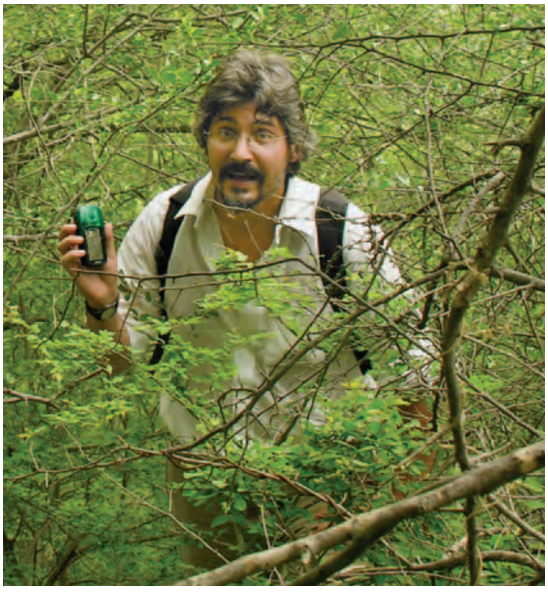
About the General Editor



PAUL ROBBINS was raised in Denver, Colorado, but has lived in India, New England, the U.S. Midwest, and the deserts of the U.S. Southwest. He received his Ph.D. in Geography from Clark University in 1996 and is currently Professor in the Department of Geography and Regional Development at the University of Arizona. His research centers on the relationships between individuals (homeowners, hunters, professional foresters), environmental actors (lawns, elk, mesquite trees), and the institutions that connect them. Working with interdisciplinary teams in the fields of biology, economics, climatology, and entomology, his projects have examined chemical use in the suburban United States, elk management in Montana, forest product collection in New England, wolf conservation in India, and mosquito borne illness and management of insect hazards in the US Southwest. His expertise includes the fields of conservation policy, grasslands ecology, and institutional ethnography. He is author of *Political Ecology: A Critical Introduction* (2004) and *Lawn People: How Grass Weeds and Chemicals Make Us Who We Are* (2007) and has served as an editor for the journal *Geoforum*.

Associate Professor, Department of Social Anthropology
York University

Introduction

WHERE DOES THE environment leave off and society begin? If the major crises and curiosities of the early 21st century are any indication, it would be foolish to attempt to demark any such boundary. When expanding production and consumption drives greenhouse gas emissions that warm the planet, which in turn influence the conditions (and limits) of economic expansion, it is unclear where the climate ends and the economy begins. If transgenic species of upland rice are designed for cold tolerance employing genes from Alaskan cold-water fish, where does the "natural" process of evolution stop and the "social" process of agricultural intensification begin? In a certain sense, owing to the intense entanglement of human beings (congressmen, farmers, veterinarians, nurses, SUV drivers, plumbers, attorneys) with nonhumans (turfgrasses, bacteria, factories, atmospheric pressure cells, weeds, elk, trees), the question seems unanswerable at best, or misleading at worst.

Ironically, this fact is not new to our era, as thousands of years of human interaction with the world around us can attest. It is notable, however, that our social and natural sciences have only recently come to grips with the incredible complexity of the world described by understanding the environment and society as being of a piece. In the last decade, there has been as a result, a perhaps unprecedented explosion of new concepts, theories, facts, and techniques that follow from such an understanding. So too, there have been remarkable efforts to move beyond the "social" and "environmental" sciences in order to pursue research and problem-solving using a new kind of knowledge. This approach to socio-environmental problems and issues explicitly does *not* seek to distinguish "social aspects" of environmental problems or "environmental components" of social issues, but instead seeks to explain and cope with the enormous implications of this inevitable complexity.

THE ENCYCLOPEDIA

In this sense the 1,200 entries, written for these volumes by experts from an incredible diversity of fields, are a first step toward diving into the deep pool of emerging knowledge. As the volumes intend, it has become increasingly essential to bring these multiplying issues, concepts, theories, examples, problems, and policies together in one place, with the goal of clearly explicating an emerging way of thinking about people and nature.

To that end, the encyclopedia was designed to include a vast range of different types of entries, including key individuals, polices, problems, processes, and theoretical concepts that sit astride what has traditionally been known as "society" and the "environment." The wealth of topics here therefore includes what the editors believe captures an integrated vision. This encyclopedia represents more than a catalogue of terms. Rather, it captures the spirit of the moment, a fascinating time when global warming and genetic engineering represent only two of the most obvious examples of socio-environmental issues. Consider fire ants, air conditioning, oil spills, and aquariums (all represented in entries here) as embodiments, objects, and artifacts of a world co-created and co-inhabited by people and nonhumans.

If it is a new world of problems and situations, it is also one of new and integrative ideas. As the "environment" becomes a concern for economists, political scientists and anthropologists, "social" forces are increasingly a concern of conservation biologists and geneticists. The result has been a great many new ideas about how the world works, what creates the daunting problems of our time, and how such issues might be addressed, whether by regulation, markets, or new ethics. Many of these ideas, of course, are not mutually harmonious and compatible. As entries in this volume demonstrate, theories of environmental management based on market efficiency may not be easily reconciled with those that focus on population, and both may certainly diverge from those centering on ethics, justice, or labor. Nevertheless, all these emerging voices and ideas are very much of their moment, and are part of a conversation that an environmentally literate citizen or student ignores at their own risk.

As such, our authors include geographers, political scientists, chemists, anthropologists, medical practitioners, development experts, and sociologists, among many others. We were fortunate, in this regard, to find experts in their fields of specialty, and to be able to draw especially upon researchers with direct fieldwork experience. Many country entries were written by authors with years (or decades) of field experience in these locations, while entries on emerging techniques and technologies were penned by designers and innovators, wherever possible.

Given that, however, all topics and issues are essentially socio-environmental ones, the process of assembling such a group of entries and authors presented certain hard choices. The choices made here reflect many of the biases of its General Editor, and an imagined and intended audience. Specifically, readers will notice that despite a great many global policy documents and treaties, the preponderance of environmental legislation and legal decisions presented here, from the Winters Doctrine to the Clean Air Act, come from the United States and other Common Law countries. So too, while countries of the world are represented, regions of North America are treated in greater detail. And while the problem of global conservation is discussed at length, most of the key examples of national parks included here are from the United States. This is because the book was firstly intended for North American readers, but also because many of these practices, theories, and laws from the North American context are being extended to (and in many cases arguably foisted upon!) other parts of the world. I would hope that while readers from the United States and Canada would learn a great deal about their own environment and society problems from reading these entries, therefore, the encyclopedia might also be useful for readers in Chile living with the environmental policy effects of University of Chicago economic theory or readers in India importing the "Yellowstone model" of national park management.

The decision to include entries for individual countries, rather than global eco-regions, was one made again with an audience in mind as well, someone who might want to know the specific conditions in Gambia for example or China. While such a decision does, at some level, reinforce a state-centered view of the world—one that is subverted precisely by environmental problems that do not respect national boundaries—it is our intention to provide a comprehensive picture that approaches, as effectively as possible, a cohesive global vision. We hope that our survey of conditions around the world strikes familiar notes for comparison and contrast, drawing some patterns from the details of regional experience.

SIGNALS AMIDST THE NOISE

And to a great degree, despite (and in part because of) the diversity of entries assembled here, it is possible to identify some constant global themes that thread through the encyclopedia. Two of the most prominent are: (1) the emerging socio-environmental problems that we face in the next century, and (2) the shifting and expanding theoretical tools available for explaining tackling these problems.

The problems that receive a great deal of attention in the encyclopedia differ greatly than those that might have been highlighted a quarter century ago. At that time, not long after the first Earth Day, an encyclopedia on environment and society might have focused more exclusively on regional and local environmental problems and their apparent intractability. At this time, the foul air hanging over American metropolises was emblematic of a fouled world, stubbornly locked into place by human activity; a nature almost irreversibly dominated by society.

Remarkably, many of these problems, while still serious issues, have actually given way to solutions, however. While many argue about the overall efficiency of the Clean Air Act, for example, it is quite clear it has had a profound positive effect on urban air quality. Deforestation is ongoing around the world, but so is reforestation, and for reasons that remain a matter of debate.

At the same time, however, issues like global warming and genetic engineering, while envisioned by the more forward-thinking observers of the century prior, could not possibly have afforded the immense amount of attention and number of related entries we see today. Nor could the concept of environmental justice, which is so clearly a part of contemporary urban environmental issues, have been so fully articulated and acknowledged. The problems and issues that we see here are definitely the greatest challenges of our time, therefore but they would have been hard to fully anticipate not very long ago. This cautions us against any self-congratulatory sense that any accounting of socio-environmental condition, no matter how comprehensive, can be a document that exists outside of its historical moment.

Similarly, the volume is brimming full of an extremely diverse and vibrant range of theoretical tools to help explain and cope with our current world, many of which simply were not "on the map" even a few years prior. The debates of 25 years ago involved pitched arguments between self-described environmentalists ("greens") and those ("browns") who argued for a protection of economic interests and growth against so-called luddites.

John McPhee's classic book *Encounters with the Archdruid*, detailing debates between David Brower's environmentalism and Floyd Dominy's pro-growth dam-building, set the tone for the period. And within each of these camps, it would not be exaggerating much to say theoretical diversity was less well developed than it is today. "Greens" often held to traditional population-based explanations of environmental crises (as many do today of course), while "browns" clung to ideas that environmental protection was in contradiction to human economic interests.

A quick perusal of the entries in this volume suggests that we live in a very different world. As environmentalists come to understand the relationship between poverty and problems in conservation, new ideas emerge from the mix. From the other side of the argument, green capitalism is offered as a bringing together of ecological and economic incentives. From the mix we see pages filled with insights from deep ecologists, Marxists, feminists, anarchists, bioregionalists, pragmatists, free marketeers, and reconciliation ecologists (among many others) offering entirely new visions of our socio-environmental condition.

And in a very real sense, we are *all* environmentalists now, a situation that is ironically both a source of a new consensus and the seed of new, more profoundly divisive debate. This revolution in thinking is by no means restricted to the so-called "social sciences," moreover. Ecologists as a prominent example, who long clung to mechanical models of equilibrium in environmental systems, have begun to shift towards more biocomplex ways of thinking about environmental conditions and change and the human role in evolution and nature.

In this sense, we think the encyclopedia is not only current and packed with essential and up-to-date information on the state of the global socio-environment, we also imagine the work to be a time capsule of its historic moment, and a record of where we stand at the start of the 21st century. From an optimistic point of view, we can only hope that the emergence of environmental debates and discourses around the world—provoked by some of the greatest calamities and problems of written memory—provides an opportunity for more new ways for thinking, behaving, and living in a more-than-human world.

We are cursed to live in interesting times. The editors hope that the *Encyclopedia of Environment and Society* helps to map out, explain, and challenge our collective thinking at this difficult juncture for our environment.

Abbey, Edward (1927–89)

EDWARD ABBEY WAS a working novelist, philosopher, lover of unfenced country, adventurer, river runner, desert rat, self-proclaimed extremist, redneck, and "agrarian anarchist." He was a man of many philosophies, peppered with contradictions and complexities. His writings criticized government, technology, corporate greed, and the unfortunate destruction of wilderness, but he also poked fun at vegetarians, made sexist comments, littered beer cans out the window of his automobile, and was a member of the National Rifle Association. James Bishop says, "He was neither left-wing nor right-wing, nor was he an outlaw. Abbey was a genuine rebel who simply did not believe in the moderns' industrial way of life."

In describing his life's work, Abbey notes, "I wrote once that environmental journalism isn't a very cheerful field of work. But I guess there was a little self-pity in that remark. I've had a hell of a good time with it, actually. I enjoy stirring people up, and I've always enjoyed making certain people angry. I write to amuse my friends and to aggravate our enemies, to give them ulcers, if possible. I make terrible threats that I have no means of carrying out…like getting rid of their Glen Canyon Dam. I like to make the opposition worry and lie awake at night, force them to hire more security guards, and the like."

Abbey's writings include over 21 books of both fiction and nonfiction. His first nonfiction work, *Desert Solitaire,* was published in 1968 and beautifully reflects his love of the nature he explored during two summers hiking and camping in southeastern Utah's canyonlands:

> In the desert I am reminded of something quite different—the bleak, thin-textured work of men like Berg, Schoenberg, Ernst Krenek, Webern and the American, Elliot Carter. Quite by accident, no doubt, although both Schoenberg and Krenek lived part of their lives in the Southwest, their music comes closer than any other I know to representing the apartness, the otherness, the strangeness of the desert. Like certain aspects of this music, the desert is also a-tonal, cruel, clear, inhuman, neither romantic nor classical, motionless and emotionless, at one and the same time—another paradox—both agonized and deeply still.

One of Abbey's more infamous fictional pieces is the 1975 novel *The Monkey Wrench Gang*, a comical thrill ride adventure about "eco warriors" Dr. A.K. Sarvis, George W. Hayduke, "Seldom Seen" Smith, and Ms. Bonnie Abbzug. This cast of characters travels around the American Southwest resorting to destructive direct action, or "monkeywrenching," of power plants, fences, vehicles, and dams to slow technological assaults on the environment. The book fueled a movement of nonviolent direct-action environmentalism; many have even called it the inspiration for the Earth First! movement: "And in that novel I tried to make a clear distinction between sabotage and terrorism. My 'monkeywrenchers' were saboteurs, not terrorists. Sabotage is violence against inanimate objects: machinery and property. Terrorism is violence against human beings. I am definitely opposed to terrorism, whether practiced by the military and state—as it usually is—or by what we might call unlicensed individuals."

Yet not all of Abbey's writings embody runaway cynicism, and often his respect and awe of the natural world shines through in vivid descriptions of plants, canyons, and rivers. Although he refused to call himself a naturalist, Abbey's books can transport readers to remote desert canyons and mountaintop lookouts. Nonetheless, there's always an ethic embodied in his work that the reader might take away in the name of wilderness protection: "A true civilization, for me, embraces tolerance as one of its cardinal virtues: tolerance for free speech and differences of opinion among humans, and tolerance for other forms of life … bugs and plants and crocodiles and gorillas and coyotes and grizzly bears and eagles, and all of the other voiceless, defenseless things everywhere that are in our charge. Any true civilization must provide for those other life-forms. And the only way to do that is to set aside extensive areas of the earth where humans don't interfere, where humans rarely even set foot."

Abbey said he wanted his body transported in the bed of a pickup truck and buried in an old sleeping bag, no coffin: "I want my body to help fertilize the growth of a cactus or cliff rose or sagebrush or tree." In March of 1989, about 200 people gathered in Saguaro National Monument, near Tucson, Arizona, for a celebration of the late Ed Abbey: "There were great tubs of a hot desert stew, concocted from meat of mysterious provenance ('poached slow elk', in the terms of this recipe) by Doug Peacock. Another close friend blew taps on a trumpet. There were grief and booze and chilies. There were bagpipes. There was joy at the privilege of having known this man, at having heard his inimitable voice." His body lies somewhere in the Cabeza Prieta Desert.

Acid Rain

ACID RAIN BROADLY refers to acidic precipitations—in wet form such as acidic rain, fog, and snow; or in dry form such as acidic gases and particles. Acid rain was first noticed in the late 1960s, when declining fish stocks were observed in Scandinavian lakes, and precipitation was found to be more acidic. Acid rain has also destroyed forests and acidified lakes in Canada as well.

The term *acid rain* is a misnomer, because even uncontaminated rain has a pH level below 7 and is therefore acidic. The addition of sulphurous and nitrous gases to the atmosphere causes precipitation to become even more acidic as they combine with water. The natural pH of rainwater is about 5.6, but the pH of acidic rain is 4.0–5.0. A decrease of one pH unit represents about a tenfold increase in the acidity of rain.

Acid rain occurs when sulfur dioxide (SO_2) and nitrogen oxides (NOx), released from fossil fuel burning and industrial processes, react in the atmosphere with water, oxygen, and other chemicals to form various acidic compounds. Sunlight increases the rate of most of these reactions. The result is a mild solution of sulfuric acid and nitric acid. When this acidic precipitation reaches the ground, it affects plants, animals, fishes, and other living things to varying degrees.

About half of the acidity in the atmosphere is composed of dry depositions blown by the wind onto buildings, homes, trees, etc. When the other half arrives in the form of rain, all of these dry deposits are also washed out. This, in turn, makes the runoff even more acidic and harmful to the environment.

High-altitude vegetation communities are more at risk from acidification because they may be exposed to the cloud bases, which have low pH values due to the acids produced by the reaction of acidification gases with hydroxyl radicals and monatomic oxygen. Areas with "acid" bedrock are also more at risk because they lack buffering capacity; this means these soils are already acidic and hence lack cations such as calcium, which react with acid soil and groundwaters to raise the pH in drainage waters.

Acid rain causes corrosion of buildings in urban areas; reduced visibility; forest damage from occult precipitation; acidification of lakes, rivers and ground water; decline in fish population (or decline in aquatic ecology); and changes in soil flora and fauna (forest and terrestrial ecosystem damage). Acid rain also damages forests by damaging tree leaves, thus limiting available nutrients, or by exposing trees to toxic substances slowly released from the soil.

Acid rain can also cause extensive damage to buildings, marble sculptures (such as Taj Mahal), limestone, slate, and mortar. These materials become pitted and weakened mechanically as the soluble sulphates are leached out by rainwater. Acid rain also increases the process of weathering.

ACID RAIN AND EUTROPHICATION

ACID RAIN IS also known to increase eutrophication. The deposition of nitrogen compounds might favor forest growth, but it disrupts ecosystems on land and in the sea. Although phosphates are the main cause of eutrophication in fresh water, nitrogen (oxides of nitrogen) is the limiting factor on land and in the sea. Nitrogen (in the form of oxides and ammonia) acts as a fertilizer in nature, but this generally means the growth of certain species at the expense of others. The impoverishment of ecosystems that results is also a real and serious problem, and the increased growth rate also increases biological acidification.

As acid rain flows through soils, both the decreased pH and increased aluminum cause chronic ecosystem stress.

Acid rain causes a cascade of effects in aquatic ecosystems that can harm or kill fishes, reduce fish populations, or even completely eliminate some fish species, thus altering the ecosystem and decreasing biodiversity. As acid rain flows through soils, the element aluminum is released into water bodies in the watershed. Both the decreased pH (high acidity) and the increase in aluminum cause chronic stress on the water ecosystem, which can either kill certain plants and fishes or limit the ability of small fish to compete for food and habitat.

Acid rain causes poor visibility and has an impact on human health. It is known to cause respiratory problems such as dry coughs; asthma; headaches; and eye, nose, and throat irritation. Sulphur dioxide mixes with water vapors and other chemicals in the air, forming sulphate particulates (smog), which is particularly harmful to people with breathing problems.

Acid rain can also harm people through the atmosphere or through the food chain—crops grown in the toxic soil, animals consumed by humans, and by drinking water. This contaminated food has been cited as causing nerve or brain damage in children.

A concern about acid rain and acidification was first raised by a Swede, Svante Oden, in the 1960s. Oden also pointed out that because the cause of acid rain is not just domestic, but due to other countries' windborne pollution, intergovernmental action was needed to solve such problems. On July 1972, 33 nations convened in Stockholm to draw world attention to acid rain's ecological threat to Scandinavian countries and Canada. Interestingly, the venue received a heavy downpour of acid rain for the entire week.

An overall understanding of the causes and effects of acid rain, and the remedial actions required, have advanced since the 1960s. Emission controls in both Europe and North America have reduced deposition rates significantly in some parts of the world, and an effort has also been made to recover damaged aquatic ecosystems. In other countries, however, further sulphur reductions are needed to stop the acidification damage to forests, soils, and lakes.

As a society, certain steps can be taken to limit acid rain by controlling the emission of gases such as sulphur dioxide and nitrous oxides (dioxide, monoxide) from fossil fuel burning and industrial processes. The best options are alternative sources of energy—apart from fossil fuels—such as wind energy, hydro power, nuclear energy, and solar energy. Automobile options include more fuel-efficient cars; hybrid vehicles; and natural-gas powered, fuel-cell powered, or battery-powered vehicles.

Another alternative is better emission-control technology, such as improved smokestack and exhaust pipe scrubbers, and using sulphur-reduced coal. Because acid rain is also linked to other environmental problems, such as climate change, society and individuals must try to help control acid rain.

Acquired Immune Deficiency Syndrome (AIDS)

AIDS IS AN acronym that stands for Acquired Immune Deficiency Syndrome, or Acquired Immunodeficiency Syndrome. This disease is caused by the infection of a retrovirus known as the Human Immunodeficiency Virus (HIV)—a virus that attacks and weakens the human immune system. Over time, opportunistic infections and diseases that can lead to severe illness or death may affect a weakened immune system. While there is no cure for HIV/AIDS, there are treatments to help manage or suppress symptoms. The best "cure" is considered to be awareness and prevention through safe sex, abstinence, and use of sterile needles.

Approximately 8,000 people die each day of AIDS-related diseases, according to World Health Organization (WHO) statistics. It is estimated that more than 25 million people have died of AIDS since it was first recognized on June 5, 1981, and that by 2007, over 65 million people have been infected with HIV. Therefore, it is not surprising that HIV/AIDS is considered to be one of the worst pandemics to affect humankind, despite global efforts for control, treatment, and prevention. This epidemic stands in the way of many countries' Millennium Development Goals (MDGs) set forth in 2002 by the United Nations (UN). In fact, one of the proposed MDGs is to halt and reverse the spread of HIV/AIDS (along with other diseases) by 2015. However, the impact of this disease is far-reaching and will continue to have detrimental social, political, economical, and environmental repercussions for decades to come.

The tragic loss of human life and the hindrance placed on societies have been devastating, but the real long-term effects are not easily predictable due to the complex nature of the disease. Infected people debilitated by the disease face incredible physical and emotional adversity. Developing nations have experienced the heaviest HIV/AIDS burden, in addition to contending with the ill effects of extreme poverty and inequalities. The social, historical, and economic roots of problems within the developing world are inextricably linked to an increased susceptibility of this disease. Sub-Saharan Africa, one of the poorest regions in the world, has been the hardest hit by the HIV/AIDS epidemic, and is home to more than 64 percent of all people living with HIV (approximately 24.5 million). South and southeast Asia follow as the next most affected regions, with over seven million people infected with HIV. North America, in comparison, has relatively low numbers with around one million infected, an HIV prevalence rate of 0.3 percent.

Young adults are the most susceptible group to be infected, leaving the elderly and child populations more vulnerable. Globally, AIDS has created nearly 13.2 million orphans, causing a breakdown in traditional family structures. Often, this leads to a displacement of children onto the streets, where they may prostitute themselves or engage in illegal activities for survival. Poor infrastructure, lack of resources and services, little political interest, stigma, denial, and discrimination are the challenges in providing effective HIV/AIDS prevention and treatment to local populations. Controversial pharmaceutical companies that refuse to make drugs more affordable to the poor, yet conduct questionable drug testing trials on the very same populations, further aggravate these frustrations.

In a recent effort to curb this crisis, the United Nations Joint Program on HIV/AIDS (UNAIDS) and WHO launched the "3 by 5" initiative in 2003, which focused on making life-prolonging antiretroviral treatment (ART) more accessible to three million of the world's poorest by 2005. While this target was not reached, the number of people receiving treatment therapy increased significantly. In 2005 alone, 8.3 billion dollars were spent on anti-AIDS initiatives. However, while many financial resources have been invested, most HIV/AIDS prevention and control programs have failed. This is partly attributed to Western-focused agendas and a lack of cultural and political understanding. One of the most important lessons is that behavioral and biomedical interventions alone cannot be successful in addressing this epidemic. In order to combat this global crisis, it is important for national leadership and political commitment to be strengthened, and for all nations to adopt a multisectoral approach.

Adaptation

ADAPTATION IS BROADLY understood to refer to the response to some type of change by organisms, individuals, and systems. How do organisms respond to habitat loss in the Amazon, and what are the implications for their reproductive success? How will humans react to climate modification in the American Midwest? What livelihood strategies will indigenous communities in Indonesia craft to address the localized effects of globalization? While these questions all direct attention to adaptations, this description of adaptation belies a contested history and the diverse views about the underlying mechanisms that determine responses to change.

Dictionary definitions of adaptation refer to the process of being adapted or adapting in order to make more suitable and improve "fit." Most environmental science and related texts are consistent with this broad interpretation and define adaptation as the genetically controlled physiological, structural, or behavioral attribute of an organism that helps it survive and reproduce in a given set of environmental conditions. This scientifically-derived explanation of adaptation is traceable largely to Charles Darwin (*The Origin of Species,* 1859) and the nearly concurrent research of Alfred Wallace in present-day Indonesia and Malaysia. Prior to this work, the adaptation of organisms to their environment was explained primarily through supernatural design and creationist interpretations.

Darwin's study of Galapagos finches, for example, revealed how subtle adaptations in beak structure through selective pressure and speciation enabled the successful exploitation of food resources and greater reproductive success. Organisms adapt in order to cope with physical change, better obtain essential resources, avoid predation, attract mates, or pollinate. Our understanding of adaptation has evolved considerably since the time of Darwin and Wallace, as modern scientific inquiry now provides far more detailed information on DNA, genetics, and mutations.

ADAPTATION AND THE SOCIAL SCIENCES

Biologically derived concepts of adaptation have also been applied to the social sciences, including those with a historical focus on environment and society, such as cultural ecology, ecological anthropology, and geography. In particular, the prominent work of Julian Steward (1955) envisioned culture as a central component of human adaptation, much like the role of genetic-information transfer in biological evolution and adaptation. Cultural adaptation as derived from a biological reference encouraged a view of adaptation as a largely functional (i.e., adaptive behavior in closed human systems was oriented toward the maintenance of stability) and rational response by individuals to change.

When derived from the biological sciences, however, meanings ascribed to adaptation only partially explain these mechanisms in human societies. In fact, there is no widely accepted explanatory framework for adaptation across the natural and social sciences, and interpretations are contested across and even within disciplines. In particular, the strict conceptualization of biological adaptation applied to human contexts has been criticized as overly "adaptationist."

First, this perspective implies that all behavioral responses can be reduced to serve some functional purpose. Yet, even in the biological sciences, the view that all features of an organism are optimally produced by natural selection has been critiqued as incomplete. Adaptive traits may arise by means other than natural selection, and thus, may include behavioral or physical modifications without a genetic mechanism. Second, those critical of applying biological concepts of adaptation to explain environment-society interactions point to the role of history, social and political contexts, and the limits of imagining human societies as closed, autonomous systems. For many scholars with Marxian roots, the starting point for adaptation is not the functional or rational response of individuals to change, but rather, social relations of production, and the manner in which adaptation is shaped by social and economic inequality.

In the social sciences, concepts of cultural and human adaptation that reflect a dialectical relationship between environment and society, the importance of social context in understanding cultural adaptation, and the influence of human agency in determining responses to change are now common. It is also recognized that individuals may adapt passively to change, but they are also likely to anticipate and respond proactively.

A variety of more recent subdisciplines and applied fields addressing environment and society relationships continue to emphasize the role of adaptation, including climate change studies, adaptive management and social learning, adaptive governance, and resilience and adaptive capacity. The climate change literature, in particular, has developed an explicit adaptation focus. It has helped to draw attention to the variable stimuli for adaptation (and whether such stimuli are anticipated); the dimensions of whom or what is adapting, and over what period of time; and the process of adaptation. With respect to the latter, adaptations may be spontaneous or deliberate, concurrent, or anticipatory. They may also be short- or long-term in scope, be localized or widespread, and reflect a range of modifications—behavioral, technological, and institutional.

While adaptation may never become an indisputable concept, the rich tradition of adaptation research will continue, remaining a key tool for those seeking to understand, explain, and predict environment-society relationships.

Adaptive Management

ADAPTIVE MANAGEMENT IS a policy framework designed to utilize scientific information in formulating and improving management strategies of complex systems. Adaptive management helps policymakers and managers learn from programs so they can take systematic action to continually improve management policies. This process involves changing assumptions and interventions in order to better respond to new information. Ultimately, adaptive management is learning by doing, and it is proactive in that it does not postpone management actions until complete data or information is gathered; essentially, it is experimentation that affects social arrangements and individual lives.

Adaptive management has been defined in various ways since its development in the late 1960s. Its most effective form—"active" adaptive management—employs management programs designed to experimentally compare selected policies or practices by evaluating alternative hypotheses.

An adaptive management system has two elements: a monitoring system to measure key indicators, and a response system to modify those indicators. Principles of adaptive management include: doing it yourself, promoting innovation, valuing and learning from failures, acknowledging that decisions are made with incomplete information, and considering all events to be learning opportunities. Adaptive management is flexible, encourages public input, and monitors the results of actions for the purpose of adjusting plans and trying new or revised approaches.

CHARACTERISTICS OF ADAPTIVE MANAGEMENT

CHARACTERISTICS OF ADAPTIVE management include: acknowledgement of uncertainty concerning the most appropriate policy for a management issue, thoughtful selection of the practices to be applied (assessment and design), careful implementation of a plan of action designed to reveal the critical missing knowledge, monitoring of key response indicators, analysis of the management outcomes in consideration of the original objectives, and incorporation of the results into future decisions.

While it was first developed for ecosystem management, principles of adaptive management have also been used in other fields. For example, the concept of learning organizations in business management, learning in the social sciences, and the scientific method all draw from principles of adaptive management. More recently, adaptive management has also been applied to conservation projects.

Adaptive management is an inductive approach, relying on comparative studies that blend ecological theories with observation, the design of planned interventions in nature, and the understanding of human response processes. Adaptive management treats management policies as experiments that probe the responses of ecosystems as human behaviors change. Adaptive management is bioregional in scope, collaborative in governance, and adaptive with respect to management perspective. As its use has become more widespread and diverse in meaning, it is also referred to as adaptive environmental assessment and management, or AEAM.

Adaptive management incorporates research into conservation action. The testing of assumptions, necessary in order to adapt and learn, involves a six-step iterative process: 1) problem assessment or outline purpose; 2) model design of the system in question, and a management plan; 3) implementation of the plan; 4) monitoring of activities that test assumptions; 5) evaluation of activities and analysis of collected data; and 6) using results to adjust or adapt the project and to learn from the experience, then repeating the cycle to further improve management efforts. The key to successful adaptive management is to complete all six steps to understand which actions work or do not work, and why.

Adaptive management became an important concept in U.S. resource management when Kai N. Lee introduced it to the Northwest Power Planning Council in 1984. Lee used the metaphor of compass and gyroscope to emphasize the integration of scientific analysis and civic participation in adaptive management. The compass, grounded in the scientific method, warns when the direction is off course, while the bounded conflict of the democratic process lends stability to humans' turbulent encounters with nature. Subsequently, different forms of adaptive management have become part of the resource planning processes of numerous federal, state, and private sector entities throughout the 1990s. A schematic appraisal of adaptive management includes four dimensions of policy design: 1) Conceptual soundness—is the idea sensible? 2) Technical—is the idea translated into practice well? 3) Equity—who are the winners and losers? 4) Pragmatic—does it work?

There are a few critiques of adaptive management. One critique is that since it is experimental, it is impossible to know which "experiment" is best for obtaining a desired management outcome. People may not desire to experiment or learn by doing, particularly if they know ahead of time the outcome they are seeking. Another critique is that the pressure to implement management strategies with limited resources is not conducive to the adaptive management process, which requires time to determine experimental outcomes as well as resources for continuous monitoring. A third critique of adaptive management is that it is not capable of fully handling the complexity of biocultural systems.

Addams, Jane (1860–1935)

JANE ADDAMS WAS an urban reformer who actively worked for social justice, particularly in the rapidly growing urban area of Chicago, Illinois

Born September 6, 1860 in Cedarville, Illinois, Jane Addams received her A.B. from Rockford College (then Rockford Seminary) in 1882. After a few years at the Women's Medical College of Philadelphia, she became ill and abandoned her studies in favor of travel. After observing the social experimentation at Toynbee Hall in London in 1887, she established Hull House, a settlement house that acted as a base for her and other women activists' pursuits. On September 18, 1889, she picked the location on Halstead Street because it was in a relatively run-down, poor, and largely immigrant part of Chicago. While the overall goal of the project was to provide diverse individuals enough space to interact with one another, thus producing socially functional citizens, the specific undertakings of Addams and her colleagues can be seen as the root of urban environmental justice movements, public health, and social work.

It is clear that the problems of the poor in industrial Chicago in the late 19th and early 20th centuries were more than social. They were also related to health and the environment. In *Twenty Years at Hull House,* Addams notes this in her description of the neighborhood around Halstead Street: unspeakably filthy roads, the obvious lack of enforcement of sanitary legislation, poorly lit streets, foul stables, and houses without sewer connections.

It was for this reason that Jane Addams and other members of her settlement house thought it essential to fight for increased labor protection and sanitary services for all neighborhoods. This fight was undertaken on many fronts. First, the women of Hull House performed in-depth epidemiological studies linking diseases, such as Phossy Jaw, to their industrial causes. They were then able to get legislation passed banning the use of certain substances in manufacturing. Second, Jane Addams and other members of the settlement house took active steps in cleaning up the neighborhood in which they lived, as Addams felt that the garbage problem was a great threat to her wards. These activities, along with city-wide studies of sanitation, led to the appointment of Addams to garbage inspector for her ward. In this role, she kept a close eye on the garbage trucks; mapped their comings and goings; made citizens' arrests of landlords who did not dispose of garbage; and eventually, provoked the city to restructure its collection system.

In addition to working in Chicago, Addams was also interested in national politics. In 1912 she acted as a delegate to the first national convention of the Progressive Party. In 1915, she founded The Women's League for Peace and Freedom. Her work in this area, with women and men, led to her become a co-winner of the Nobel Peace Prize in 1931, the first woman to receive that honor.

Among Jane Addams's many books are *Democracy and Social Ethics* (1902), *Newer Ideals of Peace* (1907), *Twenty Years at Hull House* (1910), *The Second Twenty Years at Hull House* (1930), *The Excellent Becomes the Permanent* (1932).

Jane Addams died in Chicago on May 21, 1935. She was 74 years old.

Afghanistan

AFGHANISTAN IS A landlocked country in central Asia with an area of 251,772 square miles and a population of 29.9 million (2005 estimate). Important cities include Kabul, the capital, Kandahar, Herat, and Mazar-i Sharif. Afghanistan is bordered by Pakistan, Iran, Turkmenistan, Uzbekistan, Tajikistan, and by China on the narrow Wakhan Corridor (a relic of the Great Game). High mountains and deserts dominate the landscape, with narrow river valleys providing most of the arable land. The largest agricultural region, irrigated by the Kunduz River, is in the north around the cities of Kunduz and Taloqan.

Twenty-three years of near-continuous conflict has shattered both Afghanistan's economy and infrastructure.

Socially, Afghanistan is comprised of many ethnic groups, the largest of which are the Pashtun, Tajiks, Hazara, and Uzbeks. The Pashtun and Tajiks speak distantly related Iranian-based languages. The Hazara, though believed to be ethnically related to the Mongols, speak the same form of Persian as the Tajiks. The Uzbeks speak Uzbeki, an Altaic language. The major language group is Persian, though administratively it is equal to Pashtu. Most of the population is Sunni Muslim although the Hazara and smaller groups in the northeast are Shi'a Muslims.

Though the area comprising Afghanistan shares a long history with both central Asia and south Asia, it was because of British fear that the region would provide a land route for a Russian attack on India that the era known as the Great Game evolved between competing Russian and British attempts to influence central Asia. Russia took over the areas north of the Amu Darya and the two competitors carved out Afghanistan as a buffer state between them. Pashtun kings ruled Afghanistan until an unpopular communist regime took power in 1978. Widespread dissatisfaction with the government caused the Soviet Union to invade and begin a 10-year occupation. This saw the rise of the *mujahidin*, traditionalists and Islamists who drove out the Soviets with the aid of the United States and other Muslim countries. A civil war erupted after this victory that augmented a major humanitarian crisis of millions of refugees scattered worldwide. This period of civil chaos allowed a group known as the Taliban to take control of much of the country. Many of the warring factions from the civil war coalesced into the Northern Alliance, which battled the Taliban until September 11, 2001, when al-Qaeda, a Taliban client, attacked the United States. With aerial and ground aid from the United States, the Northern Alliance overcame the Taliban.

Twenty-three years of near-continuous conflict has shattered both Afghanistan's economy and infrastructure. The majority of people are employed in agriculture, though it remains dangerous because of the large number of landmines that are leftover from the conflicts. Security also remains precarious as the Taliban have been allowed to reform and warlords dominate much of the countryside. These well-armed men rely on revenue from poppy crops that provide an estimated 85 percent of the world's heroin. For many farmers, this is the only crop that will grow in the rocky soils of the mountains. However, this provides a difficult challenge for the new government, who cannot hope to rule effectively while this narco-economy prevails.

Afghanistan's environment is so degraded by two decades of warfare that it now presents a major barrier to the nation's efforts at reconstruction. Combined with years of drought, the conflicts have drained the nation's wetlands and caused much of Afghanistan's wildlife to vanish. A United Nations Environment Programme (UNEP) Post-Conflict Environment Assessment report shows how conflict has put previous environmental management and conservation strategies on hold, brought about a collapse of local and national governance, destroyed infrastructure, hindered agricultural activity and driven people into cities already lacking the most basic public amenities.

