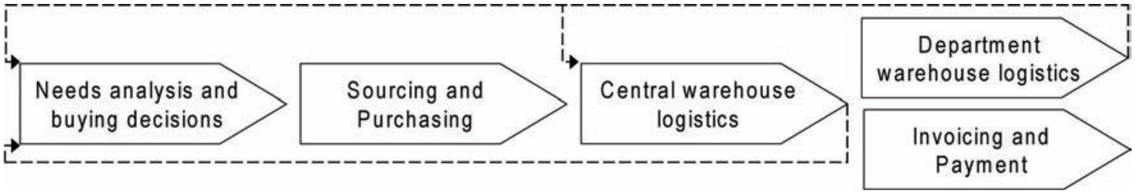
E-Procurement and E-Procurement Tools

The term "procurement" is often used in a narrow sense, associated with the sole purchasing phase, as can be seen in Panayioutou et al. (2004) or in Kim and Shunk (2004). Consequently, the term "e-procurement" is used to indicate just a class of electronic tools to link buyers and suppliers on the same network to make a deal.

Differently and according to other studies (MacManus, 2002; Somasundaram, 2004), in this work, the term "procurement" will indicate a broader process within the operations of a healthcare agency that starts with a need for a good or service and ends with its use and the payment for its supply. The procurement process then includes (see Figure 1): analysis of the needs coming from central warehouse or departments, purchase programming, sourcing choice (where and how to buy), purchasing act (through a tender or a direct order), handling of incoming material and central warehouse logistics, department warehouse replenishment, inventory control, and invoice processing and payment.

An e-procurement system then involves the whole procurement process and not just its purchasing phase. Consistently, the term "e-

Figure 1. Procurement taxonomy in the health care sector



procurement" indicates here the organizational solutions supported by ICT-based tools that allow electronic forms of procurement, potentially more effective and efficient than traditional ones, where a more or less wide-reaching and thorough process redesign is required, taking into account the whole life-time of a product or service.

The tools included in e-procurement solutions can be grouped in two main areas, which should be considered in a complementary way to streamline the whole procurement process:

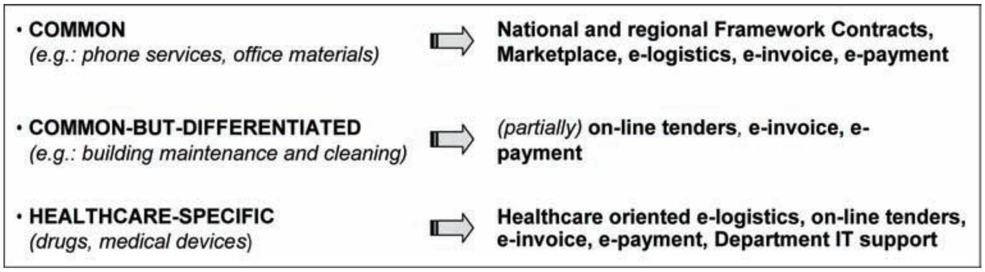
- *e-purchasing*, that includes very different tools which allows the purchasing phase to be entirely managed, from finding a product to invoicing and payment, through online tenders (*e-tendering*), or *marketplaces* and *electronic catalogues* (*e-requisitioning*), electronic invoice exchange and processing (*e-invoice*), and liquidation activity (*e-payment*);
- *e-logistics*, which aims at optimizing the management of inventories (in healthcare structures: pharmacy and the supply office) and internal goods flows, based on intranet/extranet technologies, integrating supply chain management (SCM) solutions, linking both internal and external players.

Correlation Between Spending Items and Tools

It must be taken into consideration that healthcare structures produce highly critical and specialized services vs. the rest of PAs. More than in other sectors, quality standards for many purchased goods and services (for their impact on the service quality) quality standards for many purchased goods and services (for their impact on the service quality), together with economy and timeliness of purchases, transparency of activities, and conformance to principles of competition among companies. This diversity, together with the large differences among the three spending for goods and services categories indicated above and the availability of diverse electronic tools require a careful analysis—and a segmented approach—to define (see Figure 2) which solution mostly suits each type of good/service (Federici, 2006). Then, a clear definition of the nature of the need (e.g., operating room specific devices) and a consistent purchase plan, capable of supporting both healthcare performance and economy of procurement, are necessary steps to be taken.

Goods and services within the *common* spending category, characterized by large utilization, wide offering, and repetitive purchasing quantities, can be standardized for all PAs. They are perfectly compatible with *e-requisitioning* tools, like the marketplaces and the e-catalogues based on framework contracts negotiated by a single body (at national, regional, or local level), that aggregate fractions of public demand, knock-down large standard supply contracts, perform unified tender procedures for a number of "client" entities (CONSIP, 2003) and, eventually, lower both the supply price and the administrative costs. The best opportunity for a local agency—in terms of reduction of purchase price, administrative costs, and delivery time—is therefore to turn to one of

Figure 2. Correlation between spending items and e-procurement tools



these tools; last but not least, e-logistics, e-invoice, and e-payment can improve supply management and further reduce its administrative costs.

The *common-but-differentiated* spending category consists of supplies which must absolutely guarantee the fulfillment of specific needs to the healthcare buyer. It requires the presentation and evaluation of even complex projects, for which it is difficult to define criteria for automatic score attribution. The traditional procedure can be substituted by a tender partially performed online, moving the call, presentation, intermediate, and final communications phases onto the Web (with clear benefits in terms of reduction of administrative time and costs), while keeping the offers evaluation phase off-line e-invoice and e-payment can provide further efficiency improvements.

To adequately manage the *healthcare-specific* spending, a wider e-procurement approach must be used: just looking for the lowest purchasing price might be counterproductive (Borgonovi, 2004) since the requested goods and services are highly specific and high quality levels are required. Benefits can then be obtained by redesigning the internal processes, merging several organizational changes and ICT tools on the whole procurement cycle—healthcare oriented e-logistics, online tenders, evolved forms of marketplace, e-invoice and e-payment—and providing adequate ICT supports to each healthcare cost centre (e.g., hospital wards).

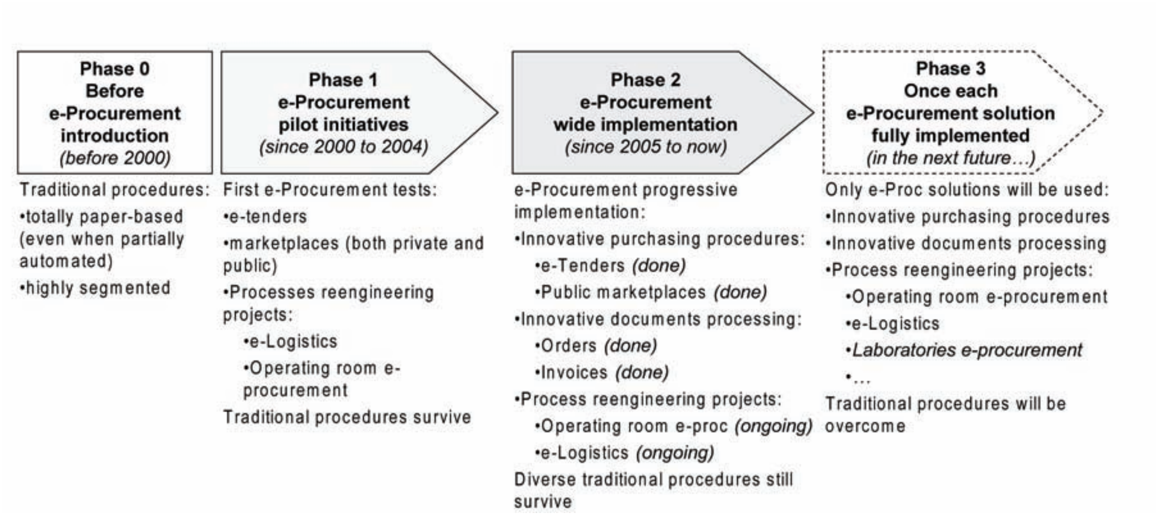
SETTING THE STAGE

E-Procurement Introduction at the LHA of Viterbo: A Long Journey

The LHA of Viterbo, aiming at gaining efficiency and reducing the expenditure for the procurement of goods and services, started in the 2000, a long journey that can be divided in four main phases (see Figure 3):

- Phase 0 (before 2000): the time before the e-procurement introduction, with traditional paper-based and highly segmented procurement procedures;
- Phase 1 (2000-2004): a period of e-procurement pilot initiatives based on different solutions, with the first e-procurement tests promoted in partnership with public and private organizations;
- Phase 2 (since 2005): a period of progressively wider implementation of diverse e-procurement solutions, that is still ongoing;
- Phase 3 (in the next future): a time of full e-procurement implementation, when the entire procurement process will be innovated and ICT-based.

Figure 3. E-procurement introduction in LHA of Viterbo



The Health Care Structure and Organization

The LHA of Viterbo, like other similar structures (Cicchetti, 2004), is organized in three areas: hospital services, territory services (first aid facilities, laboratories, etc.), and administration services. It employs about 3200 administrative and healthcare workers and provides healthcare to an Italian province (859 hospital beds) with a production value of about 350 million of euros, determined according to the individual spending allocated for each citizen of the province (a total of about 300,000 people).

As regards the procurement process, the following structures were involved, although at different levels of commitment and with diverse e-procurement solutions:

- the Procurement and Logistics (P&L) Department (in charge of tenders, purchases, and management of internal flows);
- nine different warehouses: two central (one for common goods and one for medical devices and drugs), and seven local;
- hospital wards and laboratories, which store little stocks of goods and are both applicants and recipients of new supplies.

It must be noticed that most of the structures and the procedures already operating before e-procurement introduction are still working because the innovative solutions did not substitute the former ones yet, even when fully implemented.

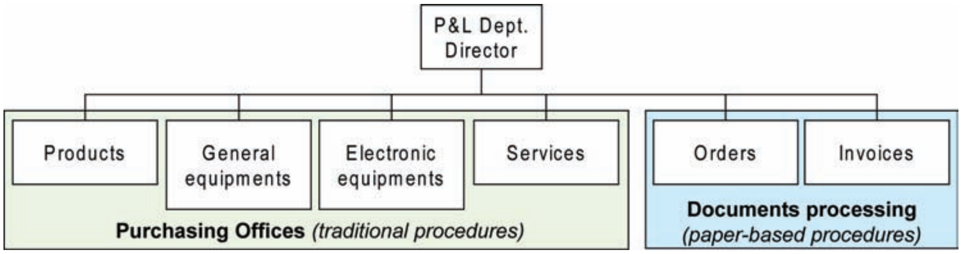
Methodological Assumptions

The above indicated assumptions about healthcare spending and its correlation with e-procurement tools—diversity in healthcare spending; broadness of the procurement process; and need to match each type of spending with the most appropriate e-procurement solution—constitute the starting concepts on which the experiences managed by the LHA of Viterbo were based.

The e-procurement project of the LHA was characterized by a diversified and systematic approach, which relied heavily on:

- the specialized competences of individual hospital wards (core structures of a healthcare agency, which actually deliver the

Figure 4. Structure of the purchasing and logistic department before the e-procurement introduction (Phase 0, before 2000)



healthcare service and are the main final users of the new tools); because of this, they were involved in the definition of the new procurement processes and took on a direct and decisive role;
- the technology and management know-how of external companies (from technology and logistics sectors); their partnership was very important in the first experimentations;
- the willingness to test diverse e-procurement solutions on pilot contexts, along the whole procurement process, before starting an extensive program for a wide diffusion; it must be considered that e-procurement was a totally new approach in those years, especially in healthcare, and there were no previous experiences to follow;
- the setting up of a review activity for each experience in order to evaluate its results in detail (which were interesting and notably different in nature and dimension from those foreseen), analyze the obstacles met (technological, organizational, and normative, as it happens for any innovation), and make the best decision about the intended wide adoption of e-procurement.

The redesign of the procurement cycle started from a detailed analysis of the need for goods and services. Specific purchase characteristics were made explicit; spending was mapped in detail, divided among *common, common-but-differentiated, healthcare-specific;* and an organic plan to link procurement needs and e-procurement solutions according to theory was prepared.

Phase 0: The Preliminary Context

Prior to starting the e-procurement introduction process, the internal situation about climate, culture, technology availability, and utilization was just similar to other analogous Italian structures and local public administrations. The purchasing activities were traditionally divided among four offices (see Figure 4), on the basis of the type of goods or services, as they are highly differentiated and specialized in healthcare, thereby implying diverse procedures and suppliers. The subject matter of the four offices was, respectively:

- products (drugs, medical devices, consumables like paper, ink, etc.);
- general equipment (furniture, cars, elevators, etc.);
- electronic equipment (medical appliances, computers, etc.); services.

This division has been maintained, as this specialization is considered useful. Therefore, the distinctive characteristics and activities of such offices, described below, are still the same existing at that period.

The activity of such offices is characterized by a knowledge oriented to correctly apply the rigid external laws (settled by the national or regional government, or by UE) and procedures (determined by the same LHA) that regulate purchases in a public administration. Another important piece of knowledge concerns information about the distinguishing characteristics of the managed type of products. To properly work in this area, the main issue is then to accumulate more and more experience in the field, while the education acquired previously to be applied in the position has little or no relevance (actually, none of the office supervisors has a degree, even less in law, as it could be expected).

The four traditional offices, which operate separately, have an average staff of four persons (generally, a supervisor and three clerks). Each of them is based on a precise division of the highly standardized tasks to be performed, that typically are sourcing of information about the product to buy (price, characteristics, suppliers), writing and revising of the tender, issuing of the same, support to the evaluation process, and award notification. Despite that knowledge is rather shared among the personnel of the same office, interchangeability is pretty difficult due to the long-lasting practice of everyone in his/her specific task. The traditional purchasing offices have then the typical form of bureaucracy. Because of their culture and organizational form, they are not flexible and not disposed to change. Moreover, even if they are effective in managing their duties, their activity is not efficient at all, as largely demonstrated by the results of the researches quoted below.

Additionally, computers are used only in the administrative offices (not in warehouses or hospital wards), and the role of IT systems is limited to automating the traditional procedures with office automation tool (word processing and occasionally spreadsheet) or legacy systems (accounting system, to check funds availability and to reserve them). Consequently, personnel are not required to have a high IT literacy.

At the beginning of the e-procurement experience, the internal climate was, and still is, highly influenced by factors like elevated level of bureaucracy, limited possibilities of career advancement, low level of responsibility, and long lasting habits to operate always in the same way (overall and particularly in areas like administration and warehouse).

These discouraging conditions to promote change were further reinforced by three other factors:

- the low cultural level outside the health departments, with only few graduated managers;
- the limited availability of different competences in staff areas: workers with a degree or a high-school qualification came all from law or accounting studies;
- the sharing of these circumstances by both employees and managers, at least middle-level ones.

Actually, the drive to introduce e-procurement in the LHA came just from two persons, both recruited after a previous career in the private sector: the former general manager and the manager of the P&L Department.

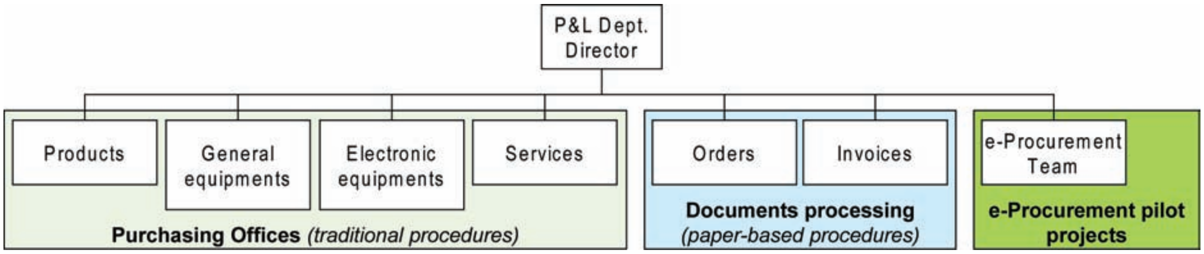
CASE DESCRIPTION

Phase 1: The Pilot Initiatives

Organizational Interventions

In order to manage the preliminary experimental phase to introduce e-procurement tools and solutions, while taking into account the obsolete culture and the poor IT education of the workers in the P&L Department, the two mentioned top managers made a strategic decision. They involved in these trials only some young people, freshly graduated in economics. At the first stage, they were two; later, two more were added. These graduates were asked to spend their postdegree training period at the LHA. As the entire staff in charge of the e-

Figure 5. Structure of the purchasing and logistic department during the e-procurement pilot initiatives (Phase 1, 2000-2004)



procurement experimentation, they were engaged full-time in it (see Figure 5).

Even though the educational level of the involved persons was quite high, this was directly used only in some part of the work (e.g., analysis of the outcomes, auditing on costs). Actually, they were selected also because of their higher IT education (although they were not IT experts) and their greater willing to innovate, compared to the workers of traditional offices. This was a successful decision, also because it isolated the persons involved in e-procurement from those still engaged in traditional procedures. Acting in this way, it was possible to adopt a trial-and-error approach in the tests, while at the same time the supplying cycle, crucial in a healthcare structure, could proceed without any inconvenience.

Many diverse ICT systems (office automation, marketplaces, platform for e-tenders, e-logistics extranet solutions, etc.) were tested by using them in real operations for a planned period, as they form the constitutive platform for e-procurement. The aim of each test was to model a new organizational solution, in order to define streamlined and more effective process and to employ human resources in more value-added tasks.

To improve the procurement and internal management of the *healthcare-specific* and *common* goods, from ward requests up to the purchasing channels (see Figure 1), the LHA designed a fully ICT-supported process, with procurement flows designed along two distinct routes, according to goods type:

- a procurement flow for nonspecific medical devices (MDs), normally used in hospital wards for routine healthcare activities (e.g., gauzes, disinfectants, etc.), and for *common* spending, involving online tenders, marketplaces, e-invoice, and e-logistics;
- another procurement flow for the specific medical devices (SMDs), used for surgical interventions in the operating rooms and for laboratory tests, with new online procurement processes aimed at optimizing the replenishment time and reducing the ward and inventory stock levels.

In the new process model, the wards, in their healthcare duty, assume a driving role, but not the responsibility to decide how to purchase specific goods.

The Trials Managed on the E-Procurement Solutions

According to the above mentioned methodological assumptions, in Phase 1 (see Figure 3) the LHA of Viterbo tested diverse e-procurement solutions before adopting them widely, in order to single out the most suitable one for each different need existing in such a complex structure. Summarizing, the experiences made in the test phase followed this path:

- in the year 2000, the first initiative was a trial of a marketplace promoted by a private merchant; despite some positive results, this experience ended quite early, when the marketplace platform failed because of the low volume of transactions;

- in 2002, even though these tools were still under construction and not yet addressed to the healthcare sector, the LHA started to use the *Public Electronic Catalogue* of the goods and services which could be purchased at predefined conditions through the *Framework Contracts* ("Convenzioni Quadro") negotiated by the Italian Central Procurement Agency (CONSIP) and the *Marketplace for the Public Administration* ("Mercato Elettronico per la Pubblica Amministrazione," MEPA), also created and managed by CONSIP (the LHA was one of the first 20 Italian PAs that took active part in the MEPA implementation);
- in 2003, a first platform for e-tenders was tested, which was later dismissed because of its lack of functionalities; it has been recently replaced by a new one, that allows to manage a tender, both partially (leaving offers evaluation off-line) or fully electronically, but does not yet support competitive online prices reductions (*e-auction*);
- the LHA also carried out two different projects on e-logistics, both promoted by private companies and based on wide outsourcing solutions supported by extranet platforms. One of them involved the central and the departments' warehouse logistics for common goods and nonspecific devices used in hospital wards for routine healthcare (e.g., gauzes, disinfectants, etc.). The other project coupled the supply of the specific medical devices used in the operating rooms with their overall logistics management, adopting an innovative "intervention-based" concept that links procurement to the surgical operations performed (according to surgical protocols defined ad hoc, which indicate the types and quantities of medical devices needed for each type of operation), instead of the traditional "stock-based" approach, which just manages the inventory levels.