Agenda 21

AGENDA 21 IS an internationally agreed action plan for the worldwide implementation of sustainable development. Alongside the Forest Principles and the Rio Declaration on Environment and Development, it was among the most important outcomes of the United Nations (UN) Conference on Environment and Development held in Rio De Janeiro, Brazil, in 1992. Agenda 21 is a nonlegally binding international agreement, meaning that its signatories are not legally obliged to implement it. However, as an example of soft law, it establishes a set of international norms and expectations that can influence government policy.

Agenda 21 contains provisions relating to human development policy and numerous aspects of resource management, including deforestation, biodiversity, agriculture, and water; and it arguably represents the most comprehensive attempt by the UN to ensure that the global economy (society) does not adversely affect the global environment (nature). Agenda 21 offers a good example of what Steven Bernstein has dubbed *liberal environmentalism*—the compatibility of economic growth and environmental protection—and codifies this relationship into a series of normative policy directions for the 21st century. For instance, it stipulates that an equitable and nondiscriminatory multilateral trading system is crucial for achieving sustainable development. The assumption here is that such a system will not only extend the benefits of trade to the world's poor, but will result in environmentally benign growth as well. Agenda 21 also specifies that trade liberalization—the removal of import and export restrictions and subsidies—will hasten the implementation of sustainable development, and calls on governments to implement sustainable development in developing countries by providing debt relief, bilateral and multilateral assistance, development financing through regional development banks, and new and additional resources. More specific provisions recognize the need to reduce unsustainable consumption, especially in industrialized economies; and that women play a vital role in implementing sustainable development. It also calls on governments to reduce perverse subsidies, decentralize natural resource management to the community level, and extend land rights to indigenous peoples.

Needless to say, the governments that drafted Agenda 21 had lofty ambitions. Many hoped that the adoption of Agenda 21 would usher in a new era of environmental sustainability around the world, while at the same time greatly reducing poverty. Sadly, although some gains have been made in both areas of development, notably chemicals management, many of the world's most pressing development and environmental problems continue unabated almost 15 years after the signing of Agenda 21. Moreover, the multilateral trading system is showing very few signs of improving market access conditions for agricultural products from developing countries. These developments have led to claims that Agenda 21 has been largely unsuccessful, and that some alternative development trajectory must be found.

Agenda 21 established the UN Commission on Sustainable Development, which was given the task of overseeing the implementation of Agenda 21. In 2002, the UN held the World Summit on Sustainable Development (dubbed "Rio+10") in Johannesburg, South Africa, to review the implementation of Agenda 21 and forge a new implementation strategy.

Agent Orange

AGENT ORANGE IS a colorless, liquid herbicide used by the U.S. Army during the Vietnam War to reduce foliage of inland forests and coastal mangroves that concealed North Vietnamese fighters. The name comes from the colored stripes emblazoned on the 55-gallon drums in which it was stored and transported.

Agent Orange is a 1:1 mixture of two Phenoxy herbicides: 2, 4-D (2, 4-dichlorophenoxy acetic acid) and 2, 4, 5-T (2, 4, 5-trichlorophenoxy acetic acid). First manufactured in the United States in the 1940s, it became widely used in agriculture by the mid-1950s and continues to be used in various parts of the world. When applied to broadleaf plants, the agent dries out leaves and causes them to drop off, though they usually regenerate within 4–6 months.

U.S. herbicidal warfare against the North Vietnamese began in 1961 with the deployment of a unique army aircraft unit, implemented under Operation Ranch Hand, which executed 6,000 spraying missions between 1965–71. Nineteen million gallons were sprayed over 10 percent of Vietnam's landmass by 1970. Specially equipped C-130 aircraft dispersed 90 percent, while backpacks, small trailers, and helicopters did the rest. Agent Orange was sprayed in 11.2 million gallons over 450,000 acres, which included—most famously—parts of the rainforest canopy covering the Ho Chi Minh Trail running through Cambodia, Laos, and Vietnam. By military standards, the operation was a success because it enhanced U.S. military offensives. The agent itself was most effective as a defoliant, because unlike many of its color-coded kin, Agent Orange is oil-based, rather than water-soluble. The chemicals were regularly mixed with diesel fuel, which provided an oil substrate not easily washed away from the waxy, tropical flora of Vietnam.

But Agent Orange has a darker side: Dioxin TCDD (2, 3, 7, 8-tetrachlorodibenzo-para-dioxin), a byproduct of its manufacturing process, has proven to be a human carcinogen. In 1969, a study by the National Cancer Institute released to the Department of Defense linked Agent Orange exposure to various health problems. These findings, along with public outcry against the U.S. government for the deliberate spraying and the diminishing support for the "Vietnamization" of the war, all helped end the military's use of Agent Orange in Southeast Asia.

In 2004, the Vietnam Association for Victims of Agent Orange/Dioxin (VAVA) sued several U.S. companies for "liability in causing personal injury, by developing and producing the chemical." Since the end of the war in 1975, American GIs, suffering from diseases such as Hodgkin's and leukemia, have won numerous court cases against chemical companies that resulted in financial compensation without admission of company wrongdoing. Similarly, VAVA provided evidence linking Agent Orange to human maladies; in particular, birth defects and mental disabilities. A year later, however, the VAVA case was dismissed on the grounds that companies that produced the Agent were not liable for the method of its use by the government. For many in Vietnam, full reconciliation with the United States will only come through a fair resolution of the Agent Orange matter.

Agriculture

AGRICULTURE IS THE practice of cultivating plants and herding animals for food, fiber, and other products. Agriculture is the single largest land use in the world and it is the single greatest employer. Nearly 38 percent of the earth's land area is in agriculture. In 2004, more than 2.6 billion people, or 42 percent of the world's population, were engaged in agriculture. 10,000 years ago, only a trivial fraction of the earth's surface was dedicated to agriculture. Since then, agriculture has replaced prairies, wetlands, forests, and other ecosystems, allowing the global population to exceed 6.3 billion. Agriculture features prominently in many debates linking environment and society. It is blamed for reducing biodiversity, polluting aquatic ecosystems with eroded soils and toxic chemicals, and contributing to global climate change. Agriculture is also at the center of the debate about genetically altered food, trade, and globalization. Developing more sustainable agricultural systems will be required to reduce the impact of agriculture on the environment and provide enough food for the projected 8 billion people who will inhabit the planet by 2036.

ORIGINS AND DIFFUSION

The first Agricultural Revolution was the transition of societies from hunting and gathering to agriculture. This transition occurred independently in numerous locations around the world, but emerged first about 10,000–12,000 B.C.E. in the Fertile Crescent in the present-day countries of Syria, Turkey, and Iraq. Plants and animals have been bred to exhibit traits that are useful to people, called domestication. It is likely that favorable environmental factors, the availability of wild plants, complex social groups, and food surplus and sedentary livelihoods were important in this revolution. The rise of agriculture is considered revolutionary because of the changes it spawned: population growth, the development of cities, and a greater specialization of labor. People's ability to transform the earth increased markedly with agriculture. The need to feed greater populations created a greater need to transform ecosystems into agricultural systems.

Paddy rice cultivation is an important agricultural system in east and southeast Asia. Small plots of land are flooded for much of the growing season, which requires careful water management—but it is highly productive and feeds millions.

Trade, warfare, and migration diffused agricultural plants and animals. The European discovery and conquest of the Americas (1492–1533) was an important moment in agricultural diffusion. The exchange of plants and animals between the Old and New Worlds is called the Columbian Exchange, after Christopher Columbus. Maize (corn), tomatoes, potatoes, cotton, cassava, and tobacco were unknown in the Old World, and commodities such as wheat, sugar, coffee, cattle, and pigs were unknown in the Americas. This exchange radically changed diets, ecologies, and even demands for labor. For example, to satisfy European demand for sugar, Africans were brought as slaves to the Caribbean and Brazil to work on a new agricultural system—the plantation.

The Columbian Exchange was equally important in Europe. Maize and potatoes became critical components of the Second Agricultural Revolution, which occurred from approximately the late 17th century to the mid-19th century in Great Britain. Agricultural production increased substantially; rotating crops, using new crops, and early mechanization allowed farmers to grow enough food for an expanding urban population. The Second Agricultural Revolution made the Industrial Revolution possible. Although the Columbian Exchange made more crops and animals available in the Old and New Worlds, humans have come to rely on fewer crops for the majority of their diet. About 200 of the 300,000 terrestrial species of plants have been domesticated. Humans rely most heavily on about 20 species for their diets, with corn, wheat, rice, soybeans, potatoes, and cassava (yucca) being the most important staple crops.

INDUSTRIALIZATION OF AGRICULTURE

During the 19th and first half of the 20th century, many technological and scientific advances were made in agriculture, especially in the United States. The steel plow, tractor, combine, and hybrid corn are examples. These technologies were the predecessors of substantial changes in agriculture that occurred after 1940 in the United States, and soon thereafter in Europe, Japan, and other developed countries. World War II and its aftermath precipitated the industrialization of agriculture, with breeding technologies, mechanization, science, and economies of scale. Until the 1940s, most agriculture utilized organic fertilizers (manure), heirloom seeds, and human and animal labor. Mules and horses pulled plows and combines; people weeded and harvested the crop by hand. Many farmers were generalists, planting several crops and raising a variety of livestock.

From 1940 to 1970, machines (tractors) and synthetic fertilizers and pesticides, or agrochemicals, replaced many of the people who worked in agriculture. Fossil fuels became the main energy source. New varieties of crops that responded well to nitrogen were developed. Fertilizer applications to U.S. farmland increased nearly 700 percent. DDT and other pesticides became common. Farmers were forced to expand their operations (economy of scale). The number of farms in the United States dropped in half, but their size more than doubled. Many farmers also became specialists, focusing on producing only a few crops or livestock. Yields increased substantially; yields for wheat and cotton doubled and potato yields tripled. Farmers relied more on inputs from other sectors of the economy, such as industry for tractors and chemical companies for fertilizers and pesticides. Similarly, crops became inputs into processed foods and other products. Soy, for example, is processed into hundreds of products, from salad dressing to tofu.

Hybrid corn exemplifies the impact of the industrialization of agriculture. Farmers became dependent on annual purchases of hybrid seed and the fertilizer it requires. Hybrid corn—produced when two stunted varieties of corn are bred—came from advances in agronomic science at the start of the 20th century, and essentially replaced nonhybrid corn by 1960. The result is high yields, but only one generation of high-yielding corn. Thus, farmers must purchase hybrid seed corn annually. To obtain high yields, many farmers apply anhydrous ammonia, a powerul nitrogen fertilizer. Some of this nitrogen has seeped into groundwater, rivers, and lakes, creating serious pollution of aquatic ecosystems. Very little harvested corn is consumed directly; approximately half of all U.S. yield is fed to livestock, especially cattle. Corn is also an important ingredient for high-fructose corn syrup.

THE DEVELOPING WORLD

Because industrial agriculture in the developed world has replaced most human labor with machines and other fossil-fuel technologies, less than three percent of the workforce in Western Europe and the United States is engaged in agriculture. Even though these farmers are very productive, agriculture accounts for a small part of the Gross Domestic Product (GDP)—less than 3 percent. In the developing world, however, agriculture remains an important employer and component of the economy. At least one third, and as much as 75 percent of the work force, are engaged in agriculture. Agriculture accounts for at least 20 percent and as much as 75 percent of the GDP of these countries.

There is considerable diversity among farmers in the developing world, in part because each agricultural system is dependent on the environment and economy. Farmers typically have relatively small plots of land and live in basic conditions or poverty. They produce both for their families' consumption (subsistence) and to sell (market). Agricultural labor utilizes people and animals, although agrochemicals and mechanization are increasingly common. Many households combine off-farm employment with semi-subsistence agriculture. One or more of the adults and the eldest children may work for wealthier farmers or migrate to a city temporarily. In much of northern China, south Asia, southern Mexico, the Andes, and parts of Africa, farmers grow grains (wheat, corn, rice, barley, sorghum); and/or root crops (potatoes, cassava); and raise livestock, especially cattle, pigs, and sheep. Farmers commonly intercrop fields, planting several crops to diversify their diet, reduce risk, and improve the soil.

Paddy rice cultivation is an important agricultural system in east and sSoutheast Asia. Small plots of land, typically close to rivers, are flooded for much of the time the rice is growing. This system requires careful water management and constant maintenance, but it is highly productive and feeds millions of people. In tropical climates, farmers are able to multi-crop, which means harvesting at least two crops in less than one year. Another common agricultural system in developing countries in the tropics is shifting cultivation. In this system, farmers cut trees and brush on a field and burn them when they dry. This process transfers the nutrients from the vegetation to the soil; seeds are planted in the ash. Farmers will commonly cultivate the field for a few years, and then allow it to return to brush and eventually forest (fallow). This system makes use of infertile tropical soils and can be sustainable if the length of the fallow is sufficient.

Plantation agriculture is also found in many developing countries in the tropics. In this system, wealthy and sometimes foreign owners control large stretches of fertile land and plant crops for export. Cocoa, palm oil, bananas, and coffee are examples. Plantation agriculture uses cheap labor, but also very modern agricultural technologies.

FACTORY FARMING

Factory farming became the logical extension of applying industrial practices to agriculture. Factory farming broadly describes agricultural systems that are intensive, usually large-scale, and designed to produce a product at the least cost in the shortest time possible. Factory farms use practices common in industry and rely on veterinary and agronomic science and agrochemicals. The term is most commonly applied to large animal confinements and greenhouses with highly controlled environments. The term is sometimes used to describe any agricultural system that is large-scale, relies on agrochemicals and monocropping (growing one crop in a field) and is either highly mechanized or uses cheap labor. This would include vegetable farming in California, fruit orchards in Spain or Israel, and soybeans in Argentina. Most of the food consumed in the developed world is produced in this fashion.

Animal confinement operations group large numbers of animals in closely controlled operations. U.S. beef cattle spend most of their lives on pasture, but when they reach a certain age and weight they are commonly shipped to large feedlots on the Great Plains—Texas, Nebraska, Kansas, and Colorado. The largest feedlots hold more than 100,000 cattle. The cattle will spend up to two months on the feedlot before they are sent to a nearby meatpacking plant, where they are slaughtered, packaged, and sent to retail outlets. The meatpacking plants are also built for economy of scale, some slaughtering more than 3,000 head per day.

This method of producing beef requires large quantities of fossil fuel energy, making it highly energy inefficient. In the case of the Great Plains, cattle are shipped hundreds of miles. Since cattle are poor converters of the energy in grains, much is wasted. Traveling great distances is stressful to cattle, making them vulnerable to illness. When they arrive at a feedlot, they are often given antibiotics. This concentration of cattle produces an enormous amount

The Green Revolution

Many of the breeding and agrochemical technologies associated with industrial agriculture were applied to crops in the developing world, starting in the 1960s. The Green Revolution refers to a major transformation in agricultural practices in the developing world based on a specific technological and institutional package, including high-yielding variety seeds (HYVs), fertilizers, and irrigation. In the late 1960s, millions of hectares of HYVs of wheat and rice varieties were planted in south and southeast Asia. The Green Revolution allowed countries to stay ahead of population growth, but it caused serious environmental problems. Most of the beneficiaries of the Green Revolution were relatively well-off farmers and the companies that sold the equipment and chemicals. The most disadvantaged, in particular women who grew subsistence crops and did not have secure land tenure, bore the greatest burdens of the Green Revolution. The Green Revolution continues, with new crops, newly targeted areas, and recognition that the impact of agricultural development must be more socially conscious and environmentally friendly.

of organic waste. Feedlots typically sell the manure to farmers, but if waste management is poor, surface and groundwater contamination will occur.

The concentration of the beef industry and the conditions in the meatpacking plants is controversial. Starting in the 1980s, the industry consolidated, meaning that companies merged or were purchased by larger companies. This left few companies to purchase cattle; only four meatpacking plants control nearly 80 percent of all cattle slaughtered, prompting complaints from farmers that the concentration has driven down prices. Concentration is also found in the pork industry, where four companies control approximately 63 percent of all hogs slaughtered. Many of the workers in the plants are poorly paid immigrants from Latin America.

Industrial practices have been applied to the chicken industry as well. Almost all chickens in the United States are raised under a system called production contract farming. A company contracts with a "grower" to raise chickens. The company provides the animals, feed, and medicine, and remains the owner of the animals. The grower provides the land, buildings, and the management/labor. The grower is paid on a predetermined price. More than half of the country's chickens come from relatively few growers who sell more than 500,000 a year.

In the developing world, many tropical fruits, such as bananas and flowers, are grown with industrial practices. Most cut flowers, such as roses and carnations sold in Europe and North America, come from Colombia, Ecuador, or East Africa. They are raised on good soils in large and highly controlled greenhouses. Agrochemicals are used to produce a "flawless" product for demanding, overseas consumers. Corporations own the rights to certain varieties of flowers, and require a royalty on every flower sold. These greenhouses are controversial for their heavy use of agrochemicals; relying on cheap, female labor; and the fact that some of the best land in poor countries is used to raise a luxury item.

Factory farming has been accompanied by the increase of corporate influence. In the latter half of the 20th century, transnational corporations (TNCs) that purchase and processes agricultural products developed global strategies, and now a few enormous corporations exert considerable control. Cargill, for example, has economic interests in many agricultural sectors around the world. They have offices in more than 60 countries and are major purchasers and processors of cocoa, wheat, soybeans, and fruit juices. They own the second-largest meat processing and turkey processing companies in the United States. For many agricultural products there are few purchasers, raising the concern that farmers are not receiving a fair price.

Only four meatpacking plants control nearly 80 percent of all cattle slaughtered, sparking price controversies.

GENETICALLY MODIFIED ORGANISMS

A more recent and controversial trend in agriculture is the increasing use of genetically modified organisms (GMOs) in agriculture. A GMO is a plant that has been altered using scientific techniques—other than breeding—to change the genetic makeup of the plant. One common form of a GMO is a transgenic plant, which received the gene(s) of a completely different species. The two most common applications of GMOs in agriculture are herbicide tolerance and insect resistance. Herbicide-tolerant soybeans tolerate an herbicide called glyphosate. Fields can then be sprayed with glyphosate, killing the weeds, but not the crop. Insect-resistant corn contains a gene from a soil bacterium called Bt (*Bacillus thuringiensis)* that produces a protein that kills a larva that would otherwise destroy the plant.

Adoption of these "biotech" crops has been remarkable since their introduction in 1996. In 2005, 8.5 million farmers in 21 countries planted more than 90 million hectares (1 hectare = 2.47 acres), half of which was planted in the United States. Soybeans, corn, and cotton account for the vast majority of the crops. The proportion grown in developing countries is growing quickly. Much of the food consumed in the United States, especially processed foods, derives from GM crops. GM seed companies and other advocates argue that GM crops are a natural extension of modifying plants that has been done since the First Agricultural Revolution. Companies are applying the knowledge of the day—genetic engineering—to plants and animals. They argue that the GM crops could produce higher yields and more food, have more resistance to pests—thus requiring less pesticide—and have desired traits, such as rice with more nutrition.

Criticisms of GM crops can be grouped into three categories: environmental, health, and political/economic. Critics worry that targeted pests will develop a resistance to Bt and that the genetic material will drift onto other plants, creating unintended "genetic pollution." The most common health concern is that the long-term consequences of consuming GM food is unknown. Labeling food with GM products is not required in the United States, but in Europe, where very little GM food is consumed, labeling is required. The political and economic concerns fit into a larger concern over corporate control over agriculture, and agricultural biodiversity. GM crops are increasingly common, but only a few corporations own the seed patents. The Monsanto Corporation, for example, owns the patents on most of the soybeans and much of the corn crop grown in the United States. Another political and economic concern is the U.S. government's interest in pushing markets for GM crops. Europe and many developing nations have resisted GM grain imports from the United States, prompting the United States to sue the European Union through the World Trade Organization on the grounds that the EU has no legitimate health reasons for rejecting the imports.

ENVIRONMENTAL IMPACTS

The environmental impacts of agriculture are substantial. Agriculture has replaced many biodiverse ecosystems with monocropping, reducing natural habitat. For example, the primary cause of deforestation in the Amazon forest in 2004 was the conversion of forests to monocropped soybean fields. Intensive cultivation practices have caused erosion, as well as clogging and degrading of rivers and other aquatic ecosystems with sediment. Agrochemicals have accompanied the sediment, polluting streams and aquifers. Fertilizer runoff creates fertile conditions for some plants and algae to thrive in lakes. Microorganisms consume the plants and lower the dissolved oxygen in the water, depriving fish and other aquatic life of dissolved oxygen. Although developed countries use most of the agrochemicals in the world, the use of these chemicals is most dangerous in developing countries, which still use some chemicals taken off the market in North America and Europe. Farmers unintentionally poison themselves, and an unhealthy chemical residue remains on many crops.

ALTERNATIVE AGRICULTURE

A number of alternative perspectives have developed in response to the perceived environmental and social effects of industrial agriculture. One such movement, agroecology, calls for the application of ecological principles to agriculture in order to create sustainable agricultural systems. Sustainable agriculture produces healthy food in a way that would not undermine the ability to do so in the future. It minimize the impact on the environment by not releasing toxic chemicals, and uses local resources and organic material to replenish soils and conserve biodiversity. Many of these practices—biological pest control, crop rotations, multi-year fallows, intercropping, minimal tilling, and raising livestock with cultivated crops—were common practices before the industrialization of agriculture. Other movements, such as buying organically grown products, are commonly based in similar principles as agroecology. Buying locally grown, organic food is touted as an important way to eat healthy, minimize damage to ecosystems, reduce energy costs, and be in touch with local environmental conditions and farmers.

CONCLUSION

More food will need to be produced to feed a growing population, but how much food will depend on yields, consumption, how efficiently food is used, and whether luxury crops (drugs, flowers, bananas) are replaced with staples. The environmental and social conditions of food production, and who benefits from it, are critical issues. Industrial agriculture has caused serious environmental problems, but has also produced an abundance of food in developed countries. Proponents of biotechnology see GMOs as a way to produce more food efficiently. Advocates of agroecology see GM crops, industrial agriculture, and corporate control of the food supply as problems, and advocate alternative agriculture as a way to produce healthy food without undermining the ability to produce in the future.

Agroecosystems

AGROECOSYSTEMS ARE PLANTS and animals interacting within a shared physical environment that has been modified by human practices to produce food, fuel, and other products. In other words, agroecosystem analysis rests upon a holistic view of human–nature interactions.

Agroecology is the study of agroecosystems. Agroecology, the study of agroecosystems, draws from the fields of agronomy, genetics, and pest ecology to understand the entire system of food production. However, the social sciences, such as sociology, political science, and anthropology, have been helping to inform agroecosystem principles. This has caused the definition of agroecology to broaden to include social systems.

AGROECOSYSTEM MANAGEMENT

Agroecosystem management, in terms of its ecological components, rests upon the principles of sustainable yields, natural pest regulation through diverse rotations, and building biologically rich soils. The goal is to design farming systems that more closely mimic natural systems. Agroecologists seek to optimize the recycling of nutrients and organic matter, creating an energy loop that requires minimal (if any) synthetic inputs.

Special features of agroecosystems include crop rotations, which provide not only crop nutrients but also help to break up the life cycles of weeds, pests, and disease, reducing the need for herbicides, pesticides, and fungicides. Polyculture, where multiple crops inhabit a single field to enhance yields and biomass, is another important feature of agroecosystem management.

Agroforestry systems, in which trees and/or livestock cohabitate and compliment each other, are also gaining in popularity among agroecologists. Animal integration, in which livestock are integrated into a farming system, is yet another feature of ecosystem management. Livestock help to not only increase biomass output, but they also play an important role in recycling nutrients (such as the nitrogen-rich manure that can be applied on fields to fertilize crops). The ultimate goal is to integrate components in a manner that increases overall biodiversity, improves biological efficiency, and maintains the self-regulating capacity of the agroecosystem.

SOCIAL COMPONENTS

Agroecosystems also have a social component. Recent conceptions of agroecology draw as much from the social sciences as the biological sciences. Well-managed agroecosystems are designed to ensure that their development processes are locally controlled by indigenous knowledge, with the idea that in the end, no one knows the local natural systems better than the area farmers. Beyond this, agroecology seeks to strengthen communities by encouraging local partnerships between people and development groups by teaching principles of agroecology to community members.

The popularity of agroecology has increased in recent years with the rise of sustainable and organic farming. These alternative models of food production rest upon many of the principles of agroecology. As an indication of their growing relationship, a number of U.S. universities are offering degrees in the areas of agroecology and sustainable agriculture, such as the University of Illinois, Pennsylvania State University, and the University of California at Santa Cruz. Principles of agroecology are also being used around the globe under the guise of sustainable development, so as to increase the self-sufficiency of rural inhabitants in less developed countries as they work to build sustainable local food systems.

Agroforestry

AGROFORESTRY IS A term used to designate land management systems that combine woody species (typically trees, palms, bamboos, and shrubs) with agricultural crops. The combination may be concurrent (both woody and crop species organized spatially, such as by intercropping), or occur in temporal succession (agricultural crops succeeded by woody species or vice versa); and in some cases it also may incorporate animal species. Various forms of agroforestry have long been practiced in diverse regions of the world; perhaps the best known examples come from studies in Asia, Latin America, and Africa.

Combining agriculture with the cultivation of tree species can have ecological, economic, and social benefits. Ecological benefits include the at least partial replacement of vegetative (tree) cover in agricultural areas to resemble the natural structure and diversity of the local forest. Restoration of vegetative cover can cause or be accompanied by improvements in soil organic matter, texture and moisture capacity; reduction in soil acidity and salinity; improved nutrient availability and cycling; and nitrogen fixation when involving leguminous species. Often, increased levels of biological (species) diversity are reported in agroforestry systems. Economic benefits include both efficiency and stability in production processes and the producton of a diversity of commodities, including food, medicines, construction materials, soil conservation, and protection.

Many proponents claim that agroforestry systems better utilize labor and tools and support a more diverse set of land management practices than either agricultural or forestry activities alone. Aside from various crop, fruit, and timber tree species, such activities may include aquaculture (fish farming), apiculture (beekeeping), or livestock farming. While some researchers consider swidden (slash-and-burn) agriculture to be one form of agroforestry for its temporal sequence of forest-crop-fallow-forest, others view agroforestry systems that incorporate the planting of leguminous species as a more sustainable production process that lessens the need for fallows. Agroforestry systems take diverse forms, and may include home gardens, enriched fallows, tree-crop combinations in fields, or mixed fruit trees in orchards.

SOCIAL BENEFITS

The social benefits of agroforestry are touted by several studies that note how most indigenous systems of agriculture involve various forms of agroforestry, often empowering otherwise marginalized social groups with access to resources and livelihoods, and preserving cultural and linguistic xtraditions. By the same token, findings caution how many development projects that promote agroforestry as a means of improving local economies while protecting the environment may introduce livelihood transformations that have inequitable effects on distinct economic classes, genders, and/or socio-cultural groups.

The designation of land tenure rights, whether formal or informal, statutory or customary, should be examined along with the effect of agroforestry systems on ecosystems, livelihoods, and living standards. For instance, tree or agricultural products that are cash crops, such as timber, coffee, and sugarcane, are typically planted in areas of secure land rights, while subsistence crops may not. However, it is important to recognize the complexity in land tenure, agroforestry systems, and their practitioners in analyzing their potential for conservation and economic development.

The International Center for Research in Agroforestry (ICRAF), headquartered in Nairobi, Kenya, is dedicated to promoting agroforestry research and development in order to stem tropical deforestation and land degradation, and improve the livelihoods of small, resource-limited farmers. ICRAF and other agroforestry-focused institutions recognize the benefits of locally evolved (indigenous) systems of cultivation, which in the tropics typically involve agroforestry systems of varying degrees of complexity. Native agroforestry systems are often distinguished from externally introduced, donor-funded, and top-down agroforestry projects for the formers' long history and particular adaptations to local ecological, economic, and social conditions.

Agronomy

AGRONOMY IS A branch of agricultural science concerning the study of soil types, crop types, and the maximization of agricultural production. Agronomists have become increasingly concerned with the issue of sustainable production. Consequently, topics studied include the relative balance of agricultural inputs and outputs, use of irrigation and fertilizer methods, selective breeding of agricultural plants and animals, and the understanding of specific local conditions and empowering local people to maintain healthy agricultural systems.

Generations of farmers have improved their production in a series of small steps; examples include soybeans, rice, and grapes. Further, farmers have developed their use of local knowledge to improve agricultural production. Such systems can prove fragile when faced with internationally sponsored, scientifically based production improvements that fail to take account of this local knowledge. The promotion of inland black tiger prawn raising in Thailand, for example, led to short-term income increases for many subsistence farmers who participated in the scheme. However, the negative impacts became clear as the lack of water inflows contributed to the buildup of pollutants, which led to the degradation of the surrounding land. Greater participation by local people might have revealed the knowledge that would have prevented this problem. Many multilateral donors, notably the World Bank, have made efforts to increase that participation.

Improvements in scientific knowledge and methodology have enabled agronomists to become increasingly effective in understanding global production methods. However, conditions are constantly changing as pollution and environmental degradation negatively affect many agricultural production systems. Consequently, much agronomy is devoted to maintaining existing production levels.

Major international agronomy organizations include the Food and Agriculture Organization (FAO), which was founded in 1945 as a specialized agency of the United Nations, and which provides technical expertise and capacity-building to countries around the world. Many universities offer agricultural departments that include agronomic interests. Private-sector organizations have also spiked their interest in agronomy, as profitable opportunities have become increasingly evident. The use of genetically modified organisms, for example, has offered considerable opportunity, and some corporations have rushed to capture those incomes. These ventures have often relied upon strict rationing of intellectual property rights, which has caused local people who fear they have lost control over their agricultural inputs. Consumer-led oppositions have also become influential and in many countries in western Europe, and the involvement of private-sector corporations in agricultural production has led to significant consumer boycotts.

Air Conditioning

AIR CONDITIONING IS the mechanical control of the cooling, heating, circulation, cleaning, humidification, and dehumidification of air. Originally, air conditioning was designed to improve industrial or manufacturing processes, and providing human comfort was only a secondary purpose.

Cooling by conditioning the air is basically a form of refrigeration. The air is cooled by evaporating a liquid with a low boiling point, called a refrigerant. General Motors produced chlorofluorocarbon refrigerants for Frigidaire in 1928, and in 1930, Freon was introduced to the public. Freon was popular until the discovery that chlorofluorocarbons (CFCs) damage high-altitude ozone, and in 1990, The Clean Air Act in the United States banned deliberate venting of chlorofluorocarbons. Hydrochlorofluorocarbons (HCFCs) and hydrofluorocarbons (HFCs) are in use today and are safer for the environment.

A COOL HISTORY

Humanity's first trials to improve air condition were simple. Possibly the very first form of air conditioning was the use of a cave for shelter. In summer, the cave provided a cooler environment than the strong sun and heat of the outdoors. Forced cooling took longer to develop.

A primitive form of air conditioning was recorded as far back as when ancient Egyptians, Greeks, Romans, and eastern Indian peoples observed that hot, dry breezes became cool and moist when moved through damp mats or over porous containers of water. Roman emperors cooled their gardens with snow brought down from mountains. Snow was also used in Baghdad in the 8th century to cool the air in the Caliph's residence, where spaces between walls were packed with it. In the early part of the 8th century, Japan improved the fan with pleats.

The work of experimental scientists contributed to the many pieces of modern, mechanical air conditioning. From Galileo Galilei's air-and-water thermoscope invention in 1592, to thermodynamic discoveries continuing through the 1800s, inventions primarily led to work with mechanical heat. However, innovation efforts soon began to focus more on refrigeration.

In 1851, Dr. John Gorrie, a physician in Florida, patented his refrigerating machine that lowered the temperature and humidity of air. Gorrie believed that cooling and drying the excessively hot and humid air, typical of the climate of the southeastern United States in summer, would improve the health of local inhabitants.

By the 1880s, mechanical refrigeration, or "manufactured air," was used commercially by cold storage, ice-making, brewing, dairy, and meatpacking companies. Another key technology that played an important part in conditioning the air of large spaces was the power plant. In 1882, the first electric power plant in New York provided an inexpensive source of energy for commercial and residential customers. Air conditioning would remain a commercial commodity until the next century.

Air circulation was also improved with the electric fan. The first commercial electric fan was manufactured by Crocker and Curtis Electric Motor Company in 1882. In 1908, the first oscillating fan came on the market. Electric fans quickly became popular in office buildings. In 1902, Willis Carrier, a mechanical engineer with the Buffalo Forge Company of Buffalo, New York, developed a spray-type temperature and humidity control. This and other innovations and improvements he developed led to his title, “the father of air conditioning.”

In July of 1902, Carrier installed his first air conditioning system at a printing plant in Brooklyn, New York, where summer heat and humidity caused paper to dampen and curl. Carrier’s system helped control the heat and humidity in the building to prevent this problem. Another engineer in New York, Alfred Wolff, who had worked on developing a system to cool textile mills, helped adapt a system for the New York Stock Exchange. In 1902, their new building was equipped with a central heating and cooling system. In 1906, Carrier patented his “Apparatus for Treating Air,” and Stuart Cramer used the term “air conditioning” for a system to control the humidity in a southern U.S. textile mill. The term used today refers to the conditioning of moisture and ventilation, which changes the air. Regardless of temperature, humidity can greatly affect certain manufacturing processes.

Before becoming a household commodity, the public experienced conditioned air in public buildings such as theaters, department stores, and trains. In 1904 at the St. Louis World’s Fair, the Louisiana Purchase Exposition featured the comfort-cooled Missouri State Building with its 1,000-seat auditorium. The New Empire Theater in Montgomery, Alabama, in 1917 was the first documented theater to use refrigeration for cooling.

MODERN ADVANCES

Besides Frigidaire’s introduction of the first “room cooler” in 1929 and Freon in 1930, other refinements began to follow Carrier and others’ initial innovations. In the 1930s, the window unit air conditioner, a more efficient solution for smaller areas, was developed. Innovations from this machine were applied to central heating and cooling systems, improving their affordability.

It was not until after resources became more available after the end of World War II that air conditioning became common to residences. In the 1950s, an advertising slogan touting the practicality of air conditioning exclaimed, “for the millions, not just the millionaires.”

The influence of air conditioning can be seen in the change of architecture in America. Homes were once commonly designed with high ceilings, deep porches, and large windows and doors to allow cross-ventilation. Landscapes were more likely to include shade trees and fountains or small pools. After buildings and homes could be cooled mechanically, one-story homes with sliding doors, picture windows and no porches became popular. Landscapes had less shaded areas. Business buildings have evolved into towering glass skyscrapers defining city skylines.

Today it is estimated that about half of all homes and 80 percent of cars in the United States have air conditioning. Air conditioning can improve work productivity, industrial processes, medical and health needs, food preservation, and human comfort. Recent innovations consider the impacts air conditioning has on resource use and environmental effects of its mechanical process.

The demands for energy required by air conditioning, however, make these increases in efficiency seem like only marginal gains. Given that air conditioning accounts for roughly 16 percent of the average U.S. household electricity consumption, and that electricity demands are currently met almost entirely by fossil fuels, it is likely that air conditioning usage is a significant contributor to greenhouse gas emissions. Cooling the home, therefore, ironically may result in warming the planet, resulting in further demands for cooling, in a potentially accelerating feedback loop. Alternative approaches to cooling that use nonelectrical sources or rely less heavily on the broader energy grid seem unlikely in the near future, and breaking the cycle of warming and cooling may prove to be a difficult challenge.

Constructed in 1977, The Trans Alaska Pipeline bisects the Kanuti River near the Dalton Highway.

Alaska Pipeline

OIL WAS DISCOVERED on Alaska's North Slope in 1967. Soon thereafter, the state of Alaska sold oil leases worth over $900 million, and established royalties that made Alaska one of the richest states in the nation. Before this could happen, oil companies needed an economical way to move the oil to market. Several ideas, such as rail transport and ice-breaking tankers, were rejected. A consortium of oil companies formed the Alyeska Pipeline Service Company to build the Trans Alaska Pipeline System (TAPS), which included both the pipeline starting in Prudhoe Bay, and the terminal facilities at Valdez, the northernmost ice-free port in Alaska. Two major interests opposed the pipeline. Alaska's native people pressed long-standing land claims and threatened to tie up the project in court unless their claims where honored. The Alaska Native Claims Settlement Act of 1971 sought to compensate the native peoples for their land, thereby eliminating this hurdle.

Many environmental groups, however, continued to oppose the pipeline, with particular concerns about the environmental impact on wildlife and habitat. Others raised concerns about potential leaks and oil spills along the pipeline at Port Valdez, and as oil traveled through Prince William Sound. Due to these concerns, engineers made several changes to the original pipeline design. Most of the pipeline north of the Yukon River was built above ground to minimize damage to tundra and permafrost. Designs were also incorporated to protect the pipeline in an earthquake, changes that proved their value when the pipeline successfully withstood the magnitude 7.9 Denali earthquake in 2002. Growing needs for domestic oil led Congress to enact the Trans Alaska Pipeline Authorization Act (TAPAA) of 1973. The vote on the bill was a tie in the Senate; Vice President Spiro Agnew broke the tie, which allowed TAPAA to go forward. The act exempted the pipeline system from provisions of the National Environmental Policy Act (NEPA), although environmental laws were followed. Construction began soon thereafter, and was completed in 1977, when the first oil tanker left Port Valdez.