The most significant experiences of those indicated above, due to their innovation rate and process broadness, were *e-logistics* (for common goods and nonspecific devices) and *operating room e-procurement*. They will be then described in more detail in the following paragraphs (see also Federici, 2005).

E-Logistics Solution

The LHA of Viterbo managed in 2002–2003 a pilot experiment about centralization and outsourcing of the warehouse function. The e-logistics program outsourced replenishment and inventory management for hospitals and offices to an external logistics service provider, with significant reduction of the operating and economic burden on the LHA. The results of such initiative reinforced the statement that savings in healthcare should be pursued by supporting the procurement processes of the structures with ICT tools and by thoroughly reviewing and integrating the logistics management (Bianchini, 2002b). With the technical support of CONSIP, a pattern was later drawn to extend this solution to other LHAs.

After making the ICT support available to all the recipient structures involved in the trial, they were provided with an easy accessible product inventory, divided by categories, and a daily loading/unloading procedure with indication of actual stock levels.

The process was activated by a need, for example (see Figure 6), born in a ward. Every day, in its healthcare duty, the hospital ward unloaded the consumed goods from its inventory and issued a replenishment request when they went beyond their minimum stock levels. The replenishment request of medical devices or supply office goods, through a software application linked to the hospital management information system, was sent to the logistics service provider periodically (once or twice a week) by the ward sister, after validation by the hospital pharmacy (in case of nonspecific medical devices). The logistics service provider, if the good was available, replenished the requesting ward inventory from its warehouse by sending the good together with electronic and paper transport documents (TD). The ward sister checked the conformity of the received good in quality and quantity with the transport document and loaded its electronic inventory. In this way, the P&L Department was informed centrally in real time about the stock levels of both the logistics service provider and of the individual wards.

The logistics service provider was the sole procurement intermediary, but it could not make any decision for new supplies, on behalf of the LHA, when a good was not available in its warehouse. The LHA outsourced the management of central inventory and delegated the unloading of ward inventories, but did not externalize the purchasing function, which remained exclusively in its hands. In case of stock-outs, the logistics service provider sent a purchase order proposal to the LHA:

- when the goods were part of a still open supply agreement, after the validation by the P&L Department, the order was mailed to the awarded supplier (see Figure 7), which sent the goods and related transport document to the logistics service provider, that then loaded its electronic inventory;
- when the supply agreement was closed, or for new goods, the P&L Department could decide to open a new tender (in a traditional way, or online), at the end of which the illustrated route between the awarded supplier and the logistics service provider was activated.

Figure 6. Replenishment request internal flow with e-logistics solution

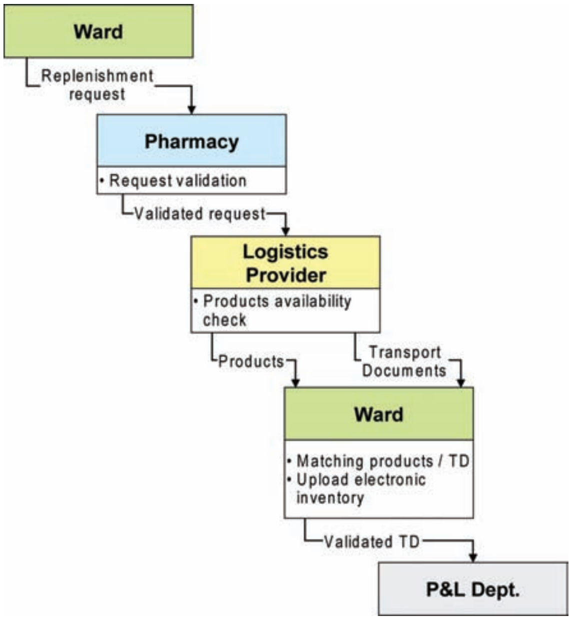


Figure 7. Supply order flow with e-logistics solution in case of an open agreement

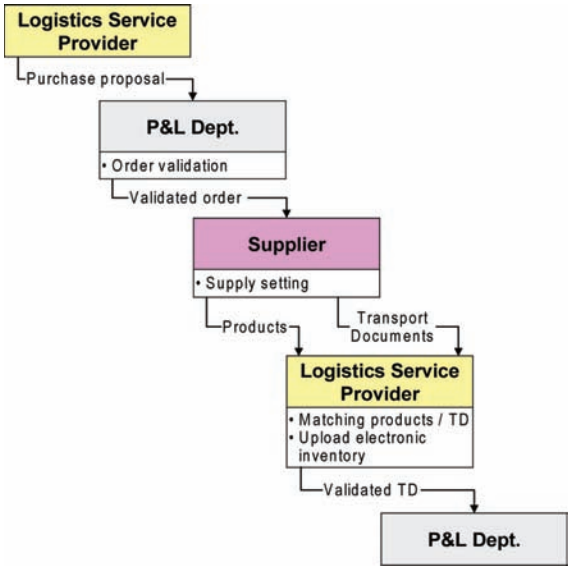


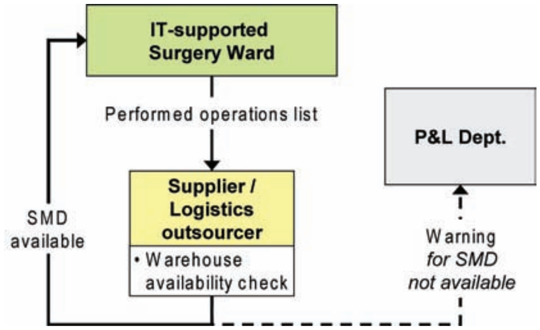
Operating Room E-Procurement

The traditional planning of operating room provisioning is performed by the hospital responsible and the pharmacist, who manage the hospital inventories by periodically sending types and quantity estimates of goods to be provided to the respective purchasing office, according to past consumption and future consumption forecast. This approach, based on estimates, generates problems in purchase planning when the hospital wards are not provided with adequate ICT supports: the pharmacist unloads the goods allocated to a ward from the inventory, as if it were consumed at once; the good might remain instead unused in the ward for an unpredictable period of time, with no indication to the pharmacist and, least of all, to the purchasing office.

The pilot experience of "operating room e-procurement" was carried out at the hospital of Civita Castellana since 2001 (it was chosen, because it is a little hospital and its ward personnel is willing to pursue innovation). The operating and technical staff of the General Surgery Department was directly involved in rethinking and redesigning the specific medical devices procurement process from scratch. The model conceived is based on:

- a novel approach to provide the specific medical devices to the operating room, based on the type of surgical operation performed (information immediately available) and no longer on the specific medical devices stock level (information that requires a large administrative work);
- the definition of surgical protocols which indicate the type and quantity of the medical devices consumed by each type of operation and allow to determine the right quantities to be reordered;
- the contractual allocation of the products supply and management to a single player, with innovative paying terms.

Figure 8. Flow diagram of operating room e-procurement process (at the end of each shift)



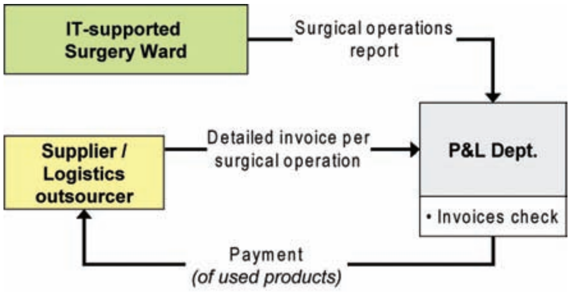
The new procurement process was supported by a shared application platform based on an extranet. At the end of each shift (see Figure 8), the ward sister sent the list of the operations performed to the supplier. The supplier, according to the product quantities indicated by the corresponding surgical protocols, knew product consumptions in real time and could thus replenish them. The goods were delivered directly to the ward which had requested them and thus covered actual needs with no intermediate steps, cost/time increase or stock-out risks.

The process ended monthly (see Figure 9) when:

- the surgery ward sent to the P&L Department the report of the surgical operations performed;
- the supplier issued a detailed invoice per surgical operation;
- the P&L Department activated the payment of the actually used products, after a brief cross-check.

At the same time, a so detailed invoice provided data to the P&L Department for an effective periodical comparative analysis of ward needs. The objective of the experimentation was to verify the operating-economic impact that a specific supply system, based on online methodologies and provisioning *per surgical operation,* would provide

Figure 9. Flow diagram of operating room e-procurement process (monthly)



vis-à-vis the traditional procedure (Bianchini, 2002a). The analysis performed at the end of the first semester of experimentation indicated that, to reduce spending, it is necessary to consider the whole supply cost and not only the purchase price, on which the procedure was focused before, in order to negotiate the lowest one.

Actually, the economic advantages were mostly concentrated in the administrative costs, which decreased from about 100 €k per semester to only 20. On the contrary, the purchase price of the operating room devices slightly increased (by 4%, due to their increase in market price); this witnesses that the project was aimed at not sacrificing the quality of supply at all. With savings on the total final cost of the specific medical devices supply of more than 73 €k per semester (30% less than the traditional approach), the experimentation of the LHA of Viterbo suggested that the e-procurement per surgical operation can provide substantial cost savings, not to be pursued by reducing the purchase costs (in order not to dangerously penalize the supply quality), but by redesigning the procurement process and thus reducing the administrative costs.

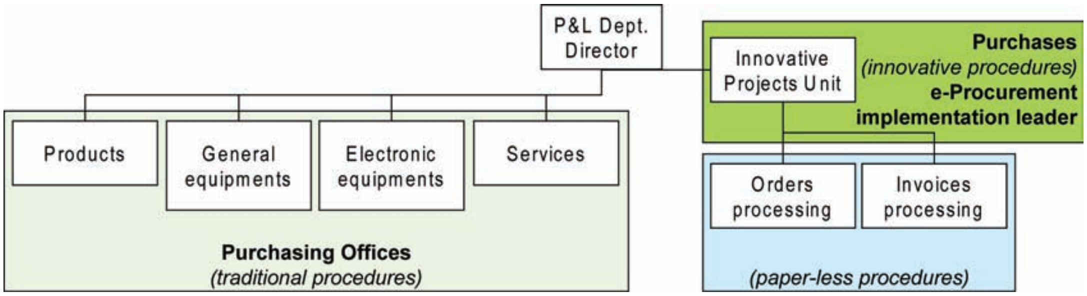
It may be interesting to examine the breakdown of savings among the various cost items:

- 42% of savings came from reducing the fixed and financial inventory costs (management cost per squared meter of inventory premises, financial costs of the capital locked into stocks, and cost of obsolete products), by outsourcing logistics and shifting the payment terms after consumption;
- 26% of savings came from reducing personnel costs (of hospital pharmacy and operating room), for the fraction linked to the inventory management activities outsourced to the logistics provider (book-keeping, product replenishment, incoming goods inspection, order/delivery expediting);
- 24% of savings came from reducing the administrative cost for purchasing and supply monitoring, by unifying sets of diverse medical devices into surgical protocol kits, instead of using a separate procedure for each type of device, and by being provided with detailed information directly from the invoices per surgical operations;
- 8% of savings came from reduced order management and invoicing costs.

Phase 2: The Progressive Implementation

Since 2005, after these pilot experiences limited in size and time although performed in real operations, the LHA of Viterbo launched an extensive program (Phase 2, see Figure 3) with the purpose of innovating the end-to-end procurement process (as seen in Figure 1), through the adoption of diverse solutions, coherently linked to the different specific requirements. The first completed steps were the implementation of multiple e-procurement solutions in two segments of the broad procurement process: purchasing and invoice processing. The changes introduced in these first steps were analyzed in detail, as summarized below. After overcoming the resistances expressed by suppliers, the full deployment of operating room e-procurement is now ending, while the implementation of e-logistics outsourcing model for common goods and nonspecific devices is still ongoing.

Figure 10. Structure of the purchasing and logistic department during the e-procurement wide implementation (Phase 2, since 2005).



New Organizational Interventions

At the end of the testing phase, when it was decided to promote the widespread adoption of e-procurement, two more graduates were selected, and the former informal project team became a unit devoted to the all e-procurement processing (named Innovative Projects, or IP).

This unit (see Figure 10) was integrated with two other offices (already moved to a totally paperless activity), in charge of orders and invoices processing, in the staff coordinated by the Director of the P&L Department. Even though innovative e-purchasing solutions are fully implemented and frequently used already, this unit is still separate from the other offices, which keep running the purchasing activity in the traditional ways.

In addition, while the traditional offices manage the sole purchasing phase, this unit not only operates as a buyer (through online tenders or direct purchases on MEPA), but also supervises the entire procurement process (including supply chain and logistics), being directly linked to external providers, warehouses (for common goods and for medical devices and drugs), and internal departments recipient of the supplied goods. Furthermore, the IP unit manages supplies regardless to the type of goods.

After being set up, the IP unit led the full implementation projects of the new purchasing solutions and of operating room e-procurement. At present, it is leading the e-logistics project introduction, managing online purchases, and supervising the go-live phase of the operating room e-procurement.

Research Findings on the Completed Implementations

After the full implementation of e-procurement solutions in purchasing and invoice processing, a detailed research was performed (Federici, 2006) in order to assess the actual organizational changes introduced and the performance benefits obtained. Five new procedures were examined: four located in the purchasing phase (two related to e-tendering, #1 and #3, and two to e-requisitioning, #2 and #4) and one in invoice processing (#5).

The analysis compared five workflow pairs representing homologous segments of the end-to-end procurement cycle (see Table 1), each related to a traditional paper-based procedure (T) and to an innovative one (I). Although very different, the compared procedure pairs receive the same input at the same stage of the procurement cycle and produce the same output in the same overall context (normative, good or service to be purchased, value of the purchase, etc.).

In order to point out the changes introduced when implementing e-procurement solutions, the following quantitative comparisons were performed between the workflows of equivalent procedures:

Table 1. Matching between the equivalent procedures considered (Legend: T: Traditional, I: Innovative)

COMPARISON	VERSION	PROCEDURE	DESCRIPTION	ICT TOOLS
1	T	Tender over threshold	Public tender for purchases of goods and services for amounts higher than the threshold set by the European Union (EU). Totally paper-based procedure	Office automation (word processing, spreadsheet, etc.)
	I	Online tender over threshold	Public tender for purchases of goods and services for amounts higher than the threshold set by the EU. Web-based procedure from initial notification, receipt of bids, intermediate communications, up to award notification. Evaluation of the bids can be performed off-line. Call must be published as for off-line tender	Platform for e-tendering Office automation
2	T	Tender over threshold	*see above*	
	I	Direct Order on e-catalogue	Purchase (also for amounts higher than the EU threshold) fully performed on the e-catalogue for PAs managed by CONSIP, which includes goods and services already negotiated through Framework Contracts. A limited choice of items is available.	Web-based catalogue
3	T	Negotiated procedure	Restricted tender procedure with few invited participants (faster then normal tender). To be adopted only in specific cases and under EU threshold. Totally paper-based procedure	Office automation (word processing, spreadsheet…)
	I	Request for Quotation (RfQ) on MEPA	Restricted tender procedure fully performed on CONSIP Marketplace for PAs with few participants selected by LHA (among the suppliers admitted by CONSIP), that can be asked for (and can submit) a technical tender To be adopted under EU threshold.	e-Marketplace (with special functions for tender asking and submitting)
4	T	Small direct purchase	Purchase directly performed with a single supplier. To be adopted for very small buying (under the threshold of € 5000) and only in specific cases. Totally paper-based procedure	Office automation (word processing, spreadsheet…)
	I	Direct Order on MEPA	Purchase directly performed on CONSIP Marketplace with a supplier already admitted by CONSIP, and only of goods or services allowed. To be adopted under EU threshold	e-Marketplace platform (with cart function)
5	T	Invoice processing	Paper-based procedure of: invoice acquisition, checks (on the accounting system and with orders and transport documents) and submitting of verified invoices to the persons in charge of payment	Office automation (word processing, spreadsheet…) Accounting system
	I	LIQUIWEB	After keying in the incoming invoice data, totally paper-less checks (on the accounting system and with orders and transport documents) and submission of verified invoices	Intranet application for invoice processing Accounting system

- three on organizational dimensions: number of the performed tasks, number of the offices, and number of the different roles involved;
- two on performance indicators: total elapsed time (in calendar days) and total effort (in minutes), calculating for each of them the standard value, and the range between maximum and minimum values.

In short, the research revealed several changes brought in by the e-procurement solutions already implemented:

- the number of tasks is almost always lower in the innovative (I), generally simpler, paperless workflows (in three cases by more than 30%);
- the number of offices involved is equal in the two versions of the workflows, except in comparisons #2 and #3 where all the evaluation or a large part of it is performed on the innovative procedures introduced by CONSIP for all PAs;
- the number of roles involved is slightly lower in the innovative (I) workflows; tenders over threshold are an exception, since the online process asks for a new activity—the technical preclassification of tenders submitted, performed by an expert in the field of the purchased goods—that is not present in the traditional (T) workflow;
- the length of the workflows (in terms of total elapsed time) is largely reduced with e-procurement in both standard value and min–max range (the reduction sometime is greater than 80%): this means that the supply contracts can be closed in a shorter and more predictable time, which is very important for critical services, like in healthcare;
- the total effort requested to achieve the same target is always lower for e-procurement workflows (I), often significantly (from 15% up to more than 90%). In three cases out of five, the reduction is greater for range than for standard value: this suggests that, besides the efficiency improvement, the use of resources could be better programmed.

The significant results measured originated anyway more from cleaning-up the workflows and using faster communication tools than from performing a deeper redesign, as suggested by the involvement of the same offices and roles, and by the similarity in the number of tasks, in each workflow pair (it must also be observed that the examined workflows refer to procedures heavily conditioned by laws and rules that limit the depth of the redesign action).

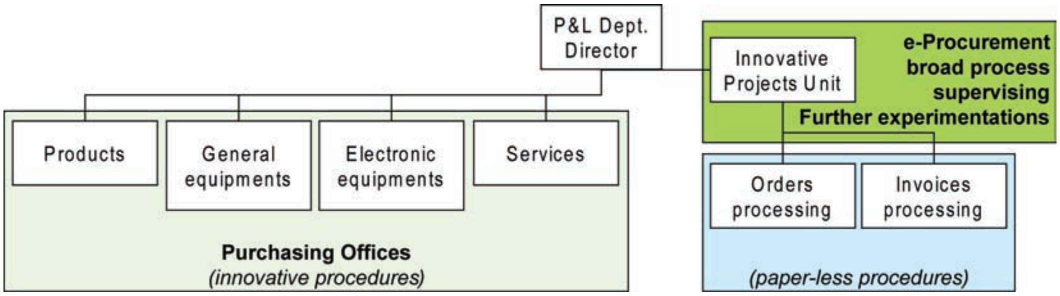
The largest differences and the best results were found in those comparisons—#2, where a tender paper-based procedure is replaced by an e-requisitioning solution, and partially #3—in which the new solutions (up to now used only for common spending) lack some activities for the buyer LHA—sourcing, evaluating, and admitting suppliers; classifying goods and services—performed in advance by an external subject (CONSIP).