Some of the environmental concerns were overstated, but the pipeline has still had an effect on the environment. The behavior of animals near construction camps was altered when people fed them, often through garbage dumps, although this did not seem to have had a major impact. Other effects have been controversial. There have been several small leaks of the pipeline. In March 2006 there was a 250,000-gallon leak in feeder pipes from British Petroleum's oil field to the pipeline, and the discovery of another leak in the same system in August 2006 shut down the Prudhoe Bay field for months while repairs were made. North Slope oil also spilled from the *Exxon Valdez* in 1989. Perhaps the most profound impact of the TAPS was socioeconomic—Alaska's population and treasury grew rapidly in the 1970s, and oil wealth and the drive to find more oil reserves to pump through the pipeline have had a profound effect on the life and culture of Alaskans.

Albania

ALBANIA IS STILL in the process of political and economic transition after almost five decades of Communist rule that ended in the early 1990s. During that period, Albania's natural resources and raw materials were regularly exploited, and little was done to promote environmental awareness. Since the shift to a market economy, environmental problems have been further exacerbated as the country has become more urbanized and industrialized. Albania is still one of the poorest countries in Europe and is the least developed country on the continent. Because of its temperate climate, Albania experiences cool, wet winters and hot, dry summers. Destructive earthquakes often lead to major environmental damage, as do alternating floods and droughts.

Fluctuating weather conditions present great risks for the 57 percent of Albania's workforce who are engaged in the agricultural sector. Employing methods that protect the environment is difficult for Albanian farmers, who do not have the financial means to modernize equipment and who sometimes lack environmental knowledge. Almost 15 percent of the population is illiterate. Nevertheless, Albania has the potential for economic growth because of natural resources that include petroleum, natural gas, hydropower, coal, bauxite, chromite, copper, iron ore, nickel, salt, and timber. Environmentally, the Albanian government is struggling to deal with deforestation, soil erosion, and water polluted by industrial and domestic effluents, but progress has been made. In 2006, a study by scientists at Yale University ranked Albania 57 out of 132 countries on environmental performance. Approximately 97 percent of the population have access to safe drinking water, and 89 percent have access to improved sanitation. The Albanian government has been relatively successful in promoting biodiversity. Of the 68 mammal species endemic to Albania, only three are threatened. Likewise, only three species of the 193 endemic bird species are threatened.

ENVIRONMENTAL ADVANCES, SETBACKS

In 1993, using financing from the World Bank, the Albanian government established the National Plan of the Action on Environment with the goals of strengthening institutions, protecting natural resources, and dealing with industrial pollution. Golemi Beach was identified as a model for maintaining clean coastal areas, and a pilot project for preserving resources and wildlife was launched at Dajti National Park. Sewage treatment facilities were erected in Vlore and Pogradec, and solid waste treatment facilities were set up in seven large cities. A major environmental study was undertaken at the Patos-Marinzes oil field of Karavasta Lagoon.

Despite major gains in promoting environmental awareness, a U.S. study in 2001 identified five major "hot spots" of environmental contamination in Albania. One is situated near a chemical plant in Durres, where about 20,000 tons of lindane are covered only by a thin layer of soil. The 80 families that live in an abandoned pesticide plant on the land face enormous health risks from constant exposure to the lindane that is present at 500 times an acceptable level in the air and water, as well as in the soil where vegetables are grown. Contamination from this and other infected sites in Albania have been spread to others by using the contaminated soil in the construction of other homes and buildings.

Although Albania has laws in place to check environmental damage, implementation continues to be difficult because of funding and personnel shortages, ignorance of existing laws, and judicial corruption. Without enforcement of fines, laws fail to serve as deterrents to polluting the environment. In 1998, Albania strengthened the powers of the National Environmental Agency, placing it under the Council of Ministers. Priorities of the agency include intensive environmental training at the national and local levels. Albania also promotes greater environmental responsibility through participation in the following international agreements: Biosafety, Climate Change, Kyoto Protocol, and Biological Diversity. International agreements that have been signed but not ratified include: Desertification, Endangered Species, Hazardous Wastes, Law of the Sea, Ozone Layer Protection, and Wetlands.

Algeria

ALGERIA WON ITS independence from France in 1962 after years of struggle. Subsequent internal conflicts erupted into open battle in 1992. Over the next six years, at least 100,000 Algerians were killed when conflict between extremists and army forces led to the annihilation of whole villages. Even though the fighting has tapered off, the Algerian government has been accused of widespread inefficiency and corruption. As a result, there is a serious housing shortage in Algeria, and water and electrical supplies are unstable. The undiversified Algerian economy is heavily dependent on petroleum, which has generated a large cash reserve that may eventually be used to deal with social problems and improve the weak infrastructure. Other natural resources include iron ore, phosphates, uranium, lead, and zinc. The Algerian government owns 91 percent of the forests and formally manages 28 percent.

Algeria has the world's seventh-largest reserves of natural gas and the 14th largest oil reserves, and is the second-largest exporter of gas in the world. The hydrocarbons sectors furnish 60 percent of budget revenues, 95 percent of export earnings, and roughly a third of the Gross Domestic Product.

Algeria's per capita income of $7,200 ranks 108th in the world. One-fourth of the population lives below the national poverty level, and 22.5 percent of the work force are unemployed. Although only 3.17 percent of the land area is arable, 14 percent of the population are engaged in agriculture. The United Nations Development Program (UNDP) Human Development Reports rank Algeria 103rd in the world in overall quality-of-life issues.

Eight percent of Algerians lack access to improved sanitation, and 13 percent lack sustained access to safe drinking water. As a result, the Algerian population of over 32 million faces an intermediate risk of food and waterborne diseases. Some areas are also at high risk for cutaneous leishmaniasis, a vector-borne disease. The literacy rate of 61 percent for adult females (78.8 percent for males) hampers government efforts to disseminate written health and environmental information.

Bordering on the Mediterranean Sea in northern Africa, Algeria has a coastline of 998 kilometers. Much of the land is high plateau and desert interspersed with mountains. Of all North African countries, Algeria is the most vulnerable to seismic activity, with 90 percent of the population and infrastructure at risk. Along the narrow, discontinuous coastal plain, winters are generally wet, and summers are hot and dry. In the high plateau, the climate is arid. The sirocco, a hot wind that transports dust and sand, appears in the summer. The rainy season often produces mudslides and floods, such as the flood that claimed 800 lives in November 2001. Algeria also experiences drought, locust infestation, and fires.

Living in the Kasbah

The Kasbah (or Casbah or Qasbah) in Algiers is the central citadel of the city and was largely built during the period of Ottoman rule from the 16th century, initially by the Turkish corsair Arroudj. The Kasbah, which overlooks the harbor, was the residence of the Bey of Algiers, the city's Turkish administrator.

In 1830 the French captured the city, massively enlarging it, but doing little to alter the Kasbah. By this time the term "Kasbah" came to refer to the entire old city, more properly known as Medina. It occupied 18 hectares, with architects coming from Granada, Constantinople (Istanbul), and even Venice. In spite of these diverse styles, because of the building materials available—mainly stone—there was a significant architectural unity about the place. With the buildings close to each other and narrow shaded streets, the temperature remains much the same year round. Originally, the area was divided into "quarters," similar to European church parishes, each having its own mosque, fountain, or tomb of a holy man.

During the Algerian War of Independence, the French were constantly attacked by Algerians who then fled into the Kasbah where, with narrow windy streets, pursuit was impossible. From January until September 1957 there was constant fighting around the Kasbah involving the highly controversial French General Massu.

ENVIRONMENTAL CONSEQUENCES

Irresponsible agricultural management has led to serious soil erosion in Algeria, and desertification has resulted from human activity as well as climatic conditions. Algeria's waters are heavily polluted because of raw sewage dumped directly into freshwater resources, and from waste products released by refineries and other industries. The ecology of the Mediterranean Sea has been seriously threatened by oil wastes, soil erosion, and agricultural runoff. Algeria also suffers from a lack of potable water.

Carbon dioxide emissions measured by per capita metric tons declined in Algeria from 3.5 in 1980 to 2.9 in 2002. Algeria produces 0.4 percent of the world's total carbon dioxide emissions. Waste management has been of particular concern in Algeria because of the age-old practice of dumping raw sewage into wadis (dry riverbeds that fill up during times of heavy rain), which transport the waste directly into the sea. Even though 30 water treatment facilities were set up in Algeria in the 1980s to deal with this problem, two decades later only two were still in operation. The contamination led to outbreaks of typhoid and cholera. The lack of solid waste treatment facilities has further damaged the Algerian environment.

In 2006, a study by scientists at Yale University ranked Algeria 63 of 132 countries in environmental performance, in line with the comparable income and geographic groups. The lowest scores were assigned in the categories of air quality and biodiversity and habitat. Of 92 endemic mammal species, 13 are endangered. Likewise, six of 183 endemic bird species are threatened.

With nearly 60 percent of the population living in urban areas and producing increasing amounts of pollution, the Algerian government launched the National Environment Plan in 2002 under the leadership of the Ministry of Regional Planning and Environment. The plan is designed to increase access to safe drinking water, improve waste management, and preserve biodiversity. The Tassili N'Adjjer and the Ahaggar have been set aside as national parks. The overall goal of sustainable development guides environmental policy in Algeria, and the government is working with international agencies to achieve this goal. Algeria has ratified the

The Hosalis

In 1921 Frances Kate Hosali, the widow of an Indian barrister, Moti Hosali, and her daughter Nina Hosali went on a holiday to Algeria, planning to spend eight months in North Africa. When they were at the Algerian port of Mostaganem, they were distressed to see the ill-treatment of domestic animals, in particular donkeys. After their return to London, they established the Society for the Protection of Animals in North Africa (S.P. A.N.A.) in 1923 to look after animals, especially donkeys, in North Africa. It always remained heavily centered in French Algeria. They had support from the Royal Society for the Prevention of Cruelty to Animals (R.S.P. C.A.) in London, and from then on, Kate Hosali spent most of her time in Tunisia, Algeria, and Morocco, with her daughter running the office in London. By the outbreak of World War II in 1939, the society had free treatment centers in twenty places in Algeria and Tunisia. Kate Hosali died in 1944 in Marrakech, Morocco, and her daughter, who continued running the main office in London, also took over overseeing the field work. In 1953 the charity was treating 100,000 animals each year; by 1984, the society had 250,000 members. Nina Hosali died in January 1987. She had been made a Member of the British Empire in 1976 for services to animal welfare, particularly in North Africa. The society continues to this day.

Allergen

AN ALLERGEN IS any substance that, if ingested, can cause an allergic reaction—a hypersensitive state that stimulates the production of reaginic antibodies, and which may have sometimes severely negative medical impacts upon the individual. Allergens include viruses and bacteria, dust, pollen and smoke particles that may be inhaled, foodstuffs, and chemicals. The allergic reaction varies from individual to individual and from place to place, since the environmental quality of the air varies according to location and time.

The huge increase of chemical substances used in foodstuffs and other consumer products mean there are many more possibilities for allergic reactions. Consequently, advice on how to avoid allergens has become increasingly prevalent in modern society. This includes warnings on consumer products, public health warnings and, rather less reliably, a whole new set of urban myths about possible contaminants and threats. Nevertheless, it is true that a small number of people can suffer severe allergic reactions to specific food items such as nuts, which can be so severe as to lead to death. The proportion of people, especially young children, suffering from asthma and other respiratory diseases triggered from allergens is sharply and significantly increasing.

As the variety and importance of allergens in modern Western society in particular has increased, along with the ability to diagnose their presence and impact, several product sectors have become increasingly important. These include advice about supposedly healthy living and eating and avoidance of possible allergens. Another is the threat of consumer boycott of products believed to contribute to allergic reaction, as well as the possibility of litigation against companies alleged to be contributing to the presence of allergens. This represents an uncertain future for a number of companies, which face future liability for their products based on allergic reactions that are just emerging or have not yet emerged. Genetically modified organisms have been cited as a particular problem in this respect because of the unknown future interaction with other complex chemicals in the environment.

Methods of preventing allergens from triggering a reaction include enhanced control over living environments, including cleanliness in kitchen and household environments; control of household pets; and greater knowledge of the constituents of newly employed consumer products. However, it may be impossible to eliminate the risk of exposure, and it may be necessary in the future for everyone to accept a potential threat of allergic reaction.

Alliance of Small Island States (AOSIS)

IN JANUARY 2005, the representatives of several small island states gathered in Mauritius to recommit themselves to a program of action for sustainable development, first adopted in Barbados 10 years previously. This meeting, attended by the United Nations (UN) Secretary General, 13 heads of state, 19 member representatives, and 11 observers, affirmed the need to focus international attention on this issue, particularly in the area of climate change. The motivation to convene was fortified by the dramatic demonstrations of the scale of natural disasters in 2004, paired with significant cuts of funding from major international bodies.

The delegates in Mauritius represented an organization created in 1990 under the aegis of the UN, the Alliance of Small Island States (AOSIS). This group acts as the lobbying voice for small island developing states (SIDS). The group currently has 39 member states, ranging in size from large islands like Cuba and Cyprus to tiny nations like Tuvalu, Nauru, and the Seychelles, plus observers from U.S. territories (Guam, American Samoa, and the U.S. Virgin Islands) and the Netherlands. Other member states such as Belize and Guinea-Bissau are not islands, but share similar coastal and economic concerns. These states share a common threat from climate change, as predicted rising sea levels threaten to displace coastal populations, damage freshwater reserves, and even completely submerge the low-lying coral atolls of several Pacific states.

PARTNERSHIPS FOR CONSERVATION

Since its founding, AOSIS has held a number of international conferences on climate change and related issues, issuing statements on vulnerability and adaptation, renewable energy development, and restrictions on greenhouse gas emissions in partnership with the leading developed states of the world. In 1996, a public hearing was held in Luxembourg on climate change and small island states, which aimed to stimulate partnership in specific commitments for carbon dioxide reductions with the European Union and the ACP (African, Caribbean, and Pacific Group of States). This was followed in 1999 by a workshop on the implementation of the Kyoto Protocol and the Clean Development Mechanism (CDM), held in the Marshall Islands with invited guests from larger states with similar coastal concerns, including the United States, the United Kingdom, Australia, New Zealand, and Norway.

EARLY WARNING SYSTEM

Since the early 1990s, ecologist and biologists have warned of the increasing danger of climate change to small island states, particularly those with limited highland areas, and those with few resources to combat meteorological disasters. These states have been viewed as a sort of early warning system for global environmental problems. By their very nature as islands, the ecosystems of these island states are isolated and vulnerable to change. AOSIS hopes to draw the attention of the world's larger states to a number of related issues, from support of tourism to wildlife conservation.

In biogeography, *island theory* focuses on the importance of equilibrium in these delicate environments, both for human and animal populations—the greater the isolation, the higher the risk. Moreover, conservation goals in such underdeveloped island states are often at odds with sustainable development goals.

AOSIS is run through the diplomatic missions of its UN members. Every three years one of these representatives takes on the role of chairman, but there is no formal charter, nor any regular budget. Collectively representing about 20 percent of UN total membership and 5 percent of global population, AOSIS is emerging as a leader in the global effort to control climate change.

Alternative Energy

ALTERNATIVE ENERGY IS the generation of power from nontraditional sources as opposed to sources such as coal and oil. The main sources of alternative energy are hydropower, wind, solar, hydrogen, bioenergy, geothermal, and hybrid technology. Currently, the most prodigious source of alternative energy is produced by large-scale hydroelectricity schemes, which account for 16 percent of the world supply of energy. By comparison, the other sources combined generate approximately 4 percent.

HYDROPOWER

Hydropower is produced by constructing a dam wall across a river to create a reservoir. The stored water is then released through turbines built into the dam wall, generating electricity. Although the generation of hydroelectricity does not produce any climate-changing emissions, the construction of large dams does cause significant environmental and social problems. When completed in 2009, the Three Gorges Dam in China will be the world's largest hydroelectricity scheme and able to generate 18,200 megawatts of power. However, the project will create a reservoir that is 412 miles (159 kilometers) long and will inundate 13 cities, submerge ancient archaeological and tourist sites, and make up to 1.2 million people homeless.

At an environmental level, a hydro-dam drastically changes the landscape and local hydrological processes. A dam hinders the movement of fish upstream, preventing them from spawning; downstream, less silt moves through the river system, starving the land of valuable nutrients. In heavily degraded landscapes, this loss of silt can be beneficial in reducing the need for dredging river estuaries. Another environmental impact of hydro technology is cold water pollution, in which the water in the deeper parts of the reservoir, normally at the dam wall, is significantly colder than at the surface. This temperature change has caused fish kills.

WIND POWER

Wind power is generated by the force of the wind, which spins rotor blades attached to a turbine.

The clean, efficient nature of wind energy has seen a rapid expansion in the development of wind farms.

Modern wind turbines can be up to 305 feet (93 meters) tall with rotor diameters larger than the wingspan of a jumbo jet (210 feet [64 meters]), and which at full power can generate enough energy to power more than 500 homes. It is a very clean and efficient method of generating power, producing zero emissions of climate-changing gases, and it competes relatively well on price with other sources of traditional sources of power.

The clean, efficient nature of wind energy has seen a rapid expansion in the development of wind farms. Energy generated by wind grew by 28 percent in 2004, and is the second-fastest growing source of alternative energy in the world. Consequently, major companies including General Electric and Siemens are now investing in the wind industry, ensuring that the cost of production becomes even more competitive with traditional forms of energy.

Wind energy is not without its critics. Due to the many social and political issues raised by the prospect of wind farming, including the availability of suitable sites, visual impacts, competing land pressures, and noise pollution fears, wind farms are increasingly being built offshore. Energy outputs can also be 50 percent higher offshore than onshore. The largest offshore wind farm in the world is the Horns Rev development in Denmark, a central plank in Danish government plans to cut carbon dioxide emissions by 50 percent, to 1988 levels, by 2030.

SOLAR ENERGY

Solar energy is created by harnessing the power produced by the sun, and can be generated in three ways. First, passive solar power manages natural light entering a building. Through the application of a combination of strategies, including correct building orientation and insulation, the temperature inside a structure can be maintained at a more comfortable level. This reduces the need for energy hungry air-conditioners and heaters.

Second, active solar power absorbs the sun's heat through solar-thermal concentration systems. The most common concentration system is a solar hot water heater. Unfortunately, these systems are not highly efficient, and during winter in many parts of the northern hemisphere, a backup supply of electricity may be required.

A third, more efficient form of solar energy is generated in photovoltaic (PV) cells, which convert the energy captured from the sun into electricity. Until recently, PV cells had not made a large contribution to the alternative energy market because of their low conversion efficiency and relatively high cost. However, recent technological advances in PV efficiency have resulted in staggering improvements and growth in its use. Between 2000 and 2004, grid-connected solar PV energy generation grew by 60 percent, and is now the fastest-growing alternative energy industry in the world.

Developments, including "thin-film" PV technology, allow any surface, such as the roof of a house, to be converted into a solar-electric power source. As of 2004, over 400,000 rooftops in Japan, Germany, and the United States were generating power in this way.

HYDROGEN

Hydrogen has been described by Royal Dutch Shell as the ultimate fuel source with the potential to revolutionize society's use of energy. Hydrogen is the most common element in the universe, and is found in water and all living things. It can be produced in many ways, including through partial oxidation from fossil fuels such as gas and from renewable sources such as wind or the sun.

When hydrogen is used in a fuel cell, the only emissions are water. As an energy carrier, meaning it can be stored, hydrogen can be used in portable devices such as cars or buses. Shell suggests that vehicles powered by hydrogen fuel cells are 40–60 percent energy-efficient compared to internal combustion engines, which only use 30 percent of their fuel energy.

Iceland is pioneering the use of hydrogen as an alternative energy and plans to have the world's first "hydrogen economy" by 2050. In Iceland, there is strong political support, a relatively small population, and a well-developed alternative energy sector (principally hydro and geothermal), which have collectively primed the conditions for the government to make significant energy changes. Iceland plans to convert all of Reykjavik's buses to hydrogen by 2013 and begin conversion programs of its entire fishing fleet in 2015. In Regina, Canada, a trial to extract hydrogen from landfill gases by solar energy has begun, and is designed to reduce greenhouse gas emissions by 2,205 pounds (1 tonne) per household per year.

The fundamental challenge in the transition to a hydrogen-based energy system is that although hydrogen is ubiquitous, releasing it and storing it in a usable form requires energy inputs, which must come from other sources. As long as these are conventional sources (oil and gas), the switch to hydrogen represents only a modest change in the overall structure and environmental impact of the energy economy. Accompanied by a switch to a set of alternative sources, however, hydrogen offers a high potential source. And while new infrastructure is also required in order to make hydrogen readily available to the public, the Tyndall Centre for Climate Change Research, a British think-tank, argues that such problems can be overcome—and that with the right levels of investment in infrastructure, high numbers of vehicles could be potentially powered by hydrogen by mid-century.

From a social perspective the introduction of a hydrogen economy has the potential to have a profound impact. With the right infrastructure, any country can produce hydrogen. This would allow the world to operate on a more energy even footing and give poorer countries access to power currently denied them.

BIOENERGY

Bioenergy fuels are an alternative source that can also greatly reduce climate-changing emissions from vehicle use. There are two key types of bio-fuels: ethanol and bio-diesel, and both can be produced from a number of food stocks including sugar, soybeans, corn, and wheat. Brazil is the largest producer of ethanol products and operates over 300 distilleries, accounting for 50 percent of global exports.

Ethanol is generally used as a 10 percent blend with gasoline (petrol) and can be used in most vehicles without the need for engine modifications. Specially designed "flex-fuel" vehicles operate with 85 percent ethanol; there are currently 4 million such vehicles in North America. Cellulose ethanol is made from nonfood stock such as straw, and as such does not compete with the food industry.

The increased use of bio-fuels by the developed world is having significant environmental and social impacts on developing countries such as Brazil. Large swathes of tropical rainforest in the Amazon Basin are being cleared to grow soybeans and sugarcane for ethanol production. This is causing significant biodiversity loss, degrading water quality, and having a negative impact upon the region's indigenous peoples, who rely on healthy, intact forests. Moral debates are also discussing the ethics of burning an edible food source for fuel while millions of people around the world face famine.

Bio-diesel is produced from a chemical reaction between vegetables and oil. Bio-diesel has similar properties to petroleum diesel fuel, but has 85 percent fewer cancer-causing agents. It is most commonly used as a 20 percent blend with petro-diesel. France is the largest user of bio-diesel, where it is commonly used for heating and mixed as a 50 percent blend with petro-diesel to power vehicles.

Biomass energy refers to the generation of power resulting from the burning of organic materials, such as agricultural and household waste in an energy-for-waste energy power station. While the use of biomass greatly reduces the amount of waste deposited at landfill sites, there is concern at the levels of carbon dioxide and methane released as a consequence of burning organic materials.

HYBRID TECHNOLOGY

Hybrid technology can significantly reduce carbon dioxide emissions from vehicle use. A hybrid vehicle is one that is powered using a mixture of gasoline and electric sources. There are several different types of hybrid vehicles, including the full-hybrid, which can be powered by gasoline or battery power alone; an assist-hybrid, which uses an electrical source when the car requires extra power; and a plug-in-hybrid, which is attached to the main power for recharging. Like the full-hybrid vehicle, the plug-in-hybrid is powered solely from an electrical source.

GEOTHERMAL ENERGY

Geothermal, or hot rock energy, generates electricity by the injection of water into a borehole in rocks with temperatures of at least 200 degrees C. The water is heated upon contact with the rock and is returned to the surface via a second borehole in the form of steam, which is then used to turn turbines that generate electricity. The cooled steam is then reinjected back into the first borehole where the process begins again. Geothermal energy can also be used to heat buildings by pumping heated water from the ground into pipes that feed internal radiators.

Researchers at the Australian National University argue that hot rock energy is a vast, environmentally friendly, and economically attractive energy source. The geothermal industry is dominated by several major companies including Ansaldo, Fuji, and Mitsubishi and is generated in many countries around the world. Use is highest in the Philippines, with geothermal energy providing approximately 27 percent of power needs. In Iceland, 85 percent of all the nation's space-heating needs are met by direct geothermal energy.

NUCLEAR POWER

Although the nuclear power industry describes itself as an alternative energy, uranium is nonrenewable and the amount to be found naturally is finite. The European Commission estimates that with current levels of uranium consumption, known uranium resources, will last just 42 years. Further, energy use during plant construction and the storage of radioactive waste makes the adoption of nuclear energy in many parts of the world environmentally, politically, and socially problematic. However, due to the overwhelming evidence of climate change and a rapid rise in carbon dioxide emissions from the burning of fossil fuels, governments and scientists, including Sir James Lovelock, the originator of the Gaia Hypothesis, are advocating an increased use of nuclear power as a means of reducing and limiting the impact of global warming.

ALTERNATIVE ENERGY INDUSTRY

The alternative energy industry is enhancing many lives through the creation of over 1.7 million well-paid jobs. Over half a billion dollars is invested each year in developing countries for renewable energy projects. No single alternative energy source can provide the world with all its energy needs, but together, the various sources can greatly reduce the reliance on fossil fuels, thus conserving valuable resources and reducing the chance of catastrophic climate change. As the global supply of fossil fuels become scarcer and their environmental consequences become more apparent and unacceptable by society, alternative energy sources will play an increasing role in meeting the power needs of the world.

Amazon River Basin

AS A DRAINAGE basin, the Amazon covers more than 7 million square kilometers in South America, making it the largest in the world. The Amazon basin encompasses portions of Bolivia, Brazil, Colombia, Ecuador, Suriname, Peru, and Venezuela, and roughly two thirds of this area fall within Brazil. Many of the main rivers of the basin are more than 2 kilometers wide, and the Amazon itself discharges roughly 175,000 m^3 of water per second into the Atlantic.

Climate in the Amazon is eminently tropical with limited variation in temperatures and more seasonal variability in rainfall, which is generally greater from November to May. Soils in the Amazon were once believed to be very fertile, but most of the basin has relatively old, weathered soils that are nutrient-poor and unsuitable for sustained agriculture. The Amazon watershed consists of different kinds of rivers. Whitewater rivers, such as the Amazon itself, are very turbid because they carry greater sediment loads, transported from clay soils by heavy rainfall during the wet season. By contrast, clearwater rivers are more transparent, but sediment-poor, and blackwater rivers have the color of tea due to plant tannins in the water. During the rainy season, river levels rise, inundating lowland forests; many fish then come into the flooded forests to feed and reproduce. Whitewater rivers deposit considerable sediments in lowland soils, and due to these nutrients, whitewater rivers have particularly abundant fish populations. The nutrient deposits also raise lowland soil fertility, and when river levels decline in the dry season, the exposed lowlands are farmed due to their relatively high productivity.

The Amazon has very high biodiversity, and as a result, the countries sharing the basin are among the most biodiverse in the world. Brazil alone holds between 10% and 20% of the 1.5 million species catalogued thus far. These numbers are low, however, since new species in the Amazon are regularly being discovered and described.

HUMAN OCCUPATION

Understanding of the initial human occupation in the Amazon is changing. It now appears that humans arrived in the Amazon at least 11,500 years ago, judging from pottery shards. Debate continues concerning Amazon's pre-Columbian populations, which informs estimates of the basin's human carrying capacity. Scholars who emphasize lower numbers call attention to the basin's limited protein sources, and note evidence of higher population concentrations near whitewater rivers.

However, archaeological evidence of sizeable pre-Columbian earthworks, roads, and centralized settlement designs in the uplands suggests larger populations than previously estimated. Similarly, ethnobotanical evidence indicates that many areas of "pristine" forest in the Amazon were modified by human use over long periods. And patches of "Black Indian soils," which resulted from disposal of large quantities of organic waste by indigenous groups, have been found in many places across the basin.

Indigenous peoples in the Amazon largely resided along rivers, which they intensively exploited. In the uplands, indigenous groups cut and burned vegetation to form small clearings, where they cultivated food crops. Such clearings were only temporarily used, as tribal groups subsequently moved on, allowing the forest to reclaim cleared patches.

European colonization of the Amazon began in the 16th century with Portuguese incursions westward from the Atlantic, and Spanish expeditions eastward from the Andes. Impressed with the luxuriant vegetation and considerable indigenous populations along the rivers, Europeans went in search of exotic commodities. This led to river-based trade in dyes, seeds, animal hides, and numerous other products, which were exported to Europe. This system was based in part on indigenous labor, often in missionary settlements. As a result, indigenous populations declined, and the Amazon economy became increasingly focused on specific commodities, leading to boom-bust economic cycles.

The most noteworthy such cycle in the Amazon involved rubber. Industrial demand for rubber in North Atlantic economies in the 19th century drove increasing extraction of raw latex from the Amazonian rubber tree. Drought in the Brazilian Northeast and propaganda by rubber estate owners prompted considerable migration into the Amazon. Rubber exports rose steadily from 1850 to 1910, and the wealth flowing into trading centers such as Rio Branco, Manaus, and Belém prompted rapid urban growth. However, English botanists smuggled rubber seeds out to Malaysia, where rubber plantations were established. Lacking the endemic pests that prevented such plantations in the Amazon, Malaysian producers soon undersold their Amazon counterparts, turning the boom to a bust.

In the 1960s and 1970s, national governments of the countries sharing the Amazon embarked on ambitious frontier development projects involving highway construction, colonization programs, and fiscal incentives for capital investment. As a result, populations in and around towns along the new roads expanded rapidly, and as colonists and ranchers arrived, they cleared large areas of forest in order to establish land claims. The new populations also encountered indigenous peoples and rubber tappers, resulting in conflicts over whether to leave the forest standing for traditional uses or to cut it down for agriculture. By the 1980s, there were violent conflicts over natural resources in many parts of the Amazon, including around large mining and oil extraction projects.

The global economic recession of the early 1980s prompted many governments to withdraw support from Amazon development. In the vacuum left by the state, social movements emerged in the Amazon, calling attention to various concerns ranging from indigenous rights to support for small farmers to loss of biodiversity.

In 1988, the murder of rubber tapper Chico Mendes transpired in the context of record levels of deforestation and burning. This called international attention to the linkage between the Amazon's social problem of human rights violations and its ecological problem of forest destruction. As a result, monitoring of deforestation has become a priority, facilitated by improving remote sensing technologies. According to Brazil's National Institute for Space Research, more than 600,000 square kilometers of forest in the Brazilian Amazon (15%) had been cleared as of 2005. In addition, Brazil and other countries accelerated designation of national parks, state forests, and biological and indigenous reserves to protect portions of the Amazon basin.

GLOBALIZATION

In the context of globalization, the Amazon has become the target of a new generation of infrastructure projects. Paving of the BR-163 highway from Cuiabá to Santarém, a north-south corridor through the heart of the Amazon, has become the topic of much policy debate in Brazil. Other infrastructure initiatives, such as paving of the Interoceanic highway through the exceptionally biodiverse southwestern Amazon, and the Madeira river dam complex, stand to bring enormous changes to the watershed.

Other worrisome changes are also evident in the Amazon. Of particular concern has been the expansion of illegal logging operations, which are impoverishing forests by removing certain tree species. Logging also degrades ecosystems by opening numerous canopy gaps that facilitate the entry of fires, which further alter rainforest ecology. Along with such alterations, low rainfall during 2005 facilitated the entry of fires into previously moist forests. Similarly, the growth of large-scale agricultural operations, especially extensive cattle ranches and mechanized agricultural enterprises, is pushing out rural populations and forming large blocs of deforested land. Governments sharing the Amazon basin see large-scale agricultural operations as efficient generators of foreign exchange to pay down national debts, but many social movement leaders view them as threats to communities who depend on small-scale forest resource extraction. The future of the Amazon is consequently very uncertain, for it is increasingly exposed to global market forces, and may be greatly affected by climate change.

Amphibians

AMPHIBIANS (GREEK, "DOUBLE LIFE") are a class of animals with vertebrae or backbones. They live part of their lives in water and part on dry land. There are over 3,000 kinds of amphibians known to scientists, most of which have smooth skin without scales. They are the least numerous of all classes of vertebrates. Amphibians first appeared during the Mississippian and Pennsylvanian Periods as land vertebrates. By the Mesozoic Era, the ancestors of present day amphibians appeared probably from the lobe-lunged fish. These ancient fish had lungs and fins with enough muscle and bone to support them on land for a brief period. The prehistoric *Labyrinthodontia* was one of the first amphibians.

There are three orders of amphibians: legless caecilians (*Cymnophiona* or *Gymnophonia*); salamanders, including newts (*Caudata*); and frogs and toads (*Salientia*). All are cold-blooded and lay their eggs in water, and most eat insects. The amphibians that live in cold climates hibernate during the winter.

Amphibians have declined in number in recent decades, partly due to human activities such as draining wetlands.

Most amphibians that live in warm climates aestivate (become dormant) during summer dry seasons. Most amphibians mate at night during rainy seasons. The eggs are laid in a jelly-like mass outside of the body and are fertilized by the male. Most frogs and toads leave the eggs unguarded, but some carry the eggs until they hatch as larvae. Frog larvae are born with gills and are called tadpoles or polliwogs. They live in water during the early stages, but undergo a metamorphosis in which the tail eventually disappears, legs grow, and the gills become lungs as well as eyes and a digestive system.

Caecilian (a legless, wormlike, tropical amphibian) males fertilize the female's eggs inside of her body. She then lays eggs that are guarded by the female of some species of caecilians. Salamanders also fertilize eggs in the female's body. In some species, such as the Japanese giant salamander, the male will guard the eggs until they are hatched.

The larvae of amphibians feed on algae, plant material, the larvae of insects, and even small animals. In turn, amphibians are the food of numerous birds, mammals, reptiles, and even other amphibians. Amphibians defend themselves against enemies with camouflage, hiding, and in the case of some species of frogs, with poison glands. All amphibians have a lateral line system of sensory organs along the sides of their bodies. The sensitive organs enable them to detect movement in water and to respond accordingly. The croaking of frogs and toads is a mating call. In contrast, salamanders and caecilians are voiceless. All amphibians have a digestive system for utilizing food that is taken in through the mouth. The Jacobson's organ, at the back of the mouth, is for smelling or tasting. The size of amphibians varies. Some are very tiny even as adults. The largest is the Japanese giant salamander, which grows to five feet (1.5 meters) in length.

Amphibians have declined in number in recent decades, partly due to human activities such as draining or polluting wetlands. A few species have become extinct. Other amphibian populations are endangered in remote areas because of climate change. The Golden Toad (*Bufo periglenes*), which is found in the cloud forests of Costa Rica, is being hurt by reduced moisture in the Costa Rican cloud forests. Other species of frogs and toads, as many as 55 in Costa Rica and Panama, are endangered. The reduction in the amount of waters has pushed adults into smaller pools, where they are more vulnerable to parasitic flies and fungi. The cloud forests in the Andes are also seeing reductions in amphibian populations.

The Japanese giant salamander is also an endangered amphibian. It lives in clear mountain streams of fast-flowing water at altitudes between roughly 980 to 3,300 thousand feet (300–1000 meters) on the islands of Honshu and Kyushu. Along with the Chinese giant salamander, these large salamanders have declined because of deforestation and damming of streams.

Analytical Chemistry

ANALYTICAL CHEMISTRY IS the branch of chemistry that uses specialized techniques to identify and understand the structure and function of chemical substances. These techniques include crystallography, spectroscopy, electrochemistry, and chromatography. Analysis depends on sound laboratory practices and the application of the scientific method for obtaining data from repeated, robustly designed experiments and then using statistical methods to determine probability to the distributions of results. Various competencies are required, therefore, and the cost of not only training suitable personnel but providing appropriate premises and equipment can be high. The practitioners of forensics, for example, have made great strides in identifying such issues as causes and times of death, evidence of poisoning, and locating microscopic scraps of evidence to tie to perpetrators. However, these activities are both labor- and capital-intensive, and so there is considerable pressure on the limited funds possible to disburse on them.

New, or comparatively new, techniques used in analytical chemistry include the consideration of the substance's interaction with gravity (gravimetric analysis), heat (calorimetry), electrical fields (electrochemical analysis), or electric and magnetic fields (mass spectrometry). Physical methods of analysis include separation processes such as chromatography, which passes liquid substances through a suitable medium with the aid of which individual components of a mixture may be identified. The enormous increases in computational power have been of great assistance in facilitating many forms of analysis. New generations of chemistry are likely to focus on biochemical substances and the processes of life and how to improve it. Researchers who can materially contribute to improving life chances and who are able to benefit from capturing intellectual property rights may obtain large profits.

Analytical chemistry and its various techniques have become increasingly important in identifying particular substances in the environment and in determining the interaction between naturally occurring substances and those introduced into the environment. Innovative techniques allied with robotics and related technologies make it possible for accurate analysis in circumstances hostile to human life to a much greater degree than in the past. This form of chemistry has helped to determine safe tolerance levels of chemical substances in the ground or atmosphere, safety of new additives in foodstuffs and drugs, culpability for dumping pollutants, and so forth. However, many of these areas are very complex and subject to lobbying from commercial interests, who may have powerful incentives for attempting to influence regulations or testing criteria.