Phase 3: Towards a Totally Electronic Procurement Process

The described scenario for the development of e-procurement is the outcome of a series of managerial decisions based on the assumption that the characteristics of the traditional and innovative sides are quite different in terms of: required knowledge, operating ways, and personnel profiles. The P&L Department Director's goal is now to completely substitute the traditional purchasing procedures with the innovative ones become usual for the agency, at least in the IP unit. Then he wants to reassign to the four traditional purchasing offices the use of the e-purchasing tools in all of their operations. To reach this target, the know-how related to the new solutions must be transferred to them, and he thinks to assign this task to the IP unit, to be performed with short courses and an extended period of support on the job.

At the end of this process (see Figure 11), the IP unit will lose its buyer role and will be in charge of controlling and auditing the broad e-procurement process and of carrying out tests on other possible innovative solutions along it. The LHA of Viterbo is now planning other innovative solutions in the procurement domain, first of all, the adaptation to the laboratory tests of the "intervention-based" concept, already introduced in operating room e-procurement. This innovation involves highly specialized goods and until now encountered the

Figure 11. Structure of the purchasing and logistic department with fully implemented e-procurement (Phase 3: in the next future)



resistances of the suppliers, which are very hard to be overcome because of their limited number.

CURRENT CHALLENGES

Various challenges are still open for the LHA in question, in order to achieve the full substitution of the traditional procurement procedures with brand new ICT-based solutions all along the end-to-end procurement process. These challenges are related to external factors and/or agents, or originate in the internal environment:

- some law restrictions and/or catalogue limitations (indicated in Table 1), which today prevent a wider utilization of the most favorable purchasing solutions for a Local Agency (like direct orders on e-catalogue and on MEPA); these restrictions/limitations should be removed by the Central Procurement Authority in order to increase the attainable improvements;
- limited suppliers' readiness to manage their sales with the innovative tools: most of them (even the biggest ones) often showed not to be prepared to (or not interested in) the most innovative solutions, which join supplies with other services and fully allocate their management on electronic platforms. This problem caused long delays in issuing the tenders both for operating room e-procurement and e-logistics, and still prevents other planned innovations.
- while the sanitary staff in the hospital wards showed a positive will to accept the new solutions, the personnel employed in the administrative areas, in the warehouses and in the laboratories, accustomed since long to work in traditional ways, appeared (and appear) culturally inadequate and resisted/resist to change. Therefore, it will be a hard task to spread innovation in all the environments involved in procurement activities;
- the adoption of new procurement solutions can ask to eliminate some structures (e.g., the centralization of inventory management in the e-logistics project will cause the closure of local warehouses), thereby originating strong resistances by the involved personnel, that should be transferred to other structures and/or change their duty.

Despite these significant obstacles, as stated above, the LHA of Viterbo is already planning other innovative solutions in the procurement domain, first of all the adaptation of the "intervention-based" concept in the procurement for laboratory tests.

CONCLUSION

Procurement in the healthcare sector is quite different from the rest of PA because of a much wider number of goods and sellers, technical characteristics and peculiarities of goods and services, impact on the delivery of critical and specialized services requiring high quality standards, and timeliness of purchases.

Also recalling the previously cited works (Federici, 2005; Federici, 2006), it can be suggested that:

- healthcare spending is highly varied and can be segmented in three categories: *common*, *common-but-differentiated*, and *healthcare-specific*;
- procurement is a process much broader than pure purchasing, which asks for carefully diversified ICT-based solutions as well as thorough process rethinking/redesign;
- to properly respond to the variety of needs and contexts in healthcare, it is advisable to appropriately segment the organizational solutions and adopt coherent e-procurement approaches.

The case of the LHA of Viterbo constitutes a long and articulated experience with positive results, as the adoption of e-procurement solutions led to greater effectiveness and significant efficiency improvements (although of largely different dimensions). These outcomes could be used to eventually materialize administrative cost reductions and/or service enhancements, while respecting organizational or normative restrictions and policies not dealt with in this work.

Some hints can be singled out from the experience, in order to assess its transferability:

- e-procurement can provide improvements also in those contexts, like the purchasing phase, where a deep process redesign is presently inhibited by law constraints;
- improvements are much larger when several tools are brought together to model brand-new organizational solutions, capable to link the supply of goods with their logistics and the processing of the related documents, along the entire procurement process;
- involvement of new resources, with higher education, IT literacy, and will to innovate, in the e-procurement initiatives;
- adoption of a progressive approach, with experimentations and succeeding implementations projects;
- temporary parallel presence of traditional and innovative procedures, until the latter are fixed, in order to secure the supply operations, crucial in a healthcare structure.

Chapter 8.11

Application of Unified Modelling Language (UML) to the Modelling of Health Care Systems:

An Introduction and Literature Survey

Christos Vasilakis
University College London, UK

Dorota Lecnzarowicz
University of Westminster, UK

Chooi Lee
Kingston Hospital, UK

ABSTRACT

The unified modelling language (UML) comprises a set of tools for documenting the analysis of a system. Although UML is generally used to describe and evaluate the functioning of complex systems, the extent of its application to the health care domain is unknown. The purpose of this article is to survey the literature on the application of UML tools to the analysis and modelling of health care systems. We first introduce four of the most common UML diagrammatic tools, namely use case, activity, state, and class diagrams. We use a simplified surgical care service as an example to illustrate the concepts and notation of each diagrammatic tool. We then present the results of the literature survey on the application of UML tools in health care. The survey revealed that although UML tools have been employed in modelling different aspects of health care systems, there is little systematic evidence of the benefits.

INTRODUCTION

Health care systems are known to be complex and, as a result, difficult to analyse and re-engineer (Berwick, 2005). Health system engineers often rely on computer modelling and simulation to assist with the analysis of existing systems and the pretesting of suggested changes. To this extend, a variety of software engineering techniques and tools have been employed (Jun, 2007). Examples include data flow diagram (Pohjonen et al., 1994), state transition diagram (Mehta, Haluck, Frecker, & Snyder, 2002), entity relationship diagram (Kalli et al., 1992), integrated definition or IDEF (Hoffman, 1997), and more recently, Unified Modelling Language, commonly known as UML (Object Management Group, 2005).

UML provides a comprehensive set of tools that can be used for documenting the analysis of a system and for developing model requirements. UML diagrams are graphical depictions that demonstrate the flow of events within the system (Object Management Group, 2005). Depending on the perspective chosen for the study (e.g., actor oriented, activity oriented), different tools are available to the analyst. Due to its versatility and the ability to analyse systems from different perspectives, UML is said to be effective in describing and evaluating the functioning of complex systems such as health care (Kumarapeli, De Lusignan, Ellis, & Jones, 2007). However, there seems to be very little systematic evidence on its benefits.

The focus of the article is to review the literature on the application of UML tools to the analysis and modelling of health care systems. To this end, we first briefly introduce four of the most common UML diagrammatic tools, namely use case, activity, state, and class diagrams. We use a simplified surgical care service as an example to illustrate the notation and concepts of each diagrammatic tool. Next, we present the results of the literature survey on the application of UML in health. The survey revealed that studies of the benefits of UML to health evaluation are an exception and most studies have used UML without an evaluative component. We conclude with a brief discussion of the results.

UML DIAGRAMMATIC TOOLS

UML 2.0 has 13 types of diagrams, which can be categorised hierarchically as follows (Object Management Group, 2005):

- Structure diagrams used to represent the elements of the system being modelled. They include class, component, composite structure, deployment, object, and package diagrams.
- Behaviour diagrams that allow the representation of what happens in the modelled system in the activity, state, and use case diagrams.
- Interaction diagrams, a subset of behaviour diagrams, that allow the representation of the control and data flow among the elements of the system being modelled. These are communication, interaction overview, sequence, and timing diagrams.

We briefly introduce here the four UML diagrammatic tools that appear in the surveyed literature, namely, use cases and use case diagram, activity, state, and class diagram. A full description of the concepts and syntax of UML diagrams is beyond the scope of this article. A plethora of user guides and technical notes are available on the subject, with the monograph by Ambler (2004) a particularly useful introduction.

We illustrate the basic concepts and notation of each diagrammatic tool by presenting simple models of a simplified care process of surgical consultation with a patient in an outpatient clinic. In general, physicians refer patients for surgical consultation if they believe the underlying health problem is amenable to surgical intervention.

Following the referral, the outpatient clinic books the patient an appointment with the surgeon and also arranges for samples to be taken if further diagnostic tests are required. At the consultation, the surgeon assesses the need for an operation by evaluating symptoms and test results. Following a decision to operate, the patient's name is registered on a prioritised surgical wait list so that appropriate time can be booked at the operating theatre of a hospital. The patient may also be educated about the operation by a specialist nurse. If an operation is not deemed suitable, then the patient may be further referred for medical treatment.

Use Cases and UML Use Case Diagrams

In software and system engineering, a use case is a technique for capturing the functional requirements of a system (Object Management Group, 2005). Each use case provides one or more scenarios that convey how a specific part of the system interacts with the users (called actors) to achieve a business goal or function. There is no standard format for detailing use cases but some tabular layout is commonly used.

The UML use case diagram, on the other hand, allows the graphical representation of a set of use cases. The UML standard sets out a specific graphical notation (Object Management Group, 2005). Use cases and UML use case diagrams not only provide clarity in terms of actors and sequence of steps involved in the event but also serve as a useful tool to present details of the actor's progression in the system.

Figure 1 shows a use case diagram depicting the process of surgical consultation with a patient in outpatient clinic. Actors are represented by stick figures and use cases by ovals. Associations between actors and use cases are depicted by edges. The "uses" arrow points to a use case that is always invoked, while the "extends" to a use case that is conditionally invoked. In the example, the surgeon always evaluates the patient's symptoms and the test results. The outpatient clinic nurse may order additional tests when booking the appointment, which in turn, may require taking samples (e.g., blood) from the patient. The actor "Patient requiring surgical consultation" is a type of the generic actor "Patient", an example of the common construct of specialisation/generalisation.

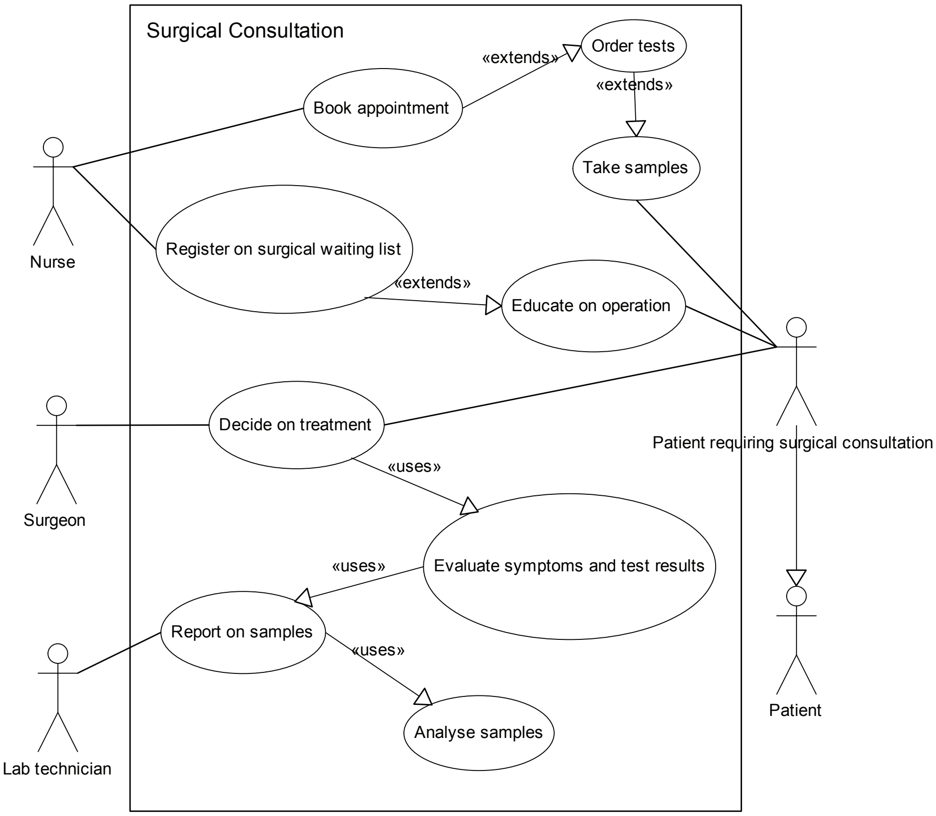
UML Activity Diagram

The purpose of the activity diagram is to depict the procedural flow of actions that are part of a larger activity (Object Management Group, 2005). In projects in which use cases are generated, activity diagrams can model a specific use case at a more detailed level. Activity diagrams can be also used independent of use cases for modelling a function, such as admission to hospital or discharge procedure. They can also be used to model system functions, such as computerised physician order systems, and complete patient pathways, such as from admission to hospital to discharge. Activity diagrams also allow the depiction of parallel activities that often occur in health systems.

In the UML activity diagram, which is based on the semantics of Petri nets, each activity is represented by a rounded rectangle. An arrow represents the transition from one activity to another. The starting point is represented by a filled-in circle and the endpoint by a bull's-eye. Activities enclosed within parallel bars happen at the same time. Diamond shaped objects denote a decision mandated by conditions stated in the brackets above the arrows.

Figure 2 shows a UML activity diagram that models the exemplar surgical care process. Following the referral to the outpatient clinic, booking the appointment and ordering of the diagnostic tests happen in parallel (for the purposes of this example). Depending on the outcome of the consultation, the patient's name is registered on the surgical waiting list if operation is deemed necessary and the patient may receive education about

Figure 1. UML use case diagram of a simplified surgical care service (surgical consultation in outpatient clinic)



the operation, otherwise the patient is referred for medical treatment.

UML State Diagram

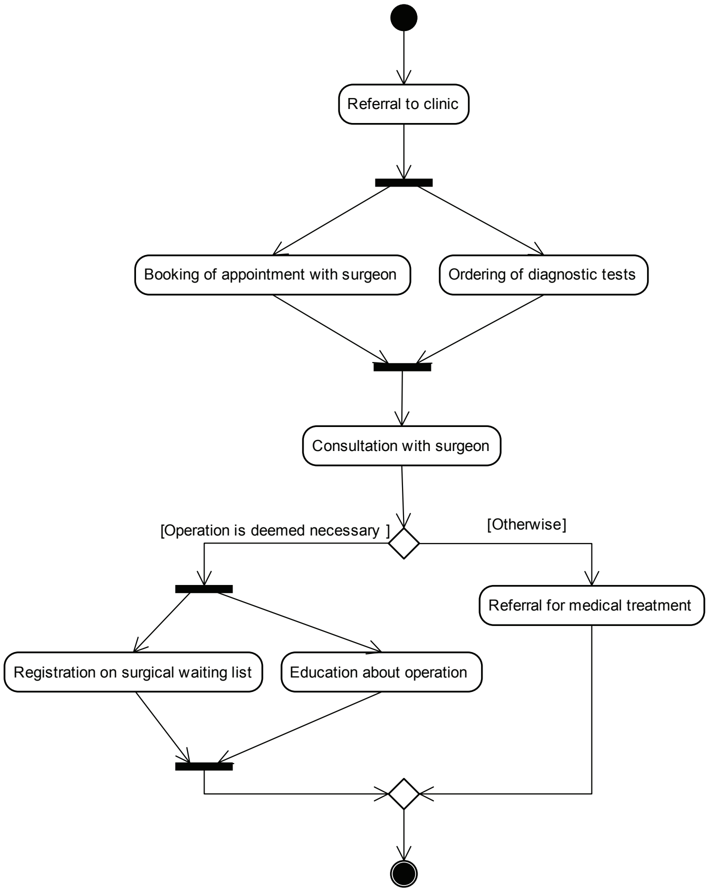
The UML state diagram is essentially a Harel (1987) Statechart with standardized notation that can describe any system that is (or can be conceptualised as) reactive, from computer programs to business processes. In this context, a reactive system—as opposed to a transformational system—is a system that constantly responds to internal and external stimuli by changing states or by performing some action.

Like state machines, a UML state diagram includes state-transition diagrams that represent the operations of a system through discrete states and transitions from one state to another. In addition, state diagrams include notions of state hierarchy, parallelism, and event broadcasting (Sobolev, Harel, Vasilakis, & Levy, 2008).

In UML state diagrams, rectangles represent states and arrows represent transitions. An arrow may have a transition label that controls the transition. The label includes the events that trigger the transition, and the condition that needs to be true for the transition to occur in square brackets. The actions associated with the transition also appear on the labels following the forward slash. Drawing states inside other states represents hierarchy. Dashed rectangles symbolise parallel states.

Figure 3 shows a UML state diagram of patient states in the example of surgical care service. Following the referral to clinic, the initial substates called "pending" of parallel states "appointment" and "diagnostic tests" are activated. When the

Figure 2. UML activity diagram of the care process of a simplified surgical care service (surgical consultation in outpatient clinic)



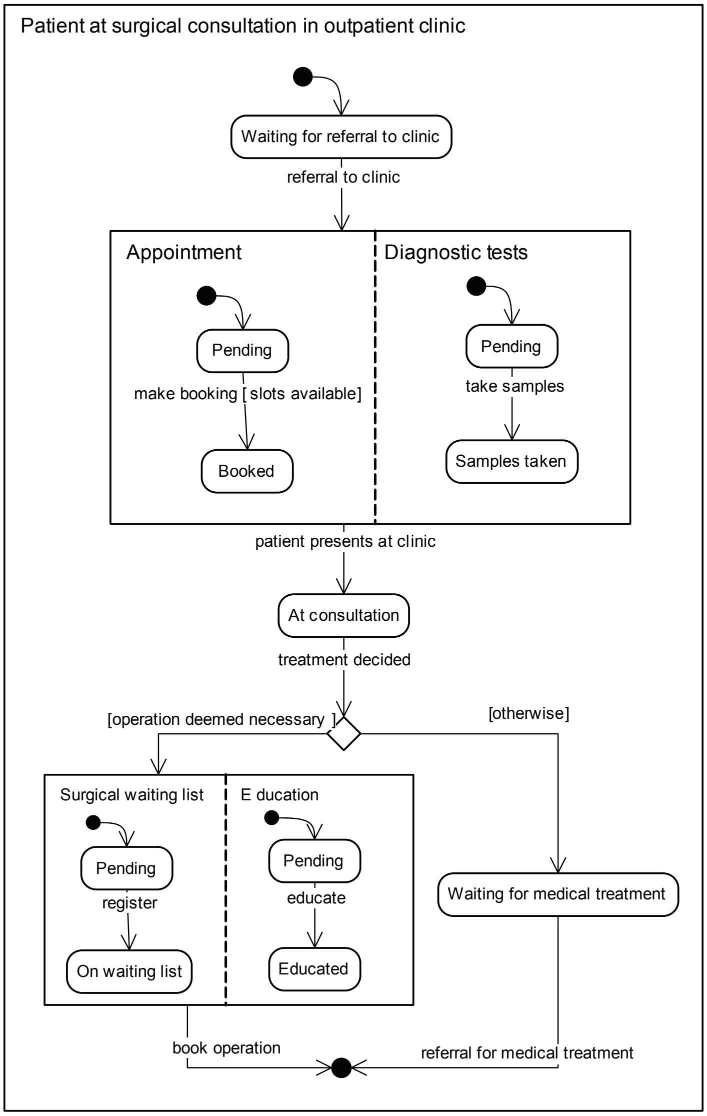
event "make booking" is fired and if there are available slots in the clinic, the patient is considered to have the appointment booked. Once the treatment has been decided and depending on the outcome, the patient state transitions to "surgical waiting list" and "education," or to "waiting for medical treatment."