Andes Mountains

THE ANDES MOUNTAINS are one of the greatest mountain ranges on earth, superseded in height only by the Himalayas. They form an enormous meteorological barrier along the spine of South America, running along the western side of the continent from Columbia south to Chile for over 4,000 miles (over 7,000 kilometers).

The Andres have over 50 mountains that exceed 20,000 feet (6,1000 meters) in height; only the Himalayas are taller. Mount Aconcagua, Argentina, only 65 miles west of Santiago, Chile at 22,831 feet (6,959 meters), is the tallest mountain in the Western Hemisphere.

Passes across the Andres usually are very high. At its widest in the Bolivian section it is over 300 miles (500 kilometers) across from east to west.

From the peaks of the Andes flow the Amazon, Orinoco, and Parana-La Plata Rivers. The Pacific side is arid in the central section range. However, the eastern side quickly descends into jungles or swamps.

There are volcanoes in three areas, which have contributed to the formation of the range. Much of the range is composed of faulted and folded rock.

Throughout much of the Andes, glaciation has shaped the mountains and valleys. There many fiords and several active glaciers in the south on the Pacific side. Glaciers were once active in other areas, even in the high elevations at the equator.

The Andes do not form a single mountain chain, but are made up of a number of ranges that are loosely joined together. In the northern section in Columbia, the Cordillera Occidental, Cordillera Central, and the Cordillera Oriental are the major ranges of the Andes.

The Cordillera Oriental runs northward as the Sierra de Perija y Motilones and the Sierra Nevade de Merida, which extend into Venezuela and on to Trinidad. Geologists disagree whether the highlands of Venezuela and Trinidad are part of the Andes. The Cordillera Central and Occidental extend into Ecuador, where a rift valley bordered by volcanoes forms a series of high basins.

The central section of the Andes extends through southern Ecuador to northern Chile and Argentina. The area is a vast highland region with many plateaus and basins formed by separate mountain ranges and volcanoes. There are eastern and western cordilleras that rim the basins and plateaus in between. The Cordillera de los Angles on the west is a chain of volcanoes, most of which are extinct.

In Bolivia lies Lake Titicaca in the Altiplano. Its high basins are above 12,000 feet (3,700 meters), and is the home of numerous Indians. Southward is the Puna de Atacma, much of which is in Argentina. The area is arid, cold, and windswept.

The southern section of the Andes runs from 27 degrees south to Tierra del Fuego. This section has some of the highest peaks, with passes at the 10,000- to 15,000-foot level (3,000 to 4,600 meters). South of 39 degrees south is a vast lake district divided between Argentina and Chile. Shaped by glacial action, the Chilean area has twelve major lakes and many smaller ones with volcanoes and primeval forests. The Argentina lake district is actively used for recreation.

The climate of the Andes is naturally cold in the higher elevations. However, it also varies in response to geographic location and moisture brought by the winds. The eastern side quickly descends into jungles in the north and the Grand Chaco in the central region, but into the arid Patagonian region in the south.

Minerals abound in the Andes. Gold and silver have long been mined in the central areas of Peru and Bolivia. Copper is a major resource in the deserts of northern Chile, while Ecuador and Columbia have produced many of the world's most beautiful emeralds.

The Spanish brought a number of new crops along with cattle. However, the llama, alpaca, vicuña, and chinchillas have been major wool producers that can handle the cold altitudes. The potato was extensively cultivated in the central Andes before the rise of the Inca empire. Vegetation is varied with many alpine plants. Coca leaf, now an illegal resource for the international drug market in cocaine, has long been used by the Indians for relief from the cold and altitude.

Angola

BETWEEN 1975 AND 2002, the Republic of Angola was involved in a civil war that began immediately after independence from Portugal. Estimates place the human cost of the war at 1.5 million lives, and an additional 4 million people were displaced. Much of the infrastructure was destroyed during the war, and Angola's attempts to rebuild it with the assistance of a $2 billion line of credit from China have been hampered by pervasive government corruption. Angola is rich in natural resources that include petroleum, diamonds, iron ore, phosphates, copper, feldspar, gold, bauxite, and uranium. The oil industry contributes around 45 percent of the Gross Domestic Product and over 50 percent of export revenue.

With a per capita income of $3,200, Angola ranks 158th in income among nations of the world. Despite a real growth rate of 19.1 percent, 70 percent of Angolans live in poverty, and 40 percent are undernourished. Approximately 85 percent of the workforce is engaged in agriculture, chiefly at the subsistence level. Unemployment and underemployment may affect as many as 50 percent of Angolans. Most social indicators point to a threatened population: a population growth rate of 1.9 percent, an annual death rate of 25.9 deaths per 1,000/population, a life expectancy of 38.43 years, an infant mortality rate of 191.19 deaths per 1,000 live births, a fertility rate of 6.8 children per female, and a literacy rate of 66.8 percent (53.8 percent for females). The United Nations Development Program's Human Development Reports rank Angola 160 of 232 countries on overall quality-of-life issues.

The excessive HIV/AIDS rate of 3.9 percent is largly responsible for high death rates. At least 21,000 people have died from this disease, and an estimated 240,000 are living with it. Because only half the population have access to safe drinking water, and less than one-third have access to improved sanitation, Angolans have a very high risk of contracting food and waterborne diseases, which include typhoid fever and hepatitis A. Angolans are also at high risk for other severe and potentially deadly diseases, including meningococcal meningitis, a bacterial infection; and schistosomiasis, which is contracted from infected water. Some locations carry additional high risks of contracting vector-borne diseases, including malaria and African sleeping sickness (trypanosomiasis).

ENVIRONMENTAL CHALLENGES

Bordering on the South Atlantic Ocean in southern Africa, Angola has 1,600 kilometers of coastline but no inland sources of water. The narrow coastal plain of Angola gives way to the vast interior plateau. Elevations vary from sea level at the Atlantic to 2,620 meters at Morro de Moco. Along the coast, the climate is semiarid. However, northern Angola's dry season, which lasts from May to October, is followed by a five-month hot, rainy season that produces periodic flooding on the plateau.

Environmental problems in Angola are caused both by demands of a large population (over 11 million) coupled with historic underdevelopment, exploitation of natural resources by both domestic and foreign firms, and long periods of war. Overuse of pasture land has caused soil erosion. The rain forest is being depleted at a rate of 124,800 hectares annually in response to the demand for tropical lumber and the use of valuable wood for fuel and cooking. In turn, deforestation and hunting have led to great loss of biodiversity. Desertification and soil erosion contribute to water pollution and the siltation of rivers and dams. A study by Yale scientists in 2006 ranked Angola fifth from the bottom among 132 countries in environmental performance, well below the comparable income and geographic groups. The lowest ranking was predictably assigned in the category of environmental health.

Over half of Angola's land area is forested, but the government has protected only 6.8 percent of lands, chiefly due to a lack of funds. Angola's rainforest is home to 1,546 species of amphibians, birds, mammals, and reptiles. Over 4 percent of these are endemic to Angola. Of 276 known mammal species, 19 are endangered, as are 15 of 265 known bird species. During the civil war in Angola, the National Union for the Total Independence of Angola (UNITA) forces purchased arms from South Africa with ivory and teak and used many large animals for bush meat. By 1990, 90 percent of the large mammal population had vanished.

The Angolan government created the Ministry for Urbanization and Environment and charged it with promoting sustainable development and conservation as established by the General Environment Law of 1998. The chief priorities of Angolan environmental policy are limiting deforestation, decreasing levels of soil erosion and desertification, developing alternative energy sources, preventing further loss of ecosystems and habitats, and improving access to safe drinking water and sanitation. The government is also dealing with the aftermath of oil spills, including one in the Cabinda province in June 2002 that led to a fine of $2 million. Angola has ratified the following international agreements on the environment: Biodiversity, Climate Change, Desertification, Law of the Sea, Ozone Layer Protection, and Ship Pollution.

Animal Rights

IN 1789, JEREMY Bentham famously asked, in relation to animals: "The question is not, can they reason, nor, can they talk, but, can they suffer?" Ovid proclaimed in the Metamorphoses, "Oh, what a wicked thing it is … to fatten on the body of another, for one live creature to continue living, through one live creature's death." John Salt, a philosopher of the early 20th century, first used the term *animal rights* and propounded many of its core contemporary ideological arguments.

It was not until the 1970s that animal rights crystallized as a political movement based around an ideological belief that animals have moral rights. Animal rights proponents differ from animal welfare advocates, such as the Royal Society for the Prevention of Cruelty to Animals, which address animal suffering and cruelty, but does not ascribe moral rights to animals.

Animal rights advocates essentially reject the idea that animals are capital goods or property that exist simply for the benefit of humans. Rather, animal rights advocates argue that no ethical basis exists for elevating membership of one particular species over another. Animal rights proponents argue that issues surrounding animal cruelty, animal experimentation, and animal rights to life deserve moral consideration. This must not to be confused with the assumption that animal rights advocates argue that animals are all equal, such as a biocentrist would; rather, that the moral rights of animals must be factored into decision making.

For proponents of animal rights, the capacity of animals to suffer is an essential factor in determining whether animals have interests. Animal rights advocate Peter Singer notes, "Pain is bad…humans are not the only creatures to feel pain or suffering, therefore, when humans take life, the rights of the creature being killed to decide its own fate needs consideration." Some philosophers, such as Arthur Schopenhauer, argue that compassion for animals is in fact related to goodness in human beings, and thus cruelty toward animals indicates a correlative lack of goodness and compassion in humans.

Similarly, the notion of sentience is used as a further basis by some animals rights thinkers to argue for animal liberation or moral consideration in relation to human use of that species. In this case, only species that are considered to possess sentience also possess rights and interests. The notion of sentience is a major factor in ethical debates over whale or seal hunting. Embracing humanity's responsibilities toward animals is sometimes called specieism.

Animal rights arguments are used to justify opposition to animal vivisection, cruelty, sport hunting, medical experimentation, and the use of animal products in cosmetics and clothing, resulting in the proliferation of animal-rights organizations.

ORGANIZATIONS AND LAWS

Some organizations target the ethical treatment and welfare of animals, including the People for Ethical Treatment of Animals (PETA), International Fund for Animal Welfare, Citizens to End Animal Suffering and Exploitation, and the Animal Liberation Network (ALN).

The environmental organization Greenpeace focuses on specific animal groups, such as marine life preservation, while organizations such as the National Alliance for Animal Legislation focus on achieving animal rights through legislative reform.

The International Association against Painful Experiments on Animals and the International League of Doctors for the Abolition of Vivisection focus on the experimentation of animals in the pharmaceutical industry. Often, organizations focus on specific species, including Bat Conservation International and the Beaver Defenders.

The animal rights movement is often subject to strong criticism. Those with a more utilitarian approach argue that the benefits derived from the use of animals, whether for medical experimentation or food, outweigh the negatives. Moreover, it is often difficult for proponents of animal rights to present clear-cut and straightforward positions on which to base their ethical and philosophical decisions.

The notion of animal rights per se has also been critiqued as primarily Eurocentric and thus a culturally biased notion. Indigenous peoples often take a very different view of their relationship to animals. While Western cultural mores may deem that hunting species such as green turtles, dugongs, whales, seals, and polar bears is cruel and unnecessary, even if conducted for subsistence purposes, indigenous peoples see hunting as a manifestation of an important cultural relationship to the species being hunted. The Inuit conceptualize the killing of whales as an essential manifestation of the respect and trust relationship between themselves and the animals. Similarly, indigenous peoples of Australia argue that their traditional butchering techniques of green turtles and dugongs is essential to maintaining the sacredness and spirituality of the hunt.

Today, many countries have laws against animal cruelty. However, some animal rights groups, such as those active in the United Kingdom and the United States, continue to lobby governments to obtain stronger legislative protection for animals. In 1992, the Swiss government legislated to recognize animals as beings, not things; as did Germany in 2002, when the Bundestag made specific alterations to the constitution to enshrine protection for animals.

Animals

FROM A BIOLOGICAL point of view, animals are living entities that are equipped with nervous systems and sensory organs that render them capable of detecting and rapidly responding to stimuli. They also differ from plants in that animals require organic matter as nourishment, whereas plants have the ability to transform inorganic molecules directly into food. While biology provides insight into the physiology and behavior of animals, social scientists study the many meanings that animals have in different societies as well as the role that animals play in human social relations. There isn't a single society in the world in which animals do not occupy a critically important place. Although in many societies—including those of the Western world—the conventional use of the word *animal* normally refers to nonhuman animals, it is important to remember that humans, too, are animals from a biological point of view. One of the social sciences' most enthralling contributions has been to study how different societies define such categories and the effects that they produce.

Often, pets enter highly important human social relations, even attaining the status of family member.

SOCIOLOGY AND ANIMAL STUDIES

Nonhuman animals, as most of nature, did not become a main research interest for social scientists until the second half of the 20th century for many reasons. First, in an effort toward emancipation, early social scientists in the 19th century attempted to distance themselves from other existing sciences—especially from biology and from psychology. One way to achieve this distance was to focus on studying phenomena that were not already being studied. Thus, the founders of the first social science—the sociologists—focused on "social facts" directly pertaining to human societies and cultures.

A second reason social scientists avoided the study of nonhuman animals and nature is that when sociology was founded, certain biological theories had been wrongfully used to explain human behavior, societies, and cultures. These theories had attempted to explain variability between societies, cultures, and ethnic groups as resulting from fundamental biological differences between humans. They proposed that general biological conditions determined human behavior and even the historical development of societies. The problem is that these apparent differences between peoples were the outcome of socially preconceived ideas rather than a reflection of actual biological facts. This bias is now known as biological determinism. It was one of the main sources of the numerous forms of racism that dominated many European and North American circles well into the 20th century. Given this historical legacy, sociologists for many generations were weary of studying topics that might seem to entail the risk of fallaciously incorporating knowledge from the natural sciences. This includes the study of animals, which was formerly the object of zoology and biology.

The third reason why most sociologists in particular ignored animals and nature in their studies pertains to how sociology conceptualized its main area of enquiry in regards to its closely related discipline of anthropology. Both disciplines were created to study societies and cultures. However, although the following division of labor no longer holds true, sociologists turned their attention to Western urban societies and anthropologists focused primarily non-Western and/or rural and maritime cultures. Therefore, anthropologists often studied societies in which people had close relations with animals and nature.

Sociologists, on the other hand, were more interested in studying human relations within urban settings, in which a smaller number of people interacted directly with nonhuman animals or in which animals did not seem to play an important role in people's lives. This assumption was incorrect. Animals do occupy a crucial space in urban industrial societies as companion pets, lifeguards, or psychological therapists; in research laboratories, where medical and cosmetic products for humans are tested; and as the food that people consume. Sociologists are now interested in studying all of these roles that animals have.

Finally, sociologists have traditionally been reluctant to study animals because one of the main premises in sociology has been that only humans are capable of verbally articulating abstract ideas and achieving self-conscious understanding of one another. More recently, some social scientists have argued that even though animals are not capable of speaking, they can still communicate with humans at different levels. These sociologists are working toward developing a theoretical and methodological framework that will allow them to account for the peculiarities of human–animal communication.

Social scientists do not study animals in and of themselves. They investigate animals only insofar as animals enter the world of human societies and thus acquire social and cultural significance. There are many criteria used to categorize and describe social scientific approaches to animals. For the sake of simplicity, it is possible to divide the sociology and anthropology of animals into the following themes.

First, there is the study of animals as social constructs, whereby social scientists explore how different societies attribute symbolic or cultural meanings to animals. This includes research on how animals are represented, how animals become part-and-parcel of human relations, and how humans define themselves in connection to animals. Second, there is the study of animals as social products and as participants in societies. This entails, for example, research on the social history of animals, as well as the role of discourses and ideology in the establishment of power relations between humans and animals. Third, there is an emerging area of sociological enquiry that focuses on the new ethical and philosophical issues that recent developments in science bring forth. It is definitely worth looking at these approaches in greater detail in order to understand how they shed light on societal-animal relations.

ANIMALS AS SOCIAL CONSTRUCTS

Social scientists have repeatedly proven that at least for human beings, the meaning of things emerges as an outcome of social interaction, that is, as things acquire a social life. This approach is known as symbolic interactionalism. For example, an cup used in one society for holding a drink may be seen in another society as a sacred object.

The same is true of animals. Depending on social or historical context, the same animal can be seen as food, as a pet, as taboo, or even as a source of prestige. Such is the case of the pig. For example, suckling pigs are best known in Portugal as a culinary delicacy, while in German urban centers, keeping pigs as household pets has become a trend. In Jewish societies, there are strict taboos prohibiting the ingestion of pork, while in Papua New Guinea, pigs are collected and traded as a sign of prestige. The approach to dogs is another way to understand this point. In most Western societies, dogs are seen as pets. Often, they enter highly important human social relations and are even attributed the status of family member. Many psychological studies have shown that grieving the death of a pet dog can be as painful and stressful as grieving the loss of a human family member. On the other hand, there are many societies where dogs are perceived as working animals and live in completely separate quarters from their owner, such as hunting dogs in the United Kingdom or sheepdogs in the Swiss Alps.

All of the above means that in addition to being living biological entities, when animals are brought into human societies, they also become socially constructed beings. Animals must be understood not only from a biological and behavioral perspective, but also in terms of how they are conceptualized in a culture. The meanings that are attributed to animals are often ambiguous; not only can the same animal vary from one society to another, it frequently falls between categories within one society.

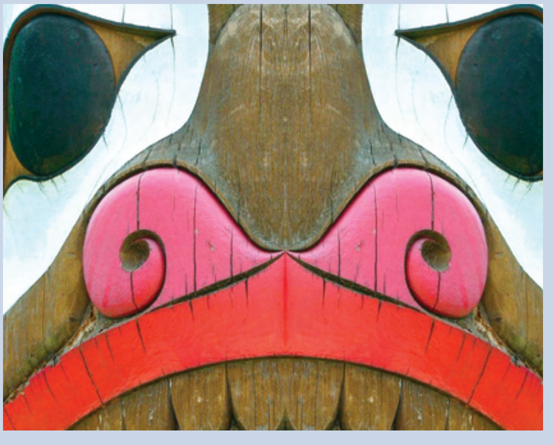
The distinction between wild and domesticated animals is a case in point, especially when it comes to zoo animals. When animals like leopards and African elephants are displayed in a zoo, they are usually presented as wild animals. Still, zoo leopards do not hunt for their food as they would in their original habitat, nor do elephants migrate across vast territories as they would in Africa. In fact, zoo animals are managed on a carefully studied schedule and environment. Usually, they even require human intervention to mate and reproduce. These animals are certainly not wild, but they are hardly domesticated, either. They are somewhere in between.

On another level, this example also entails an ambiguous definition of the relation between the notion of natural and nonnatural animal environments. It is assumed that the animal's native environments was a natural environment, which contrasts starkly with the human-made environment of the zoo. However, these distinctions are also the result of socially constructed assumptions. In many cases the so-called natural environments had been transformed long ago by other human beings who historically occupied those spaces. In turn, most contemporary zoos try to mimic the ecosystems from which the zoo animals were brought; in some cases, zoos are the closest thing to animal ecosystems that have been destroyed.

Totemic Relationships

Anthropologists have studied many cultures where a person's identity is acquired through their special relation to an animal. For instance, in clan societies, each is identified as having a unique relation to a particular animal species. These relations between humans and animals are known as totemic relations, and they are often represented symbolically in objects that are called totems. In the case where humans develop totemic relations with animals, people are believed to carry within them the spiritual characteristics of these animals. Examples include the intelligence that is attributed to coyotes, the ingenuity of foxes, and the nobility and wisdom of elks.

From a cultural point of view, non-Western societies are generally less prone to conceptualize human identity and human nature in opposition to that of animals. Examples are societies where people hunt, such as the Cree of northern Canada, who argue that unless a hunter can be partly like a deer and communicate with the deer on its own terms, killing the animal is immoral and very likely to fail. Although this way of thinking is more predominant in non-Western societies, it is not exclusive to them. Sports teams, such as the Toronto-based Raptors basketball team and the Chicago Bulls, brandish images of their mascot to indicate the teams' identification with their mascot animals' extreme agility and aggressiveness.



Finally, animals in Western societies are sometimes considered the opposite of what it means to be human. In other words, animals are portrayed as humanity's symmetrical "other"—as if humans were not animals themselves. Humans thus develop their own sense of identity by establishing contrasts that they attribute to animals. There are abundant examples: "You're an animal," "You eat like a pig," "You're chicken," "You dog!" As harmless as they may seem, these distinctions produce serious effects in terms of how humans treat animals, turn them into commercial goods, or legitimize their position of power and control over animals. It is important to understand how these distinctions developed in the Western world, and to know the role that these contrasts play in the development of social and cultural notions of identity among humans.

With the Renaissance and the Enlightenment periods, scientific thinking increasingly began to substitute for religious thought as the means to understand the world. In this context, rationality and objectivity became the two central tenets of the new emerging order. The most important scholars of this period thought in dualistic terms, or "either/or" through mutually exclusive categories. Consequently, they believed that in order to be rational one must reject all emotions, and that in order to be objective, scientists must rely on special tools and instruments that explain the world as it is beyond our senses. The French philosopher René Descartes was a major proponent of this new line of reasoning. He proposed that the interference of the human senses and emotions distort humans' view of the world and impede them from knowing the truth. In time, modern science's primary mandates became the removal of emotion and sensory information from scientific endeavor so that it would not interfere with the full development of human rationality and objectivity.

Descartes and many of his contemporaries believed that the capability for rationality and objectivity was uniquely human, and that this capability meant that humans were unquestionably superior to all other animals. As feminists have pointed out, this prejudice also carried over into arbitrarily defined categories used to create a hierarchy among human beings. Western white males were seen as the most rational of all human beings, and thus superior to women and other humans—with animals at the very bottom of this scale. Recent work by philosophers, critical theorists, biologists, and neurologists has shown that these Cartesian premises are not only unfounded, but they promote serious injustices and abuses. A prime example of these contributions is the work of Antonio Damasio, an American neurologist, who has proven that rational thought is actually not possible if a person's brain is affected in areas allotted to emotion. In fact, he discovered that emotion enables rational thought.

Within the framework of Cartesian thinking, animals came to symbolize all that humans were not supposed to be. Animals were said to operate on the basis of instinct, when humans were trying to achieve unprecedented levels of rationality. Controlling animal-like urges and needs became a central preoccupation in most European societies. Linked to this way of thinking, the Bible was successively interpreted toward reinforcing the notion that there is a great divide separating humans from nature, and from animals.

The curriculum taught in schools during the past few centuries has also strengthened this worldview. Slowly, these ideas permeated almost all areas of Western thought and action. It has been only in the late 20th century and early 21st century that Western societies have begun to again recognize that humans need to rethink their existential links to all other animals. Some scholars criticize previously dualistic assumptions that separate humans from all other animals. Consequently, they also critique the notion that humans are superior to other animals and nature, and that humans have the legitimate right to control the lives of animals without any ethical considerations. The word *specieism* is now entering the vocabulary of many people who are critical of these resulting prejudices.

Humanity has inherited a complex legacy of ideas and assumptions about the relationship between humans and animals. A plethora of concepts circulating in most contemporary societies simultaneously presumes that humans are completely separate and superior in relation to all other animals, *and* that animals and humans are ontologically linked at the same existential level, thus mutually affecting one another. This seeming contradiction reflects ancient philosophical debates. At least since the time of the first Greek philosophers—Socrates, Plato, Aristotle—Western thinkers have been faced with the philosophical challenges that animals pose to humans. This is because while humans are animals like any other, at the same time, they are the only animal known to articulate thoughts in an abstract, symbolic language that can be written and communicated through generations. The Western world's most famous philosophers have produced numerous text on the meaning of being human in relation to being animal. Other participants in these discussions include Martin Heidegger, Ludwig Wittgenstein, Friedrich Nietzsche, Edmund Husserl, Jürgen Habermas, Maurice Merleau-Ponty, Jacques Derrida, and Gregory Bateson. They have pondered the moral status of animals, the extent to which human language truly separates humans from all other types of animals, the ethical basis and legitimacy for human dominance over animals, and also—in the case of Bateson—whether our failure to recognize that we are part of an interconnected, living system will eventually lead to our demise.

One of the current challenges in the social sciences is to understand and represent animals in a way that is closer to their own perceived realities. This is sometimes called an eco-centric or animal-centric perspective. The anthropologist Annabelle Sabloff has proposed that one possible strategy is for humans to develop a new language of metaphors for revealing values and logics that are not human. This would entail a search for new metaphors that would reflect the changing nature of human–animal relations from one of domination to one of simultaneous acknowledgement and mutual respect. Other authors, such as Erica Fudge, argue that before this can happen, humans will have to realize the many contradictory—and often cruel—ways in which humans perceive and relate to animals.

Research on the social history of animals, as well as discourses and ideology on animals, will play a key role in shedding light on these debates.

ANIMALS AS SOCIAL PRODUCTS

Animals also enter human societies as commodities. From this perspective, animals are studied as material objects in the form of goods that are produced, bought, and sold within societies. There are social, scientific approaches that study the relationship between transforming animals into material commercial products and the histories of the ideologies and practices of different societies. Their proponents

Anthroprocentrism

The fact that animals are imbued with many layers of social meaning raises interesting philosophical challenges in regards to humans representing animals. While the tendency to create a dualistic divide between humans and animals can lead to "specieism" and its related abuses, sometimes an excessive effort to focus on human-animal similarities can be equally unproductive. Such is the case when people project human qualities onto animals, which portrays animals as possessing characteristics and motivations that are typically human. The process of understanding animals through the projection of human qualities, emotions, and motivations onto animals is called anthropocentrism.

An example occurs in the context of whale watching. Tourists are delighted when dolphins approach their boat and seemingly engage with humans in play. Dolphins jump beside the boat, moving close enough at times to stare into the eyes of the humans. Assuming that this behavior is motivated by a desire to play—or even to communicate—with human beings is a projection of human-centered motivations onto these cetaceans. Marine biologists have noted that people are arriving at these conclusions without much information about what is actually going on. In a great number of cases identifying this type of cetacean behavior, it was alpha male dolphins who swam near the boats, getting close enough to "check things out." Normally, there is a much larger pod of juvenile dolphins as well as pregnant, nursing and junior dolphins nearby, and the alpha males are engaging with the boats to determine any threat as well as warn the people on the boat that they are there to defend their pod if necessary.

argue that the varied range of past and present societies is a direct reflection of different social arrangements between human beings to produce the goods they need. Since these theories explain societies as the result of the relation between such material arrangements and these societies' worldviews, the analytical model that they propose is called historical materialism. It is heavily influenced by the work of Karl Marx and Friedrich Engels.

Basically, followers of Marx contend that the basis of the social structure of any given society derives from what is produced, how it is produced, and how this is exchanged. For instance, the structure of a hunter-gatherer society is directly related to the acquisition and exchange of goods that are openly available to all members of the society. No one owns the land where the society's members hunt, and no one owns the tree from which fruits are collected. Within these settings, when there is a concept of ownership, it refers to community ownership. Such areas are known as commons. Having access to the goods is dependent on one's hunting skills and ecological knowledge rather than on owning the resources. However, hunting is a very demanding and precarious activity; according to a historical materialist perspective, members of hunter-gatherer societies tend to cooperate in order to cope with these challenges. Some of its members focus on gathering fruits and greens, which they share with hunters who, in turn, reciprocate when their hunting efforts are successful. Some historical materialists also argue that males and females cooperate in taking on different tasks so that the women can stay in the community and take care of children while men travel the long distances required by hunting. The major point of historical materialism is that there is a relation between the social arrangements that develop toward the satisfaction of material needs and the worldview of societies.

In addition, historical materialists have shown that social class relations emerge from the distinction between owning animals and having access to them. When applied to different societies, this analytical model shows how even more complex divisions of labor lead to the structuring of societies and to the development of related ideologies. More complex forms of divisions of labor often lead to the emergence of classes when certain groups of individuals gain control over resources or means of production. For example, when animals were domesticated and land was turned into private property, the new class of landowners could decide who had access or not to the animals and means to produce agricultural foods, as well as for what price. Obviously, those in control of the means of production are in a much more powerful position to make decisions about their communities' histories.

As with the hunter-gatherers, the class structure of agrarian societies was also reflected in worldviews and cultural values. For example, in medieval Europe aristocrats promoted the idea that they had inherited a God-given right to own land as a way to maintain the extremely unequal distribution of land between aristocrats and peasants. In controlling most of the land—peasants normally only possessed miniscule marginal gardens for basic crops—the aristocrats also controlled access to animal husbandry. In so doing, they ultimately determined who could consume animal proteins and, again, at what cost.

Even though Karl Marx attributed an important space in his work to discussions of nature and of animals, his interest is not in these subjects *per se*, but on how humans come together to use them as resources. It is humans who are at the center of his writings. For Marx, human beings are very different from all other animals because humans possess creativity and consciousness and are capable of transforming themselves in ways that they envision—thus making their own histories and destinies. Insofar as humans are capable of imagining a future and of taking the actions that make this future come to fruition, they are imbued with agency. Marx argues that even though people are often subjugated and exploited by other more powerful humans, they possess the capability to become aware of their condition of being oppressed and engage in revolutionary action to overcome this state of affairs. For a long time the pervasiveness of Marx's arguments led many scholars to assume that because animals are not capable of conscious awareness, and not capable of planning actions toward an idealized future, they lacked agency.

More recently, sociologists and philosophers have been rethinking this premise. They search for ways to show that even though animals do not display signs of being capable of the high levels of conscious awareness displayed by humans, they too can potentially exercise their will to produce the outcomes that they desire. Animal agency may be different from that of humans, but it this does not mean that it does not exist. What is missing is a better sociological and philosophical approach to the investigation of animal agency.

Many scholars have been tackling this issue since the emergence of postmodernism in the 1960s. They began by critically questioning and challenging the dichotomous thinking, which presents humans and animals as dual opposites, that marked Western though since the times of Descartes. Postmodern thinkers were the first to point out that these distinctions are socially constructed, and that they produce major effects. They are directly related to how animals are treated in any given society and the extent to which they are abused and exploited. Societies that see animals as bearing absolutely no common ground with humans tend to legitimize the most extreme forms of inhumane treatment of animals. In turn, societies that conceptualize humans as also being animals tend to be more engaged in practices that secure a minimal level of respect and proper conduct towards nonhuman animals. The most current debates center on cultural ideas and discourses about animals, the status of animals in relation to human beings, and issues of ethics in human–animal interaction.

NEW ANIMALS, NEW ETHICAL ISSUES

Finally, a new kind of animal may soon live among us as the result of the most advanced human technological innovations. These are new animals that are created in laboratories out of the transferal of genes from one species to another. These are animals that have been genetically modified such that they contain genes from species they could never reproduce with outside the lab context. In particular, there are now animals who carry a certain percentage of human genes. These are normally created so that their organs can be harvested for human use without the danger that the receiver of these organs will reject them upon transplant. These new animals will certainly play a very important role in future human societies and may potentially save many human lives. Their existence raises many philosophical, ontological, and ethical issues that have yet to be fully understood.

An examples of a totemic relationship includes the mix of intelligence and playfulness attributed to coyotes.

Animism

THE WELL-KNOWN BRITISH anthropologist Edward B. Tylor defined *animism* in his classic 1871 book *Primitive Culture* as a belief in spiritual beings. He theorized that this was the ultimate basis of all of the religions of humankind. Animism derives from the Latin *anima,* which refers to spirit, soul, or life-force.

Animists believe that supernatural forces permeate and animate nature, including animals, plants, waters, rocks, and other environmental phenomena. Whether these forces are envisioned as personal or impersonal, they are thought to influence humans. Shamans and priests, part- and full-time ritual specialists, respectively, attempt to communicate with and thereby influence the spiritual realm.

Animism is by far the oldest religion of humanity as evidenced by Neanderthal burials and associated artifacts at Shanidar cave in northern Iraq, which archaeologists have dated to around 60,000 years ago. Pollen analysis of the plant remains over the graves indicates that these were from flowers of species known to currently grow in the region to have medicinal properties. The antiquity of other ancient religions, by contrast, extends back only a few thousand years.

By far the most widespread of all religions, animism is common in hunter-gatherer, fishing, farming, and pastoral societies throughout the world. Furthermore, it forms a substratum in the religion of many people who would identify themselves primarily with Buddhism, Christianity, Hinduism, Islam, or another so-called world religion. Moreover, not only does animism survive and thrive in the religious beliefs of a multitude of diverse cultures, it has also been revitalized in areas where it was long suppressed, such as Europe and North America, where it may be referred to as neopaganism.

Australian Aborigines believe that their kinship is directly connected to ancestral spirits in the biotic species and land forms of their environment, a phenomenon referred to as totemism. Uluru (Ayres Rock) is one of the most famous, sacred places in nature in Australia. Many people in Southeast Asia believe that spirits dwell in rice, trees, caves, and rivers as well as in various small shrines constructed near their community, home, or business. Traditional Hawaiians recognized supernatural power or *mana* in sharks, forest plants, rocks, volcanoes, tides, streams, wind, rainbows, and numerous other natural phenomena. Many related taboos, rituals, institutions, and practices helped manage and conserve their environment. In modern America, some individuals suspect that if a black cat crosses their path, it may cause bad luck. In short, the majority of the some 7,000 cultures in the world today believe in some kind of supernatural forces in nature.

In addition to its antiquity, universality, ubiquity, and vitality, animism is also significant because it is the original nature religion. Most indigenous societies that pursue animism are relatively sustainable ecologically. Indeed, many have flourished for centuries or even millennia in the same general area without causing irreversible resource depletion and environmental degradation to the ecosystems in their habitat. In such societies, nature is not merely a reality that provides economic and recreational resources, but it has inherent spirituality. Accordingly, nature deserves special respect and care, and, in some cases, reverence. Animists recognize the unity of nature, spirits, and humans as integral components of the web of life. The interrelationships and interdependencies within environmental systems are elemental principles of animism as well as of the Western science of ecology. The ecological resonance of animism is probably part of the reason for its persistence. It may also contribute toward the diminution or resolution of environmental problems and crises. Indeed, some environmentalists consider themselves to be neo-animists or eco-pagans.

Antarctica

ANTARCTICA IS THE fifth largest of the world's seven continents. Its land mass is located at the South Pole and lies almost entirely inside of the Antarctic Circle. The South Pole, near the Queen Maud Mountains, at 90 degrees south, is also about the geographic center of the continent. Most of the Antarctic continent extends to the Antarctic Circle at 66 degrees 30 minutes north of the South Pole. The size of the continent of Antarctica is 5,400,000 million square miles (13,985,936 square kilometers.). Its land area combined with its ice cap makes it larger than either Australia or Europe. The ice cap that covers almost all of Antarctica is more than two miles (3.2 km.) thick in most places. The Atlantic, Pacific, and Indian Oceans surround the island continent of Antarctica. Some have called the ocean waters around the continent the Antarctic or Southern Ocean; however, the general scholarly opinion is that it does not have a true ocean. The Transantarctic Mountains separate the continent into the larger region of East Antarctica and the smaller region of West Antarctica. The Indian and South Atlantic Oceans surround the East Antarctica area. West Antarctica faces the Pacific Ocean.

The land in West Antarctica between the Transantarctic Mountains and the Marie Mountains is covered with a thick sheet of ice. If the ice cap were to melt, much of West Antarctica would turn into islands because the area is mostly below sea level. West Antarctica is part of the Pacific "ring of fire" and contains several active volcanoes. It was formed later than East Antarctica. Geological studies of East Antarctica have revealed that this area is composed of Precambrian shield. Other geological surveys have found small deposits of copper in the Antarctic Peninsula, coal beds in the Transantarctic Mountains, and traces of other minerals including gold, zinc, lead, iron, and manganese. The mountain ranges and volcanoes of West Antarctica contain the continent's highest elevation, reaching to a height of 16,864 feet (5,141 meters), on the Vinson Massif in the Ellsworth Mountains near the Antarctic Peninsula. The Antarctic Peninsula is an S-shaped range of mountains that is really an extension of the Andean Mountains. Islands in proximity to the peninsula include the South Shetland Island and Deception Island, which is also an active volcano.

The area of East Antarctica has a mountainous coastline with a rift

Mawson's Huts

Mawson's Huts are a collection of buildings located at Cape Denison, Commonwealth Bay in the Australian Antarctic Territory. They were built and then occupied by the Australasian Antarctic Expedition (A.A.E.) in 1911–14, which was led by the Australian geologist and explorer Sir Douglas Mawson (1882–1958) who had been the first person to reach the summit of Mt. Erebus.

The most famous building at this site, known as Mawson's Hut, was where the eighteen men of the A.A.E. main base party stayed. It had been prefabricated in Sydney and then shipped to Antarctica by the A.A.E. in 1912. Other huts include the magnetograph hut, which was used to calibrate variations in the south magnetic pole; and the transit hut, which was used as a makeshift astronomical observatory.