UML Class Diagram

A class diagram describes the static structure of a system by showing the system's classes, their attributes and methods, and the relationships between the classes (Object Management Group, 2005).

A class, indicated by a rectangle, can be thought of as a blueprint for defining similar objects. Each object is an instance of a class and encapsulates both state, in terms of attributes, and behaviour, in terms of methods. Attributes (or properties) are shown in an optional compartment below the class name. Each attribute is shown with at least its name, and optionally with its type, initial value, and other information. The class methods (or operations) appear in a second optional compartment. Each method is shown with at least its name, and additionally with its parameters and return type. The association between two classes is indicated by a line. The number of objects participating in the association, known as multiplicity, is given by an optional notation at each end of the line

Figure 3. UML state diagram of patient states in a simplified surgical care service (surgical consultation in outpatient clinic)



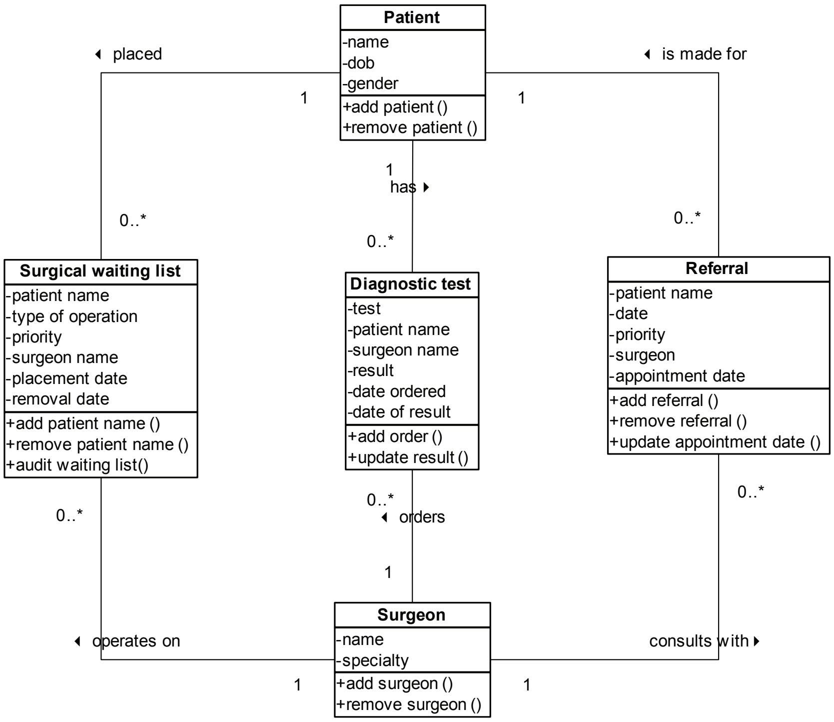
("0..1" if none or only one object participates in the association, "1" exactly one, "0..*" zero or more, "1..*" at least one).

In the example shown in Figure 4, a patient may have none, one, or more referrals (on different dates). Each referral has a priority, is made to the named surgeon, and the appointment slot is updated once it has been scheduled. Patient names are placed on the surgical list of a surgeon following the consultation. A surgeon may be associated with no patients or many. A class diagram may convey a lot more information that is omitted here in the interests of brevity.

Application of UML Tools to Health Care

For the literature survey, we searched the medical literature for articles that demonstrate the application of UML tools to the broad area of health

Figure 4. UML class diagram of a simplified surgical care service (surgical consultation in outpatient clinic)



care. We included all articles that demonstrated the application of any of use case and UML use case diagram, UML activity diagram, UML state diagram, and UML class diagram. Eighteen papers were identified to be relevant to this review, found via published (as listed in Pubmed) and grey literature search. The literature survey identified use cases and use case diagrams (11 papers), and activity diagrams (13) as the most common UML tools of the four included in this survey used in health system analysis. Some studies have reported on the use of class diagrams (3) but none on the use of UML state diagrams. The search yielded very little evidence of a systematic evaluation of the benefits of using UML in the analysis of health care systems.

The retrieved literature can broadly be classified into three categories according to the application domain: modelling health care processes, evaluating and modelling clinical guidelines, and evaluating and generating requirements of information systems in health care. We now briefly review each collected article according to the these categories.

Modelling Health Care Processes

Recent work by Jun (2007) and Jun, Ward, and Clarkson (2005) aimed at providing the effective application of various modelling methods to health care with the end goal of enabling professionals and managers to understand care processes more clearly, manage risk, and as a result improve patient safety. Among the modelling methods evaluated was the swim lane activity diagram, which is a variation of UML activity diagram where activities are grouped according to the actors involved or in a single thread. Three case studies were used to illustrate the methods: patient discharge, diabetic care process in GP practise, and prostate cancer diagnosis process in the hospital. The findings of the case studies were evaluated against benchmark goals of enhancing understanding and validated via key user review of findings.

Cruz, Gramaxo Silva, Soares, Oliveira, Serrano, and Paulo Cunha (2002) reported on the experience of the using UML use case diagrams as a tool to optimise hospital processes. The diagrams were developed at two levels of abstraction: a global use case diagram to represent the main processes of the care services examined, and detailed use case diagrams to study parts of the system seen as critical bottlenecks. Activity diagrams were to be developed in subsequent project phases to model dynamic concepts of each detailed use case. Although Cruz et al. (2002) concluded that UML helped in communication, discussion, and validation of the different steps of the project, there was no evaluation of these benefits.

Goossen et al. (2004) looked at the feasibility of mapping and modelling of nursing care process information to some international standards. They represented the nursing care process as a dynamic sequence of phases, each containing information specific to the activities of the phase, and used UML to represent this domain knowledge in models. A UML activity diagram was developed as a model of a generic nursing care process. After creating a structural model of the information collected at each stage of the nursing process, various working groups mapped that information to other standards as a means of validation. An activity diagram of a generic nursing process was also developed as a problem solving approach to patient care and a UML class diagram enhanced this view and demonstrated further the care process from a nursing perspective. The authors concluded that their study produced a good model of the nursing care process but that improvements could still be made. However, despite the self critique of the study, the authors did not evaluate the UML activity and class diagram benefits and drawbacks as a means to study health care processes.

Spyrou, Bamidis, Pappas, and Maglaveras (2005) proposed an extension of UML to model processes in the health care domain using workflow modelling techniques. The work presented in the article extends the UML activity diagram to support workflow characteristics as well as standardised clinical documents that are handled by the processes. The extended notation was then used to model the flow of patients in a regional health system. No evaluation of the benefits was reported.

Lyalin and Williams (2005) aimed at improving the way cancer registration and other processes are described through enhancements in the notation of UML activity diagrams. The article illustrates a UML activity diagram used to describe the process of cancer registration and which was enhanced by allowing the depiction of timeline, duration for individual activities, responsibilities for individual activities, and descriptive text. The authors claim that this provides for clarification of the process of cancer registration and can broaden its understanding among different specialists. Lyalin and Williams (2005) included an extensive description of benefits and weaknesses of activity diagrams and a comprehensive activity diagram of death clearance process at cancer registry. The authors conclude that the enhancements add value to the tool and cite the positive response they received after using the enhanced UML activity diagrams in a cancer registry best practices development workshop.

Similarly, Saboor, Ammenwerth, Wurz, and Chimiak-Opoka (2005) aimed at improving UML activity diagram by developing and testing a process modelling method which included details of clinical processes necessary for a systematic and even semiautomatic quality assessment. The premise of the authors' work was that UML is only a descriptive tool that does not allow for comprehensive quality assessment. Subsequently, Saboor et al. (2005) proposed a new modelling method based on the UML activity diagram with extra notations to allow for evaluation. The method was validated by modelling various versions of the process of ordering a radiological examination. It was suggested that further evaluation of improvements on the UML activity diagram were needed.

Evaluating and Modelling Clinical Guidelines

Sutton, Taylor, and Earle (2006) developed a computerised system to allow hypertensive patients to be monitored and assessed without visiting their family doctors. The Web-based system, created using PROforma, made recommendations for continued monitoring and for changes in medication. PROforma is a language that allows clinical guideline to be expressed in a computer-interpretable manner. The study concluded that PROforma proved adequate as a language for the implementation of the clinical reasoning but lacked notational convenience. Hence, UML activity diagrams were employed instead to create the models that were used during the knowledge acquisition and analysis phases of the project. Sutton et al. (2006) also reported on the application of UML activity diagram to represent the clinical guidelines in the management of hypertensive patients. The authors praised the notational convenient of UML but did not systematically evaluate its benefits.

In similar fashion, Hederman, Smutek, Wade, and Knape (2002) compared a technique for representing and sharing clinical guidelines (GLIF) with UML activity diagram. The authors concluded that there are clear potential benefits in using a mainstream modelling language such as UML as opposed to a specific clinical guideline representation technique such as GLIF. The potential benefits include availability of modelling tools, the ability to transfer between modelling tools, and to automate via business workflow technology. However the authors provided no systematic evaluation of the benefits of employing UML tools in health systems, but rather focused on the utility of UML activity diagram in general.

Evaluating and Generating Requirements of Information Systems

Maij, Toussaint, Kalshoven, Poerschke, and Zwetsloot-Schonk (2002) looked at the problem of alignment between information and communication technology (ICT) infrastructure and business processes in health care organisations. The paper investigated whether the combination of Dynamic Essential Modelling of Organisations, that is a business process modelling methodology, with UML can solve the problem. It used the example of a screening case study on the management of preoperative centres and focused on developing an efficient information system. Maij et al. (2002) used UML use cases to derive the functionality of the information systems. It also provided a use case diagram and description for a transaction at the preoperative centre. The authors concluded that the combination of the two techniques is useful in aligning business processes and functional features of ICT infrastructure and should help the end-user to develop a better understanding with regards to the relationship between the two areas. Although the paper did include a brief discussion of UML, it did not provide a systematic assessment of its utility in health care.

Lee, Bakken, and John (2006) briefly reported on the use of UML tools (use case, activity, and sequence diagrams) to store and present the functional requirements of a handheld-based decision support system for morbid obesity screening and management. The authors stated that UML is useful in depicting processes related to management of clinical based guidelines, facilitating discussion and agreement in developing data model, and in aiding the design of Web-based prototype.

Lunn, Sixsmith, Lindsay, and Vaarama (2003) reported using UML activity diagram to model various processes of monitoring care and use case diagrams to generate requirements for the development of an information system intended to support planning in the provision of elderly care services. The study is a good example of the application of UML tools in health but provides little guidance in terms of actual benefits and weaknesses.

Weber et al. (2001) aimed at developing a tool to support clinical trial centres in developing trial specific modules for the computer-based documentation system of paediatric oncology. The research carried out an object-oriented business process analysis for a clinical trial conducted at a German hospital. The results comprised a comprehensive business process model consisting of UML diagrams and use case specifications, which included use case diagrams ("manage trial," "plan trial," "conduct trial," "document course of therapy," and documentation view of the latter) and an example of use case specification. Weber et al. (2001) concluded by recommending the use of object-oriented analysis in the context of therapeutic trials but did not carry out the an evaluation.

LeBozec, Jaulent, Zapletal, and Degoulet (1998) described a UML approach to the designing of a case-based medical imaging retrieval system for pathologists. The authors created UML use case and class diagrams to illustrate the steps of the case-based reasoning systems methodology used to develop sound knowledge systems in pathology. The diagrams were used to visualize the relevant objects and to evaluate the model before implementation, and included use case diagram of the image retrieval system and use case with corresponding scenarios chart. The authors concluded that, although further evaluation is required, UML seems to be a promising formalism improving the communication between the developers and users.

Aggarwal (2002) highlighted the benefits of the UML in specifying, visualising, constructing, documenting, and communicating the model of a health care information system. It illustrated the usage of use cases and use case diagram, activity and class diagram by employing simplified examples of a nurse submitting a blood-count order, a physician order system, and of an emergency room.

Ganguly and Ray (2000) discussed the development of a methodology for the design of interoperable telemedicine systems based on UML. Their research focused on the feasibility of the development of agent-based interoperable telemedicine systems and used the example tele-electrocardiography in the case study. Among the tools suggested for system design, Ganguly and Ray (2000) used a UML use case diagram to describe a distributed electrocardiogram system.

Finally, Hoo, Wong, Laxer, Knowlton, and Wan (2000) had as an objective to develop software that facilitates more efficient and effective utilisation of medical images and associated data in biomedical research. The area of focus was assisting clinicians in presurgical evaluation of patients with medically refractory epilepsy as an example. The authors drafted use cases to summarize operational scenarios of clinicians using the system and used UML class diagrams to describe object-oriented concepts of the system.

DISCUSSION

In this article, we introduced four common UML diagrammatic tools (use case, activity, state, and class diagrams) and used original models of a simplified example of surgical service to illustrate their usage. We also presented the findings of a literature survey on the application of these tools to the modelling of health care systems. The survey identified a number of articles in which UML tools were used but very limited systematic evaluation of their benefits.

One notable exception is the recent work by Jun (2007) where a variety of modelling methods, including a variation of UML activity diagrams, was evaluated for their utility in modelling health systems. Jun (2007) identified that only a limited number of modelling methods have been considered or evaluated for purpose of use in health care settings. Following systematic evaluation by health care professionals, Jun (2007) concluded that there is no single method preferred by all users or applicable to all areas but there is a strong case for using a variety of modelling techniques in enhancing the understanding of care process among practitioners. This work is, to our knowledge, the only comprehensive evaluation of different process mapping tools in health care and provided a clear insight to the benefits those methods can offer to the system, practitioners, and the patient. Similar evaluation may also be needed for all UML tools before firm recommendations can be made as to their applicability.

Despite the obvious analytical applicability, also pointed out by Jun (2007), state diagrams have not been used in the analysis of health care systems. The closest case is in an analysis of biological systems by Roux-Rouquie, Caritey, Gaubert, and Rosenthal (2004), where the utility of UML state diagrams to describe and specify biological systems and processes was examined. Roux-Rouquie et al. (2004) mapped biological concepts to UML ones and presented state diagrams with states and substates of the active and inactive enzymes, and with concurrent substates at molecular and phenotype levels. Outside the UML notation, the original Statecharts notation that forms the basis of the UML state diagram notation has recently been used in the modelling and simulation of a cardiac surgical service (Sobolev et al., 2008; Vasilakis, Sobolev, Kuramoto, & Levy, 2007).

CONCLUSION

It is apparent from this literature survey that UML has a role in the analysis of health care systems. There are clear benefits, especially in terms of clarity of communication and repeatability, if a standardised and rigorous notation is employed broadly. However, the application of UML to the modelling of health care systems is probably not as prevalent as in other application domains, at least as it is documented in the medical literature. Therefore, it is essential to conduct a thorough evaluation of the use and potential benefits of UML in a health care context if more wide spread application is to be recommended.

ACKNOWLEDGMENT

This work was partially supported by an award from the Strategic Promotion of Ageing Research Capacity (SPARC) initiative. The authors acknowledge the support they received from the Harrow School of Computer Science, University of Westminster, as well as the generous advice they received from Prof. Peter Millard, Prof. Peter Lansley, and Dr. Elia El-Darzi.

Chapter 8.12

Coding and Messaging Systems for Women's Health Informatics

David Parry
Auckland University of Technology, New Zealand

ABSTRACT

Recording information about symptoms, observations, actions, and outcomes is a key task of health informatics. Standardization of records is vital if data is to be used by different groups, and transferred between organizations. Originally, coding focused on causes of death and other outcomes. Such systems include the international classification of diseases (ICD). However, more recently the need to allow communication between health organizations has encouraged the development of standards such as health level seven (HL7). Further work has focussed on vocabularies such as systematic nomenclature of medical terms (SNOMED), which allow standardised recording of any health-related information. Coded data is necessary to allow computers to assist in decision making and for audit purposes. With the rapid development of computer networks and the Internet, there has been a growing effort to include semantic information with computer data so that the meaning of the data can be bound to the data store. The chapter discusses these standards and the areas that are undergoing rapid development.

INTRODUCTION

"We need three types of clinical information standards: document structuring standards; term lexicons; and ontologies"(Gardner, 2003)

Coding and messaging systems allow the standardisation and systemisation of information storage and transmission in healthcare. They allow the accurate and structured representation of information which can be used to impart a common understanding. The aim of this chapter is to introduce some of these systems along with the theory that underlies them and the uses to which they are put. These approaches are particularly important in women's health informatics for a number of reasons:

- In pregnancy it is common for women to be cared for by a number of healthcare professionals, and communication between them should be precise and efficient
- Past outcomes and complications often have a great influence on the care plans for women in subsequent pregnancies, and this information is much more effective if standardised. Information recorded in previous pregnancies may be useful for risk prediction if presented in a suitable format.
- Government agencies and healthcare organisations require accurate and extensive information in order to fulfil their information needs. Information relating to births has been collected for centuries, and improvement in morbidity and mortality can only be noted with standardised recording.
- Funding and fee for service are often related to the case mix of the institutions providing the care.
- Health Surveillance and audit of outcomes is particularly important for screening programmes and also to understand long-term trends such as the general rise in operative deliveries.
- Research in the area of women's health often requires re-examination of clinical records generated in the past. Accurate coding allows the selection of suitable records and patients for research studies as well as linkage between history, intervention and outcomes.
- An exciting area of research is the development and use of decision support tools that use historical data to provide patients and clinicians with guidance concerning the likely outcome of clinical decisions and the natural history of disease. This sort of decision support is covered in more detail in Chapter XV.

For all these reasons, coding of clinical events, diagnoses and interventions is an important part of an information system designed to support women's health.

At it's heart, coding is a systematic and reproducible method of recording pertinent information for the improvement of management of healthcare. Messaging involves the transmission of healthcare information in a standardised and efficient format within and between information systems that are involved in the care of people.

In terms of system efficiency, coding can dramatically reduce the amount of data stored, and also increase the usefulness of this data for analysis. However the coding process is demanding and requires care and understanding of the principles of the coding system being used.

The next section of this chapter gives some background to the development of modern coding and messaging system. The main varieties of coding systems in use currently (ICD, READ, DRG) are described in the coding systems section. Messaging systems are then described including health level 7 (HL7) and Digital Imaging and Communications in Medicine (DICOM). More complex and complete systems for recording information including some controlled vocabularies such as SNOMED and ontologies are then described. Finally a discussion of the state of the art, and some future areas of development is contained in the final section.

BACKGROUND AND HISTORY

Medicine has grappled for many years with the need to have efficient means of communicating data about patients, diseases and treatments. From the time of Hippocrates, writing down clinical information has been a major part of health care. Comparison between patients, and agreement on diagnosis and symptoms requires agreed recording and communication standards. Medical language has been sometimes seen as a barrier between professionals and lay people, but precision and flexibility are vital even if a private language appears to be in use. Precision and comprehensibility are not mutually exclusive. When computers are involved the need for standards becomes even more important despite valiant efforts over many years in attempting to teach computers to understand natural language (Rosenfeld, 2000). Indeed medical work can be seen as concerned primarily with information communication, storage and transformation. Unambiguous and precise communication of information is vital and a major issue in healthcare (Coiera & Tombs, 1998).

Coding clinical observations has a long history in women's health, for example the "Bishop Score" (Bishop, 1964), derived as a scoring system using various observations in order to aid decision making in induction of labor.

A very precise and often formalised natural language, including a large number of specialised words and compounded terms is taught to clinicians in training. This allows precise description of anatomical features, symptoms etc. and also the construction of new descriptors by combination of existing ones. Although this process is dynamic, for example the term "Gestational proteinuria and hypertension" has recently replaced "Pre-Eclampsia" in many units it does not usually cause difficulties in communication. However, the general tendency as in many fields is to avoid ambiguity rather than encourage standardisation. Thus, a great many synonyms are used and often the preferred term is different in different specialities or countries. This issue makes data processing related to medicine difficult, and for that reason a large number of coding systems have been proposed and a number are currently in use. Ultimately, any coding system is based around an ontology – although this may not be made explicit to the user of the system.

There are 3 main types of coding system:

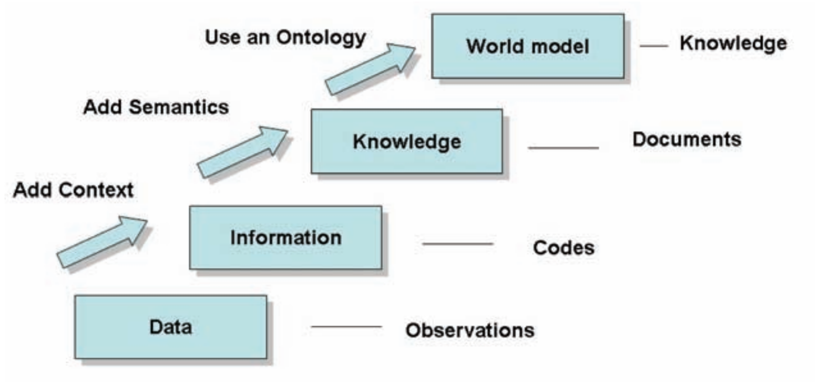
1. Hierarchical systems with fixed codes or terms determined by some central body, for example the International Classification of Disease version 10 (ICD10) (World Health Organization, 2001). In most cases these systems allow a patient to have membership of more than one code simultaneously, although many systems, such as Diagnostic related groupings (DRG's) require the identification of a Primary ICD diagnosis code. Sometimes membership of more than one lowest level code in the same branch is not allowed. Medical Subject Headings (MeSH) are another example of this type of coding system (U.S. National Library of Medicine, 2001).
2. Format-based systems, that specify the allowed format without giving a complete lexicon of the terms – for example the health level 7 (HL7) messaging system. Interestingly the 3rd version of this standard is beginning to include semantic information and standards. (Health Level Seven Inc)
3. Vocabulary systems such as SNOMED that allow the construction of descriptors from primitive elements (American College of Pathologists, 2000).

Often only type 1 is given as a "true" coding system. However, such systems are less useful than the others at communicating a dynamic status, for example in the case where a patient's diagnosis is not yet definitive, or when symptoms may or may not be significant.

Semantics of Coding

Ultimately all coding systems attempt to represent clinical information in a way that can be understood by humans and/or computers. The job of coding involves a standardised representation of a particular significant piece of information. However coding systems are beginning to go beyond the concept of simply being controlled vocabularies or dictionaries, and instead focussing on the importance of meaning, and use. Much of this work can be linked to the concepts of "the semantic web"(Berners-Lee, Hendler, & Lassila, 2001),

Figure 1. Data to knowledge



although work in the medical domain actually preceeded this initiative. As defined on the WWW consortium website (http://www.w3.org/2001/sw/) "The Semantic Web is about two things. It is about common formats for integration and combination of data drawn from diverse sources, where on the original Web mainly concentrated on the interchange of documents. It is also about language for recording how the data relates to real world objects". The semantic web, then involves being able to extract the useful data from complex documents that are generated from heterogeneous sources, and provide a method to allow this data to be analysed and made useful. It also allows data to be related to the real world.

In terms of practical implementation, sematic web research involves the manipulation transfer and analysis of documents written in a suitable format across the Internet.

In the context of healthcare, this means that all records, messages and documents can contribute to a picture of the state of the patients, without the need for overarching single electronic health record. The key to semantic interoperability is that the definitions for what things mean are common, if this is done then every piece of information around the patient can in theory be accessed assuming there are suitable procedures, controls and interfaces. In the case of the semantic web, this common understanding has been built on the basis of standard data type diagrams (DTD's) for XML documents, and some approaches such as HL7 level 3 are implemented in XML(Dolin et al., 2001).

A general model of the role of coding and semantics is shown in Figure 1.

Because observations can be converted to a standard form or code, many observations can be represented in a single document, and assuming that the mapping between observation and code is consistent, then a collection of documents can be represented within a world model.

Coding, Messaging and Workflow

By allowing consistent formatting and transmission of information, the process of transferring information between systems and users can be simplified. Coding of diagnosis for example, allows protocols to be set up that distribute information in a way that supports appropriate patient care. Thus coded data about symptoms, diagnosis or treatment can act as metadata to a fuller description of a current patient state, their likely prognosis and the protocols that need to be followed to ensure appropriate care. For these reasons, early, accurate coding is important.

Traditionally coding has been a post-event activity, often based around the discharge summary, and performed by trained clinical coders. Associations of clinical coders such as the Professional Association of Clinical Coders PACC-UK (http://codeinfo.org/paccuk/index.html), and the American Association of clinical coders and auditors (http://codeinfo.org/paccuk/index.html). Post-event coding has the advantage that the diagnoses and procedures are more likely to be certain at this stage, and there may be written artefacts to guide the coder. This approach is particularly attractive when coding is primarily a source of information for reimbursement to the treating institution, as it allows a holistic view to be taken of activity, along with income from that activity. However the disadvantages of this approach include the fact that coded data is then not available to the clinical team during the event, that mistakes or misunderstandings can be generated by the need of coders to interpret non-coded information, often from a wide variety of sources, and the disruption to clinical practice of having paper records being sent to the coding department.

As electronic health records have become more common, coding at the point of care, or near to the point of care has become attractive. This obviously reduces the time taken to produce codes, can reduce data storage requirements in clinical records, and can allow the codes to be used immediately in decision support applications such as PRODIGY(Wilson, Purves, & Smith, 2000) (now known as CKS). Disadvantages of this approach include the need to train clinical users in often complex coding schemes, the lack of time in many clinical encounters and the danger of propagating uncertain diagnoses through a system.

Accuracy of coding by non-experts can be improved by using specific paper templates or electronic systems to support selection of the correct code. These have been shown to produce results comparable with that of expert coders(Silfen, 2006). The time taken to code can also be reduced by using cascading menu approaches, where the user navigates through the hierarchy that is present in many codes such as Read or ICD10, for example choosing first the system or site and then being presented with intermediate context-sensitive choices. By using this approach, decisions on coding and the required precision can be made more easily with less risk of grossly inaccurate codes and a better understanding of the subtle differences between them (see Figure 2).

Users of Information

Clinical staff actually treating the patient are major users of information. In addition, there is a need for communication between hospital staff and community care professionals including GP's, Pharmacists and family planning professionals. Non-clinical cares including social services may also require information. Insurance companies, charity funders and governmental organisations require data in the form of activity reports and for statistical purposes. Obviously the patients themselves can use their own information Efficient and effective coding allows large scale databases to be constructed, which can be anonymised to allow statistical analysis, for example in terms of prescribing trends. An example of such a database is the UK General Practice Research Database (Walley & Mantgani, 1997). Similar databases can be used as sources of recruitment for clinical trials, or for audit purposes.

In the US a major user of coded information is the Medicaid system, and this has used Diagnostic Related Groups (DRG's) to identify the severity and hence expected cost of treatment of patients. Software –GROUPER – is used to convert diagnosis and procedure information into a DRG, in this case a case mix index. (CMI). Health care facilities can then calculate their actual costs, compared to the reimbursement derived from funding sources.

Along with clinical and research uses coding assists with accurately describing the mix of patients being seen, auditing of the outcomes compared with other centres and estimation of effort. Other scoring systems measure the likelihood of survival in intensive care – for example

APACHE, and have been shown to be good at predicting outcome (Beck, Taylor, Millar, & Smith, 1997), fortunately, although not specifically designed for women's health. There are a number of systems to measure nursing intensity or worklaod – for example the therapeutic intervention scoring system (TISS)(Keene & Cullen, 1983), although these systems are not necessarily very useful for calculating nurse/patient ratios (Adomat & Hewison, 2004).

Clinical staff can use historical coded information to audit their practice, as well as comparing their Casemix with other professionals and linking input to output. Pregnancy care is particularly interesting in this regard- especially in terms of the decision to intervene. The problem is difficult to analyse because outcomes for mother and baby are usually good whatever the decisions made. Essentially, if an intervention is made, comparison with a group where intervention has not been made is difficult because the outcome set is very unbalanced, with good outcomes in the vast majority of cases. By looking at large series of deliveries and analysing the decisions made, then there has been some understanding of the decision making process, but this remains an area of active research (E.C. Parry, Parry, & Pattison, 1999).

CODING SYSTEMS

Coding systems in medicine exist to remove ambiguities, simplify representation, assist with audit and outcome analysis and support decision making as well as having a major role in administration of healthcare systems. Historically, the coding of disease and especially cause of death has been intimately linked to the collection of statistics. Coding systems can trace back their origins to at least the "Bertillon Classification of Causes of Death," which was introduced at the end of the 19th century. Generally, coding occurs at the end of an episode, for example the method

Table 1. ICD 10 procedure codes

ICD10 Code	Description
10D07Z3	Extraction of Products of Conception, Low Forceps, Via Natural or Artificial Opening
10D07Z4	Extraction of Products of Conception, Mid Forceps, Via Natural or Artificial Opening
10D07Z5	Extraction of Products of Conception, High Forceps, Via Natural or Artificial Opening
10D07Z6	Extraction of Products of Conception, Vacuum, Via Natural or Artificial Opening
10D07Z7	Extraction of Products of Conception, Internal Version, Via Natural or Artificial Opening

of delivery of a baby is coded after the baby is delivered.

ICD10

The international classification of diseases is currently in its tenth version (World Health Organization, 2001). This system is administered by the World Health Organisation and is free to use. ICD10 covers a vast range of diagnoses as well as procedures and modifiers. IC-10-CM (clinical modification) which is used for diagnosis includes alpha numeric codes that are 1 to 7 digits long, based largely around anatomical site, followed by disease process and then modifiers. ICD-10-CM is available from the Centres for disease control (http://www.cdc.gov/nchs/about/otheract/icd9/icd10cm.htm) and contains over 68,000 codes in the July 2007 release. Pregnancy codes begin with an 'O' and the modifier generally relates to the trimester.

Gynaecologic disorders do not have their own initial letter but are classified according to the site or type of illness. ICD10 PCS (procedure coding system) is as the name suggests a means of coding procedures. Previous releases of ICD combined the procedures and the clinical descriptions but these are now separate. There are over 86,000 procedures listed in the July 2007 release. Some examples of codes relating to obstetric procedures are shown in Table 1.

ICD codes are designed so that they are increasingly precise from left to right so that when searching for particular diagnoses, one can use select a portion of the code to give the correct degree of precision. For example, looking at Table 2 it can be seen that a search for O104.1* would give all the secondary hypertension patients no matter which trimester they were in.

Read

Read codes were developed for the primary care sector by Dr. James Read in the UK and version 3 was delivered in 1995 (O'Neil, 1995). Read codes are not free to use, but many countries have purchased a licence for use in their healthcare system. Their use is widespread in the UK and has enabled the general practice research database to be built up, containing anonymised data about eight million people(Walley & Mantgani, 1997). This large dataset has been used for investigations into women's health issues, for example (Bromley, Vries, & Farmer, 2004) on the use of hormone replacement therapy. Read codes come in a number of varieties but are generally related to an hierarchy in which successive characters of the code identify the anatomic location or the condition or the procedure more precisely. In many countries Read codes are being superseded by SNOMED CT.

Diagnostic Related Groups (DRG)

DRG's were originally developed to compare casemix between hospitals, so that health providers with more complex cases were not penalised compared to those with simpler workloads. Because of

Table 2. Examples of ICD-10-CM codes with descriptions

ICD10 Code	Description
O104.11	Pre-existing secondary hypertension complicating pregnancy, first trimester
O104.12	Pre-existing secondary hypertension complicating pregnancy, second trimester
O104.13	Pre-existing secondary hypertension complicating pregnancy, third trimester
O104.19	Pre-existing secondary hypertension complicating pregnancy, unspecified trimester

this role, DRG's are linked closely to values for cost of care and length of stay. DRG's comprise a much smaller list of categories than other coding systems- for example in the Austalian DRG system there are only 17 Obstetric codes and 20 Gynaecological ones. Perhaps surprisingly, this reduced granularity and focus on severity of illness or difficulty of treatment can make coding difficult as the code use terms such as "catastrophic" or "severe" complications, which may be difficult to impliment. Recent work in Australia has shown wide variations in the reporting of DRG's (Coory & Cornes, 2005), and this has implications for the idea of paying standard fees per DRG, rather than the calculated cost of service. Similar problems exist if using DRG 's to measure quality of outcome, or level of care. In the obstetric domain, a particular problem is that there is not always a causal link between the risk to mother and baby, the procedure performed, or the outcome of the procedure. For example, a "ceasarian section with catastrophic complications" (O01A) can occur in a pregnancy that is assessed as low risk, whereas an "Vaginal Delivery without Catastrophic or Severe complications" (O60B), can occur after extensive efforts in pregnancy evaluated as being at high-risk of complications.

The DRG system grouper can accept ICD10 codes as an input. Recently work in Taiwan (Yang & Reinke, 2006) has demonstrated that a severity score comparable to DRG can be calculated directly from the ICD10 values.

MESSAGING SYSTEMS

Role of Messaging Systems

Messaging systems allow transfer of information between health information systems. It is very common to have multiple organisations dealing with the care of a woman, during a particular episode. Communication between organisations, and hence between information systems is therefore vital. Such communication occurs in many domains outside healthcare, and is seen as an important factor in increasing efficiency (H.R.Johnston & M.R. Vitale, 1988). Messaging systems allow information to be transferred between systems by using interfaces rather than a common system. Therefore if one part of the system changes, then only the interface needs to change rather than the whole system. However, it is attractive to extend the role of messaging systems to become document storage and management systems., and this expansion has occurred in the case of the most commonly used system – Health level 7(HL7).

HL7

HL7 is so called because it sits at the top of the International standards organisation (ISO) Open system interconnect (OSI) standard . This means that HL7 is associated with the *application* layer, which is the highest one of the model. This corresponds to the application layer of the TCP/IP protocol. In practical terms this means that HL7 messages can be transmitted by any system that is OSI compliant HL7 is administered by the HL7 organisation (http://www.hl7.org/) and is an American National Standards Institution (ANSI) standard. Originally HL7 was a simple messaging protocol, designed to encapsulate clinical information by providing standardisation of formats and minimum data sets. In this approach it has been very successful, with large-scale adoption across many countries and systems, particularly in the area of pathology results and pharmacy orders. Within the message format the vocabulary used is dependent on the application but the Logical Observation Identifier Names and Codes (LOINC) Vocabulary (Huff et al., 1998) is often used.

Health level 7 version 3 has been developed since 2001 to incorporate a clinical document architecture based around XML representations of clinical notes (Dolin et al., 2001). This representation is much more semantically rich than previous approaches and has caused some debate as to whether this will improve the standard or reduce its applicability.

OTHER SYSTEMS

Medical Subject Headings (MeSH)

Medical subject headings (MeSH) are the index terms used by the National library of Medicine (USA). MEDLINE covers more than 11 million journal articles, published since the 1960's and beyond. Historically, MEDLINE can trace its heritage back to the work of Dr. John Shaw Billings (1838-1913) who served as a surgeon in the American Civil War and the director of the National Library of Medicine between 1865 and 1895. During this time "INDEX Medicus" was first published (1879). Index Medicus is an expanding, regularly updated, bibliography covering many medical journals, containing information about author, source, subject and often an abstract of the article. MEDLINE has acted as a successor to this effort. Around 500,000 articles are added to MEDLINE every year, from more than 5000 journals. MEDLINE is accessible via a number of sites including "PubMed" and "Ovid". MEDLINE is available via CD ROM and via the Internet in the PubMed format at no cost to users. Other related databases such as CINHAL (mostly nursing–related) and PSYCHLIT are available from the National Library of Medicine. (Table 3)

MeSH codes are of the form <A00.000...> where A represents an alphabetic character and 0 is a digit between 0-9. As the name suggests MeSH is a hierarchy, with branches being represented by adding 3 digit combinations separated by full stops. Up to 4 extra XXX digit sets can be included.

It is important to note that MeSH is a bibliographic indexing scheme rather than a coding system for describing disease. Thus the choice of index terms is driven by the need to categorise documents, rather than clinical activity. Although arranged as a hierarchy, terms can occur in

Table 3. Root headings for terms taken from MeSH

Code	Description
C13	Female Genital Diseases and Pregnancy Complications
A16	Embryonic Structures
A01.673	Pelvis
A16.378	Fetus
A16.254	Embryo
A16.759	Placenta
A16.950	Zygote
A16.631	Ovum
C02.800	Sexually Transmitted Diseases
C13.371	Genital Diseases, Female
C13.703	Pregnancy Complications
E04.520	Obstetric Surgical Procedures
F03.600	Mood Disorders
F03.800	Sexual and Gender Disorders
G08.520	Reproduction
M01.438	Multiple Birth Offspring

multiple locations, which raises issues with the disambiguation of terms if MeSH is used for the analysis of documents or ontology construction (D. T. Parry, 2006).

DICOM

Digital Imaging and Communication in Medicine (DICOM) is a standard that was jointly developed by the American College of Radiologists and the National Electrical Manufacturers Association(NEMA) in the early 1980's. Currently NEMA holds the copyright for the standard – available from its website http://medical.nema.org/, and although the standard is version 3 the latest revision is known as the 2007 version. DICOM covers the representation, transport and storage of images, originally mostly X-rays, but now extending to ultrasound, MRI, waveforms and other data. DICOM at its simplest level is a file format, which combines patient and other data with the image. In essence the clinical information and patient information are inseparable from the image. This approach is used to avoid non-identifiable images, or wrongly identified images, being produced. Each DICOM file has only one image, but this can be composed of a number of frames which allow for the production of Cineloops. The DICOM standard allows a number of image formats including JPEG, MPEG and lossless JPEG to be used in the file. In terms of transporting the data, DICOM 3 supports transport over TCP/IP, and there are a number of HTTP based approaches, so that conventional web services can be used. DICOM can also deal with files that are transferred or stored on CD's DVD's and other physical transfer media. Some work has been done on assessing the image quality of images compressed using lossy and non-lossy methods(E.C. Parry, Sood, & Parry, 2006),in the context of transfer of obstetric ultrasound images via cheap memory sticks.

The DICOM standard includes "structured reporting", so that the radiology report is included in the file. Recent work (Zhao, Lee, & Hu, 2005) has shown that this can be represented in a XML format, thus increasing the portability and verifiability of the reports.