Mawson's huts are one of only six surviving collections of buildings from the early 1900s, and the Mawson's Huts Foundation was established to look after them. Between 1997 and 2005 it has carried out some repair work on these huts, in which there are still many relics of Mawson's time, including books and even tins of food from his expedition.

valley that cuts deep into the continent from the Indian Ocean to the Prince Charles Mountains. Glaciers move down the mountain valleys in Antarctica to the oceans. In the summertime, they drop or "calve" icebergs. Many of these will later be blown up into ice packs against the Antarctica landmass. Most of East Antarctica is a plateau covered with ice with a depth of greater than two miles. The average height of the plateau is 10,000 feet (3,000 meters). Sastrugi, which are ridges of ice and snow, are formed on the plateau by strong winds that can exceed 100 miles per hour. The climate of Antarctica is extremely cold and dry. The South Pole and its surrounding environment is a cold desert that receives only about two inches (five centimeters) of snow each year. The coasts of the continent are moist and receive up to 24 inches (61 centimeters) of snowfall each year. There are a few places in the Transantarctic Mountains and elsewhere where valleys are free of ice and snow. The winds sweep these valleys so fiercely that snow cannot accumulate.

Despite the fact that Antarctica has a cold desert climate, it contains so much ice that about 70 percent of the freshwater on earth is to be found there. Some engineers have explored the possibility of towing icebergs from Antarctica to desert regions of the world where they would be used for fresh water.

LIFE IN THE ICE

There are very few plants in Antarctica. In some lakes and on the continental edge, algae grow on snow at times, turning the areas into pink or green tinged snowfields. In other places, mosses and lichens cling to rocks despite the harsh environment. A tiny wingless midge (fly) survives on the Antarctic mainland. However, most insects are parasites such as lice, fleas, mites, and ticks found on seals or birds. While the Antarctic continent is a cold, virtually sterile desert, the waters surrounding the continent are teeming with life. Plankton and krill abound in the nutrient rich waters off the continent. Other sea animals include squid and various kinds of fish. These smaller life forms provide a rich diet for many species of whales, seals, and penguins.

Antarctica has several kinds of seals. In the 19th century, they were hunted for their fur. The southern elephant seal is the largest kind of seal in the world. Other seals include the Ross seal, Weddell seals, Crabeater seals, Antarctic fur seals, and Leopard seals. There are four kinds of penguins found in Antarctica. Unable to fly, penguins are excellent swimmers. The Emperor penguin is probably the most famous of all Antarctic wildlife. About four feet (1.2 meters) tall, they are known for their mutual care of the egg produced by a breeding pair. After laying the egg, the male Emperor penguin puts it onto his feet, where it is incubated. The most common penguin is the Adelie, which builds nests of pebbles on the beaches. Chinstrap penguins and Gentoo penguins inhabit the Antarctic islands and the Antarctic Peninsula. King penguins, macaroni penguins, and Rockhopper penguins nest in the islands north of Antarctica. In addition, there are over 40 species of flying birds that spend the summer in Antarctica, including cormorants, gulls, pirons, albatrosses, and terns.

Krill is the food of Blue whales, Fin whales, Humpback whales, Minke whales, Right whales and Sei whales. The Blue whale is rare, but is the largest animal that has ever lived. Other whales in Antarctic waters include Sperm, Southern Bottlenose, Southern Fourtooth, and Orcas (Killer). These whales eat fish and squid, while Orcas prey on seals, penguins, and other smaller whales. There are over 100 species of fish found in Antarctic waters. These include Antarctic cod, icefish, and plunderfish. In the 1800s, whalers and seal hunters killed great numbers of whales and seals, but they have since been protected by international agreements.

The only human settlements in Antarctica are scientific research stations. Some are used only in the summertime, while a few are occupied in the winter. No country exercises sovereignty over Antarctica. The United States has rejected a claim to the continent, but has reserved the right to do so because seven other countries have made claims. These are Argentina, Australia, Chile, France, Great Britain, New Zealand, and Norway. In 1959, 12 countries signed the Antarctica Treaty. The agreement and additional later agreements form the Antarctica Treaty System.

Anthropocentrism

ANTHROPOCENTRISM, OR "human centeredness," has been a much-debated concept in environmental ethics and philosophy over the last few decades. It describes the belief that human concerns outweigh the needs of other species or that environmental preservation and conservation possess only instrumental value, meaning that no inherent demand for environmental protection exists beyond its potential to benefit human society. In opposition to such anthropocentric attitudes, early environmentalists such as John Muir and Aldo Leopold believed nature had intrinsic value, and they alternatively envisioned a biocentric ethics that would value the planetary biodiversity of flora and fauna equally with human civilization. Others have described the transition from anthropocentrism to a holistic ecocentrism, in which the totality of the ecosphere would have greater moral status than the part played by human society.

Elements of anthropocentrism can be discovered in many cultures. The philosophic origins of the idea in the West can be traced to Aristotle, who wrote in *Politics,* "Nature has made all things specifically for the sake of man." However, many place the origins of anthropocentric thinking in Judaeo-Christian biblical scripture that emphasizes the divine role given to human existence, as well as the importance of human dominion and stewardship over all other life on earth.

In a modern scientific context, the proto-ecologist Ernst Haeckel was one of the first to inveigh against theological anthropocentrism during the 19th century, critiquing it along with anthropomorphism and anthropolatrism, as an antiscientific form of anthropism that fallaciously opposes humanity to the natural order. In his view, which accords with scientific beliefs today, humanity should not be understood as either divinely created or the end product of a directed evolutionary lineage, but rather as a contingent member of ongoing biological and ecological processes that share similar evolutionary promises and risks with many other species.

Yet, it has been claimed that modern science itself is anthropocentric. Environmentalists such as those involved in the Deep Ecology and Ecofeminist movements have argued that the scientific revolution developed out of the anthropocentric ideas of Early Modern figures such as Francis Bacon and Rene Descartes and Enlightenment thinkers, who were concerned with the mastery and instrumentality of nature as well as with the perfectibility of nature by human intervention, respectively.

The historian Lynn White made a more radical critique that linked the environmental destructiveness of modern science and technology to a Western ideology rooted in Judaeo-Christian anthropocentrism in his highly influential 1960s essay, "The Historical Roots of Our Ecological Crisis." White felt that Christianity should be described as the most anthropocentric of any religion, and that it negatively affected Westerner's views of nature by ideologically legitimating exploitation of the environment and nonhuman animals. This provided the necessary conditions for the emergence of rapacious forms of science and technology that has resulted in the domination of the natural world.

White engendered a firestorm of criticism, however, and many have since argued that the Judeo-Christian tradition, when properly interpreted, offers a sound environmental ethic of stewardship. Ideas outlining human stewardship, it is claimed, are undeniably anthropocentric but do not result in granting moral license to be irresponsible with the environment. Rather, when humans act as stewards over divine creation, they are charged with its proper care and protection.

Types of anthropocentrism, then, may be outlined as "strong" and "weak." Strong anthropocentrism believes that humanity can rightfully do with nature as it wishes, while weak anthropocentrism believes that human control of nature comes with additional responsibilities to ensure that environmental uses are sustainable over the long term. In this respect, some environmental ethicists now point out that, whether based in religious or scientific views, anthropocentrism is not a major cause of environmental destruction per se, but rather its sweepingly strong and absolute forms are the most problematic.

As ecological crises continue to mount in the present day, however, the biocentric and ecocentric challenges to anthropomorphic attitudes and values have been widely adopted by a variety of environmental groups and Green political organizations. Those supporting biocentrism and ecocentrism argue that weak anthropocentrism amounts to a reformist position that is incapable of mounting a significant critique of mainstream practices, and that new ethics are required to defend nonhuman species, the environment, and society from the catastrophic overuse of nature as a resource. Anthropocentric philosophies are therefore controversial; while they have defenders within the environmental community, those who seek to radically transform Western tradition toward environmental sustainability often target them for blame.

Anthropology

DERIVED FROM THE Greek *anthropos* (human) and *logia* (study), anthropology is the study of humans, past and present. Ideally, the perspective of anthropology is expansive, comparative, and holistic, tackling questions such as why people behave as they do and what accounts for human diversity. Two basic foci—cultural and biological variation—have preoccupied proto-anthropologists for millennia and continue to drive the discipline today. Anthropologist Eric Wolf described anthropology as "both the most scientific of the humanities and the most humanistic of the sciences."

DEVELOPMENT OF THE DISCIPLINE

During the 15th century, Europeans set sail in search of additional trade routes, and they encountered peoples and places, flora and fauna previously unknown to them. Developments in maritime technologies and the invention of the rifle aided European influence and imperial expansion, facilitating in myriad ways greater intercultural interactions as well as processes of acculturation (forcible culture change).

By the start of the 19th century, Europeans had traveled and collected vast amounts of information regarding different peoples and their environs, feeding speculations about "human nature" and "human society" on a global scale. Around this time, the word anthropologist came into use in the English language. Formalization of anthropology as an academic profession occurred in 1884, as Sir Edward Burnett Tylor accepted the first university position in anthropology as a University Reader at Oxford.

Ethnography, which refers to the written, photographic, and/or motion picture account of cultural anthropological fieldwork, and anthropology in general, were linked to imperialism and colonialism. The same European countries expanding their spheres of influence requested ethnographic data about colonized people in order to figure out how to manage them.

Some colonial era ethnographers, such as Evans-Pritchard, were renowned for their defense of indigenous ways of life, and still others actively critiqued the colonial enterprise (e.g., Franz Boas). However, not all of the so-called great colonial powers developed a discipline of anthropology—Portugal and Spain did not—and not only colonials collected anthropological data. Colonial administrators also relied heavily on accounts from missionaries, merchants, and other travelers.

The three major homes of academic anthropology today derived from 19th- and 20th-century hubs of imperial expansion. They are continental Europe, Britain, and the United States. Although of similar roots and some convergence, there have been differences in approaches among them. There are many and varied thinkers and movements that have contributed to the discipline of anthropology. For example, proto-anthropology can be traced back to Herodotus (5th century B.C.E.) and his detailed cultural descriptions; and contemporary anthropology can also be described as an outcome of the Age of Enlightenment and its varied attempts to methodically examine human beings through empirical research. Heavily influenced by natural history and the theory of evolution through natural selection, 19th-century anthropologists adopted the notion of "progress" to describe changes in human cultural practices over time.

Lewis Henry Morgan of the United States, fascinated with American Indians and cultural change, provided great contributions to kinship studies in the late 19th century. Drawing on his own fieldwork, other ethnographic accounts, and responses to questionnaires he had distributed to missionaries and travelers, Morgan embraced ethnology, the comparative study of human societies. Morgan's book *Ancient Society* (1877) codified the cultural evolutionist position in anthropology, proposing that some human societies had progressed more than others. This universalist and unilineal theory of human development drew from French philosopher Montesquieu and included three stages: savagery, barbarism, and civilization. The first two stages included subdivisions of lower, upper, and middle; new inventions marked transitions from one stage to the next, such as the use of fire, pottery, and so on. These stages of development tracked differences and changes in technology, political organization, and kinship systems. Karl Marx and Friedrich Engels viewed Morgan's work as validating historical materialism and also providing comparative data from nonindustrial societies. Engels would later write *Origin of the Family, Private Property, and the State* (1884), paralleling Morgan's *Ancient Society* and tying their materialist strategies together.

Another ethnologist, Edward Burnett Tylor of Great Britain, published *Primitive Culture* in 1871 and employed the same three stages of development as Morgan, but added that civilization included an advance in happiness and certain moral qualities. Tylor drew his conclusions from comparative research on religions, which he suggested were universal responses to universal experiences, and he traced religious evolution from animism to polytheism to enlightened monotheism. Like Morgan, Tylor's comparative method considered living "tribal" peoples as examples of prehistoric societies that had yet to evolve into the higher stages of development. Significantly, Tylor defined culture as "that complex whole which includes knowledge, belief, arts, morals, custom, and any other capabilities and habits acquired by man as a member of society." As it turns out, Tylor the Englishman gave American anthropology "culture," its basic unifying concept, and Morgan, an American, founded detailed kinship studies, which has since become the forte of the British.

EARLY 20TH CENTURY

By the end of the 19th century, some anthropologists openly rejected the unilineal evolutionist paradigm, and the 20th century opened with wide-ranging support of some combination of diffusionism, historicism and, eventually, structuralism and functionalism. For example, Austro-German anthropology, rooted in geographic and linguistic studies, analyzed culture complexes, their ecological constraints, and how they developed historically.

As Morgan's work indicates, anthropology in the United States arose in part from concerns for the cultures and histories of populations native to North America. This line of anthropology was furthered via the Bureau of Indian Affairs and the Smithsonian's Bureau of American Ethnology. The honorific title of "Father of American Anthropology" belongs to German-born and educated Franz Boas, also known as Papa Franz. Boas founded the first major department of anthropology at Columbia University in 1899. A proponent of what became known as historical particularism, Boas advocated participant observation and "total recovery"—a holistic approach in collecting data to understand the historical events that may have led to the development of particular cultural facts. Among Boas's more famous students were Ruth Benedict, Margaret Mead, Alfred Kroeber, and Robert Lowie.

Due in large part to Boas's influence, American anthropology has typically been divided into four fields: 1) archaeology—the study of material remains of human societies, usually from the past, to describe and explain human behaviors; 2) biological/physical anthropology—the study of humans and nonhuman primates as biological organisms through primatology, biological evolution, forensics, osteology, population genetics, and so on; 3) linguistics—the study of human language, its variations, social uses, relationship to culture, and changes over time; and 4) cultural/sociocultural anthropology—the study of human beliefs, values, and behaviors, such as ideology, production and consumption patterns, kinship, gender roles, exchange, politics, religion, and art.

While Boas was shaping American anthropology, A.R. Radcliffe-Brown and Polish-born Bronislaw Malinowski were busily shaping British social anthropology. Malinowski and Radcliffe-Brown proposed functionalist paradigms, which were far less interested in reconstructing a society's history than Boasnian historical particularism. Rather, functionalists focused on analyses of how societies operated and held together in the present. Based on his extensive participant-observation fieldwork in the Trobriand Islands, Malinowski developed psychological functionalism to describe how cultural institutions meet basic physical and psychological needs of individuals within a society. Malinowski's students included E.E. Evans-Pritchard, renowned for his work among Nuer and Azande peoples in Sudan, and Raymond Firth, a key economic anthropologist.

Radcliffe-Brown created structural functionalism, which studied various aspects of society in terms of how they functioned to maintain the society as a whole. Drawing on French sociologist Emile Durkheim, Radcliffe-Brown subscribed to the notion that society was somehow distinct from its members and as such molds individuals' behaviors. These functionalist theories were conceived by European anthropologists and applied through studies of peoples in European-held territories.

POST–WORLD WAR II TO THE PRESENT

Because of the discipline's growth, post-World War II anthropology has become a collection of more specialized subfields that cut across the four fields outlined previously. Three of the fastest-growing examples include development anthropology, medical anthropology, and environmental anthropology. Medical anthropologists study meanings of and relationships among health, disease or illness, healing practices, and social systems. Development anthropologists may also examine human health and nutrition as they look at global, economic contexts within which "development" takes place, with a focus on implications of international trade, investment, international lending institutions, and debt. Environmental anthropology focuses on the relations between humans and their environments. Contemporary environmental anthropology has grown out of and/or co-evolved with cultural ecology, founded by Julian Steward; ecological anthropology, for example, Roy Rappaport's work on ecosystemic homeostasis; human ecology; and ethnoecology, which refers to how people name, classify, and otherwise conceptualize flora, fauna, and human activity within the environment.

Founded in 1902, the American Anthropological Association (AAA) now has over 10,000 members and is the world's largest organization of individuals interested in anthropology. Completion of a doctorate is necessary to achieve full professional status as an anthropologist. Directly linked to the academy, one could also work as a field archaeologist, or within museums, research institutions, physical anthropology labs, area studies, or ethnic/multicultural centers.

Outside of academic institutions, cultural and linguistic anthropologists may work as research directors; science analysts; and program officers in federal, state and local government, international agencies, nonprofit organizations, health care institutions, marketing firms and research institutes. Biological anthropologists may work in biomedical research, forensics, genetics laboratories, and pharmaceutical firms.

Anthropomorphism

ANTHROPOMORPHISM IS THE attribution of human qualities—specifically, complex emotions, reasoning, and motives—to anything that is not human. Most religions describe the divine in human terms, even though divinity is defined as something inherently beyond the human. The tendency to put a human face on celestial bodies and on features of the topography dates to religious beliefs that deities had assumed those forms. Other deities were said to have assumed animal forms, and myths have reinforced totemic associations of certain animals with particular characteristics—for instance, owls with wisdom, foxes with cunning, and swans with elegance.

In popular culture, the sun and the moon are still often represented not only as having features, but also as being capable of emotive expressions. Enduring features of the topography such as mountains and rivers are often described as old men. Some pet owners may believe that their dogs and cats enjoy being dressed in hats, sweaters, and booties. Other pet owners may believe that a dog or cat is capable of smiling or frowning in response to events. Some plant owners may truly believe that their plants not only are responsive to soothing or harsh sounds, but also are capable of feeling happy or sad. This sort of anthropomorphism occurs even when natural phenomena are destructive—for instance, Atlantic hurricanes that are given human names such as Katrina and Rita.

Anthropomorphism has become a point of contention when it has been used to heighten the impact of arguments about environmental choices or about what constitutes humane treatment of other creatures. For instance, describing a logging or mining practice as the "rape" of the environment stigmatizes that practice. Likewise, describing orphaned animals as being overwhelmed by sorrow or grief following the deaths of their mothers transforms natural selection into a heart-rending melodrama. However, the survival of adult bears (or any adult carnivore) often depends on their being able to find easy kills among orphaned animals. Even the use of the term "orphaned" illustrates the pervasiveness of anthropomorphism that prevents many from thinking clearly about how other species may be very different from humans.

This lack of clarity has muddied issues such as what constitutes the humane treatment of wild and domesticated animals harvested for food or clothing, of animals used in the testing of medical treatments and cosmetics, and of animals kept in zoos and other exhibitions. Traditionally, the sense of the urgency of these issues has intensified the more closely related the species has been to man. Primates are most likely to be described in anthropomorphic terms, as are almost all other mammals. At the other end of the spectrum are insects, fish, and reptiles—none of which provoke much sympathy. Interesting exceptions are amphibians and birds, which, despite having eyes with the flat, inhuman aspect associated with fish and reptiles, are capable of producing sounds that appeal to the impulse to anthropomorphize.

Knowledge of the ways in which other species perceive the world is very limited, and it may always be limited by the inability to completely transcend human perceptions. Some investigators who have been especially concerned about human mistreatment of other species have argued that other species do not respond to experiences in a manner comparable to human emotions, but they may still be capable of feeling. The newest type of anthropomorphism involves the attribution of human qualities to machines, in particular to thinking machines such as computers that may someday be capable of artificial intelligence.

Antibiotics

ANTIBIOTICS ARE CHEMICALS used to fight diseases caused by pathogens such as bacteria, fungi, or protozoa. Only a few antibiotics are effective against just a few viruses. Antibiotics can be used to fight infections because they are toxic to specific microbes. They may be prescribed to prevent infection when the immune system is impaired, or when there is a risk of endocarditis (inflammation of the lining of the heart). Before the advent of modern antibiotics, many patients experienced a uniform progression of the disease to the death. Antibiotics were originally produced from selected mold and fungi found in the earth, air, or water.

Since the 1930s, thousands of antibiotics have been found in nature; however, only a few (over 60) have been found to be safe for use as medicines. Most modern antibiotics are made synthetically by chemical means. Millions of tons of antibiotics are manufactured every year in a process that brews a culture of the microbe that produces the chemical that is the active agent in fighting a disease. After the antibiotic broth is filtered, the antibiotic molecules are combined with a resin that is washed to collect the pure antibiotic crystals.

In the late 1800s, a Danish bacteriologist, Hans Gram, classified bacterial infections as either gram positive (G+) or as gram negative (G-). Bacteria in these categories are sensitive to some drugs, and not to others. If an antibiotic fights only a few bacteria infections, it is called a limited-spectrum drug. If it fights a wide variety of bacteria that are both G+ and G-, it is called a broad-spectrum antibiotic.

Antibiotics are manufactured by "brewing" a culture of the microbe that produces the active disease-fighting agent.

Bactericidal antibiotics are drugs that kill bacteria by causing a disruption in its cell walls, causing the bacterial cell wall to turn into water and allowing water to flood the cell. It then explodes, killing the bacteria. They do not have any affect upon human tissue. Other antibiotics are bacteriostatic drugs, which work by disrupting the growth of bacteria. This allows the immune system to have time for fighting successfully the infection. The most common forms of antibiotics include aminoglycosides, macrolides, penicillins, tetracyclines, and cephalosporins. Each works in a different way.

The aminoglycosides include drugs such as gentamicin, anikacin, and tobramycin, which prevent bacteria from producing protein; however, they can damage internal ear nerves and the kidneys. Macrolides also disrupt protein production by bacteria. Erythromycin, a macrolide, can cause bowel discomfort.

Sir Alexander Fleming discovered penicillin in 1928. Many kinds of bacteria are destroyed with penicillin drugs, which destroy bacteria cell walls. However, it can cause side effects ranging from a rash or fever, to life-threatening allergic reactions (anaphylaxis). Tetracyclines can destroy both bacteria and other organisms, and prevent the production of protein in many germs. However, side effects such as gastric discomfort, sensitivity of skin to sunlight, liver damage, or kidney damage may occur. The cephalosporins, which disrupt bacteria cell wall formation, are antibiotics that are effective against a wide range of bacteria. Cefaclor is a commonly prescribed cephalosporin. At times, physicians will prescribe a combination of antibiotics in order to ensure the destruction of the infectious bacteria and to reduce the risk of drug resistance. This can happens if a bacteria simply mutates, or if it is able to develop a growth mechanism that allows it to grow unaffected by the drug. Or, the bacteria may produce an enzyme that neutralizes the drug.

Antimicrobial resistance to antibiotics drugs is a growing, global problem that has alarmed some health care professionals, because diseases once "conquered" are returning in the form of strains that are resistant to older antibiotics. It has arisen because bacteria not killed by a specific antibiotic were able to reproduce, carrying that characteristic that resisted the drug. If a patient fails to take a full course of medicine or take it as directed, resistance may develop. Resistance has been found in strains of tuberculosis, sexually transmitted diseases (STDs), and other diseases that now pose a renewed threat to human and animal health.

While powerful antibiotics are available, serious questions have been raised about the wisdom of administering these drugs to patients with lifestyles that suggest they may not follow proper treatment procedures and may increase the likelihood of new strains of resistant bacteria developing and transmitting to others. The consequences could be the spread of diseases for which there are few, if any, treatments available.

The overuse of antibiotics has exacerbated this problem, with widespread prescription of antibiotics by physicians for conditions that rarely respond to the treatment, such as childhood ear infections. Antimicrobial soaps and other commercial consumer products may also accelerate the evolution and adaptation of various microbes toward immunity. Antibiotics have been used as a food preservative by the food industry, and ranchers and farmers also use antibiotics in order to stimulate animal growth. The degree to which this widespread use may further influence the resistance of microbes remains a controversy, especially as the livestock industry has rapidly industrialized.

Besides side effects, antibiotics can have other negative consequences. For instance, some antibiotic drugs may become toxic if they are taken after their effective date. Since 1900, the world's population has grown enormously. Antibiotics have played a major role in that growth. However, the emergence of resistant microbes poses a grave threat to the future of human life and health.

Antiquities Act

THE ANTIQUITIES ACT of 1906 was the first law in the United States to designate and protect archaeological sites and artifacts. It gave the president the right to declare by public proclamation the creation of "national monuments, historic landmarks, historic and prehistoric structures, and other objects of historic or scientific interest" based on archaeological significance. In addition, looting of related artifacts was made illegal on federal lands.

The Antiquities Act has three primary parts. First, it calls for the prosecution of persons who excavate, appropriate, injure, or destroy any historic or prehistoric ruin or monument or any artifact on federal lands, and specifies penalties for those convicted of these offenses. The act specifies that any person convicted of appropriating, excavating, injuring, modifying, or destroying any historic or prehistoric ruin or monument, or any artifact, is to be fined no more than $500, be imprisoned for a period not to exceed 90 days, or be both fined and imprisoned at the discretion of the court.

Second, the act empowers the president to declare areas of public lands as U.S. National Monuments, reserving, modifying, or accepting private lands for this purpose of conversion to monument status as well. Since its passage in 1906, the act has been used by 14 out of 18 presidents (the four nonusers being Richard Nixon, Ronald Reagan, George H.W. Bush, and George W. Bush). Congress also has the power to declare national monuments, having done so in 29 cases. Of the 105 national monuments proclaimed under the Antiquities Act, 46 are larger than 5,000 acres and 28 are larger than 50,000 acres. Hunting and grazing are often allowed within the boundaries of U.S. National Monuments, because they are usually managed less stringently than U.S. National Parks. In addition, it is not uncommon for a national monument to ultimately be redesignated as a national park. In fact, 25 percent of America's national parks were originally designated as monuments under the Antiquities Act and include such wonders as the Grand Canyon, Arches, and Bryce Canyon. Noteworthy implementation of the act has included Theodore Roosevelt declaring 18 national monuments in nine states, Jimmy Carter declaring 56 million acres in Alaska, and Bill Clinton designation of 1.7 million acres for Grand Staircase–Escalante National Monument in 1996.

Finally, the Antiquities Act permits the examination and assessment of ruins, excavation of archeological sites, and the collection of objects of antiquity on lands owned or controlled by the United States, including federal marine environments on which submerged cultural resources are located. The act permits and/or regulates related salvage procedures. The act establishes that such permissions are under the jurisdiction of the appropriate secretary of the land being investigated (i.e., Departments of Interior, Agriculture, and Defense). The secretary may authorize the institutions deemed qualified to conduct such examination, excavation, or gathering.

The act requires that "examinations, excavations, and gatherings" are conducted for the benefit of museums, universities, and colleges, and/or other recognized scientific or educational institutions, for the purpose of increasing the knowledge of such artifacts, and that the collections from such "gatherings" be made a part of public museum displays and collections.

Appalachian Mountains

THE APPALACHIAN MOUNTAINS, a prominent mountain range in the eastern North America, extend from central Alabama northeastward into Newfoundland and Labrador. The Appalachians are geologically an old range. Several mountain-building episodes in geologic history have resulted in a complex system of ranges and valleys and the presence of significant deposits of anthracite and bituminous coal, which have provided the basis for economic development in the region. The Appalachians represent the physical dividing line separating the vast central basin and the eastern seaboard.

During the colonial era, the Appalachians were a barrier to the inviting agricultural regions to the west. Prior to the end of French and Indian War in 1763, the regions immediately to the west of the Appalachians were considered hostile territory. The region remained essentially inaccessible following 1763 by virtue of a British proclamation in that year limiting colonial settlement eastward from a line marked by the mountain summits. This restriction was eliminated following the Revolutionary War, and people on the eastern seaboard began a migration to the west through the Cumberland Gap and the Hudson-Mohawk Corridor in New York, a transportation route that remains important.

The term Appalachia has been used generally in reference to the entire mountain system and more specifically in identifying the central and southern sections of the Appalachians prominent for high levels of poverty, economic exploitation, and environmental degradation. The Appalachian Regional Commission (ARC), an organization representing both federal and state governments, is devoted to improving conditions in the region. The ARC has created taxonomy of economic development categories to identify counties within the region. The categories include distressed, transitional, competitive, and attainment. Distressed counties have per capita incomes not exceeding two-thirds of the national average. Transitional counties rank somewhat higher than the distressed category, but are still lower than national averages. The competitive grouping ranks below the national average in unemployment and poverty, but income levels remain at least 10 percent below the national average. Finally, counties at the attainment level are on a par with the remainder of the country in income level, poverty rate, and level of unemployment. Appalachia has been the recipient of federal assistance for poverty alleviation and economic revitalization for decades. In recent years the region has benefited economically from a rise in tourism.

The widespread forest cover in the Appalachians became the basis for a flourishing forestry industry early in the region's settlement history. However, within the past several decades the forest cover has suffered from the deposition of acid rain and high ozone levels. The primary sources of air pollution are coal-fired electrical generating plants in the midwest and the Gulf states. The general pattern of airflow in this region of North America is west to east and the particulates emanating from the power plant smoke stacks mix with moisture in the atmosphere and fall as acid rain over the forested areas of Appalachia.

Foxfire Books

The first of the Foxfire books was published in 1972 and was compiled by B. Eliot Wigginton (b. 1942), a high school teacher in Rabun County, Georgia, who had persuaded his students from Southern Appalachia to collect local stories and write about legends and customs. Many of these were first published in magazine form.

Eliot Wigginton started the project partially out of curiosity, but also to empower his students and give them confidence. He felt he had access to much local folklore that would otherwise go unrecorded. In 1966, these vignettes appeared in *Foxfire Magazine,* named after a type of local fungi. Demand was so great that these appeared in book form six years later.

The topics covered details on preserving fruit, recipes such as apple butter, burial customs, stories about local witches, animal care, the handling of snakes, faith healing, and information on how to make fiddles and soap; there were also accounts of beekeeping, spinning, tanning hides and carving wood. Wigginton edited the first nine volumes: *Foxfire 9* was published in 1986. He was awarded the MacArthur Foundation fellowship three years later. *Foxfire 12* was published in 2004.

Appropriate Technology (AT)

DEFINING APPROPRIATE TECHNOLOGY (AT) is difficult; it means many things to many people, and what may be understood as appropriate to one community may not be consistent with another. In broad terms, the National Center for Appropriate Technology (NCAT) describes AT as a technology that is simple to apply, is not capital- or energy-intensive, uses local resources and labor, and protects environmental resources and human health. Practical Action, a nongovernmental organization (NGO), suggests that AT takes advantage of local resources, uses and employs recyclable materials, is affordable, and generates local employment in its application.

AT emerged as a movement during the 1960s in the context of economic theory that argued that Western models of development were unsustainable, environmentally degrading and would not provide benefit to the world's poor. Ernst Schumacher is regarded as the founder of the AT movement and is best known for his seminal work, *Small Is Beautiful: Economics as if People Mattered*. Schumacher, an economist, argued that the world's poor did not benefit from modern technological advancement because it wasn't affordable, accessible, or appropriate to their circumstances. Therefore, he suggested that an intermediate or appropriate form of technology should be developed, at a small scale that built upon the existing skills and knowledge base of local communities. The use of such technology would ensure all people, including the poor, maintain improved standards of living and that natural resources are managed sustainably for future generations.

In 1966, Schumacher founded the Intermediate Technology Development Group, designed to reduce poverty around the world by the application of AT principals. Now known as Practical Action, the group coordinates projects in Latin America, East Africa, Southern Africa, and South Asia. Their projects are established to assist communities to develop AT in the areas of food production, agroprocessing, energy, transport, small enterprise development, shelter development, small-scale mining, and disaster mitigation. For example, projects aimed at encouraging the use of indigenous food crops and the sustainable harvest of wildlife have been trialed in order to facilitate increased food production without degradation of the natural environment.

Unlike Practical Action, NCAT was founded to improve the living standards of poor Americans, not those in developing countries. During the 1973 energy crisis, the cost of fuel rose dramatically because the Organization of Petroleum Exporting Countries (OPEC) stopped supplying the United States and Western Europe with oil due to their support for Israel during the Israeli war with Egypt and Syria. Consequently, many poor Americans could not afford to heat their homes. To help conserve and reduce the amount of energy required to heat a building, NCAT devised AT solutions, such as super insulation, and designed technological solutions that were appropriate for poorer households. NCAT now primarily focuses on sustainable farming techniques, such as reducing chemical use.

In Australia, the Centre for Appropriate Technology (CAT) manages projects designed to improve the lives of Aboriginal peoples living in remote areas where access to modern technology is limited, unaffordable, or not appropriate in environmental or cultural contexts. Like indigenous peoples all over the world, Australian Aborigines face severe socioeconomic challenges. CAT provides AT that is not only cheap and easy to maintain, but also helps build the skills capacity within a local communities through the provision of training and information sessions in appropriate formats (such as brochures and training guides in local languages).

APPROPRIATE TECHNOLOGY ADVOCACY

The AT movement also performs a significant advocacy role. For example, CAT advocates funding for capacity-building programs and for the adoption of the Sustainable Livelihoods model into Australian policy design and decision-making processes for remote aboriginal communities. The Sustainable Livelihoods model is an international program that evolved from a research paper by Robert Chambers and Gordon Conway in 1991, called "Sustainable Rural Livelihoods: Practical Concepts for the 21st Century." This model, which has since been championed by government and NGOs, aims to reduce poverty. It is based on ensuring that when development decisions are made in poor countries, the decisions are designed to be appropriate and will ensure benefits accrue to the whole community, not just the ruling elite. Practical Action advocates for the development of policies and practices within the United Kingdom and European Union (EU) that will benefit the world's poor.

It is important to note that AT does not advocate abandoning modern technology. Rather, modern technology should be delivered on a small, localized scale, such as a Remote Area Power System (RAPS) that will generate electricity for remote communities where it is not technically or economically feasible to be connected to a main power supply.

As the pace of technological advancement increases, developing nations are being left farther behind and the gap between the technologically rich and poor is growing ever wider. Increasingly, developed countries are defending their economic interests more aggressively and only countries with strong institutional arrangements are able to take part and benefit from globalized markets. Therefore, AT will increasingly play a significant role in providing the world's poor, isolated, and rural communities with access to technology that enhances and provides benefit to their lives.

Aquaculture

AQUACULTURE IS THE controlled cultivation of aquatic organisms, such as fish, mollusks, crustaceans, and plants. Aquaculture may take place in oceans, rivers, lakes, ponds, or manufactured tanks. The first known records of aquaculture are from China, circa 889–904 C.E., where carp was farmed in flooded rice fields. This system took advantage of excess water, while at the same time fertilizing the earth and clearing the land of weeds. Thirty percent of the marine products consumed today come from aquaculture, which is currently the world's fastest-growing food producing sector.

Aquaculture has experienced rapid growth and expansion on a global scale since the 1980s, while most wild-capture fisheries are in decline. International development agencies and state and local governments herald aquaculture as a means of economic development, resource diversification, and food security. Some scientists argue that it can be a strategy for taking the pressure off of wild fish stocks in order for them to recover. On average, seafood accounts for 16 percent of all animal protein in the human diet, making it the most important single source of high-quality protein.

Aquaculture is a global phenomenon, with a diversity of scale and levels of market integration. In some countries, aquaculture is practiced at a subsistence level, while other countries are internationally engaged in an industrialized process of fish production and export. Asia is the world leader in aquaculture production, due to its historical foundation in the process. Latin America has experienced a sharp rise in aquaculture production, with an average growth rate of 18 percent per year during the 1990s. The market is expanding most rapidly in North America, growing by approximately 13 percent per year in recent years.

The primary increase in aquaculture products has occurred in Low Income Food Deficit Countries, further reinforcing the view that the practice is a nutritional and economic resource. Many countries, including the United States, have encouraged aquaculture research and development as a means to meet the growing demand for seafood products in the face of a significant decline in wild populations. If environmental and social needs can be met, aquaculture might help alleviate poverty and hunger, while generating employment, though the actual effects of its rapid promulgation on local populations remain controversial.

Aquaculture at the industrial scale is relatively new and is still in the process of adaptation. Some concerns have emerged that the cultivation of certain species on intensive scales is ecologically harmful. Although aquaculture occurs in a controlled environment, cases of escapes, contamination, and spread of disease have been documented, all of which may harm the natural ecosystem in the surrounding area. For example, studies in Chile have shown that escaped salmonids can colonize their new, nonnative environment, resulting in resource competition and potentially altering local ecosystem processes. Shrimp production in Asia and other parts of the world has resulted in the deforestation of mangroves and wetlands in order to create space for shrimp ponds. The cultivation of carnivorous fish depends on the extraction of wild fin-fish that are converted to meal for fish food. In some parts of the world, this has meant depleted stocks for local fishermen, who still depend on these species for a supplement to their diet or for income. Experts have recently recommended that endemic herbivorous or filter feeders be farmed, rather than nonnative carnivorous species, in order to avoid some of these potential problems. Another suggested solution is to farm exclusively in terrestrial, man-made tanks where all stages of production could be managed, including the disposal of waste.

The future of aquaculture depends on cooperation between stakeholders, including regulatory agencies, industry, scientists, and fishermen in order to achieve responsible and sustainable aquaculture operations. Improving technology and species diversification can promote sustainable marine resource consumption, and may benefit a wider range of consumers. The diverse ecological, sociocultural, and political interests make this a challenge, though one that has the potential to be met. Global cooperation is paramount for the diffusion of successful information and technology to establish and maintain sustainable practices. Under the right conditions, aquaculture may help to meet demands for this important resource while establishing socioecological improvements that can benefit human and biophysical ecosystems. The positive and negative economic, political, and ecological impacts of the rapid transition toward aquaculture, however, are still being assessed.

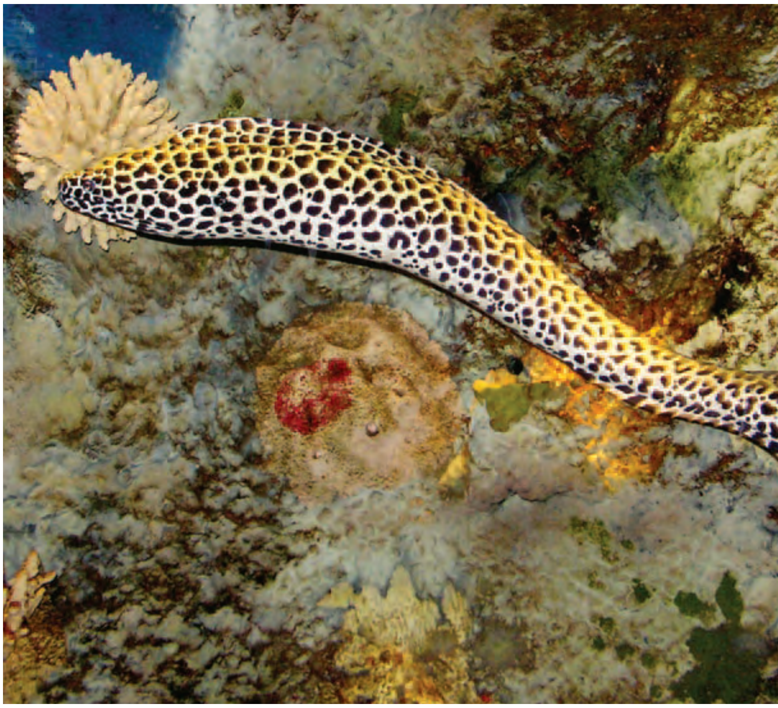
Aquariums

FISH HAVE BEEN raised in captivity since at least 2300 B.C.E., when people raised them for entertainment and to satisfy their intellectual interests. In addition, animals, shellfish, and plants have been kept as part of aquariums. In the 1800s, home aquariums became very popular in England. As interest spread, many people journeyed to the nearby English coasts in order to gather fish, plants, and other creatures. These were then kept in the available containers that constituted the aquariums of the day. Soon, attention turned to the fresh waters for aquarium specimens. Many homes became supplied with a lake in a glass bowl with specimens taken from local streams and lakes. Businesses began selling aquariums and aquarium supplies, aiding the growth of aquarium keeping. By the end of the 1800s, merchant ships were carrying tropical or other exotic species of fish and aquarium species from all over the world to supply home aquariums. Books were written on species of sea and fresh water fish, plants, and other living organisms. By the 2000s, large producers of goldfish, tropical fish, snails, and other aquatic creatures were marketing the creatures in specialty aquarium supply outlets.

Successfully keeping a healthy home aquarium requires equipment—an aquarium tank, tank cover, water filter, lighting, heater, and thermometer. A home aquarium should approximate the aquatic environment of the fish that will live in the tank, with rocks, gravel, sand, wood, and plants. Tropical fish, saltwater fish, or temperate-climate fish have different habitat requirements. Water chemistry is crucial if the fish and other aquatic creatures are to flourish. The filter supplies air to oxygenate the water. The heater maintains a constant water temperature that reduces stress on the aquarium's inhabitants. Proper feeding and cleaning is also crucial to maintaining a healthy aquarium.



With the decline of wild marine life, public aquariums are promoting good resource stewardship.

PUBLIC AQUARIUMS

As interest in home aquariums grew in the 1800s, large public aquariums were opened in the Gardens in Boston, Massachusetts, Germany, Austria, and elsewhere. Public exhibitions of the watery world of lakes, rivers, and oceans generated enormous interest. Many of these original aquariums, as well as some operating today, were built as places of entertainment for the public and as commercial enterprises for their owners. There are now several hundred great public aquariums around the world. Most, such as the Georgia Aquarium (Atlanta) and the Long Beach Aquarium (California), are places of entertainment, education, and research. They require millions of dollars to build and to maintain. They are usually a cooperative effort between foundations, civic boosters, state and local governments, universities, schools systems, and marine or aquatic research bodies.

Some of the great aquariums are organized around a theme. The Monterey Bay Aquarium and the Osaka (Japan) Kaiyukan Aquarium are focused on Pacific Ocean creatures and plants. Both have been built on the edge of the Pacific Ocean. The Monterey Bay Aquarium pumps in ocean water from the Pacific and circulates it through their display tanks in order to keep the water chemistry and the environment as natural as possible. The water is filtered in the daytime to remove impurities, so aquarium patrons can clearly see the octopus, sharks, stingrays, sea otters, aquatic plants, and fish. At night they use unfiltered seawater to nourish the exhibits in a manner similar to the wild. Other public aquariums have been built around a different theme. The Tennessee Aquarium in Chattanooga is a freshwater aquarium, organized around the theme of aquatic creatures in the Tennessee River. As patrons walk down a four-story ramp, they pass exhibits that trace the course of the Tennessee River from its origin high in the Appalachian Mountains until it meets the Gulf of Mexico, where its saltwater exhibits are displayed.

Many factors contribute to the continued success of public aquariums. Crucial to success are its volunteers, who supply an eager, unpaid workforce. Dedicated volunteers serve as docents, teaching visiting school children about the creatures and plants on display. Other volunteers, wearing scuba equipment, enter the tanks to clean them. Without the vast number of volunteer hours, the educational and research services of their aquarium could not exist. One of the favorite exhibits in the public aquariums is the seals, sea otters, or other mammals at feeding time. The animals seem to be trained to do tricks by their handlers, when in reality the "tricks" are used to measure their responses, or to prepare them for detailed physical exams by a veterinarian as needed. The modern aquariums conduct research on oceanic problems such as sterility in whales. They also have programs for breeding the specimens on exhibit, which enhances the survival of some species and provides a way for restocking exhibits. Surpluses can also be traded or shared. With the decline of marine life caused by overfishing or pollution, the public aquariums are promoting good resource stewardship. They are also educating the youth in ways to care for the waters of the planet.

ECOLOGICAL CONCERNS

Home aquariums can create ecological problems if unwanted specimens are dumped into local fresh water bodies and become invasive species. Critics of aquariums also suggest that many ocean-roving species (including great white sharks, for example, and many sea mammals) should not be kept in captivity, and that the central purpose of aquariums, like zoos, is generating revenue, rather than meaningful conservation or education. Most major breakthroughs in understanding aquatic species, they point out, are not made through observation in captivity, but instead in situ, seeing species in the context of their larger environment. Despite these criticisms, the number and distribution of aquariums is expected to increase greatly in the next century.

Arbor Day

ARBOR DAY IS a nationally celebrated observance that encourages tree planting. It officially takes place in the United States on the last Friday in April, although each state may have its own Arbor Day based on the planting season. Globally, many other countries have created their own Arbor Day based on the U.S. model. The day began in 1872 when journalist J. Sterling Morton, the editor of Nebraska's first newspaper, proclaimed the holiday in Nebraska. It has been widely cited that one million trees were planted on the first Arbor Day, in part due to prizes offered to individuals and counties for planting the most trees.

Tree planting in the United States was not new in 1872. Euro-Americans planted trees for windbreaks and ceremonial purposes for the previous four centuries. In addition, tree-planters such as John Chapman (Johnny Appleseed) preceded Morton, but unlike Chapman, who planted trees as a religious mission, Morton promoted tree planting as a catalysis to environmental change. He claimed that tree planting in the semi-arid plains would induce rainfall needed for agriculture and hence framed tree-planting as patriotic. By 1907, Theodore Roosevelt was speaking of Arbor Day in patriotic terms as well, "Arbor Day… [will give you] a day or part of a day to special exercises and perhaps to actual tree planting, in recognition of the importance of trees to us as a Nation." By 1882, Arbor Day traditions were brought to schools around the country, teaching children about the duty of planting trees.

Currently, the biggest promoter of Arbor Day is the National Arbor Day Foundation, a nonprofit organization that promotes the planting of trees and the celebration of Arbor Day. With each $10 membership, the foundation sends the member 10 trees. On a larger scale, the foundation organizes educational programs and the Tree City program. Cities must meet requirements such as tree care ordinances, a community forestry budget of at least $2 per capita, and an official Arbor Day celebration to be officially declared a Tree City.

Arbor Day, and those who promote the celebration, have not been without critics. Some point out that Arbor Day was founded in Nebraska, a treeless plain, under the notion that the land would be better with trees, even though the landscape prior to the arrival of the European Americans did not contain trees. The Environmental Protection Agency (EPA) has also been criticized for publishing a list of how many trees one must plant to offset environmental damage done with other activities. In this case, tree planting is seen as a way to make up for environmentally damaging behavior instead of promoting a change in behavior. In addition, the forestry industry often heralds its achievement by publicizing the number of trees planted; however, the vast monoculture tree plantations are often planted with the fastest-growing species, not with the most ecologically appropriate. Although these critiques are not against the concept of planting trees, they disagree with the rhetoric of these organizations, which tout tree planting as a panacea instead of seeing it as an act with political outcomes.

Arctic

COMPOSED OF THE northernmost residents of Alaska, Canada, Greenland, Scandinavia, and Russia, the arctic's population of 4 million is a heterogeneous blend of indigenous groups and immigrants, both utilizing the region's natural resources in mixed subsistence and cash-based economies. Together they sparsely populate an extreme environment characterized by tundra vegetation or boreal forests bordered by oceans teeming with wildlife. Indigenous arctic peoples such as the Aleut (Unangan), Yupik, Athabascan, and Inupiaq of Alaska; the Inuit of Canada and Greenland; the Saami of Scandinavia; and the Yakut, Yukagirs, Chukchi, and Evenks of Siberia were traditionally small nomadic groups who moved seasonally in pursuit of wildlife resources such as sea mammals, fish, and birds, as well as land mammals such as caribou, moose, and bear. These groups have always been renowned for their remarkable adaptive abilities in a challenging environment to which they are both economically and culturally connected.

Today, arctic residents live in diverse settings ranging from small villages of less than 100 people to large cities such as Murmansk in Siberia, which has a population of over 300,000. All communities are tied in some way, however, to the region's rich natural resources and industries based upon the exploitation of minerals, fish, and timber. Indigenous arctic populations are increasingly feeling the pressure of industrial expansion and resource extraction in their territories, as well as an influx of both migrant labor and tourists. All arctic residents of the 21st century now face dual concerns in the large-scale industrial extraction of their natural resources to meet the needs of a burgeoning global economy and in the spectre of the warming trends currently indicative of climate change predictions.

COLD FACTS ON CONSERVATION

Mining of nonrenewable resources such as gold, copper, iron, oil, coal, and natural gas provides the majority of revenue generated from arctic industries. Oil and gas extraction and refining in particular are vitally important industries in the arctic, but also stimulate debate over conservation concerns of some of the most environmentally pristine areas of the world, such as in the dispute over oil drilling in Alaska's Arctic National Wildlife Refuge. Overfishing of both the North Pacific and North Atlantic is also a contested issue for the arctic region, because not only does it put wildlife populations at risk, it also endangers traditional lifestyles based upon both subsistence and commercial fishing. Corporate fishing enterprises have been rapidly replacing small boat fisheries on the arctic coast since the 1970s, and challenge the existence of some coastal communities that are precluded from participation by restrictive access legislation. Large-scale deforestation of Siberia's boreal forests since the disintegration of the Soviet Union is also at issue in not only changing the arctic landscape, but also in the more global concern of contributing to atmospheric warming by eliminating carbon sinks.

According to the Arctic Climate Impact Assessment organization, climate change in the arctic will subject arctic residents in the future to changing weather patterns, melting of sea ice, rising sea levels and coastal erosion, thawing of permafrost, and changes in vegetation, as well as the appearance of new wildlife species or disappearance of others. Changing weather patterns make traditional methods of weather prediction more difficult as the frequency of storms increases, in addition to the potential for disasters caused by both slides and avalanches. Melting sea ice directly impacts the viability of marine mammal populations that use it for a habitat.

However, while climate change places some constraints on arctic peoples, it might also engender opportunities such as the opening of northerly trade routes with a reduction in sea ice. In addition, in some areas, the introduction of new species such as more northerly runs of Pacific salmon would be welcomed changes for some arctic peoples and industries. Traditional livelihoods would alter in other ways, however, such as with a northward shift of the boreal forest, which could result in an expansion of the timber industry. However, this would also entail a reduction in tundra, which would in turn affect traditional pasturelands of arctic reindeer and caribou herds. Despite the environmental challenges arctic residents face from both industrial exploitation of resources and climate change, governance of the region is characterized by a high level of international cooperation for environmental protection. The establishment of the Arctic Council in 1999, for example, brings together members from all eight nations with arctic lands and considerable indigenous participation providing opportunities for comanagement of resources.

Arctic National Wildlife Refuge

THE ARCTIC NATIONAL Wildlife Refuge (ANWR) is located along the Arctic Ocean in Alaska, east of the main North Slope oil fields, and bordering on the U.S.-Canadian (Alaska-Yukon Territory) border. It encompasses over 19 million acres of land. It is home to a great deal of wildlife, and may also contain oil. The federal government created the refuge in 1960, after a campaign by nationally known conservationists and scientists, as the Arctic National Wildlife Range. The range was somewhat smaller than the current refuge; in 1980, the Alaska National Interest Lands Conservation Act (ANILCA) expanded the "range" and made it a "refuge." According to the U.S. Fish and Wildlife Service, which manages ANWR, the refuge contains 45 species of land and marine mammals, perhaps the most famous (and controversial) of which is the vast porcupine caribou herd, the largest of several herds that inhabit the region. The three wild rivers in the refuge also contain 36 species of fish, and at least 180 species of birds.

In enlarging ANWR, the ANILCA created three basic parts of the refuge. Two of them, the refuge and the wilderness area, encompass 17.5 million acres. The remaining 1.5 million acres is the coastal plain, where oil is likely to be available, but which is also the natural habitat of caribou and other species. The coastal plain, known as the "1002 area" after that section of the ANILCA that mandated a study of the wildlife and petroleum resources in the refuge, is the focus of debate over oil exploration in the refuge. Proponents argue that there are between 600,000 and 9.2 million bbl (billions of barrels) of economically recoverable oil in the coastal plain. Opponents argue that production would not exceed 0.8 percent of world production annually, and, would be unlikely to reduce the world price of oil. Natural gas may also be abundant, and plans are underway to build a gas pipeline from the North Slope through Alaska and Canada to southern markets.

ANILCA section 1003 prohibits oil exploration and production in the 1002 area. Congress has the power, however, to repeal section 1003, and has attempted to do so. In 1989 it seemed likely that such an attempt would succeed, but the effort was stopped in its tracks by the *Exxon Valdez* oil spill, which raised questions about the oil industry's ability to responsibly produce and ship oil. In late 2005, congress again attempted to open ANWR, but it failed in the face of a threatened senate filibuster. In 2006 the House of Representatives voted to open up the area in the wake of rapidly escalating oil prices; once again, the senate failed to pass similar legislation. British Petroleum's partial shutdown of its nearby Prudhoe Bay field due to a pipeline leak illustrated the need for more oil production, and the continued environmental problems caused by oil.

Argentina

WITH A LAND area of 2,780,092 square kilometers, Argentina is the second largest country of South America with an estimated population in 2006 of 40 million people. Two main units constitute the physical environment: the Andes in the west, and the much older and eroded Eastern massifs, now reduced to plains. The Andean region can be divided into two mountain ranges. The northern Andes, where the highest elevations are to be found (including the highest peak in the western hemisphere, Aconcagua, at 6,959 meters), are characterized by an arid climate and sparse herbaceous vegetation. The southern Andes, with smaller heights but more rainfall, offer a landscape that is a mosaic of forests, lakes, and glaciers. Eastern Argentina is formed mostly by undulating plains replenished by the alluvial materials of the large Paraná and Paraguay rivers in the so-called Mesopotamia region of the north, and the endless grassy plains of El Chaco and La Pampa toward the center and the south. The fluvial network is dominated by the large Rio de la Plata in the north (formed by the Paraná and the Uruguay rivers), the drainage basin of which exceeds 3.1 million square kilometers.

The recent environmental challenges faced by Argentina are closely related to the country's path since the early 1990s of specializing in the production of raw commodities (especially agricultural and mining products) for the growing demand of the global markets. The expansion of the agricultural frontier (wheat, maize, and increasingly, soybeans, to provide for European and Asian demand) toward the west, as well as the detriment of extensive grazing, has exacerbated traditional problems of soil erosion (about 25 million hectares of cropland and pastures were affected to some degree at the end of the 1990s) and desertification, as well as creating new problems, such as the proliferation of pesticides (between 1992 and 1996, sales of pesticides went from $400 million to almost $800 million). Moreover, Argentina is second in the world (after the United States) in the use of genetically modified crops.

Mining is rapidly expanding in the foothills of the Andean region. The exploitation of copper and gold ores has been facilitated by the substantial incentives given by the Argentine government to foreign companies (especially American, British, Spanish, and French). In 1993, the sector was freed from regulatory hurdles, and exports rose from $200 million in 1996 to $1.2 billion in 2004. Many local communities, however, have complained about the increasing levels of cyanide and other heavy metals found in the streams close to gold and silver operations.

Potential pollution by raw commodity production is also the source of international conflict. In 2006, Argentina requested the intervention of the International Court of The Hague to halt the construction of two polluting pulp and paper factories on the Uruguayan side of the fluvial border between the two countries.

Heavy flooding, especially of the northern rivers, has become a recurrent problem in the last decades of the late 1990s and early 2000s. Uncontrolled urbanization of flood-prone land (above all by poor populations) has contributed to an increased death toll from flooding in the Buenos Aires area and in other cities in the same time period. Some evidence indicates that the flooding may be due to an increase in precipitation and river flows (including a 30 to 40 percent increase in the Paraná and Uruguay Rivers) during the period 1950–2000. Furthermore, the water levels of the Rio de la Plata rose about 17 centimeters during the 20th century. For example, in May 2003, flooding by the Salado River resulted in 900 dead or missing and forced the evacuation of 36,000 in the city of Santa Fe. In 2005, the World Bank approved a substantial credit to finance the construction of flood control works in the capital.

Argentina is home to the oldest protected area in South America (1903) and also the oldest National Park Service (1932). In 2003, about 6.3 percent of the total area of the country was held under some kind of protection. The country has 11 Ramsar sites (wetlands of international importance designated under the Ramsar Convention) and 10 Biosphere Reserves, including spectacular areas such as the Perito Moreno Glacier in the south. Although not forced to do so by the Kyoto Protocol, Argentina has signed a voluntary program to reduce greenhouse gas emissions to combat climate change.

Opening of Patagonia

Humans lived in the southern part of Argentina, and also of Chile, known as Patagonia, from at least the 13th millennium B.C.E. It was first noted by Europeans when Ferdinand Magellan's expedition passed by in 1520. Later, Charles V of Spain (reigned 1516-1556 as "Charles I") conferred western Patagonia on Simón de Alcazaba Sotomayor, who sent Rodrigo de Isla to cross the region. However, his men mutinied and they never explored the whole of Patagonia.

Gradually, during the latter years of the sixteenth century, many more Europeans reached Patagonia, including Francis Drake, who sailed past in 1577 in the first part of his voyage around the world. However, it was not until the late eighteenth century that concerted attempts opened up the region for settlement and for agriculture. The founder of Chile, Bernardo O'Higgins, sent an expedition that formally established the city of Punta Arenas in 1848, six years after O'Higgins had died. It grew quickly, serving as a stopping-off point for the ships taking prospectors to the 1849 Californian Gold Rush. The nearby Argentine city Río Gallegos was founded in 1885.

In the late nineteenth and early twentieth centuries Patagonia—both Chilean and Argentine—were opened up for agriculture with many large sheep farms established. A number of the families there have close connections with those in the Falkland Islands (Islas Malvinas).

In 1921 there was a massive series of strikes in Argentina Patagonia, which were exploited by Anarchists who tried to take power. These were savagely put down by the local landowners, including the well-known Menendez family. Patagonia is now well-known through two books: *The Uttermost Part of the Earth* (1948) by E. Lucas Bridges (1874-1949), and *In Patagonia* (1977) by Bruce Chatwin.

Arid Lands

Growing populations in arid lands exert pressure on local resources, extending cultivation into marginal areas.

ARID LANDS ARE characterized by low rainfall and high evapotranspiration. Depending on definition, they are also referred to as drylands, or alternatively, as one category within drylands. For this purpose, arid lands are described in their broader definition as drylands. Drylands encompass arid, semi-arid, and sub-humid zones where average annual rainfall is lower than total evapotranspiration (classified using the aridity index). Drylands generally exclude true deserts, such as the Sahara, which are considered hyper-arid and are of low productive potential and consequently low population density. Drylands cover 41 percent of the earth's land surface and support more than one-third of its population. Every continent contains drylands that often cover extensive areas. However, they are most extensive in Africa and Asia. Australia, the United States, Russia, and China have large dryland areas. Other countries, such as Botswana, Burkina Faso, Turkmenistan, and Iraq, however, have nearly all of their area classified as drylands. Some of the commonly known drylands include the Sahel (Africa), the Australian Outback, Patagonia (South America), and the Great Plains (North America).

ENVIRONMENT AND POPULATION

Popular misconceptions conceive drylands as empty spaces that are barren and unproductive. In reality, drylands are complex ecosystems with unique biodiversity and environmental goods and services that provide a basis of living for millions of people. Drylands cover a range of ecosystems that are highly heterogeneous in their topography, climate, geology, and biodiversity. Drylands are comprised of deserts (except hyper-arid deserts), grasslands, savannas, shrublands and woodlands, agricultural lands, and urban areas. Plants and animals have to cope with scarce water supplies due to low annual rainfall, high variability, and high temperatures. Most species have adapted to the conditions, such as plants that have deep and extensive root systems and photosynthesize at night, and animals that stay inactive during the day. The lack of reliable rainfall makes other water sources, such as groundwater, streams, and dew, even more important.

Drylands are generally exposed to climate regimes that are not favorable for crop production, as rainfall patterns are unpredictable. Nonetheless, more than two billion people live in drylands, mainly in developing countries. Here, populations are among the poorest in the world. Particularly in Africa, South America, and Asia, inhabitants are heavily dependent on dryland resources to meet their basic needs. Drylands lag far behind in economy, infrastructure, well-being, and development terms. For instance, infant mortality in drylands in developing countries is twice as high as in nondryland areas, and 10 times higher than in developed countries. Moreover, access to clean drinking water and adequate sanitation is inadequate and leads to poor health conditions.

Although drylands are considered marginal for agriculture due to limited water resources, they currently account for more than 40 percent of the global cultivated area. Communities make a living as small-scale farmers or livestock herders and rely on drylands for wood fuel, construction materials, and medicinal plants. However, people are highly vulnerable to periodic droughts and are affected by food insecurity. While the majority of populations live in rural areas, large cities are located in drylands, such as Cairo, Mexico City, Teheran, Cape Town, and Las Vegas. Drylands have supported people's livelihoods for thousands of years. Their communities are highly resilient and have developed sustainable lifestyles and systems allowing them to survive in these harsh conditions and manage limited natural resources. Drylands are also the origin of important food grains (such as wheat, sorghum, barley, and millet).

CHALLENGES AND OPPORTUNITIES

Over time, there have been misunderstandings surrounding drylands and the human impact on these systems. One of the most controversial debates concerns that of land degradation and desertification. During the early 20th century, scientists started raising concern about degradation, blaming vegetation change on overgrazing, deforestation, and unsustainable land management. Global estimates on land degradation in drylands vary considerably anywhere from 20 to 70 percent. The coexistence of high levels of poverty and food insecurity with high rates of land degradation in drylands has led to the understanding that these factors are closely related. This relationship can best be described as a downward spiral of poverty and degradation, where resource-poor farmers place increased pressure on the land, while degradation affects land productivity, leading to a decline in crop yields and contributes to food insecurity. In recent years, however, evidence suggests that the relationship between poverty and land degradation is not always that causal, but highly dependent on local conditions. It is also understood that climate plays a more prominent role than previously assumed.

LIVING IN THE DRYLANDS

Drylands have some of the highest population growth rates in the world. This is not only true in developing countries, but also in the developed world. States in the southwestern United States, such as Nevada and Arizona, have some of the fastest growing populations in the country due to substantial in-migration. Within the context of high growth rates, urban areas are rapidly expanding, and growing demands for food and water have significant impacts on dryland environments. Growing populations are placing increasing pressure on available resources, which may result in the extension of cultivation into more marginal areas. Resource conflicts are increasing and destabilizing people's ability to cope with natural disasters. Land degradation, in combination with increasing populations, may trigger severe food crises in the future. These processes are anticipated to worsen over the next decades, as population growth is likely to exacerbate resource scarcity problems. Continuing oil development and ambitious water developments are anticipated to significantly impact drylands. Moreover, forecasts predict significant impacts of climate change in drylands, where drier and hotter climates are expected. This may affect agricultural potential and food security.

Drylands will continue to supply a range of goods and services and possess comparative advantages that may provide opportunities in the future. If water supplies can be stabilized, drylands provide good conditions for food and forage production. Wild varieties of major food crops are sources of plant genetic materials for developing drought-resistant crops. The potential for alternative energy production is high, through solar and wind power.

Unique landscapes and biodiversity attract tourism. There is also the potential for drylands to act as carbon sinks to mitigate climate change.

Considering their economic importance, geographic extent, environmental diversity, and human welfare, drylands should be placed high on political agendas. Historically, this was rarely the case, due to their remoteness and the perception that drylands are simple ecosystems of little economic value. With population growth, dwindling resources, and climate change, food insecurity in drylands is likely to worsen. The challenge faced by the international community is to sustain growing populations in drylands, while alleviating poverty and safeguarding the environment.

The reduction of poverty in drylands needs to become a priority, particularly within the context of international development efforts (such as the Uited Nations [UN] Millennium Development Goals). The UN declared 2006 the International Year of Deserts and Desertification, creating a platform for discussion and research.

Aristotle

ARISTOTLE, WITH PLATO, were the two Greek philosophers who most influenced Western thought, including views of the natural world. Aristotle's original and systematic compilation of observation and speculation shaped the history of science and philosophy for centuries.

Aristotle wrote treatises on nearly every branch of human knowledge, from politics to poetry. He was profoundly interested in the facts of nature, and his best scientific work includes a number of volumes on biology, which formed the greatest synthesis of his time. Of note are his studies of the anatomy and physiology of Mediterranean animals, which show him to be a keen observer and anatomist. His work was not without error, however. Some of his more improbable ideas appear to have come from secondhand data or folklore.

Aristotle classified animals by genera and species and arranged over 500 of them into hierarchies, some of them having correspondences with modern classification systems. He also wrote on earth science, including observations on the hydrologic cycle, as well as on other terrestrial and celestial phenomena, and he presented a model of cyclical changes in the earth's history over great spans of time.

ARISTOLE'S *SCALA NATURAE*

Aristotle proposed a system to make sense of the relationship between natural beings. His *scala naturae,* or ladder of life, ranks all species from the simplest to the most advanced in terms of their "soul," or organizing principle. Plants were the lowest forms of life on the scale, having a soul that preserves itself. Animals were above, with a soul that allows them sensations, desires, and movement. Humans shared the principles of the ranks below them, but also had a rational element, which was uniquely their own. This teleological system was authoritative in Western thought until at least the 17th century.

Aristotle considered the universe as ultimately perfect, so he did not allow for any empty spaces on this ladder nor for any change in species. This restrictive concept of fixed species was not entirely rejected in science until Darwin's evolutionary theories suggested a more dynamic vision for the natural world.

It is also indicative of Aristotle's failure to recognize that the earth is neither stable nor eternal.

The "ladder of life" analogy is considered anthropocentric in that it encouraged the view that humans are the ultimate beneficiaries of the lower stages on the scale of nature. It also places humans in the privileged position of being the only species having *logos,* or reason. This criticism has been rejected by some philosophers who point to Aristotle's frequent discussions of animal intelligence as evidence that he saw some form of kinship between humans and animals and had a gradual continuum in mind for species, not a series of distinct gaps. Other philosophers argue that Aristotle's ethics provide a basis for concern for others, even nonhumans.

One of the reasons why there is much speculation about Aristotle's views on environmental issues is that he, and most Greek philosophers, said almost nothing about the subject directly. It appears that they did not see their environment as threatened, despite evidence that environmental degradation was occurring in the ancient world. Many environmentalists regard Classical and biblical attitudes toward the environment as insensitive and thus bearing some measure of responsibility for today's ecological crisis. Despite this, several ecophilosophers feel that the writings of the founders of Western philosophy make a positive contribution to discussions of environmental ethics.

Armenia

ALTHOUGH LANDLOCKED, THIS Asian country has 1,400 square kilometers of inland water. The climate of Armenia is highland continental with hot summers and cold winters. Rivers tend to be fast flowing. Much of the terrain is mountainous, with elevations ranging from 400 to 4,090 meters. Because of the mountains, travel within Armenia is often difficult. In addition to frequent droughts, Armenia is subject to occasionally severe earthquakes that damage the environment and threaten human lives. For instance, an earthquake that hit Leninakan (Gyumri) in 1988 cost 25,000 lives.

Armenia's limited mineral resources include small deposits of gold, copper, molybdenum, zinc, and aluminum. After a long period of industrialization and resource exploitation under communism, many Armenians have returned to agrarian production. Approximately 18 percent of the land is arable, and the soil is particularly fertile in the Aras River Valley. Some 45 percent of the population is involved in agriculture. Nevertheless, Armenia imports most of its food.

Around 65 percent of Armenians live in urban areas. With a current population of 2,982,094, Armenia has a negative growth rate (minus 0.25 percent). The per capita income of $5,100 places Armenia in 129th place in world incomes. Experiencing a poverty rate of 43 percent and an unemployment rate of 30 percent, Armenia is still struggling to regain equilibrium as an independent nation.

ENVIRONMENTAL CONCERNS

Eight percent of Armenians do not have sustained access to safe drinking water, and 16 percent do not have access to improved sanitation. The United Nations Development Program (UNDP) Human Development Reports rank Armenia 83rd among 232 nations in overall quality-of-life issues.

Environmental problems, many of them legacies of authoritarian rule and conflict with neighbors, including Azerbaijan, are extensive in Armenia. The soil is heavily polluted from the use of pesticides such as DDT. Around 12.4 percent of land area is forested. Extensive deforestation began during the energy crisis of the 1990s, as Armenians burned trees for firewood. Illegal logging has continued in response to the demand for timber.

The Hrazdan and Aras Rivers are heavily polluted, and drinking water supplies have been threatened by the draining of Lake Sevan as a hydropower source. Desertification has become an issue in certain areas, and the government has replaced parks and other natural areas with homes and businesses. In 2005, the government announced plans to build a major highway through the Shikahogh Nature Reserve, placing 1,000 species of plants and wildlife at risk and destroying tens of thousands of trees.

While 7.6 percent of Armenia's land is protected, reserved areas are vulnerable to the whims of the government. Of 84 endemic species of mammals, 11 are threatened with extinction. Four of 236 species of birds are also endangered. Environmentalists around the globe are greatly concerned about the reopening of the Metsamor nuclear power plant, which closed after the 1988 earthquake.

There is considerable international pressure on the government to shut down the plant. A study by Yale University in 2006 ranked Armenia 69th of 132 countries on environmental performance, slightly below the relevant income and geographic groups. The lowest scores were in the categories of air quality, water resources, and sustainable energy.

The Ministry of Nature Protection, in conjunction with the Ministers of Health, Agriculture, and Urban Development, is responsible for implementing environmental law in Armenia. In the late 1990s, the government passed a bevy of environmental laws within the framework of the National Environmental Action Plan. Particular laws targeted the problems of desertification, ozone depletion, water resource management, and organic pollutants. Since 2000, new laws have been enacted that include land, water, and mineral resources code. Additional modernization of environmental laws is underway.

Armenia has signed the following international agreements: Air Pollution, Biodiversity, Climate Change, Kyoto Protocol, Desertification, Hazardous Wastes, Law of the Sea, Ozone Layer Protection, and Wetlands. The agreement on Air Pollution–Persistent Organic Pollutants has been signed but not ratified.

Army Corps of Engineers (U.S.)

FOLLOWING THE Revolutionary War, where military engineering proved important to American independence, President George Washington and Congress recognized the need for a group of experts to help the American armed forces and the early Republic. The Continental Congress had organized this corps of the army in 1775, and the U.S. Congress followed suit with its formal legal creation in 1802. Over the next 40 years, the corps was repeatedly disbanded and reestablished according to need. While the corps distinguished itself in military activities throughout the 19th century, the corp's development coincided with the great period of westward expansion and economic growth, especially through the development of harbors and waterways, which would become the agency's central task for the next century and a half.

In its early stages, the Army Corps of Engineers were central to exploration in the U.S. West, including expeditions through the Rocky Mountains. They also surveyed the lines for the earliest western railroads. So too, they assisted in the planning and construction of important public buildings, especially construction projects in the area of Washington, D.C., such as the Capitol, the General Post Office, the city's aqueducts, the custom houses, and the marine hospitals.

The main objectives of the corps, however, came to relate to matters of river and harbor improvement and the interest of commerce and speedy transit between locations. The corps was crucial in the planning and construction of the Panama Canal, coastal surveys, and planning and construction of lighthouses. In addition to water infrastructure, this mandate expanded over time to include services in the area of responses to natural and manmade disasters and environmental management and restoration. An important part of civil works is the maintenance and improvement of channels of water to help with their navigation. The corps also works to protect against flood damage to areas where high amounts of wreckage are prone to occur. They advise communities on zoning regulations and warn people about possible flooding conditions in their area. During the period from 1991 to 2000, the United States suffered from $45 billion worth of property damage, and the Corps of Engineers estimates that they prevented more than $208 billion of further damage.

EMERGENCY RESPONSE

The Corps of Engineers also responds to such disasters and emergencies on state and local levels. Most of these situations involve water emergencies and the corps conducts their activities under the Stafford Disaster and Emergency Assistance Act and the Flood and Coastal Emergency Act. Water research and development is another program supported by the corps for the general public. The facilities set up by the corps conduct research in areas like water systems, soil and rock mechanics, earthquake engineering, coastal engineering, and also the effects of weapons on specific structures.

Perhaps the Army Corp's greatest challenge has been its mission, assigned since 1850, to manage flooding on the Mississippi River. It has done so through the construction of a complex system of locks, dams, and levees that have fundamentally transformed the river into a tame transportation system. The costs of doing so have included the destruction of a great many wetlands and the creation of many high maintenance locations where levees hold back flood waters against growing populations, as in New Orleans.

At times, this development-oriented mission has put the corps into conflict with both environmental interests and political agencies and offices. Most notably in 1977, shortly after the election of President James Earl Carter—himself an engineer—announced his intention to de-fund 19 planned water development projects (predominantly dams), eleven of which were Army Corps projects. Through their congressional allies on the appropriations committee, the corps was able to maintain its ongoing projects and actually extend funding for new water management projects over the next year. The successful showdown with the president shows the power and independence of the Army Corps and the way its development-oriented mandate has aided in building alliances for protection of its federally budgeted projects. Nevertheless, it remains a target of the environmental community, who continue to associate the corps with destruction of native waterways and habitat. An increased effort on the part of the corps to reach out to this community has yielded only limited results.

The corps has demonstrated remarkable adaptivity, however, in the face of changing political and environmental conditions. While maintaining its military mission, it has expanded its domestic mission, and come to face continued challenges to its budgets and existence by taking on more new responsibilities. When the National Environmental Policy Act was passed in 1969, for example, with its added burden of environmental impact assessments for all federal activities, the corps embraced the problem and revised its procedures to become one of the key providers of such assessments for the government.

A further example of this adaptation is the remarkable turnaround of the corps from a dredger and filler of wetlands to an agency that now protects and constructs them. Through Section 404 of the Clean Water Act, of 1972, the corps became a key provisioner of permits for dredging and filling wetlands, and an agency increasingly associated with conservation efforts. Indeed, the U.S. Army Corps of Engineers has come to be a specialist in ecosystem restoration, environmental stewardship such as protecting wildlife habitats from pollution and wetlands and waterway regulation. The corps also assists in the cleanup of sites that are contaminated with hazardous and radioactive waste.

The U.S. Army Corps of Engineers is currently made up of approximately 34,600 civilian members and 650 military members. Some of these people include biologists, hydrologists, geologists, engineers, and scientists. The corps headquarters is in Washington, D.C., and there is another satellite headquarters in Alexandria, VA. The corps is separated into eight divisions and is supported by 41 local districts.

Arsenic

ARSENIC IS AN elemental metalloid that has an atomic number of 33 and symbol "As" in the periodic table. Its name originates from the Greek word *Arsenikon* (meaning potent). It is a common element found in nature, although not in its pure elemental form but rather in ores and sulfides. Arsenic is commonly found in geologic sediments and rocks, generally in the forms of arsenopyrite, orpiment, realgar, lollingite, and tennantite. Arsenic is usually a grayish or yellowish element, and it sublimes into its oxide form upon heating.

Arsenic occurs in high amounts in the sediments of many countries, most notably Bangladesh, India, Cambodia, Laos, Vietnam, China, the United States (primarily the southwest), and Argentina.

Arsenic is commonly used in pesticides, herbicides, alloys, and semiconductor material. It has historically has been used in paint (e.g., Paris Green), pressure-treated wood, cosmetics, and antibiotics (among various other medicinal purposes). However, such uses have largely been discontinued due to the toxic nature of arsenic. Arsenic is extremely poisonous, and small quantities can kill instantly. As such, arsenic has often been called the "king of poisons" and the "poison of kings," due to its historical use in alleged and real deaths and murders, and difficulty of detection. Arsenic has been linked to the deaths of famous figures, such as Napoleon Bonaparte and King George III.