Because of its origins, DICOM is an extremely precise standard, designed to allow accurate reproduction of images in various formats.

Unified Medical Language System (UMLS)

UMLS is an extremely large repository of concepts and related terms for use in biomedical science. Developed by the National Library of Medicine (NLM), it includes not only its own subject hierarchy (MeSH), but also the metathesaurus, which incorporates ontologies from other sources (Nelson, Schopen, J., & N., 2001). These have lead to the identification of currently over 800,000 strings, with about 330,000 unique concepts. The NLM is to be congratulated for not only providing an extremely large lookup table for these concepts (MRCON), but also providing a list of the relations between them (MRREL). The UMLS also contains the SPECIALIST lexicon, of medical and non-medical terms and the semantic network, that allows complex semantic relations to be checked and constructed. The recent releases of UMLS (Anantha Bangalore, Karen E. Thorn, Carolyn Tilley, & Lee Peters, 2003) have incorporated a new object model and implementation of the system using Java and XML.

Ontologies

An ontology acts as guide to the relationship between concepts in a domain, which may or may not themselves represent physical objects. An ontology is useful for purposes of knowledge sharing and reuse, in fact an ontology can "express formally a shared understanding of information" (Noy et al., 2001) page 60. That is, by understanding the relationships between objects then the interaction between objects, the operations that can be performed on them, and the appropriate position of new objects becomes easier. Tacit ontologies seem to exist in everyday life, as people generally appear able to share knowledge of relations in normal activities. An ontology employs a richer set of relations than a hierarchy, which normally just consists of "is-a" relations. For example one can say in a anatomical ontology that the uterus is contained within the abdomen, and that the fetus is contained within the uterus in normal pregnancy. Hence the fetus is contained within the mother's abdomen. However other relations are possible – so for example the uterine artery can be said to be supplying the fetus via the placenta. Many ontologies have extremely rich sets of relations available e.g. Unified Medical Language System (UMLS), WordNet, PROTÉGÉ. The relations for UMLS are described in Chapter 2. There has been a great deal of interest recently (Musen, 2001) in the construction of ontologies for representing medical knowledge. In many ways an ontology is similar to an XML document, or a class in an object-orientated programming language (Ensing, Paton, Speel, & Rada, 1994). The representation encodes a hierarchical structure, with inheritance of properties from root to branch, with additional attributes at each level. The advantage over the fixed hierarchy of say ICD10 is that such ontologies can be modified with the inclusion of new branches or leaves, and the location of such a new item can give information about it even to users that are not aware of the new terms used. This approach has been encoded in XML, for use in clinical guidelines (Harbour & Miller, 2001) and anatomy. Effectively an ontology allows the users to agree on quite complex relationships between items, and what the consequence of those relationships are – thus in the relationship above, if an item supplies another item then if the original item is disrupted, this may affect the final one – so reduction in blood flow in the uterine artery leads to reduction in blood supply to the fetus.

Systematized Nomenclature of Medicine-Clinical Terms (SNOMED CT)

SNOMED CT is a clinical vocabulary currently administered by the international health terminology standards development organisation (IHTSDO) http://www.ihtsdo.org/. Member countries are; Australia, Canada, Denmark, Lithuania, The Netherlands, New Zealand, Sweden, United Kingdom and United States. SNOMED CT (**S**ystematized **No**menclature of **Med**icine-**C**linical **T**erms) was originally developed by the American College of Pathologists, and contains more than 600,000 concepts. SNOMED is organised as an "is-a" hierarchy. Exploring the SNOMED hierarchy is a very good way to begin to understand its power and browsers such as cliniclue (www.cliniclue.com) and SNOB are freely available within the countries that are part of IHTSDO. Synonyms for concepts are also included, and there are concepts that link concepts, across the hierarchy. Concepts are futher categorised into observable entities, diagnoses etc. For example "Pregnancy" code 289908002 is an observable entity and lies below " Female genital tract functions" (289907007) in the hierarchy. Conceptual Relations to other concepts – including disorders of pregnancy etc. are also available. As a vocabulary SNOMED can be used to generate documents using standardised terms – just like natural language, two parties need to use the same vocabulary in order to understand each other.

Evaluation of coverage(Penz JF, 2004) has demonstrated that SNOMED-CT was able to code 90% of previously unresolved narratives, using automated tools. Other recent work has shown that by using SNOMED, coding of free-text clinical documents may be amenable to automation (Patrick, Wang, & Budd, 2007). This demonstrates that the coverage and arrangement of SNOMED concepts is sufficient to allow understanding, and opens the prospect of electronic health records that combine the ease of use of free-text by humans while storing data that can be analysed by machine.

DISCUSSION

Coding and messaging systems can be seen as part of a continuum of semantic richness, beginning with controlled vocabularies and ending with complex semantically rich documents. The essential role of coding and messaging systems is to enable sharing of both information and understanding. This is particularly important in the area of women's health where patients are often cared for by a wide variety of clinical workers, sometimes coming from different organisations. Conversion between systems will remain an important function for informaticians for the foreseeable future, along with extension and refinement of such systems. Perhaps most importantly the choice of the correct standards to use will continue to challenge system developers and health providers. With the replacement of READ by SNOMED CT in the UK as part of the major "connecting for health" initiative, a more stable landscape seems to be emerging.

Efficient and effective coding and messaging offer the vision of a "world minimum dataset" sharing information between the national and regional datasets that exist around the planet. International comparisons, but more importantly use of such data to identify and support best-practice may lead to improved care especially for particularly rare conditions or combinations of them. However tt should always be remembered that the woman is at the centre of women's health and these tools, while useful, should not mask the individual. Perhaps there is a role for "coding for clients", so that the experiences of women can be recorded and given the attention it deserves. Coding does not replace care, but it can support it.

FUTURE RESEARCH DIRECTIONS

Undoubtedly there has been an enormous effort in the fields of coding and messaging. Two challenges still exist, the need for organizations to adopt and use these standards and agreement on the combination of standards to use. HL 7 appears to be the strong front-runner in the messaging field, and with version 3 seems to be merging into the world of web services and the semantic web. Similarly SNOMED CT appears to be the future of controlled vocabularies, although world-wide adoption relies on governments joining the standards organization, which may be a rate-limiting step. The example of the WHO maintaining and developing ICD may be an example of the way forward in the future. Moving from proprietary to open standards is a theme across computing, and with the development of the semantic web and interoperability, health care will move the same way. Indeed if women are to control the use of their health data, means of coding and decoding health information for consumers of health may be a major issue in the next few years.

Chapter 8.13

The S'ANT Imperative for Realizing the Vision of Healthcare Network-Centric Operations

Nilmini Wickramasinghe
Illinois Institute of Technology, USA

Rajeev K. Bali
Coventry University, UK

ABSTRACT

In the information-intensive environment of healthcare, the networkcentric approach has been proffered as one that allows free and rapid sharing of information and effective knowledge building required for the development of coherent objectives and their rapid attainment. This article asserts that if we are to realize such a vision it is imperative to draw upon strong rich analysis tools and techniques and thus calls for the application of Social Network Analysis combined with Actor-network Theory (S'ANT).

INTRODUCTION

Environmental complexity of healthcare operations is often magnified by the presence of multiple actors (agencies, governmental bodies, global organizations, etc.) who perform within the same space, but use a wide variety of independent and non-intercommunicating platformcentric tools. As a consequence of the resulting chaos, the attainment (mission) of healthcare goals (objectives) is uncertainty – rather than being information-driven (von Lubitz and Wickramasinghe, 2005; 2006e). In response to the inefficiency of the highly fragmented programs to address even the most urgent aspects of healthcare across the globe, a demand for the development of a new rule set (Barnett, 2004; Onen, 2004; Olutimayin, 2002; Banjeri, 2004) governing the future actions began to emerge – the quest for the "doctrine of global health."

In response to this void von Lubitz and Wickramasinghe (2006b-e) proffered the doctrine of networkcentric healthcare. This doctrine finds its operational predecessor in the military application of information and decision support system networks based on uniform and widely distributed access, collection, processing, and dissemination standards (Cebrowski and Garstka, 1998). The doctrine calls for the development of interconnected information grids that, together, constitute a powerful and well-structured network that facilitates information sharing among all participants within the operational continuum (space, see Cebrowski and Garstka, 1998; Stein, 1998). Consequent to improved information sharing is the enhancement of its quality and integrity which, in turn, escalates the level of situational awareness that is the foundation for efficient, real-time collaboration among the involved entities, their self-synchronization, and operational sustainability. The overall operational effect of networkcentricity was a dramatic increase in mission effectiveness (Cebrowski and Garstka, 1998) whose success, even at the earliest trial stages, led to the adaptation of networkcentric concepts by several armed forces across the globe. For the same reason, the doctrine begins to find its place in the modern, ICT-driven business world (ibid).

THE CONCEPTUAL BASIS FOR NETWORK-CENTRIC OPERATIONS

The cardinal details of the networkcentric doctrine of healthcare operations have been described in detail by von Lubitz and Wickramasinghe (2006b-e). The doctrine is rooted in the pioneering work of Boyd (1987) (see also von Lubitz and Wickramasinghe, 2006b-ed-e) who analyzed the process of decision making and the fundamental principles of interaction with, and control of, a fast paced and dynamic environment. Critical research-based projects (as applicable in the area of information systems and health) have a growing tradition of qualitative inquiry. Despite its relativist ontology, actor-network theory places a strong emphasis on empirical inquiry and so actor-network theory is ideally suited to the generation of detailed and contextual empirical knowledge (Doolin B and Lowe A, 2002). Following its initial military applications, Boyd's OODA Loop as it is presently known, found many adherents and practical uses in a wide variety of civilian applications including medicine (von Lubitz et al., 2004 von Lubitz and Wickramasinghe, 2006a-e).

THE NATURE AND DEFINITION OF THE DOCTRINE OF NETWORK-CENTRIC HEALTHCARE

Following the inate nature of actor-network theory, the intricate and mutually constitutive character of the human and technology (in the processes and relationships of illness and health) has been demonstrated (Prout, 1996). In addition to this "micro" example, successful interaction with complex sets of macro-environments (macro-environment galaxies) such as global healthcare (which comprises a vast array of independently identifiable macro-environments) presents an insurmountable task *unless assisted by a highly sophisticated, multilayered network of ICT that incorporates a full range of telecommunication platforms, sensors, data storage elements, analytical nodes, and dispersed access points, the operation of which provides flexible command and control and rapid response capabilities.*

The doctrine of networkcentric healthcare has its roots in networkcentric computing (von Lubitz and Wickramasinghe, 2006b-e) whose practical development has been greatly facilitated by the rapid progress of various areas of ICTs (e.g., HTML, TCP/IP, Web, JAVA, XTML, etc (– refs Hironaka, 1992, Valdes et al., 2003)). The principal task of networkcentricity in healthcare operations is to develop the state of *information superiority.*

The state of information superiority provides the actors with the critical *operational advantage* that allows them to determine and dictate the direction and tempo of all activities in a collaborative, highly coordinated manner which, in turn, reduces the time needed to reach the preset objectives in the most effective and economical manner. Even the sketchy and largely anecdotal reports of the events surrounding Hurricane Katrina operations indicate quite clearly that the absence of the state of information superiority was one of the principal culprits in the resultant leadership failures, absence of coordination, and a number of avoidable post-hurricane fatalities (e.g., CNN News, ABC)

Unsurprisingly, in order to be executed efficiently, healthcare operations must be conducted within the intersecting territory of three mutually interconnected and functionally related domains (von Lubitz and Wickramasinghe, 2006b-e; Garstka, 2000):

- The *physical domain* which encompasses the structure of the entire environment healthcare operations intend to influence directly or indirectly, e.g., elimination of disease, fiscal operations, political environment, patient and personnel education, etc. Information within this domain is the easiest to collect, analyze, and disseminate.
- The *information domain* contains all elements required for generation, storage, manipulation, dissemination/sharing of information, and its transformation and dissemination/sharing as knowledge in all its forms. It is here that all aspects of command and control are communicated and all sensory inputs gathered.
- The *cognitive domain* relates to all human factors that affect operations, such as education, training, experience, political inclinations, personal engagement (motivation), "open-mindedness," or even intuition of individuals involved in the relevant activities. Difficulties in metrics relevant to the cognitive domain notwithstanding, a body of experimental studies begins to emerge that will, ultimately, provide close quantitative relationships to other domains that govern healthcare operations space (e.g. Bodner et al., 1986; Roberts and Clifton, 1992; Back and Oppenheim, 2001; Newby, 2001; Wetherell et al., 2002; Abel-Smith, 1989).

Hence, fundamental to the doctrine of networkcentric healthcare operations (HNCO) is "*unhindered networking operations within and among all three domains that govern all activities conducted in healthcare space and are based on free, multidirectional flow and exchange of information without regard to the involved platforms or platform-systems and utilizing all available means of ICTs to facilitate such operations.*

THE PHYSICAL CONSTITUENTS OF THE WORLDWIDE HEALTHCARE NETWORK

The essential and enabling element of HNCO is the Worldwide Healthcare Information Grid (WHIG) that allows full and hindrance-free sharing of information among individual domains, their constituents, and among constituents across the domains. In order to perform such a function, the WHIG must consist of an interconnected matrix of ICT systems and capabilities (including communication platforms, data collection, storage, manipulation/dissemination, and sharing), associated processes (such as information and knowledge storage and retrieval, management and their dissemination/sharing), people (e.g. healthcare providers/investigators, administrators, economists, politicians, lawyers, ICT personnel), and agencies (governmental and NGOs (Non-Governmental Organizations) at local/national/international level).

The required technology (von Lubitz et al., 2005) and individual components of WHIG already exist (von Lubitz and Wickramasinghe, 2006b-e), and their role and interactions in the context of networkcentric operations described in a greater detail elsewhere (von Lubitz and Wickramasinghe, 2006b-e), the grid itself needs yet to be constructed based on universally accepted and shared operational and security standards and protocols that will allow free and unfettered access to all actors within the healthcare space Once developed, the Grid will facilitate information sharing and enable joint development of objectives, precise characterization of missions necessary to attain these objectives, allocation of adequate resources, and continuing monitoring of progress. The latter will, in turn, permit not only timely intra-operational interventions (e.g., modifications of the mission profile, changes in resource allocation) but, even more significantly, assist in the development of the unified command structure necessary for the synchronization of currently non-related and often disorganized and discordant efforts conducted within the same segment of healthcare space. That such controls are required in very large scale operations is demonstrated by several studies showing that, in the developing countries in particular, the currently disorganized conditions of healthcare aid often result in inefficiency and inappropriate application of the available resources (Abel-Smith, 1989; Howard, 1991; Collins and Green, 1994; Schneider and Gilson, 1999; Buse, 1999). However, as demonstrated by the activities related to Hurricane Katrina, even in a highly developed and technologically advanced nation like the US similar errors appear to prevail. The reasons for the prevalence of these difficulties have been discussed elsewhere (von Lubitz and Wickramasinghe, 2006e).

Access to the WHIG is facilitated through "smart" portals (described in detail in von Lubitz and Wickramasinghe, 2006b-e) that provide the gateway to all operationally pertinent information existing within the network. Operational (pertinent) knowledge support is derived through a semi, or fully automated search of WHIG by the information processing capabilities and decision support capabilities of the smart portal, followed by the equally semi, or fully automated assembly, analysis, and pertinent knowledge derivation. Based on agent technologies, and contrary to the majority of the existing portal systems, the "smart portal" is fully active, and its operations provide relevant data, information, and knowledge based on cross-domain objective analysis of all relevant facts rather than those that may be, often erroneously and subjectively, classified as relevant by the human operator.

One of the critical attributes of the smart portal is the ability of its agents to navigate easily and autonomously throughout the entire grid system. Navigation of such type must be based on a well structured grid map that will assist in determination of the source of the incoming information, its nature, validity, pertinence, and ultimate destination. Some of the involved processes have been described in a prior paper devoted to network-based simulation training of First Responders (von Lubitz et al., 2004.) Presence of universal standards is among the fundamental prerogatives determining the ability of the smart portal and its agent to locate, analyze, transform, and disseminate all relevant information and knowledge located throughout the WHIG network. Absence of such standards appears to be among the principal reasons that perpetuation of platformcentricity in the existing decision support systems. As a consequence, vital information existing within healthcare-irrelevant networks remains hidden from its potential users. Once again, the operational difficulties caused by the lack of across-the-board standards governing information acquisition, storage, analysis, dissemination, and retrieval are well exemplified by the problems encountered by healthcare personnel in the immediate aftermath of Hurricane Katrina.

While portal automation does not free the human controller from the process of definitive decision-making, the portal serves as a powerful decision support system capable of more complex analysis of pertinent facts and of the determination of outcomes resulting from a large number of the possible permutations of these facts. Metcalfe's Law predicts that linking of smart portals and their individual computing/analytical capabilities to the WHIG will produce massive increase of the available decision support power and accuracy that will be readily available to the actors within the healthcare operational space. Still absent from the scene of large scale, combined healthcare operations, networked smart portals find their rapidly growing implementation in military operations (e.g., battle space analysis and situation-relevant mission assignment) and, on a much smaller scale, in the pharmaceutical industry (e.g., Novartis, see Markoff and Schenker, 2003.) The complexities of networkcentric operations are invariable linked to the issues of security and data/information integrity and, given the total access to WHIG provided by the smart portal to all actors within the operational space, it is vital that the highest level of security protocols are maintained at all times.

RICH ANALYSIS TOOLS AND TECHNIQUES

In order to design, develop and thereby successfully realize the vision of networkcentric healthcare it is vital that rich analysis tools and techniques are fully utilized. If we look in the social theory literature, two appropriate candidates include Social Network Analysis (SNA) and Actor-Network Theory (ANT).

Social Network Analysis (SNA)

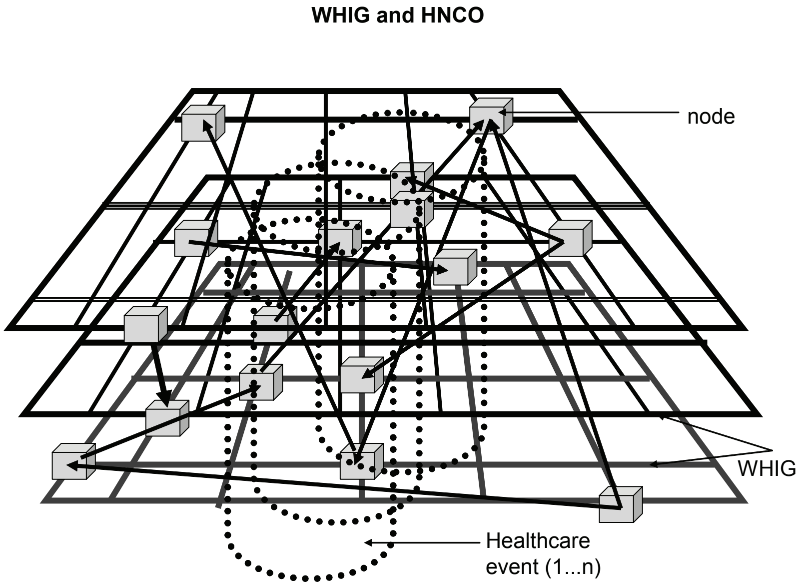
SNA is a technique that facilitates the mapping and measuring of relationships and flows between people, groups, organizations, systems as well as all information/knowledge processing organizations and thereby enhances metacognition with respect to the representation of organizational knowledge in networks (Wasserman and Faust, 1994; Niessen 2007). People and groups are represented as nodes while the relationships or flows are represented by links. Taken together this analysis of nodes and links builds the network under consideration. The location of actors in such a network is critical to a deeper understanding of the network as a whole and the participation of individual actors. Location is measured by finding the centrality of the node.

In terms of centrality three considerations become important in any SNA; degree of centrality – in other words how many people connect with you, betweenness – or whether or not you are located between two key actors in the network and thus may play a "broker" role, and closeness – or ones position relative to others (especially key players) in the network. In addition, it is important to note if there exist boundary spanners: actors who bridge or overlap into different networks, or peripheral players: actors who are perceived as unimportant.

One way to improve the current state-of-the-art in SNA is to develop new ways to produce interval/ratio measures of relations between the various individuals in the organization to determine the strength of their ties (Liebowitz, 2005). Analysts of social networks are interested in how the individual is embedded within a structure and how the structure emerges from the micro-relations between individual parts (Hanneman, 2002).

To illustrate the value for SNA within HNCO let us look at Figure 1. Within the WHIG structure various healthcare events (denoted by cylinders labeled healthcare event 1…n) have been highlighted. If we return to the earlier discussion of Hurricane Katrina, it is possible to think of one of these events as Hurricane Katrina. In this context the nodes (cubes on WHIG) represent various actors. What becomes of crucial importance in the emergency and disaster state of Hurricane Katrina is the distance or centrality of key actors since the key actors are the important decision makers and in such a context rapid prudent decision

Figure 1.



making can save lives. Clearly, in such a context the understanding of who/where the boundary spanners are as well as the betweenness and closeness constructs are key in designing a superior network that will enable at all times appropriate and speedy decision making to ensue. It is also useful to note that SNA can be used in post facto analysis to facilitate necessary lessons learnt that can be applied to the future state. Thus the incorporation of SNA into the continuous design and development of HNCO is going to facilitate the realization of a well structured network that will indeed support all the complex and dynamic operations in healthcare.

Actor-Network Theory

As noted earlier healthcare is a complex domain. Specifically, the roles of different healthcare players including payers, providers, healthcare organizations and regulators as well as their respective interactions with WHIG and how WHIG in turn might facilitate, modify or even impede their tasks. To facilitate a superior understanding a sufficiently rich and dynamic lens of analysis can be found from the application of Actor-network Theory (ANT).

ANT embraces the idea of an organizational identity and assumes that organizations, much like humans, possess and exhibit specific traits (Brown, 1997). Although labeled a "theory", ANT is more of a framework based upon the principle of generalized symmetry, which rules that human and non-human objects/subjects are treated with the same vocabulary. Both the human and non-human counterparts are integrated into the same conceptual framework.

ANT was developed by British sociologist, John Law and two French social sciences and technology scholars Bruno Latour and Michel Callon (Latour, 1987, 2005; Law and Hassard, 1999; Law, 1992, 1987; Callon, 1986. It is an interdisciplinary approach that tries to facilitate an understanding of the role of technology in specific settings, including how technology might facilitate, mediate or even negatively impact organizational activities and tasks performed. Hence, ANT is a material-semiotic approach for describing the ordering of scientific, technological, social, and organizational processes or events.

CONCEPTS OF ACTOR-NETWORK THEORY

Table 1 presents the key concepts of ANT and their relevance to network-centric healthcare operations.

THE S'ANT APPROACH TO RESEARCHING NETWORK-CENTRIC HEALTHCARE

The S'ANT approach is a hybrid approach that combines the respective strengths of SNA and ANT in order to facilitate the realization of HNCO. Such an approach requires the identification and tracing of specific healthcare events and networks to "follow the actors" (Latour, 1996) and investigate all the relevant leads each new actor suggests. The first step is thus to identify these actors (or actants), remembering that an actor is someone or something that can make its presence individually felt and can make a difference to the situation under investigation. Thus, in HNCO the actors would include: medical practitioners, nurses, medical instruments, healthcare organizations, regulators, patients, equipment suppliers, medical administrators, administrative computer systems, medical researchers, and so on. In a particular operation (or event) it is important to identify all relevant actors before proceeding further.

The next step is to 'interview' the actors. With human actors this is, of course, quite straightforward, but with non-humans it is necessary to find someone (or something) to speak on their behalf. For an item of medical technology this might be its designer or user, or it might just be the instruction manual. The aim of this step is to see how these actors relate to each other and the associations they create – to identify how they interact, how they negotiate, and how they form alliances and networks with each other. These 'heterogeneous networks' consists of the aligned interests held by each of the actors.

Human actors, such as medical practitioners, can 'negotiate' with non-human actors such as X-Ray or dialysis machines by seeing what these machines can do for them, how easy they are to use, what they cost to use, and how flexible they are in performing the tasks required. If negotiations are successfully completed then an association between the medical practitioner and the machine is created and the machine is used to advantage – the network has become durable. If the negotiations are unsuccessful then the machine is either not used at all, or not used to full advantage.

Once this is developed it is then important to apply the techniques of SNA to map the flows of pertinent information and germane knowledge throughout this network and thereby not only enhancing the metacognition of the system but also the ability to rapidly extract and utilize the critical knowledge to support prudent decision making and at always a state of being prepared and ready (Wickramasinghe and von Lubitz, 2007; von Lubitz and Wickramasinghe, 2006 a;f)

The main advantage of the S'ANT approach to considering HNCO is in being able to identify and explore the real complexity involved. Other approaches to technological innovation, Innovation Diffusion for example, put much stress on the properties of the technology or organisation themselves, at the expense of looking at how these interact. Unfortunately in doing this they often tend to oversimplify very complex situations and so miss out on a real understanding. The ANT approach of investigating networks and associations provides a useful means to identify and explain these complexities as well as track germane knowledge and pertinent information. This

Table 1. Key concepts of ANT

Concept	**Relevance to HNCO**
Actor/Actant: Typically actors are the participants in the network which include both the human and non-human objects and/or subjects. However, in order to avoid the strong bias towards human interpretation of Actor, the neologism Actant is commonly used to refer to both human and non-human actors. Examples include humans, electronic instruments, technical artifacts, or graphical representations.	In HNCO this includes the web of healthcare players such as provides, healthcare organizations, regulators, payers, suppliers and the patient as well as the clinical and administrative technologies that support and facilitate healthcare delivery.
Heterogeneous Network: is a network of aligned interests formed by the actors. This is a network of materially heterogeneous actors that is achieved by a great deal of work that both shapes those various social and non-social elements, and "disciplines" them so that they work together, instead of "making off on their own" (Latour, 2005).	WHIG is clearly the technology network for HNCO. However it is important to conceptualise the heterogeneous network not as WHIG alone but as the aligning of the actors with WHIG so that it is possible to represent all interests and thereby provide the patient with superior healthcare delivery. Given the scope of healthcare operations and the global nature of HNCO there will be numerous power dynamics within and between groups of actors. This will be a critical barrier to enabling the well functioning of networkcentric operations. The key is to carefully align goals so that healthcare delivery is truly patient centric at all times.
Tokens/Quasi Objects: are essentially the success outcomes or functioning of the Actors which are passed onto the other actors within the network. As the token is increasingly transmitted or passed through the network, it becomes increasingly punctualized and also increasingly reified. When the token is decreasingly transmitted, or when an actor fails to transmit the token (e.g., the oil pump breaks), punctualization and reification are decreased as well.	In HNCO this translates to successful healthcare delivery, such as treating a patient in a remote location by having the capability to access critical information to enable the correct decisions to be made. Conversely, and importantly, if incorrect information is passed throughout the network errors will multiply and propagate quickly hence it is a critical success factor that the integrity of the network is maintained at all times.
Punctualization: is similar to the concept of abstraction in Object Oriented Programming. A combination of actors can together be viewed as one single actor. These sub actors are hidden from the normal view. This concept is referred to as Punctualization. An incorrect or failure of passage of a token to an actor will result in the breakdown of a network. When the network breaks down, it results in breakdown of punctualization and the viewers will now be able to view the sub-actors of the actor. This concept is often referred to as depunctualization.	For example, an automobile is often referred to as an unit. Only when it breaks down, is it seen as a combination of several machine parts. Or in HNCO the uploading task of one key actor, be it a provider or a regulator is in reality a consequence of the interaction and co-ordination of several sub-tasks. This only becomes visible when a breakdown at this point occurs and special attention is given to analyse why and how the problem resulted and hence all sub-tasks must be examined carefully.
Obligatory Passage Point: broadly refers to a situation that has to occur in order for all the actors to satisfy the interests that have been attributed to them by the focal actor. The focal actor defines the OPP through which the other actors must pass and by which the focal actor becomes indispensable (Callon, 1986).	In HNCO we can illustrate this by examining the occurrence of a disease or catastrophe. A recent pertinent example is SARS which caused a major epidemic crisis and required a united, co-ordinated global response to focus on finding a cure and treating affected victims. A similar co-ordianted immediate response was required in the aftermath of Hurricane Katrina or the Tsunami that struck the countries of the Indian ocean in December 2004. Such incidents form the catalyst for developing shared goals and united focus of effort so necessary to effect superior healthcare delivery.
Irreversibility: Callon (1986) states that the degree of irreversibility depends on (i) the extent to which it is subsequently impossible to go back to a point where that translation was only one amongst others and (ii) the extent to which it shapes and determines subsequent translations.	Given the very complex nature of healthcare operations (von Lubitz and Wickramasinghe, 2006b-e) irreversibility is generally not likely to occur. However it is vital that chains of events are continuously analysed in order that future events can be addressed as effectively and efficiently as possible. This is at the very essence of HNCO.

is paramount if the doctrine of network-centric healthcare is to be successfully realised.

CONCLUSION

The presently disorganized state of global healthcare indicates the need for the development of an operational doctrine that will provide a unifying rule set for all future efforts. To address this void, the doctrine of networkcentric healthcare operations was proposed by von Lubitz and Wickramasinghe (2006e). This doctrine has several advantages: first, a similar concept is already implemented with significant success by the military establishment. Hence, the "lessons learned" can be readily adopted into the civilian environment. More importantly, however, by permitting free flow of information among currently disconnected entities and fields of healthcare operations, the networkcentric doctrine allows vast improvement in information management and use in all activities related to healthcare – from individual patient provider contact to massive, international relief operations as seen following the Tsunami of 2004. Moreover, networkcentricity permits generation of the currently absent comprehensive, multifaceted, and unified body of knowledge necessary to conduct healthcare activities in a manner addressing present inequalities through a consistent knowledge-based effort rather than, as it is presently done, through the erratic application of ever increasing funds.

The existing evidence from military applications and from the still limited e-business experience, indicates the soundness of networkcentric philosophy and the practical usefulness of the doctrine. In view of the already staggering costs of healthcare and continuing deficiencies of its delivery, the need for transformation is more than evident. Moreover, the dynamic drive of the European Union toward dissemination of large scale computing networks and toward their practical use in daily operations of the constituent nations (Markoff and Schenker, 2003) indicate clearly show the direction in which healthcare will also move with an ever increasing speed. We believe that networkcentric healthcare offers the most tangible and obtainable means of such transformation, and that, in similarity to science, business, and warfare (Smarr, 1999) every effort should be made to pursue the tenets of the doctrine as the platform for changing the face of the global healthcare. However, and most importantly, if HNCO is to become the new paradigm for healthcare delivery in the 21st century it is vital that a rich set of analysis tools and techniques be employed. To this regard we have presented the S'ANT approach, a hybrid analysis which draws together the strengths of two well established social theory techniques; namely social network analysis (SNA) and actor-network theory (ANT). We plan to engage in further exploration of the benefits of such a powerful analytic approach in our future research and close by encouraging other researchers to do likewise.

Knut Staring
University of Oslo, Norway

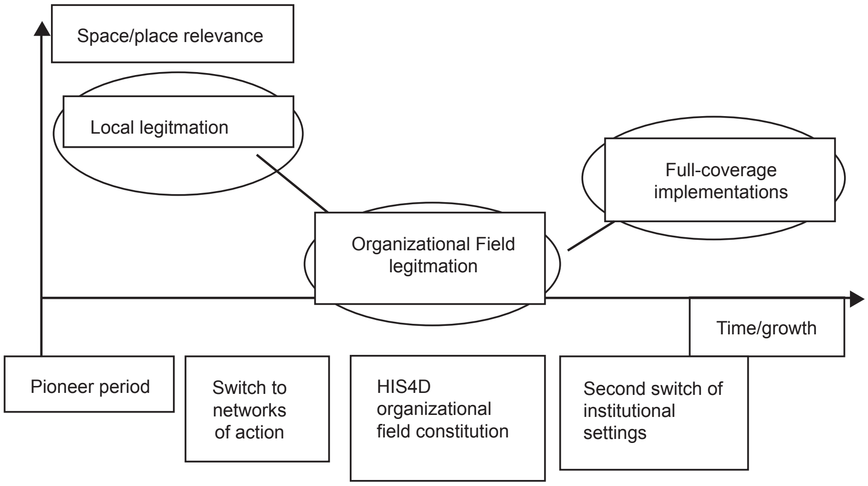
ABSTRACT

This article addresses the institutional scaling of information systems through the interplay of globally distributed free and open source software development with organizational processes. Through examining various phases of a long term project to implement information systems for the public health care sector in resource-poor countries, we highlight changing sources of acceptance and legitimation. The analysis centers on the balance between local and global levels, from pilot sites, through an emerging broader organizational field, to increasingly involving national level institutional settings. In parallel to the established view of the scaling of ICT implementations as relating to complexity and risk in the form of unintended side-effects of the growth of a system, the authors highlight the qualitative switch between regulatory contexts. Shifting relations to local institutions means that scalability requires actors to interact with quite different organizational cultures, accountabilities and communicative practices.

INTRODUCTION

ICT infrastructure and information systems have come to play a vital role in globalization. Walsham (2008) highlights three major aspects of this phenomenon: software outsourcing, virtual

Figure 1. A model to interpret shifts in PHIs over time



teams, and information system (IS) rollout. In this article we examine shifts over several years of globally distributed development and rollout of an open source information system targeted at the public health care sector in developing countries, which touches on all three aspects. In following the development of a system as it co-evolved with the various settings in which it was embedded, we highlight shifting sources of legitimation in institutional processes involved in health information systems implementation. The attention to changing sources of acceptance and legitimation frames our view on knowledge between local cultures and related stakeholders, in the interplay with global free and open source software (FOSS) development.

Paraphrasing Bowker (2000), health information systems operate simultaneously at the concrete level of design and implementation (fields in a database, capacity building, integration of datasets and organizational practices…) and at an abstract level (dealing with the relationships between information science, organization, public health, and global software development, among others). Thus, social studies of science and organization have a significant contribution to make to the process of growing information systems in order to create tools for health monitoring and policy making. For this, we need to historicize our action and its organization: "it is vital to dissolve the current disjunction between database (as technical storage medium) and policy (as way of acting in the world). The production of the database is productive of the new world we are creating." (ibid).

By examining the scaling of development and implementation of health information systems in developing countries, this article aims at understanding collaborative knowledge development across heterogeneous networks of local, national and global actors, and between public health workers and FOSS developers in dissimilar contexts. We will use "PHIs" as an acronym to refer jointly to PHI (Project for Health Information) and HIS (Health Information System, the principal software developed within the project). This hybrid acronym represents the socio-technical nature of the actor-network. PHIs began in South Africa in 1994 as health services underwent major restructuring post apartheid, aiming at standardization of information for local action. Subsequent international expansion underscored tensions between the local and the global (Rolland and Monteiro: 2002) related to knowledge gaps and communication practices affecting rollout and institutionalization. After nearly five years, the project to cross the South African border and be initiated in Mozambique. In the following two years, early prototype implementations were started in Malawi and India. Tanzania, Vietnam and Cuba (which was abandoned quickly) and Ethiopia followed in a couple of years. After 2002, a number of pilots flourished, mainly in South and East African countries, with different degrees of development and institutionalization. It is impossible to clearly delinate periods for all countries involved, because of the "karstic" dynamic of the project in most places: a pilot can be started, achieve some acceptance, remain dormant for indefinite time, be activated again depending on new conditions, and so on.

Figure 1 illustrates a model to interpret shifts in PHIs over time. The vertical axis indicates the intensity of relevance of specific places and local settings. The horizontal time line relates to the stages of PHIs evolution we have identified: pioneer, field constitution, and full-scale implementations, demarcated by 1) a switch of legitimation from local contexts to an organizational field, and 2) a further switch to legitimation relying on state structures.

FIRST SWITCH: FROM LOCAL BOUNDS TO ORGANIZATIONAL FIELD

This section aims at illustrating how changes to the PHIs are significant to understand the different set of regulatory forces which affect ICT development and implementation when shifting from accountability in a local context, to accountability in relation to the larger field constituted by organizations engaged in the same kind of activity.

PHIs engaged in bottom-up, participatory software prototyping to develop a district-based HIS with rapid iterations and a focus on flexibility (Braa and Hedberg: 2002). Legitimation at the local level was achieved by embedding the system into the organizational setting, and aligning with the needs of staff at all levels, as well as with local educational arrangements. Such sensitivity to local organizational cultures contrasted strongly with mainstream development strategies, and in turn provided a strong foundation for successful provincial and eventually national acceptance in South Africa in 1999. We open our empirical account with a quote from an implementer who was involved in the project from the early days:

South Africa in 1994 was at a turning point in the history of the country; a time of hope, uncertainty and potential chaos. People were both hopeful and fearful; hopeful of a more open, transparent and inclusive society, fearful of the way in which this change would happen. In the health services, major restructuring was happening across the board. Equity, redistribution and integration were central themes in the shift from a fragmented hospital based medical model to a Primary Health Care Approach driven by a nurse based community model within a district health system. New health worker cadres, managers and colleagues coupled with new services and systems created an atmosphere of chaos. Waves of consultative teams were making the rounds, asking questions about problems, but also promising sweeping reform. This was met by skepticism. Voluntary retrenchment, early retirement and 'new face' promotions were the order of the day. The users of the service were also more demanding. Health workers knew things were 'not right' and that different strategy and work practices were both required and desired. However, it seemed that there was a new way of doing the old job every other week. Everything was up for grabs; an opportunity for research by 'outsiders' who would come in, implement a new practice and leave staff with 'the mess'. Soon things would revert to the old tried and tested ways. It is into this chaotic arena that PHIS began to peddle its wares; not with the middle managers, but with health workers at facility and district levels. Would the tools, *models and practices advocated by PHIS have had the same impact a decade later? It is argued that 'timing was everything'; that the period of transition provided a crucial window of opportunity for the project*

Indeed, under apartheid, the South African health services were highly fragmented according to racial categories. Also, the health system had been oriented towards hospital services, with primary health care delivery poorly developed. This legacy meant that change in the organization of reporting became a major element in the processes of re-defining the health system after the fall of apartheid.