ARSENIC CONTAMINATION

In recent years, concerns about arsenic in groundwater and drinking water supplies have become a major concern. The World Health Organization (WHO) advises that drinking water should not have more than 10 microgram/liter (or parts per billion, ppb) of arsenic, as higher doses can prove to be cumulatively toxic. Arsenic ingestion can lead to gastrointestinal problems, headaches, and nausea when in smaller doses, but higher doses and chronic poisoning can lead to melanosis and keratosis of the skin, liver and kidney failure, heart problems, gangrenes, cancer, and eventually death. As such, small quantities of arsenic in drinking water (from naturally occurring arsenic in the geology or from agricultural and industrial pollution) can lead to various health symptoms of arsenic poisoning (also often called arsenicosis) over numbers of years.

One of the worst cases of arsenic poisoning is in Bangladesh, where over 35 million people are consuming well water with high concentrations of arsenic. The arsenic in geologic deposits has shown up in high concentrations in groundwater that is predominantly used for drinking water and irrigation purposes. Tests of well water have shown that over

2 million tubewells contain arsenic that is greater than the Bangladesh government's standards of allowable arsenic (at 50 microgram/liter or 50 ppb); note that this standard is not the same as the WHO's standard. Drinking water with more than 50 ppb of arsenic generally means that the person has one in 100 chance of getting cancer; presently there are over 40,000 arsenicosis patients in Bangladesh; the figures are expected to rise as more patients are identified, and because symptoms can take 5 to 15 years to fully manifest themselves. Given the large number of people currently consuming poisoned water with inadequate alternative water sources, the WHO has termed the case the "worst mass poisoning of a people in history." Present attempts to provide safe water include removing arsenic from contaminated water and nongroundwater-based water options.

In the United States, arsenic in drinking water supplies caused considerable debate in the last few years. The change of government standards from 50 ppb to 10 ppb meant a greater investment in removal costs. Some politicians argued that the standard should have been below 10 ppb, in order to make water more arsenic-free; the costs involved as well as the lack of compelling need to do so are generally argued to be reasons of retaining the WHO's recommended standard. How much arsenic is deemed safe is thus both a scientific and technological issue as well as an economic and political one.

Asbestos

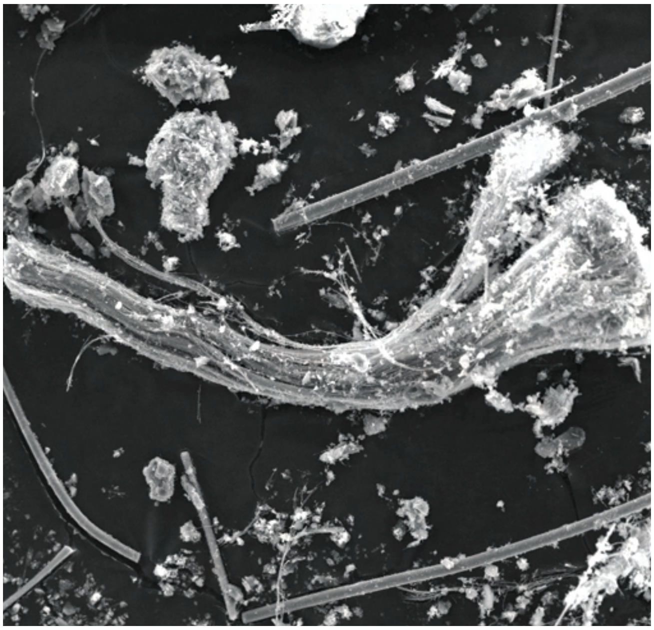
ASBESTOS IS A mineral that is separable into long and thin fibers and was used extensively in building work. Because of its toxic effects, asbestos has subsequently been phased out of uses in which it comes into contact with people, although lingering health impacts remain, as do issues concerning litigation and liability.

Although there are several different minerals that can be considered to be asbestos, the overwhelming proportion is in the form of Chrysotile ($Mg_3Si_2O_5(OH)_4$), which is a hydrous magnesium silicate known for thousands of years to be resistant to fire and also possibly injurious to health. Asbestos appears in its chrysotile form as a white fibrous mineral. Two other forms of asbestos, blue asbestos (Crocidolite) and brown asbestos (Amosite) are also important in industry and are known to be more dangerous than white asbestos.

Asbestos-bearing rock is quarried from mines and then crushed and blown to free the fibers from the accompanying rock. The longest fibers are spun into yarn, while the shorter ones are converted into various building materials, some mixed with concrete. It is the qualities of resistance to flame and chemicals that makes asbestos usage so popular with building materials and thousands of other applications. Although in itself it is difficult to work with, because of its physical characteristics, asbestos does mix well with other substances, which makes it much more versatile. Together with cotton, it has been used to form fabrics for applications such as brake linings, insulation, and safety clothing. Public buildings in many countries have been lined with asbestos for flame retardant purposes, as too were many public housing units.

PRODUCTION

Industrial-scale production began in Italy during the nineteenth century, with mines subsequently opened in many countries. The principal producers of asbestos became Canada, particularly Quebec and the Urals region of Russia. Production has subsequently declined as new health and safety regulations have restricted its use in most countries. Mine production of 3.5 million tons of asbestos in 1996 is not likely to



Chrysotile asbestos, detected in trace levels in dust and airfall debris at the World Trade Center site after 9/11.

be exceeded in the future, although production continued in earnest in China, in particular, including at several forced labor camps. Statistics about asbestosis and asbestos-related lung cancers from China are, unsurprisingly, not freely available.

INDUSTRIAL RESPONSIBILITY

Breathing in asbestos fibers leads to a lung condition known as asbestosis or the form of lung cancer known as mesothelioma, which is a deadly and swift-acting disease. Prolonged exposure to asbestos, such as living in a house in which asbestos has been used for insulation, can be sufficient for asbestosis to be caused. It was not until the 1970s that sufficient information became available for definitive judgments concerning the dangers posed by asbestos and, since then, regulations discouraging and then preventing its use have been introduced into many countries of the world.

However, this progress remains very slow, and thousands are killed annually by exposure to the substance. Moreover, the long latency periods between inhalation of asbestos fibers and the onset of disease, and the tardiness in implementing bans in the past, means that more deaths are expected in the future. The International Labour Organisation (ILO), for example, estimates that around 100,000 people contract diseases annually because of work-related asbestos exposure. Deaths in developed countries will be intense as well, since asbestos has been used in many public buildings. The extent to which this occurs was revealed around the time of the 9/11 terrorist attacks in the United States, when the concentrations of asbestos in many buildings became part of the public domain for the first time. Issues surrounding liability in terms of exposure to asbestos remain unresolved in the United States, where corporate interests have been trying to limit responsibility. The engineering company Halliburton made a $4.2 billion settlement to claimants in 2004 as a result of suits field against a business it had previously purchased. Some have claimed that asbestos exposure may prove to be the largest potential burden for business in the foreseeable future.

Although new uses of asbestos are inhibited in most parts of the world, exposure still occurs when buildings are demolished and the insulation revealed, or else ship breaking or similar industrial activities undertaken. Clearly, the poor workers of the world are disproportionately likely to suffer from this exposure because safety equipment and policy is expensive and may be difficult to obtain. Disincentives exist, therefore, and tend to discriminate against the poor and the vulnerable. Some countries, notably Canada, where asbestos mining remains an important industry, have been slow to introduce regulations to restrict the export and use of the substance, and have continued to promote its use in other countries.

Aswan High Dam

LOCATED ON THE Nile River, just north of the border between Egypt and the Sudan, the Aswan High Dam slows the flow of the Nile River northward through Egypt. Finished in 1971, the dam controls flooding, insures a reliable and regular water supply to irrigated farms along the river, and provides hydroelectric power and water for human consumption and industrial use to the rapidly expanding populations of Cairo and other cities of Egypt. Behind the dam lies Lake Nasser, which contains some 200 billion cubic feet of water and is about 500 kilometers long and, on average, 12 kilometers wide.

Like most major dam projects, the Aswan High Dam has attracted many critics since the initial announcement of the plans for its construction. Environmentalists have worried about the effects on the river's ecological balance. Cultural observers have expressed concerns about the effects on people displaced by Lake Nasser. And antiquarians have bemoaned the loss of identified but as yet unexcavated archaeological sites.

FLOODING

In most years, the annual flooding of the Nile was a boon to Egyptian farmers. But at regular intervals, heavy floods washed away their crops, or drought dramatically lowered the river level and made it very difficult for farmers to fill their irrigation canals. The dam permits controlled and year-round releases of water. As a result, Egyptian farmers have been able to increase their output from one to three harvests per year, depending on the crop.

In addition, more than 950,000 million acres of newly irrigated land have been brought into production. On the downside, the dam has encouraged urban growth, which has eliminated about 600,000 acres formerly devoted to agriculture. Moreover, the controlled flow of the river has reduced the delta-building that formerly resulted from the river's heavy seasonal flooding. In fact, the reduction in the silt carried seaward by the Nile has resulted in increased erosion of the existing delta and adjacent shoreline. Along the river below the dam, the water table has risen, causing a buildup of salts in the soil that reduces fertility.

The construction of the dam has meant the demise of the sardine fishing industry in the Nile, but increased catches in the waters off the Nile delta have been attributed to concentrations of nutrients caused by the dam, and the development of a major fishing industry in Lake Nasser remains a promising if as yet unrealized possibility. The dam has dramatically increased the growth of vegetation in downstream stretches of the river, but that vegetation has been harvested for agricultural use as compost.

PUBLIC HEALTH EFFECTS

The dam has produced similarly mixed effects in terms of public health. On the one hand, the project has been a public-health blessing, ensuring that Egypt's population will have the sort of reliable water supply that is the most important factor in reducing the incidence of diseases—such as enteritis and hepatitis—that plague Third World nations and reduce their economic output. On the other hand, the expansion of perennial irrigation following the construction of the dam facilitated the spread of the gambiae mosquito, a key carrier of malaria, which became the focus of a resulting national health campaign. So too, the concentration of this water supply in one place also increases the incidence of other waterborne parasitic diseases such as schistosomiasis.

Ironically, the people most likely to experience increased incidences of these parasitic diseases have been the 100,000 Nubians who were forced to relocate when Lake Nasser covered the sites of their former villages and towns. In the end, the most dire predictions about increases in waterborne parasitic diseases have not proven accurate—in large part because the dam has made possible the increased development of water treatment plants and the broader availability of safe drinking water. But the tradeoffs of the Aswan High Dam demonstrate that while large-scale technologies solve environmental problems, their unintended consequences inevitably cause some as well.

Atlantic Ocean

THE ATLANTIC OCEAN forms a broad s-shape from the Arctic Sea to the north and from Antarctica to the south. North America and South America are to the west; Europe and Africa are to the east. It is about half the size of the Pacific Ocean and slightly larger than the Indian Ocean. It covers 31,800,000 square miles (36,000,000 square kilometers) or 16 percent of the Earth's surface. If marginal seas are included, the coverage is nearly 20 percent. The ocean's principle marginal seas are the Caribbean Sea, the Gulf of Mexico, and the Hudson and Baffin bays to the west; the Arctic, Greenland, and Norwegian seas to the North; the Baltic, North, Mediterranean, and Black Seas to the east; and the Weddell Sea to the south. The Atlantic Ocean proper refers to the ocean minus its marginal seas.

The equator divides the Atlantic Ocean into the North Atlantic and the South Atlantic. Drake Passage (between the island of Tierra del Fuego and Antarctica) and the Magellan Strait (between Tierra del Fuego and South America) connects the South Atlantic to the Pacific Ocean. A broad stretch of water separating Africa and Antarctica connects the South Atlantic to the Indian Ocean. The North Atlantic's connection to the Pacific Ocean follows a circuitous series of straits among the northern Canadian islands to the Arctic Sea and thence to the Bering Strait.

Plate tectonics have given rise to the general topography of the seafloor. The gigantic north-south trending Mid-Atlantic spreading ridge makes up about one-third of the sea bottom and divides the Atlantic Ocean rather evenly into western and eastern halves. The ridge in most places rises to within

South Georgia is an island in the South Atlantic Ocean, about 1,300 kilometers east of the Falkland Islands.

about 1.5 miles (2.5 kilometers) of the surface and occasionally breaches the surface to form prominent oceanic islands: Iceland, the Azores, Ascension, St. Helena, and Tristan da Cuhna. On either side of the ridge are abyssal plains. The plains extend from the base of the mid-ocean ridge to the base of adjoining continents. The name "plain" implies that this part of the seafloor is a monotonous, uninteresting place. Actually, abyssal plains are remarkable for their deep sediments and life forms. On the landward sides of the plains, the sea bottom rises gently landward as continental shelves (submerged portions of continents). The average depth of abyssal plains is about 4 miles (6.5 kilometers). The ocean's average depth (without its marginal seas) is about 2.5 miles (4 kilometers), owing mainly to the Atlantic Ocean's broad, shallow continental shelves, which make up 13 percent of the Atlantic Ocean proper. The greatest depth (28,224 feet or 8,605 meters) is Milwaukee Deep, in the Puerto Rico Trench, north of Puerto Rico.

Available solar energy, which decreases with increasing latitude, affects the ocean's climate as well as its temperature and salinity levels. The high sun angles of the equatorial latitudes create warm tropical waters, a belt of low surface pressure, convergent trade winds, and convective thunderstorms. Salinity levels in this zone are especially low where large rivers—such as the Amazon, Orinoco, Niger and Congo Rivers—empty freshwater from the heavy rains into the sea. Moreover, the broad extent of tropical waters in the North Atlantic serve as the repository of heat energy that feeds an annual supply of tropical storms and hurricanes there.

Poleward of the equatorial low-pressure belt are subtropical high-pressure cells in each hemisphere. The high pressure inhibits cloud formation, so the annual rates of evaporation and salinity levels are high there. In the middle and subpolar latitudes, cyclonic storms form over the oceans. The storms generate above-average wave heights that are hazardous to ships and coastlines.

In polar latitudes, the air is formidably cold due to low sun angles and long winter days. The cold air pulls prodigious amounts of heat from the ocean, causing water temperatures to drop at or near the freezing mark. Salinity levels at these latitudes are high due to sea ice formation, which leaves salts concentrated in the remaining seawater. Icebergs shed from glaciers on Greenland and Baffin Island in the North Atlantic; and from Antarctica in the South Atlantic, venture into the middle latitudes as far as 40 degrees N and 50 degrees S latitudes before melting.

CURRENTS

Due to the Coriolis effect on wind-driven surface currents, major currents in the North Atlantic flow clockwise, whereas those in the South Atlantic travel counterclockwise. Each of these broad circulating loops (gyres) has an equatorial current component that flows parallel to the equator, a warm current section that carries tropical heat to polar latitudes, and a cold current that returns to the equator to store more heat from the tropical sun. The circulating water moderates the global temperatures by absorbing and transferring surplus tropical heat to polar regions. The Atlantic Ocean is also part of a global conveyor belt of Thermohaline (vertical) circulation that affects the global climate.

The Atlantic Ocean has continental, oceanic, and coral islands. The largest continental islands are made of bedrock exposures, such as Great Britain, Ireland, Greenland, and Newfoundland. Glacial deposits form smaller islands, such as Long Island (New York) and Martha's Vineyard (Massachusetts); barrier island deposits make up Hilton Head (North Carolina), Chincoteague (Virginia), and Fire (New York) islands.

Oceanic islands rise from the deep ocean floor rather than a continental shelf and are usually of volcanic origin. Atlantic examples of oceanic islands include the Azores Islands, the Canary Islands, the Cape Verde Islands, Iceland, and the Lesser Antilles. Coral islands can be of either the continental or the oceanic type. Most of those in the Atlantic Ocean are the high parts of a large limestone platform situated on continental shelves. The Bahamas and Florida Keys are examples of this type. Oceanic coral islands sit atop submerged volcanoes and are most typical of the western Pacific Ocean; Bermuda is an example of this island type in the Atlantic Ocean.

Atmosphere

THE ATMOSPHERE IS an envelope of gases surrounding the solid earth. This mixture of gases provides the oxygen we need to live and is responsible for the global diversity of weather phenomena. In addition, the atmosphere protects life on the earth's surface from the harmful effects of high-energy solar radiation and keeps the average temperature of the earth at a life-sustaining level through the natural greenhouse effect.

Although the atmosphere is a fluid, it is prevented from escaping out to space by the force of gravity. This downward gravitational pull compresses the lower atmosphere, meaning that atmospheric density is highest near sea level and decreases as one ascends. As a result, most of the atmosphere is held very close to the earth's surface; approximately 90 percent of the atmosphere is within a mere 16 kilometers (10 miles) of sea level. The atmosphere doesn't have a real top—it fades away gradually as one moves away from the planet.

Atmospheric pressure is due to the weight of the overlying atmosphere pulled down by gravity. At sea level, with the entire atmosphere above us, atmospheric pressure is approximately 1,013 millibars, or 14.7 pounds per square inch (psi). As we move higher, there is less atmosphere above us, and so atmospheric pressure decreases with height. At 35,000 feet, the altitude of a typical cross-country airline flight, the air pressure will be only about 20 percent of the value at sea level.

COMPOSITION OF THE ATMOSPHERE

The composition of the atmosphere is dominated by three gases: nitrogen, oxygen, and argon. These gases are called "permanent gases" because their concentrations are nearly constant over time and space. Nitrogen (78 percent of the atmosphere) and argon (1 percent) are largely inert, meaning that they are used in very few geophysical or biological processes. Oxygen, which is crucial for nearly all life on earth, accounts for about 20 percent of dry air.

In addition to the permanent gases, there are several other gases known as "variable gases," which show up in changing amounts over time and space. Two of the most important variable gases are carbon dioxide and methane, both of which are potent greenhouse gases. The third, extremely important variable gas is water vapor, which is a strong greenhouse gas and is necessary for the formation of clouds and precipitation.

While air pressure shows a simple pattern of decreasing with height, another important atmospheric variable—temperature—exhibits a more complex vertical pattern. Changes in temperature above sea level allow us to divide the atmosphere into four layers: the troposphere, stratosphere, mesosphere, and thermosphere.

The source of the energy that warms the earth, drives the circulation of the atmosphere and ocean, and makes life possible is the sun. Energy travels from the sun to the earth in the form of electromagnetic (EM) radiation. Solar radiation is often referred to as "shortwave radiation," because the sun mainly emits radiation like visible light and ultraviolet (UV) radiation, which are characterized as having relatively short wavelengths. The atmosphere is largely transparent to these types of radiation, so most solar energy passes through the atmosphere and is absorbed by the earth's surface, which causes the surface to warm up.

As the earth's surface warms, it transfers energy to the overlying atmosphere through conduction and radiation. Because the main source of heat for the lower atmosphere is actually the ground, atmospheric temperature decreases with ascention, up to an elevation of about 12 kilometers (7.5 miles). This lower layer of the atmosphere, which contains nearly all weather phenomena, is called the troposphere.

Above the troposphere, atmospheric temperature begins to increase with height, in a layer known as the stratosphere. This layer contains most of the ozone (tri-atomic oxygen) in the atmosphere. Ozone is very good at absorbing the most dangerous forms of UV radiation. Because ozone in the stratosphere absorbs a significant amount of UV energy, the stratosphere gets warmer as you ascend through the ozone layer. The absorption of harmful UV radiation in the stratosphere provides protection to life at the surface.

The stratosphere continues up to a height of about 50 kilometers (31 miles). Above the stratosphere is the mesosphere (50–80 kilometers), which, like the troposphere, is characterized by decreasing temperature with height. Above the mesosphere is the thermosphere, which shows increasing temperature with height until the atmosphere eventually fades away. The mesosphere and the thermosphere together contain only about 0.1 percent of the atmosphere.

Compared to the sun, the earth emits what is referred to as "longwave radiation," which refers to forms of EM radiation like thermal infrared that have longer wavelengths than UV and visible light. The atmosphere is much less transparent to longwave radiation than it is to shortwave radiation, and so much of the energy emitted by the earth is absorbed by the atmosphere. The gases that are responsible for this absorption of longwave radiation are called greenhouse gases, and water vapor, carbon dioxide, and methane are the most prominent. The atmosphere also radiates longwave energy, and some of this radiation travels downward to the surface. This exchange of energy between the lower atmosphere and the earth's surface is the greenhouse effect, and it results in the earth's surface being about 30 degrees Celsius (54 degrees Fahrenheit) warmer than it would be without an atmosphere.

HUMAN IMPACT

Over the past century, human activities have had several important impacts on the atmosphere. The first of these is global warming, or the enhanced greenhouse effect. Various human activities such as the burning of fossil fuels, forest clearing, and agriculture have increased the atmospheric concentrations of greenhouse gases like carbon dioxide and methane. With more of these gases in the atmosphere, more longwave energy is absorbed, which causes the temperature of the lower atmosphere to rise. The average global temperature has increased by approximately 0.6 of a degree Celsius (1.1 degrees Fahrenheit) over the past century, and much of this warming is due to human-caused greenhouse gas increases. There have been many attempts to reach an international consensus on reducing greenhouse gases, including the Kyoto Protocol (1997). However, the United States, the world's largest emitter of greenhouse gases, has not signed on to the treaty.

The second major impact that humans have had on the atmosphere is the depletion of the ozone layer. Synthetic chemicals known as chlorofluorocarbons (CFCs) have been widely used as coolants, solvents, and propellants in aerosol sprays. Unfortunately, some of the CFCs released at the surface mix upward to the ozone layer. There, CFCs combine with and break apart ozone molecules, causing a thinning of the ozone layer. Ozone depletion was first noticed over Antarctica but has been observed over the northern hemisphere as well. Without the protection of the ozone layer, more damaging UV radiation reaches the surface, leading to increased occurrences of skin cancer and cataracts in humans, as well as having detrimental effects on animal and plant life. The dangers of ozone depletion were recognized in the 1970s, and an international agreement to phase out CFCs known as the Montreal Protocol was reached in 1987. Although the Montreal Protocol has successfully reduced CFC emissions, the concentrations of these gases in the stratosphere will remain high for decades, and the damage to the ozone layer will be slow to heal.

Atmospheric Science

ATMOSPHERIC SCIENCE IS the study of the atmosphere and the processes that take place within it. It has traditionally been divided into three related but separate disciplines: climatology, meteorology, and aeronomy. Climatology focuses on the statistical analysis of changes within layers of the atmosphere for extended periods, ranging up to centuries long or more. Meteorology relates to the short-term changes in the conditions of the lower layers of the atmosphere. Aeronomy, in contrast, focuses on the changes and dynamic processes taking place within the upper layers of the atmosphere above the troposphere.

Topics within atmospheric science include the chemistry of the atmosphere, the radiative processes that determine the distribution of heat within the atmosphere, and the formation and behavior of clouds. Since a number of important indicators and effects of climate change and future climate change are observed within the atmosphere, scientists working in this field have become in some cases embroiled in controversy.

While there is a broad consensus among scientists as to the impact of global climate change and its interrelationship with the actions of man, there are some who disagree and some who, motivated by political or financial reasons, attempt to obfuscate the reality of scientific data. Atmospheric science contributes to the investigation by providing rigorous collection of data, interpretation of trends, and provision of a suitable context for understanding climatologic phenomena. Understanding of these phenomena is limited by the paucity of high-quality data sets for many parts of the world dating to more than a few decades ago. Trying to rectify this lack of data has led scientists to add new types of data to try to monitor atmospheric change in the past.

Atmospheric scientists have broadened the scope of the science to also include the study of the atmospheres of other planets and of aspects of planetary science in general. The improvements in computational and observational technologies have been of considerable importance in developing these fields of study. This is particularly true in the area of computer modeling of other planets, as well as the atmospheric change that may be taking place in the future. This form of modeling is very complex because the weather system is chaotic and subject to variables which are difficult to capture effectively. This complexity has facilitated the politicization of the subject because there are so many different arguments that can be made and which are difficult to refute without extensive data collection and analysis.

Atrazine

ATRAZINE IS A white, crystalline, solid, organic compound that is soluble in water and does not exist naturally in the environment. When pure, it is odorless and not very volatile, reactive, or flammable. It is widely used as a selective herbicide to prevent and/or to stop the growth of broadleaf and grassy weeds in crops—corn, sorghum, sugarcane, pineapples, macadamia nuts, soybeans, etc.—and in conifer reforestation plantings. It is also employed as a nonselective herbicide on highway and railroad rights-of-way, noncropped industrial lands, and fallow lands.

Atrazine was deemed to be the most widely used herbicide in the United States from 1987–89, but presently its uses are greatly restricted. Classified as Toxicity Class III—slightly toxic—it is not available to the general public and may be purchased and applied only by certified users.

Atrazine enters the environment primarily through spraying on farm crops, but may also be found in soils as a result of its formulation, manufacture, and disposal. If it enters the soil, it may be taken up by the plants growing in the ground or broken down by microbial activity and other chemicals, particularly in alkaline conditions, even if biodegradation takes a long time. If it enters the air, it may travel as far as 186 miles (300 km) from the application area, or it may be broken down or adhere to particles, such as dust, and then settle. If it is washed from soil into streams or groundwater, it will remain there for a long time, as its breakdown in water is quite slow.

While the general population is not habitually exposed to Atrazine, farm workers, chemical sprayers, and manufacturing and railway workers may be regularly exposed to it. Therefore, the Occupational

Safety and Health Administration (OSHA) has set limits of Atrazine content in workplace air: five mg/m³ for an eight-hour workday and a 40-hour workweek. Individuals who drink water from wells that are contaminated with Atrazine may also be exposed to the chemical. To protect human health, the Environmental Protection Agency (EPA) has set nonenforceable levels for chemicals that do or may cause health problems in drinking water for all public water supplies: The maximum contaminant level for Atrazine is set at three parts per billion.

HEATH AND ENVIRONMENTAL IMPACTS

Although Atrazine does not tend to concentrate in living organisms such as clams or fish, the EPA has also set maximum levels allowed in foods at 0.02-15 parts Atrazine per million. In specific circumstances, people who absorb Atrazine orally, by inhalation, or through the skin may suffer from some or all of these acute poisoning symptoms: abdominal pain, diarrhea, vomiting, eye and mucous membrane irritation, and skin reactions.

Studies on animals have shown that exposure to high levels of Atrazine for relatively short periods of time can provoke in some species damage to the heart, liver, lungs, kidneys, and adrenal glands as well as blood pressure alterations, muscle spasms, and weight loss. In laboratory animals, a lifetime exposure to high levels of Atrazine can cause reproductive and cardiovascular damage, retinal and muscle degeneration, and cancer. However, Atrazine is not expected to have similar effects on human health because of specific biological differences between humans and test animals.

Audubon Society

AMONG THE OLDEST and largest national conservation organizations in the world, the Audubon Society maintains a century-long commitment to protecting birds and other wildlife through a network of state chapters and regional centers. The National Audubon Society sponsors annual Christmas Bird Counts, publishes the definitive Peterson's Wildlife Guides as well as other books and magazines about nature including the magazine *Audubon*, and sponsors and actively lobbies for environmental legislation. The Audubon Society also maintains local chapters in each of the fifty states, the U.S. Virgin Islands, and nine Latin American nations that promote citizen science, education, and outreach.

INITIAL SOCIETIES

The first Audubon Societies were direct descendants of the scholarly American Ornithologist's Union (AOU), founded in Cambridge, Massachusetts in September of 1883. Concerns that professional hunters were bringing many species of birds to the verge of extinction unified the membership the following year, and they began definite actions towards conservation. Identifying the largest portion of the slaughter of birds as supplying the millinery and fashion trade, the AOU members drafted and endorsed a model bird protection law, and encouraged the formation of bird protection societies and antibird-wearing leagues.

In February of 1886, AOU member and publisher George Bird Grinnel used his magazine *Forest and Stream* to promote the formation of conservation clubs to educate the public and denounce the wearing of bird products. Grinnel also suggested that the clubs be named Audubon Societies, after the famed naturalist and painter John James Audubon (1785–1851). Within a year, Grinnel began publication of *Audubon Magazine* as the organ of the rapidly growing organization, which already counted 300 local chapters and 18,000 pledged members. But the lack of a central authority and treasury undermined the attempt, the magazine ceased publication after only one year, and this first attempt at a national Audubon movement stalled out.

Although the first effort failed, the purpose and ideals of the Audubon Movement continued, and on February 19, 1896, the cousins Harriet Hemenway and Minna B. Hall organized the Massachusetts Audubon Society with the sole purpose to convince the ladies of fashion in Boston to forgo wearing plumes and other bird products. Their success prompted the revival of Audubon societies across the United States, and with the regularization of dues and a centralized treasury, the Society was able to fund the publication of *Bird Lore* magazine, a bi-monthly devoted to the study and protection of birds and renamed *Audubon Magazine* in 1941. Organized at a national level in 1905, the National Audubon Society was highly visible in the key conservation campaigns of the twentieth century, including the passage of protection acts for migratory birds throughout the western hemisphere, species reintroduction, and wilderness protection.

ANTI-DDT CAMPAIGN

In perhaps its most famous campaign, the National Audubon Society was in the forefront of the fight to ban organochlorine insecticides, especially DDT, in the wake of the publication of Rachel Carson's *Silent Spring* (1962). The Society highlighted the connection between the decline in bald eagle populations and the indiscriminate use of chemical pesticides, and made the banning of DDT a matter of national pride. With many other conservation groups, the Audubon Society was able to claim victory in 1972 when DDT was banned in the United States followed by a dramatic recovery in eagle populations. Faced with stagnant membership numbers and increasing competition from other conservation organizations, the Audubon Society is planning to step back from general environmental advocacy to a more focused emphasis upon community education and building grassroots advocacy for its core issues of wildlife conservation.

Australia

AUSTRALIA IS THE world's sixth largest country by land area (7,692,024 square kilometers, excluding external territories), but is sparsely populated. 86.2 percent of the population of just over twenty million people lives in one percent of the land area of the continent. This is mostly near the east coast, with a smaller population concentration in the south-west corner. The average population density of the country is less than two people per square kilometer, which is very low compared to 26 people per square kilometer in the United States and 238 people per square kilometer in Britain. Australia, in the southern hemisphere, is the driest of the inhabited continents, with much of the country being classified as arid or semi-arid. Inland settlements are often based on mining activities. Australia has 36,700 kilometers of coastline.

Australia has been home to indigenous people for at least 40,000 years. While sometimes known collectively as Aborigines, the diversity of indigenous peoples should be recognized, and the Torres Strait Islander people should also be considered as indigenous. This diversity is highlighted in the variety of languages that were present in Australia. There were about 250 Aboriginal languages at the time of European incursion into Australia; further division into dialect differences gives some 600 distinct linguistic varieties. This makes Aboriginal Australia one of the most diverse areas of the world linguistically, and in some districts an 80-kilometer journey will pass through the territories of three languages less closely related than English, Russian, and Hindi," explains language scholar Nicholas Evans.

The country of Australia is a federation of six states which were former colonies of Britain. There are also a number of territories, including two self-governing territories. These are the Northern Territory (where Darwin is the largest city and capital) and the Australian Capital Territory, which is the location of the national capital of Canberra. In 1901 Australia had a population of 3,773,801, excluding indigenous people who were not counted in the Census. The largest city was Sydney, with a population of 496,000. Other significant cities included Melbourne (478,000), Adelaide (141,000), Brisbane (119,000) and Perth (61,000).

The six states, their state capitals and largest cities in descending order of population, are New South Wales (Sydney, with a population exceeding four million people), Victoria (Melbourne), Queensland (Brisbane), Western Australia (Perth), South Australia (Adelaide) and the island state of Tasmania (Hobart). There are also over seven hundred local governments in Australia. The structure and resources of the local governments vary enormously. For example, there are 37 local governments in Sydney, ranging in population from 256 364 in Blacktown to 12 692 in Hunters Hill.

The history of European exploration in Australia is complex. There are claims of Portuguese exploration, and reliable evidence of Dutch exploration of the northern and western coasts. Dutch vessels sailing to Batavia (modern Jakarta, Indonesia) were sometimes shipwrecked on islands off the Western Australian coast if they did not turn north in time. Despite extensive Dutch knowledge of the coast of what they called "New Holland," it was not until 1770 that Captain James Cook claimed the continent for the British crown, narrowly defeating French explorers in this endeavour. The actual settlement did not occur until 1788, when Sydney was founded as a

Walter Burley Griffin

Canberra, the capital of Australia, was designed by Walter Burley Griffin who was born in 1876 at Maywood, near Chicago, Illinois, the son of George Walter Griffin, an insurance agent. Walter Burley Griffin—he always used his full name—worked for the famous architect Frank Lloyd Wright and then began work by himself in Illinois. After the formation of the Federation of Australia, the Australian government decided to build a new capital and Griffin's design won the competition. The contract which was subsequently drawn up placed the architect in effective control of the planning of the city and many of these ideas were thought to be extremely extravagant. Griffin foresaw the importance of the motor car, and Canberra is the only city in Australia that rarely has any traffic "jams," in spite of the massive growth of the city in recent years.

Walter Burley Griffin spent seven years as federal director in charge of building Canberra. His plans, hugely influenced by the City Beautiful and Garden City movements, were controversial with his plan to have the city as a series of concentric circles, and an artificial lake, subsequently named Lake Burley Griffin. However he constantly battled with bureaucrats and although cleared of malpractice by a Royal Commission in 1917, he resigned three years later. He continued to design buildings and projects in Australia.

In 1935 Griffin left for India where he had the task of designing the new library for the University of Lucknow. However when he was there he took ill, and died in 1937 of peritonitis. His widow, Marion Lucy Mahony, who had also trained under Frank Lloyd Wright, and whom he married two months after winning the competition to design Canberra, tried to continue without him. She later returned to Chicago.

penal colony on the shores of Port Jackson, or what the local Eora people called Werrong. Other Australian cities had different foundation histories. Private settlers established Melbourne as a settlement. Perth was originally settled as a free colony in 1829, but imported convict labour from 1842 onwards. By the late 19th century, some of the key components of Australia's urban pattern, and the structure of individual cities within this urban pattern, were in place. The largest Australian cities have always held a high degree of primacy (that is, the dominance of the largest city in relation to the rest of each state). The degree of primacy is less in Queensland due to the presence of other large urban centers.

The composition of the population is diverse. While there were many English and Irish people among the early settlers (not all of whom arrived by their own free will), Australia has benefited enormously from many other nationalities. Other industries, such as pearling, relied on various non-European workers. Aboriginal people were crucial in the establishment and survival of the pastoral industry in many parts of Australia. Following the second world war, "displaced persons" from many southern and eastern European countries migrated to Australia. More recent waves of immigration have included refugees and other settlers from Vietnam and other parts of Asia, and even more recently from countries such as Lebanon.

Australia also has great diversity in its environment, ranging from tropical rainforests to deserts. The north of Australia is geographically close to Papua New Guinea and Indonesia. The south of Australia is more temperate, with Perth having a "Mediterranean" climate. Water use is a major environmental issue, and the lack of reliable annual rainfall limits settlement and land use activities in much of Australia.

Australia is richly endowed with both non-renewable energy resources such as coal and natural gas, and renewable energy resources such as solar, tidal and wind power. Energy commodities are a major source of export earnings in Australia and development of these resources in a sustainable manner is a primary policy goal of the country. One of Australia's main objectives in developing a sustainable energy policy is to ensure that the country's energy sector is well placed to take advantage of economic and environmental opportunities and challenges that

Bob Brown

Bob Brown, the leader of the Australian Green Party, was born in 1944 at Oberon, New South Wales, Australia, moving to the island of Tasmania during the 1970s. He had a medical practice for many years, and was a founding member of the Wilderness Society and the Australian Bush Heritage Fund.

Bob Brown rose to national prominence over his campaign to save the Franklin River, a largely untouched natural resource in Tasmania. In a referendum about the government's proposal to dam the river, the public were given the choice of which type of dam they wanted rather than being offered the option of rejecting the dam altogether. The referendum saw up to 45 percent of the voters spoiling their ballot papers, most writing "No Dam" on their ballot paper, an unprecedented action in Australian politics, and led to the victory of the Bob Hawke Labor government in the federal elections that followed, with Hawke promising not to build a dam.

In 1983 Bob Brown and 1500 other people were arrested in the protests over the Franklin River Dam, and on his release, he was elected to the Tasmanian House of Assembly—the state legislature—holding the seat until 1993. Three years later he was elected to the Australian Senate. From 2002 until 2004, the Greens held the balance of power in the senate and Bob Brown gained international attention for interjecting during a speech by George W. Bush to the Australian parliament—Brown being a vociferous opponent of the war in Iraq. Bob Brown has won many awards including the 1987 United Nations Environment Program Global 500 Award, and the 1990 Goldman Environmental Prize. In 1996 he was named, by the British Broadcasting Corporation's *Wildlife* magazine, as the "World's Most Inspiring Politician." The author of several books, his *Memo for a Saner World* (2004) describes some of his career and also details his political aims.

will emerge both domestically and internationally in coming years.

ENVIRONMENTAL ISSUES

The Australian government is aware of the environmental challenges that are currently facing the country, including urban air quality, pollution and climate change. In order for Australian energy exports to remain competitive in world markets, the government realizes that it is both economically and environmentally in its national interest to produce these resources in the most efficient manner possible.