In addition to early experiences in Mongolia and South Africa, one of the project initiators drew upon prior experience from HIS research in Ghana, which had gone through a process of health system restructuring towards more action-oriented information management, developing the idea of rationalizing information. The proposed design strategy was based on the assumption that an IS consists of much more than the technical artifact, with a focus on local level and community based Participatory Design (PD). PD approaches were seen to be of particular importance as they may function as a means for community empowerment, and possible relations between community participation and PD as practiced in the Scandinavian tradition were explicitly explored. The Scandinavian PD tradition has had a focus on the workplace. However, discussing PD in a developing country context, the focus shifts from the workplace to the community (Titlestad and allTitlestad and all: in press). In referring to the three rationales for using PD approaches suggested by Greenbaum and Madsen (1993); i.e. the pragmatic, the theoretical and the political perspectives, it was proposed to add the community perspective. So PHIs developed a vision "to support the development of an excellent and sustainable health information system that enables all health care workers to use their own information to improve the coverage and quality of health services within our communities", and the process towards HIS was based on local management and community structures and addressed local needs. Motivation, commitment and the creation of a sense of ownership of the system by all interested parties were deemed to be of vital importance.

Based on the experiences in pilot projects, a six step model was developed within PHIs for health information system development and implementation:

1. Local team and commitment are crucial. Get people from the community on board and find concrete activities in which they can participate
2. Situation analysis (information audit)
3. Set objectives, targets and indicators
4. Create district based information system and structures
5. Training of staff - local empowerment; i.e. focus on data needed to make local decisions to improve coverage and quality of services
6. Creating a district information culture: i.e. the information needs to be used on a regular basis, allowing the IS to be improved gradually. Analysis of data should become a daily routine aimed at improving service delivery

By the turn of the millennium, HIS had been officially endorsed as a national standard in South Africa, and pilot projects were commenced in several provinces; KwaZulu-Natal, Mpumalanga, Northern Cape, and the North West Province. However, the project expansion was not only a internal to South Africa. Due to the relative success the project had experienced so far, it was believed that a similar approach and philosophy might be translated to other similar countries, and PHIs crossed the border to Mozambique. The launch of the project in Mozambique marked the beginning of what would later become a remarkable widespread geographical expansion of PHIs.

The initiation of PhD and Master study programs shared between the coordinating university and partner institutions in Mozambique represented a new way of gathering resources for project implementation while strengthening local education programs. The new organizational and cultural environment meant new challenges for the PHIs approach, both theoretically and empirically; e.g. as the relative success in South Africa had in part relied on a "window of opportunity" due to a general wish for change, in other countries existing systems and entrenched interests proved significant obstacles to smooth implementation of the system.

In the case of Mozambique, PHIs started as a pilot project in three districts. A distinct difference between South Africa and Mozambique was the required sources of legitimation of the project. Although the pilot projects created local interest, lack of top-level support hindered substantial results in the highly centralized decisionmaking structures of the public sector. In addition, contrary to what had been the case in South Africa, stability was valued over change. However, learning form the Mozambican experience with limited impact from pilots in small geographical areas, it was also acknowledged in the project that without sufficient coverage, both in terms of hierarchical geographical span and in relation to the various health programs, results were hard to obtain. To deal with need for scale and coverage, the actions of PHIs were expanded from three districts to three whole provinces. Despite formal support for this from ministry level, real change in the sense of approving the replacement of existing reporting routines never came through, with the effect that the PHIs initiatives always came as an additional burden to the standard routines for health staff. Lack of real top-level commitment in the centralized HIS context of Mozambique meant that the project lost a lot of momentum.

In South Africa, the initially community driven, bottom-up effort was transformed to an official national standard. The South African PHIS project itself went through a formalization and professionalization processes and was established as a separate legal entity. In Cuba, the very concept and method of user-participation – typical of the Scandinavian approach- did not fit well with the local context, thus the theoretically "context-sensitive" way of making robust systems was found to be highly incompatible with local conditions. Participatory design carries a strong democratic inscription which ran into severe obstacles within the public health hierarchy. Although the delivery of health services was decentralized in Cuba, the decision making power was not, and bottom-up approaches were seen as a threat to the political system as a whole. Health personnel proved uncomfortable with new powers, responsibility and risks of making decisions. In Ethiopia, initial successes in pilot regions proved hard to translate to the national level, and the ministry decided to rely on the expertise of a local company to develop their own system (incorporating many of the same principles), rather than relying on the open source PHIs network.

Still, over time, PHIs got acceptance in a number of countries with widely differing political and organizational cultures. Its bottom-up, not-for-profit approach legitimated pilots in Malawi, Cuba, Mongolia, and India. In all cases, the expansion was afforded through the alignment of health authorities, educational institutions, research centers, and FOSS philosophy and development practices (which provided affordances for such a diverse set of actors).The establishment of such relations linked local and global networks of actors, through a negotiating process which tended to be legitimized in local needs. At the same time, the formal education part of the network was significantly expanded by enrolling a significant number of master and PhD students.

Gradually, PHIs became a globally dispersed network of small scale IS implementations (with South Africa the only nation-wide rollout). A perspective on action research and actor network theory was developed, with the claim that "local interventions need to be part of a larger network to be robust" and handle the twin challenges of sustainability and scalability. Working in multiple contexts provides opportunities for cross fertilization in a network, whereas narrowing down on one best practice exposes the project to the risks of volatility, which usually characterizes the institutional environment in developing countries. This loosely-coupled organizational form was termed "Networks of Action" (Braa et al.Braa et al.: 2004), and provided agility and cross-legitimation, but also exposed a risk of spreading too thin, and missing institutionalization. Furthermore, alliances were formed with other players active in developing countries, such as projects on medical record systems and UN organizations. A couple of UN initiatives indicated the necessity of appraising the big picture and scoping out an architecture able to cover most of the functions carried out by health systems, from local clinical encounters via district and provincial administrations up to national and global monitoring and evaluation efforts. One approach to this is Enterprise Architecture (Stansfield et al 2008).The result was a switch of legitimation from local contexts to an emerging organizational field of HIS for development (HIS4D). Following a Neoinstitutional view (Powell and DiMaggio: 1991), organizational field denotes the frame of reference of organizations engaged in a specific activity, their interactions constituting a recognized area of activity.

The introduction of the HIS system could also have negative effects, and was seen by some to somewhat paradoxically divert attention from quality of care to data quality. The gradually closer influence of the organizational field and international organizations entailed a transition in emphasis from local participation to the production and use of information for broader monitoring, and also from management and quality of health care to management and quality of health information. The collected data elements were increasingly defined on the basis of international standard requirements. While in the first period of PHIs information was tightly coupled with local contexts, the expansion of the project produced a partly autonomous "information space" with specific issues not necessarily evident at the micro level, e.g. duplication of indicators. Therefore, the growth of the project itself, and of the related information sphere, implied a switch from emphasis on local legitimation processes to legitimation in more global socio-technical issues (such as technological choices, adoption of internationally accepted standards and datasets, relation to millennium development goals) embodied in international donor requirements.

To sum up, after the first switch from local legitimation to a more global organizational field as arena of activity, HIS began to inscribe a different context characterized by new priorities, where key players (software companies, international donors, health standards and goals) were no longer local, nor immediately perceptible from the implementation level.

SECOND SWITCH: FROM ORGANIZATIONAL FIELD TO FULL-SCALE ROLLOUT

The requirements and challenges involved by a full-scale roll-out are different from the tacit convergence, compliance, and isomorphism that organizational fields tend to produce. Indeed, full-scale roll-outs imply a return of influence from specific regulatory environments, although at a different scale and political level.

The challenges of scaling are usually seen as related to increasing demands in terms of workload, scope of the system, and range of functionalities that must be supported. Such escalation of complexity in turn produces a proliferation of side-effects. Awareness of this expanded risk is crucial, and tallies well with the PHIs case. However, beyond these challenges, scaling up from a pilot phase to full scale rollout also entails shifts in institutional setting. Whereas pilots are an institutionalized way to test the capabilities of a system in real life settings, a wider rollout is regulated by different rules and accountabilities. The involved actors must not only increase their capacity, but also learn to deal with very different institutional constraints, implying different values, orientations, and legitimated patterns of action.

A PHIs member stated:

it's very useful to use achievements on the ground to show the possibilities of the system. [...] The general problem is the lack of leader bottom-up activities didn't manage to get turned around on the top level." A number of recent cases within PHIs show that the bottom-up approach, which characterized the beginning of the project, was turning into a more top-down one. The South African story was still leveraged for negotiations, but local pilots no longer seemed as central: Having succeeded on a national level in South Africa and being tied into the organizational field globally provided the needed legitimacy for other goverenments to consider the software, but meant that less attention was given to the original philosophies propounded by the project. This aspect is quite clear in recent implementations, where local health authorities asked to shut off some of the functionalities of HIS, frequently the ones which make the system useful at local level (i.e. local data analysis). "They don't care about information for action" a PHIs action-researcher lamented. Even when pilots were started to test system viability in a country, power remained at the central level. Accordingly, decentralization and local empowerment no longer seemed determinant for PHIs action. A similar top-down focus was exemplified by the following comment from a key decisionmaker in an African country: "I would prefer a new system using the already accepted WHO indicators."

So, while focus gradually shifted to full-scale implementations to cover large areas like a state or a country, a re-allocation of resources was required to comply with the needs and requirements of the institutions responsible for health in those areas. Accountability was achieved by establishing national NGOs in South Africa, India and Vietnam, and countries like Malawi sought to emulate this. Contracts were entered into with national authorities and with the UN. While the ability to draw on the global network was of continuing importance, engagement with bureaucratic structures and politics became increasingly salient. Those aspects are now empirically presented.

For a longe time, there was a sustained push from the core software developers to introduce regularly scheduled and thoroughly tested stable releases, instead of having implementers constantly downloading and using untested source code directly from the FOSS repository and thus needing a lot of assistance. However, constant pressure from the field for improvements and new features made this impossible to enforce, and it was not until the fall of 2008, after extensive field trials in Sierra Leone, that the core team felt confident enough to declare a 2.0 "final" release (as opposed to the previous "milestones" and "beta"), and thus lending it legitimacy. However, in accordance the with FOSS philosophy (see e.g. Raymond: 1999), unpolished software that works can generate a lot of interest, and for a presentation at WHO headquarters in Geneva in May 2008, a rough solution was created to demonstrate how patient data in a medical record system could be aggregated into an increasingly accepted indicator exchange format and then imported into HIS. This helped raise the legitimacy of both solutions, as part of an emerging Country Health Toolkit of interoperating components - which in itself was thought of as a response to the needs of full rollouts: In several developing countries, the PHIs project was met with requests to also help set up patient records, and in one African country, the Ministry of the Interior wanted assistance from the Ministry of Health in coming up with a software solution for national person IDs, starting

Table 1. Changes in organizational characteristics in the second shift from networks of action to full coverage rollout

Networks of action	Full coverage rollout
bottom-up	top-down
centrifugal expansion	centripetal focus
agility	stable capacity
open communication	internal discussion
global scope and functionality	national and local customization
spreading thin	Consolidation
selection of favorable conditions for success of pilots	capacity to cope with the variety of situations that the state presents
occasional competition between pilots	one system (up-front competition for tender)
loosely structured	formal organizations

with newborns and patients visiting clinics, but gradually using the same for issuing passports, licenses etc.

In India, transition from pilots in one district and in individual states to national level operations made it possible to engage authorities in a thorough revision of what data should be collected and used to calculate key indicators, with a focus on the PHIs "information for action"-approach, which resulted in a new consensus around a dramatic reduction in the number of data items collected. However, cases such as Cuba and Tajikistan can serve as examples of local (national) settings resisting change and forcing accommodation to different institutional forms. As five year plans were already in place, emphasis was on replicating a very detailed statistical information gathering apparatus, rather than a South Africa style complete overhaul according to the philosophy of using information for district level action.

The full scale rollouts meant new challenges for the PHIs approach. The project became characterized by two paths to institutionalization, one through the health information infrastructure on which PHIs is active, the other within academia, with the issue of scalability as a common denominator. As such, health information infrastructure has not yet stabilized, and one may well ask whether for PHIs the research arena is the stage with the field action taking backstage, or if it is the other way around. We do not have a definitive answer to this, time and results will tell. For the time being, research forms a backstage for ministries of health of several developing countries, but -at the same time- they are backstage for the information system research community which reads about implementations and challenges in those contexts. Considering the potentially never ending retrospective reconstruction of the backgrounds of institutionalization, we do not propose a definitive judgment. Rather we highlight the intimate relation - and continuous interchange - between ideas and actions. This is particularly relevant for large technical systems, which co-evolve with the ideas they support and are supported by. We assume that this 'double hermeneutic' (Giddens: 1982) is pertinent for understanding the evolution of infrastructures. Paraphrasing Bowker (2000), we might say that the PHI-promoted information infrastructure operates simultaneously at the concrete level of participatory design and implementation (fields in a database, capacity building, integration of datasets and organizational practices) and at an abstract one (dealing with the relationships between information science, organization, public health, and global software development, among others).

The issue of scalability became an official topic in the research group which remained at the heart of the network. This is how it was spelled out in a manifesto draft:

We take a broader view on information infrastructures to include both the technical components such as the technologies and standards, and also the interconnected social and organizational elements such as work practices, human resource issues, politics, and other institutional conditions. [...] key research issues of the group:

- *Scalability, or how to generate and manage growth*
- *The tension between standardization and flexibility;*
- *How can global work processes and infrastructures be controlled (or managed) (e.g. practical as well as legal, regulatory and institutional systems around OSS issues)*
- *What kind of risks are involved (produced);*
- *How can learning and innovation take place and be supported and taken into account within global work processes and infrastructure development;*
- *How are information infrastructures different in the context of "third world" countries, and what different approaches and strategies are required for their cultivation to support socio-economic growth processes*
- *How are information infrastructures (or: how can information infrastructures be) maintained, sustained and institutionalised?*
- *And first of all: The interaction between these.*

More on the action side of this action-research effort: In 2006 one of the Indian team members said during a focus group that she was surprised by the short period it took in South Africa to gain the momentum for exponential growth. Although it can be misleading to compare post-apartheid South Africa to India, such differences raised a question both among PHIs coordinators and in the university corridors: "Can it be that the chances to bootstrap and establish an infrastructure depended so heavily on historical contingencies and causalities?"

In India, the presence of powerful software entities, both public and private, combined with a strongly hierarchical tradition to make it hard to pursue a bottom-up approach. In one state, while the local team was putting its efforts in the health facilities, an agreement of the state health department with a national public company resulted in an intermittent halt to all activities. A conference about information technologies for development provided an opportunity to discuss with a broad audience of researchers and practitioners: one of the issues pinpointed was that the halt may have marked a crisis of the PHIs bottom-up approach to HIS development and implementation. If so, it is important to understand why top-down agreements coexist with bottom-up rhetoric (one of the sparking questions of this submission). Our interpretation is that the HIS4D organizational field had become much more crowded, and this necessitated situating the project in relation to a number of new actors, moving and affecting considerably more resources. Negotiations tend to be at state level, and this is where the balance between different approaches has to be explicitly and tacitly negotiated.

The case of a southern state of India is of particular interest, both because of a strong tradition of self-reliance and independence from both global and national trends (which made the organizational field less crucial in comparison to local considerations), and PHIs use of FOSS (which facilitated alignment with official state policy). Indeed, the state government official policy documents state:

ICT has opened up the possibility of radically different information exchange patterns by facilitating faster and more efficient dissemination of information. It can play a vital role in sustaining the

> *democratic ethos of the Indian society and ensuring a high level of transparency and accountability in governance [...] The Government has a comprehensive view of ICT as a vehicle for transforming Kerala into a knowledge-based, economically vibrant, democratic and inclusive society. By the term "inclusive," the Government means that the benefits of the socioeconomic transformation possible through ICT should reach every single citizen of the State. This policy document defines the Government's vision, mission and strategy for achieving the same. [...] The Government's vision is to turn Kerala into a knowledge society with sustainable economic growth, social harmony and high quality of life for all. The Government realizes that Free Software presents a unique opportunity in building a truly egalitarian knowledge society. The Government will take all efforts to develop Free Software and Free Knowledge and shall encourage and mandate the appropriate use of Free Software in all ICT initiatives.*

This state policy identifies a meso-level between global trends and local specificity, which is crucial in situating full coverage implementations of HIS. Indeed, FOSS technologies are what make PHIs an acceptable vector of ICT-based transformation, because they promise inclusion and democratic development. Practically, the software is expected to be more under control of local authorities and developer teams. Both philosophically and practically, the state government maintains that FOSS can be used to enact cooperation and communal property, which is more consistent with its own ideological dispositions and long term development strategies.

Table 1 summarizes the second shift in software and organizational characteristics.

DISCUSSION

The notion of "counter networks" (Mosse and Sahay 2003) draws upon Castells' (1996) argument that social development in the context of globalization is related to the use of ICT, and determined by the ability to establish synergistic interaction between technological innovation and human values. Central in this connection is communication between "nodes" in a network. Marginalized groups may counter their exclusion through the creation of such counter networks. This is the line that PHIs explicitly followed, focusing on education, research, improvement of communication practices both inside the health care hierarchy and with the population in general.

The opening figure illustrates the fluctuating relevance of local legitimation: in the fledgling period, it was crucial. As the influence of the organizational field strengthened, global trends began to dominate. Finally, state-wide implementations again required an emphasis on specific conditions, though differently from in the pilot stage. Commonly, the challenges of scaling ICT implementations are seen as related to escalation of complexity in terms of workload, functions, and scope, combining to trigger proliferation of side-effects and risk. In parallel to this view, we highlight the qualitative switch between regulatory contexts, on top of the quantitative growth of a system. Shifting relations to local institutions (organizational culture, public authorities, politics etc) means that scalability requires actors to be able to relate to quite different cultures, accountabilities and communicative practices. From the case presented here, we can see how the accepted scope shifted from local health facilities needs in post-apartheid South Africa (when the aim was consolidation of health systems for different races through the integration of information flows for local action) to the identification of common problems and converging resources from a variety of settings. Such networks of action supported the expansion of the project. But interlinked pilots needed another kind of institutional legitimation to expand. So to avoid the risk of spreading thin, state decision makers had to be involved, to support broader implementations. At that point, information requirements from health systems were more rooted in basic routines, rather than experimental implementations. In the second switch, from the networks of action to full, centrally sanctioned rollouts, the requirements were qualitatively different. To roll out, there is an expectation of something more robust and smoother. The software must be intuitive and user friendly, capable of handling large datasets, professional quality manuals must exist, and extensive training conducted (at one extreme, training involved 24 000 people in one Indian state). Such changes explain the adoption process by linking it to the socio-technical capacity of matching diverse institutional settings. Looking at the oscillation between different sources of legitimation, we can understand how the transformative role of ICT (Avgerou, 2007) actually played out in the different phases of the scaling. The qualitative shifts between phases counteract a linear conception of ICT diffusion.

We can note a re-positioning of the PHIs strategy: from the original bottom-up approach, things have been steered more towards a top-down focus, which shifted from the community and health facility to ministerial levels. It is claimed within the network that pilots are still organized at district level. This is surely characterizing PHIs approach to localization of its interventions. Nevertheless, it has to be acknowledged that local appropriation and empowerment of health personnel is currently not the driving force of adoption, as it was initially in South Africa. "Cultivation" is still an important element of PHIs action, but capacity building and incremental change are not pursued directly at the district or community level, but rather at the ministerial level in most infrastructural hubs. Consequently, the 'seeds' are different: graduate health informatics programs, system coverage of wide regions and numerous health programs (TB, malaria, reproductive health etc), relations between public administrators and internationally active organizations, the constitution of software developer teams, etc.

In this sense, efforts to establish a health information infrastructure can be seen as institution building activities, changing according to available sources of legitimation.