In 1999, in a comprehensive effort to outline the environmental responsibilities of the Commonwealth, Australia enacted the Environment Protection and Biodiversity Conservation Act. The legislation attempts to coordinate national, state and territory measures to protect the environment, providing for Commonwealth leadership, while still respecting state and territory authority. As of 2002, however, Australia's environmental progress was still slowed by a lack of clear federal leadership. For instance, in 1997 in Kyoto, Japan, Australia agreed to limit its increase in greenhouse gas emissions to 8 percent above 1990 levels by the 2008–2012 time period. According to the Australian Greenhouse Office, this represents approximately a 30 percent reduction against current business-as-usual scenarios. However, the country has not yet decided upon a national abatement strategy. In March 2002, Australia and the United States concluded the U.S.-Australia Bilateral Climate Agreement in order to jointly investigate ways to achieve the two countries' Kyoto greenhouse gas emissions goals without ratifying the protocol.

Other significant sectors of the Australian economy include manufacturing, tourism and education. These industries are increasingly mechanized, often resulting in increased production but little or negative growth in employment. Developing the Australian economy to be more ecologically sustainable economy will be a challenge.

PHIL MCMANUS
UNIVERSITY OF SYDNEY

Austria

WITH A PER capita income of $32,900, Austria is the 15th richest country in the world. The quality of life among the 8,184,691 people is high, in great part because of the welfare state that provides social security and health care to the Austrian people. The United Nations Development Program (UNDP) Human Development Reports rank Austria 17th among the world's nations in overall quality of life. The landlocked country has a temperate, continental climate, with cold, wet winters and moderate summers with frequent rainfall. The Alps in the western and southern section of the country are a major feature of the country's geography, and landslides, avalanches, and earthquakes are common. Austria's natural resources include oil, coal, lignite, timber, iron ore, copper, zinc, antimony, magnesite, tungsten, graphite, salt, and hydropower.

During the post–World War II period, Austria underwent major political, economic, and sociological transformations. By the mid-20th century, some 60 percent of Austrians were engaged in agriculture and forestry, and most practitioners had little knowledge about protecting and conserving the environment. Because of past agricultural practices, Austria requires that all sewage sludge for application in agriculture be analyzed to monitor levels of dioxin. As urbanization accelerated, a population shift occurred, with two-thirds of the population residing in the valleys and lowlands of Austria. Currently, only 4 percent of the workforce is engaged in agriculture and forestry.

Increased urbanization also led to greater numbers of vehicles using fossil fuels in congested areas, motivating the government to pursue alternative energy resources. At present, Austria generates 0.3 percent of the world's carbon dioxide emissions. Forty-seven percent of Austria's 2,562 kilometers is forested, and timber is a key industry. One-third of Austria's land is under national protection, and the government has been relatively successful at protecting the 83 mammals that are endemic to the country, with 7 percent of those species threatened. Bird life is even better protected, and only three species of the 230 birds endemic to Austria are threatened.

ENVIRONMENAL CONCERNS

Austria's major river is the Danube, which it shares with several other European countries. Historically, all riparians have worked together to manage the river. In the mid-1980s, major problems developed because large agricultural and industrial practices in cities such as Vienna, Budapest, and Belgrade were dumping waste in the Danube. Testing revealed that 30 percent of the Danube's tributaries had also become highly polluted. The Bucharest Declaration of 1985 brought eight Danube nations together to formulate environmental policies. Through subsequent agreements, riparians have identified four environmental goals: establishing and monitoring the use of the river, settling the issue of liability for cross-border pollution, defining rules for protecting wetland habitats, and creating guidelines for development that protect and conserve the environment. As a result of improved conditions, Austria has successfully reintroduced salmon into the Danube.

In 2006, Yale University ranked Austria 6th of 132 nations in environmental performance. Austrians are justifiably proud of their strong commitment to maintaining clean air and drinking water, for promoting recycling, and for establishing excellent sewerage connections. Austria's entire population has access to safe drinking water and improved sanitation. The government has been particularly successful at integrating environmental policies among the energy, transport, agricultural, and forestry sectors.

Austria has reduced air pollutants and promoted renewable energy. The country has also improved the quality of both surface and ground waters, and pollution abatement has continued to be a financial priority. Nevertheless, in 2003, the Organization for Economic Cooperation and Development presented the Minister for Agriculture, Forestry, Environment, and Water Management with 44 recommendations aimed at further improving Austria's existing environmental programs. The recommendations dealt with improving environmental management and increasing the number of protected areas.

Austria has established support for the following international agreements: Air Pollution, Air Pollution–Nitrogen Oxides, Air Pollution–Persistent Organic Pollutants, Air Pollution–Sulfur 85, Air Pollution–Sulfur 94, Air Pollution–Volatile Organic Compounds, Antarctic Treaty, Biodiversity, Climate Change, Kyoto Protocol, Desertification, Endangered Species, Environmental Modification, Hazardous Wastes, Law of the Sea, Ozone Layer Protection, Ship Pollution, Tropical Timber 83, Tropical Timber 94, Wetlands, and Whaling.

Independent Scholar

Automobiles

AUTOMOBILES ARE WHEELED and powered vehicles of various designs that have become hugely popular around the world for personal transportation, leisure, and status. Huge numbers of automobiles have been produced in the century since their first appearance, and they have had enormous effects on urban and suburban lifestyles, distribution of goods and services, the demand for oil and the global political system, and also on the environment. As large tracts of ground are placed under road tarmac, thousands of people are killed or injured yearly, and large amounts of gases are burned in the engines and released.

Automobiles are generally powered by petroleum or similar products derived from oil, which is burned under controlled conditions in an engine chamber, which then drives cranks that turn the wheels. This basic system is made greatly more complex by the addition of numerous systems and sub-systems that range from air conditioning to satellite guidance systems to safety features. The various configurations of systems, together with stylistic and engine power characteristics, contribute to a range of products that vary significantly in both size and cost. Automobiles have tended to become safer, larger, and more powerful as time has passed.

In countries where suburban lifestyles enable people to occupy comparatively large living areas and roads to match, the negative impacts of personal use of automobiles are not always easy to detect. However, in some developing countries, where road systems may be narrow, disorganized, and poorly maintained, the regular and very heavy traffic jams are very striking and very obviously produce negative effects in terms of noise and air pollution, deterioration of the road system, and also great inefficiencies in the use of time that strongly impact social, family, and working life. These problems have been slightly eased in recent years with the provision of some limited public mass transportation schemes. Additional measures to regulate traffic have included the imposition of tolls, such as the Congestion Charge levied in central London, and the permitting of entry only for odd or even numbered registration plates on consecutive days. However, the number of deaths and injuries continues to mount.

Although most countries enforce strict limits on drinking alcohol while driving, these limits are not always policed effectively and this, together with reckless driving, poor road safety conditions, and the sheer weight of traffic, has led to a situation in which some 1.2 million people are killed annually around the world, with another 50 million injured, and these figures are set to increase by 60 percent by 2020 based on current trends and as the ability of people in developing countries to purchase their own automobiles increases.

POLLUTION

Pollution caused by automobiles has been reduced to some extent by the imposition of the use of catalytic converters in all automobile models in Western countries and by the removal of lead from most varieties of petroleum. However, pollution reduction depends to some extent on efficient maintenance of vehicles; this is often not feasible in developing countries, which may in any case be importing second-hand automobiles with lower pollution standards in order to reduce costs. The main pollution problem with automobiles is the release of micro-particles in the exhaust smoke, which are the burnt and partially burnt remnants of fuel used to power them. These particles can cause bronchitis and other respiratory problems, which are believed to lead to hundreds of thousands of deaths per year. While the risk to individuals of serious health effects is small, the pollution covers a very wide range of people, and so becomes significant at the level of large communities. Numerous other dangerous gases are also released, including carbon dioxide and sulphurous and nitrous oxides, which may also contribute to global warming, acid rain, smog, and other hazards.

PRODUCTION

Automobile production in its early years relied upon skilled artisans employing similar techniques to those used to make horse-drawn carriages. It was Henry T. Ford, founder of the Ford Motor Corporation, who created the first mass production system involving the factory conveyor-belt system in building the Model T. This system featured specialization of activities within the factory and restriction of variants in the product portfolio to produce automobiles, which were for the first time aimed at the common consumer. On opening the factory, some 350,000 items could be produced annually with a unit price of $950; a decade later, the production total had been raised to 1 million automobiles annually with a unit cost of just $350. The result was a huge increase in the number of automobiles on the road, as people had the opportunity for the first time to control their own long-range transportation and to take advantage of the social and leisure opportunities it provided.

The attempt to provide large-scale, low-cost automobile manufacturing was replicated in a number of countries around the world, notably in Germany, where the Volkswagen organization produced large numbers of its cars for German citizens. Large-scale automobile production was generally restricted to Western countries until after the end of World War II. However, since then it has spread to most regions of the world as the manufacturing cost has been reduced in comparative terms and, to remain competitive, manufacturers have switched their production bases offshore to countries that are the intended destination for the finished automobiles and that offer lower labor and production costs.

The automobile manufacturing industry offers significant size of production sufficient for economies of scale and of scope. At the same time, a number of aspects of the manufacturing processes have matured to the extent that the use of robot technology and advanced manufacturing techniques have increasingly been replaced by human labor in a number of large companies. As regular automobile production has come to be dominated

Auto pollution in Western countries has been reduced by mandatory catalytic converters in new vehicles.

by Japan, South Korea, and other Asian countries, leaving specialty and luxury niches to be filled by some European countries, so too has production of related items such as motorcycles, pickup trucks, buses, coaches, and trucks.

The rising cost of oil has stimulated the search for alternative formulations, featuring various types of vegetable oil matter and similar items. To date, these attempts have not been wholly successful as concerns persist as to the possibility of engine damage and other technical issues, together with achieving consumer acceptance. Further, from an environmental perspective, it is not yet clear that the alternatives suggested to date would offer a superior solution than already exists. More success seems to be likely in terms of electric engines, either used entirely on their own or in combination with existing petroleum engine technology. Although reliability and battery recharging issues have not been fully resolved, many promising models have already been produced. The use of other types of energy to fuel automobiles does not appear to be feasible, as a regular flow of power to a small and highly mobile unit does not fit with current understanding of how to make solar, wave, or nuclear energy fueling work.

John Walsh
Shinawatra University

Azerbaijan

WHILE STILL STRUGGLING to assert its independence after the collapse of the Soviet Union, the Asian nation of Azerbaijan became involved with its neighbor Armenia in an armed territorial dispute over the area of Nagorno-Karabakh that continued from 1988–94. By the time a tenuous truce was declared, Azerbaijan had lost 16 percent of its territory and was forced to deal with the internal displacement of 571,000 Azerbaijanis. Economic problems and widespread corruption have plagued the country. However, Azerbaijan's generally untapped petroleum resources have improved economic prospects since a consortium of Western oil companies began pumping a million barrels a day from Azerbaijan in 2006. Other natural resources include natural gas, iron ore, nonferrous metals, and alumina.

Approximately one-fifth of Azerbaijan is arable, and 41 percent of the population is engaged in the agricultural sector. The population of 7,911,974 has an annual per capita income of $4,600, and the country is ranked 140th in world incomes. Nearly half of Azerbaijanis live below the national poverty line. Around 23 percent of the population has no sustained access to safe drinking water, and 45 percent lack access to improved sanitation. The United Nations Development Program (UNDP) Human Development Reports rank Azerbaijan 101st in the world on general quality-of-life issues.

Although Azerbaijan borders the Caspian Sea for approximately 800 kilometers, the country is landlocked. Rivers tend to be fast flowing and are generally not navigable. The climate is dry, semiarid steppe, and the terrain is diverse. The flat areas of the Kura-Araks Lowland are mostly below sea level. The Great Caucasus Mountains cover the northern section of Azerbaijan, while the Karabakh Upland is located in the west. The capital city of Baku is part of the Apsheron Peninsula that juts into the Caspian Sea. Azerbaijan is subject to severe droughts.

ECOLOGICAL CHALLENGES

Local scientists maintain that the Apsheron Peninsula and the Caspian Sea are the most ecologically devastated areas in the entire world. The sea has been polluted by decades of oil spills and raw, inadequately treated sewage. There is evidence that water levels are rising, posing a threat to coastal areas. Baku experiences severe air pollution. Although there are only 43 cars per 1,000 people, Azerbaijan produces 0.1 percent of the world's carbon dioxide emissions. Chemical and metallurgical industries are major polluters, and soil and water pollution have resulted from oil spills and the use of the pesticides and toxic defoliants. Birth defects and other illnesses have been linked to pollution.

Just over 13 percent of the land is forested. While the government has protected 6.1 percent of this land, pristine areas of Azerbaijan were destroyed during the conflict with Armenia, when highways were built for army use. Of 99 endemic mammal species in Azerbaijan, 13 are endangered. Similarly, eight of 229 endemic bird species are threatened. A 2006 study by Yale University ranked Azerbaijan 95th of 132 countries on environmental performance, well below the relevant income and geographic groups. The score on sustainable energy was abysmally low at less than 10 percent. Low scores were also given in the areas of air quality, biodiversity and habitat, and environmental health.

The State Committee for the Environment is responsible for implementing environmental policy in Azerbaijan and serves as the administrator of 14 state reserves and 20 preservations. In 1992, the government adopted the Environmental Protection and Nature Utilization, which established specific standards for environmental protection and compliance. In 1999, the Law on Environmental Protection and the Law on Environmental Safety established a new framework for additional legislation designed to make environmental policy more effective and responsive. Penalties for noncompliance with environmental laws include suspension or closure of polluting enterprises and the suspension of construction financing.

Azerbaijan has signed the following international agreements: Air Pollution, Biodiversity, Climate Change, Kyoto Protocol, Desertification, Endangered Species, Hazardous Wastes, Marine Dumping, Ozone Layer Protection, and Wetlands.

Bahrain

WITH A LAND area of only 665 square kilometers, the island of Bahrain is home to 698,585 people, including 235,108 nonnationals. Bahrain's strategic location in the Persian Gulf among larger and more aggressive nations forces the government to balance its own needs against the demands of its neighbors. The ruling amir, who proclaimed himself the king in February 2002, launched major economic and political reforms in Bahrain. Since oil reserves are rapidly declining, Bahrain has shifted its economic focus to petroleum processing and refining, which provide around 60 percent of export receipts and government revenues. In addition to oil, natural resources include associated and nonassociated natural gas, fish, and pearls. The development of Bahrain as an international banking center has also helped to replace lost oil revenues.

An unemployment rate of 15 percent has been a major cause for concern, particularly because it is concentrated among young adults. With an annual per capita income of $20,500, Bahrain is ranked as the 50th richest nation in the world. In 2004, Bahrain and the United States signed a Free Trade Agreement that, if ratified by both governments, should further boost the Bahraini economy. All of Bahrain's urban residents have access to safe drinking water and improved sanitation. The United Nations Development Program Human Development Reports ranks Bahrain 43 of 232 countries on general quality-of-life issues.

Bordered by the Gulf of Bahrain, the archipelago has a coastline that extends for 161 kilometers. The land area is comprised of low desert plains rising to a low central escarpment. The arid climate of Bahrain produces mild winters and hot, humid summers. Periodic droughts and dust storms have combined with desertification in Bahrain to produce degradation and loss of arable lands. Less than 3 percent of total land area is devoted to agriculture, and only 1 percent of the workforce is engaged in this sector. Since the islands lack freshwater resources, sea water is used. Bahrain is within the route by which petroleum is transported to the West. Consequently, coastal areas are suffering from degradation caused by oil spills and discharges from tankers, oil refineries, and distribution stations. Extensive damage to coral reefs and sea vegetation has also occurred.

With 90 percent of the population living in heavily industrialized urban areas, carbon dioxide emissions have climbed in Bahrain from 22.6 per capita metric tons in 1980 to 30.6 per capita metric tons in 2002. The islands produce 0.1 percent of the world's supply of carbon dioxide emissions. Consequently, the Environmental Impact Assessment has formulated stiff requirements for improving air quality in Bahrain.

In 1977, the government of Bahrain began enacting a body of environmental laws designed to protect natural resources and promote responsible land use and development. In 1980, the Environmental Protection Committee and the Environmental Protection Technical Secretariat were established to work with other government agencies by coordinating environmental policies and enforcing laws and regulations. In 1996, the Environmental Affairs Agency, which includes the Directorate of Assessment and Planning and the Directorate of Environment, assumed the responsibility for promoting sustainable development through the implementation and enforcement of a series of environmental policies related to human health as affected by environmental practices, the protection and rehabilitation of natural resources, and the control of biodiversity.

Bahrain is home to hundreds of flora and bird species and possesses the largest colony of cormorants in the world. Special interest has been focused on conserving the mangrove forests of Hawar Islands, increasing supplies of safe drinking water, and improving waste management. In addition, Bahrain has participated in the following international agreements: Biodiversity, Climate Change, Desertification, Hazardous Wastes, Law of the Sea, Ozone Layer Protection, and Wetlands.

Baikal, Lake

KNOWN AS THE Pearl of Siberia, Lake Baikal is the oldest, largest, and deepest freshwater lake in the world. Some 395 miles long and 50 miles wide, it contains about one-fifth of the fresh water on the globe, more than the five Great Lakes combined. More than 330 rivers and major streams feed it, but the Angara River is the only waterway that flows out of the lake. Because Baikal is very well oxygenated to even its lowest depths, and geographically isolated, it provides a rich ecosystem for an unusual range of animal species, including more than 50 species of fish and large mammals such as bear, moose, elk, deer, and the nerpa seal. Tens of millions of crayfish of several different varieties dispose of most of the natural waste in the lake. One of the clearest lakes in the world, with visibility from the surface to depths of 50 meters or more, the lake is a major tourist site, attracting about two million visitors each year. In addition, there are sites of historical and cultural interest. Olkhon Island, the largest of the lake's 30 islands, is traditionally identified as the birthplace of Ghengis Khan.

The world-class ski resort and hotels share the lake's 1300 miles of shoreline with several large-scale industrial concerns. Most significantly, the Bakailsk Paper Works empties about 140,000 tons of wastewater into the lake every day. When the plant was constructed in the mid–1960s, Soviet officials emphasized the extensive system of pollution controls built into its design. But when those controls proved inadequate, the pollution provoked what has since been recognized as the beginnings of the Russian environmentalist movement. In 2003, at the request of Russian President Vladimir Putin, the United Nations expedited a $22 million loan to modernize the Paper Works and to significantly reduce its pollution of Lake Baikal while protecting the remote region's largest employer. The construction of the Irkutsk Dam also created environmental issues on Lake Baikal because it raised the water level of the lake and precipitously reduced the population of some of the smaller fish species, upsetting the entire food chain among the fish in the lake.

The nerpa seal is the only freshwater species of seal and lives only at Lake Baikal. In 1995, the population of nerpa seals at Lake Baikal was estimated at about 100,000. But, in addition to the effects of industrial pollution, economic desperation in the former Soviet Union led to widespread poaching of protected wildlife species, including the nerpa seals. By 2000, the population had been reduced by half, to approximately 50,000. The situation was so serious that, in 2001, the Russian government invited Greenpeace to assist in discouraging poaching during the spring months when female seals are most vulnerable to poachers because they are reluctant to abandon their newborn offspring. Government officials estimated that this intervention reduced the poaching by close to 80 percent.

Lake Baikal features several deep rifts that provide singular opportunities for scientists studying both geological and climate change. In the 1990s, Russian and American scientists collaborated on drilling sediment cores from the Baikal rifts that provided data on about 250,000 years of climate history.

Balance-of-Nature Paradigm

BALANCE-OF-NATURE IS A metaphor that invokes the ideal of a universe of interrelated components that operate in harmony undisturbed by external interventions. The concept of a balance in nature is part of many cosmologies around the world. In Chinese philosophy, this ideal is symbolized by the yin (earth/female) and the yang (heaven/male). The Greeks had several deities with the power to generate and order the universe. As a common thread through these beliefs, all things were believed to be interconnected to preserve order, predictably, and resilience in nature.

The concept of the balance of nature was an implicit assumption in ecology for centuries and has influenced both its theory and practice. The principle of a balance of nature is also evident in the early conservation movement. In 1864, George Perkins Marsh wrote in *Man and Nature* that nature should be undisturbed by people so that the landscape can become almost unchanging and permanent in form. The paradigm, known as classical equilibrium, is seen in many concepts central to ecology such as bio–geography, population dynamics, carrying capacity, stability, and homeostasis. Thus, a significant feature of classical equilibrium ecology is based on the assumption that all ecosystems follow a linear path toward an end state. If left alone, undisturbed by humans, all ecosystems were potentially self-regulating, and could reach a stable "climax" state.

ECOLOGICAL ANTHROPOLOGY

Early ecological anthropology was also characterized by a search for a balance in the human ecosystem. While classical equilibrium ecology places humans outside of ecosystems, early human ecologists placed people at the center of the ecosystem. Importantly, the human ecology model retained many of the principles found in equilibrium ecology. The human ecosystem was believed to be a closed, self-regulating system that was culturally, structurally, and functionally complete. This approach informed the work of anthropologist Roy Rappaport, whose early research was concerned with humans as a species that participates in ecosystems in ways that are fundamentally similar to how other animals participate.

For Rappaport, cultures can be conceptualized as adaptations of particular groups to a particular ecosystem. Rappaport's approach, known as cultural materialism, is best exemplified in his seminal book *Pigs for the Ancestors: Ritual in the Ecology of a New Guinea People* (1968), in which cultural phenomena are explained in terms of material factors among people and the natural environment. Rappaport attributes the ritual pig feasting and warfare among the Tsembaga Maring of highland

New Guinea as an event that was critical in regulating the size of human and animal populations. *Pigs for the Ancestors* has become a classical case study in human ecology, exploring the role of culture in resource management and the application of systems theory to a human population. In a similar way to ecologists who applied the balance-of-nature metaphor to ecosystems, Rappaport and other human ecologists believed that if the human ecosystem was left undisturbed by outside forces (in this case, political and economic forces), then it would remain in a balanced, closed state of homeostasis.

PARADIGM SHIFT

The powerful metaphor of the balance of nature came into question in the 1970s and 1980s in both ecological and social sciences. Ecological studies began to demonstrate that equilibrium conditions are rare and that disturbance events are so common that most ecological systems never reach a climax stage. Ecologists describe key ecological processes as nonequilibrium (or disequilibrium) dynamics, open to restructuring through disturbance regimes and historical contingencies. Emerging nonequilibrium theory conceptualizes ecosystems as nested hierarchies of patch mosaics, and ecological dynamics are viewed as the outcome of composite patch dynamics. Daniel Botkin, a pioneer in the theory of nonequilibrium ecology, maintains that nature is in fact not in balance and disturbance is ubiquitous, if not the norm. This is not to suggest that there is no ecological stability, but rather that balance is embedded in patterns of fluctuation and ecological persistence and can be seen as order within disorder.

This paradigm shift in the ecological sciences was mirrored by a similar shift in the social sciences. Just as ecologists began to recognize that ecosystems do not remain productive indefinitely, but rather require periodic disturbances, anthropologists and geographers began to rethink humanity's role in actively shaping the landscape. It was once commonplace to talk about "pristine" areas of rainforest where "ancient" or "primeval" primary forest could be found, untouched by human hands. However, recent research in anthropology and geography has shown that much of the tropical forests around the world are the product of generations of selective human modification and interventions. These modifications are often responsible for the diversity of species, which previously might have been attributed to "natural" or nonanthropogenic forces.

Many scientists herald the transition from concern with equilibrium, homogeneity, and determinism to a widespread acceptance of nonequilibirum, heterogeneity, and disturbance in ecosystems as an important paradigm shift in ecology. This paradigmatic shift has significant implications for resource management. Conservation efforts, which often aim to remove human presence from landscapes, can focus on "real people-centered conservation," or what the geographer Karl Zimmerer calls "nature-culture hybrids." One example of this shift can be seen in the controversial issues surrounding wildfires in the western United States. Fire suppression polices, once the hallmark of forest conservation, have been replaced with the controlled-burn policy that acknowledges natural forest fires help regenerate the forest ecosystem.

Bananas

IN 1870, A strange fruit became a novelty purchase in New York food markets. By 1904, bananas had become the most popular fruit in the United Kingdom, and growing demand for bananas in North America and Europe lay the foundation for profound and ongoing environmental and social impacts in producer countries. Bananas, whether eaten raw (dessert bananas) or cooked (plantains), belong to the genus *Musa*. Up to a dozen bunches of fruit grow in one year from the single stalk of a fleshy plant often mistaken for a tree. The hundreds of cultivated banana varieties are sterile hybrids derived from two wild species native to Southeast Asia. Lacking viable seed, domesticated *Musa* are propagated by felling the stem to allow new shoots to grow from the rootstock. This process may go on indefinitely, or shoots can be transplanted to minimize soil depletion and maintain yields.

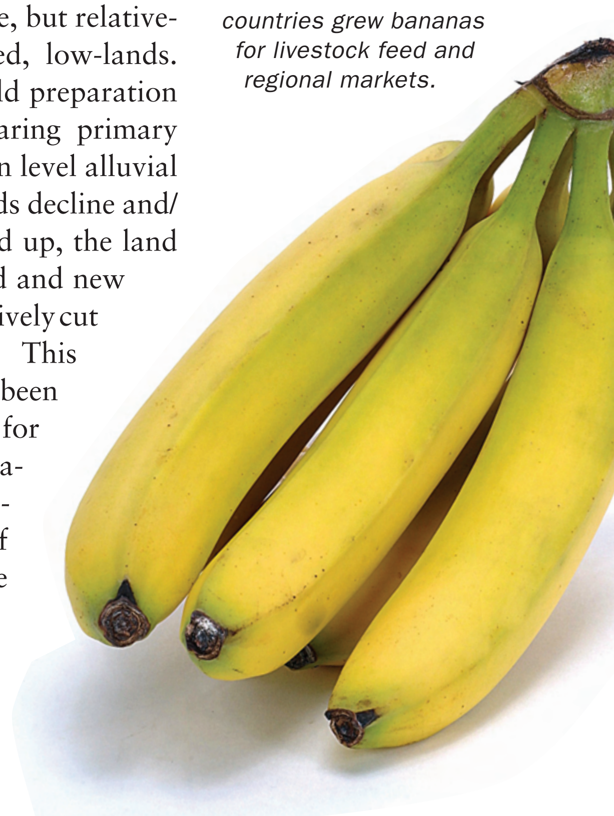
Bananas are rich in carbohydrates and nutrients (including potassium, phosphorus, calcium, and Vitamin C). A hectare of well-managed plants on rich soil can yield some 16,000 kilograms of fruit per year under hot, wet conditions. Their ease of cultivation, high yield, year-round productivity, and versatility of preparation have long made bananas attractive to people living in the tropics. The crop had spread from South Asia to Africa and the Mediterranean via Arabian land routes by at least 1 C.E., and was known throughout West Africa by the 15th century. In 1516, Spanish friars brought plants from the Canary Islands to the modern-day Dominican Republic. The banana proved so popular among tropical America's native peoples that its cultivation often diffused faster than the pace of European exploration. In 2006, millions of small farmers in 122 countries grew bananas—typically interplanted with other crops on small plots—for consumption, as livestock feed, and to supply regional markets. Approximately 80 percent of all bananas grown are eaten in the country of origin, with the highest levels of consumption in Brazil, India, the Philippines, Burundi, Indonesia, and China.

About 20 percent of global production is destined for export. In 2003, Latin American and Caribbean countries, dominated by Ecuador, supplied 80 percent of world exports, with the Philippines, Cameroon, and Ivory Coast accounting for most of the remainder. The top global banana importers were the United States, the European Union, Japan, and Russia. In 2000, total international trade was estimated at $4 billion, and was dominated by a handful of companies.

Production methods for export bananas vary. In Ecuador and the Caribbean, for example, bananas are often contract-farmed by small producers on plots rarely exceeding 50 hectares; planting stock and agrochemicals are provided on credit by a banana company. In Central America, multinationals own or rent vast tracks of land, often at favorable rates. These plantations are effectively run as enclave economies. Laborers are housed and fruit is processed on-site; company-owned facilities are also used in subsequent sea transport, ripening, storage, and distribution. As a result of this vertical integration and economies of scale, most bananas go from harvest to supermarket shelves in less than one month.

Export-bound banana cultivation has an appalling environmental record, which is best exemplified by banana plantations in Central America (which in 2003 supplied 30 percent of global exports). In the late 1800s, United States and British entrepreneurs coerced, threatened, and cajoled nascent republics into ceding vast tracts of land for banana cultivation on prime, but relatively unoccupied, low-lands. As today, field preparation involved clearing primary rainforests on level alluvial soils. As yields decline and/or pests build up, the land is abandoned and new fields successively cut from forest. This pattern has been responsible for the devastation of massive areas of biodiverse coastal rainforests from Belize to Panama.

In 2006, millions of small farmers in 122 countries grew bananas for livestock feed and regional markets.



Nutrient-demanding banana monocultures are typically maintained with massive inputs of synthetic fertilizers, fungicides, herbicides, and pesticides (pesticides alone can account for up to 35 percent of plantation production costs). Often applied aerially, chemical misuse has damaged plantation-edge forests, and caused the build-up of nematode populations and toxic chemicals in soils. Further, bananas require constant, but not excessive moisture. On plantations, channels are dug to drain water in the rainy season and irrigate in the dry season.

This greatly enhances soil erosion, as well as the delivery of silt and agrochemicals to local waterways. Due to their coastal locations, banana plantations have been blamed for considerable estuarine and coral reef pollution in the Caribbean. In addition, the on-site washing of harvested bananas adds to water demand and contaminated runoff. During the sorting process, up to 35 percent of bananas are rejected (mainly due to blemishes), and may be dumped along with cut stems into nearby streams, where their decomposition starves the water of oxygen; it is estimated the volume of this waste is equal to that of shipped fruit.

Serious human-rights abuses are also associated with the banana export industry. In the 20th century, violent and deadly repression of labor unions, denial of basic workers' rights, and the abuse of migrant laborers have been rife. Banana companies proved so meddlesome in the domestic policies of Central American nations that the latter became known as Banana Republics. For example, in 1954, the United States-based United Fruit Co. encouraged the CIA and U.S. State Department to back the coup and exile of democratically elected Guatemalan president Arbenz, who had championed the redistribution of idle banana holdings to landless peasants. In 1992, Chiquita's threat to withdraw grower contracts caused the government of Panama to cancel a planned increase in the national minimum wage. Today, banana workers continue to struggle for adequate protection from toxic agrochemicals, the right to unionize, better living conditions, and wages commensurate with rising company profits (contract growers currently earn an estimated five to 10 percent of a banana's final retail value; plantation workers, one to three percent). They accuse banana companies of keeping prices artificially low, and of rotating their operations internationally to avoid accountability to labor and environmental laws.

Since the 1990s, organic and Fair Trade initiatives, targeting environmental and social conditions in the banana industry, have met with modest success. Chiquita and other companies are now experimenting with sustainable farming methods to lessen the environmental impact of cultivation, including continuous cultivation, integrated pest management, crop rotation, and the reuse and recycling of wastes. Bananas too blemished for store shelves are processed into juices and baby food. Contract farmers, especially in the Caribbean, are also organizing into certified Fair Trade cooperatives that work with alternative distributors to sell their sustainably grown fruits for a living wage. Their success relies on the willingness of consumers to pay a premium for fairly traded organic bananas. To date, the movement has had greater success penetrating European than North American markets.

Bangladesh

BANGLADESH IS FORMALLY called the People's Republic of Bangladesh. It is a small, deltaic country located in South Asia, with India to the north, west, and east, Myanmar to the southeast, and the Bay of Bengal (Indian Ocean) to the south. Bangladesh's land area of about 144,000 square kilometers with

147 million people (2006 estimate) makes it one of the most densely populated countries in the world. Agriculture forms the mainstay of the economy, and the majority of the population lives in rural areas, with increasing urban growth. The capital, Dhaka, is one of the fastest urbanizing cities in the world.

Bangladesh was a part of Pakistan after the Partition by British colonial rule in 1947. In 1971 it won its independence from Pakistan. Bangladesh has a parliamentary democracy, although several factors plague its rule: political instability, corruption, and poor governance. Economically, the country has made strides in developing a manufacturing base in ready-made garments (by exploiting cheap labor), along with production of other export items (such as shrimp, jute, and tea). As one of the poorest countries in the world (in terms of per capita income), development in areas of human resources, economy, literacy, and health remain enormous challenges for the government. Gender disparities in most arenas remain high, despite the country being one of the few in the world with a female head of state.

Three major rivers (Ganges, Brahmaputra, and Meghna) and numerous smaller rivers and tributaries make the country very lush and flood-prone. The country is largely flat; most landmass is one to 10 feet above sea level. The monsoon climate also means that annual rainfall in the summer months is fairly high, which contributes to the floods. In addition, tropical cyclones that form seasonally in the Bay of Bengal also cause considerable flooding from storm surges. Such natural hazards are compounded by the extreme poverty and high density of dwellings, where the social and economic outfalls are considerable for a struggling population. Marginalization of poorer people into floodplains and coastal areas further increases their vulnerability to such hazards.

Environmental problems from deforestation and loss of biodiversity are also concerns in Bangladesh, as large tracts of land are often converted to agriculture as well as to support the illegal timber trade. Recent growth of shrimp aquaculture has resulted in the loss of areas of the Sundarban mangrove forest, which is a World Heritage Site and home of the Royal Bengal Tiger. Surface water pollution has historically led to water-borne illnesses and high infant mortality rates from consumption of contaminated water. Recent changes to drinking groundwater has also come under threat from naturally occurring arsenic in the aquifer, thereby exposing over 30 million people to arsenic poisoning. Beyond water quality, water quantity also poses a problem in many areas with fluctuating groundwater tables, as well as seasonal water shortages. Disputes with neighboring India over controlling river flow remain politically contentious as a result. Air pollution from a growing number of vehicles and industries are also increasing in urban areas. As a result, many development projects in Bangladesh are focusing on the numerous environmental issues as part of overall development endeavors.

Basel Convention

ONE OF THE legacies of the industrial revolution has been the production of large quantities of hazardous waste, which over the last century has presented a serious challenge for disposal. Moreover, tightening of environmental regulation in industrialized countries in the late 1970s and early 80s led to a dramatic increase in the cost of disposing of hazardous waste. Producers and traders started looking for cheaper ways to get rid of "toxic" waste, such as shipping it to developing countries and to eastern Europe, which lack the technical capability, knowledge, and/or regulatory framework to treat this waste in an environmentally safe manner. Poorer countries were likely to accept exported wastes because their high international debt loads and weak economies positioned them poorly to reject any income-generating activities. As the problematic and unjust nature of the international toxins trade became better recognized, concern led to developing and implementing international controls. This culminated in the drafting and adoption of the landmark global Basel Convention, under the aegis of the United Nations. The Convention was adopted on March 22, 1989, by the Conference of Plenipotentiaries, which was convened at Basel (Switzerland) from March 20 to March 22, 1989.

FRAMEWORK FOR CONTROL

The Convention has set up a framework to control the "transboundary" movement of hazardous waste (hazardous waste can be toxic, poisonous, explosive, corrosive, flammable, ecotoxic, and infectious) across international frontiers with the aim of protecting human health and the environment by minimizing hazardous waste production whenever possible by using environmentally sound management techniques. This recognizes that a long-term solution to the stockpiling of hazardous wastes is a reduction in the generation of these wastes, both in terms of quantity and hazardousness. This means addressing the issue through an "integrated life-cycle approach," which involves strong controls from the generation of hazardous waste to its storage, transport, treatment, reuse, recycling, recovery, and final disposal—keeping track of it from cradle to grave.

The main goals of the Basel Convention are to ensure that generation of hazardous waste is reduced to a minimum; to ensure that as much hazardous waste as is possible is disposed of within the country of their generation; to establish enhanced controls on exports and imports of hazardous waste; to prohibit transportation/shipments of hazardous wastes to countries lacking the legal, administrative and technical capacity to manage and dispose of them in an environmentally sound manner; to cooperate on the exchange of information and technology transfer; and to work toward the harmonization of standards, codes, and guidelines.

These objectives can be achieved through factors such as active promotion and use of cleaner technologies and production methods; further reduction of transportation of hazardous wastes; prevention and monitoring of illegal traffic of hazardous waste; improvement of institutional and technical capabilities; helping to build up the capacities of developing countries and countries with economies in transition to deal with hazardous waste more effectively; and further development of regional and sub-regional centers for training and technology transfer.

The Basel Convention was adopted in 1989, but it did not come into force until May 5, 1992, when the Convention was ratified by 20 countries. As of February 2004, 158 countries had ratified the Basel Convention. Nations that have ratified the Convention are allowed to ship hazardous wastes to and from countries who are parties to the Convention, but not to countries or through countries that have not ratified it. The Convention permits an exception to this requirement if a separate bilateral agreement covers relations with a given trading partner that is not a party to the Convention. Article 11 of the Basel Convention allows parties to the Convention to develop such a bilateral agreement as long as the agreement reflects the environmentally sound management practices of wastes.

To highlight the scope of trade in hazardous wastes and hazardous recyclable materials: in 2002, Canada exported 340,000 tons of hazardous waste, primarily destined for northeastern and central United States. In the same year, Canada imported 423,000 tons of hazardous waste, 97 percent of which originated from the United States. Approximately 46 percent of imports and 70 percent of exports were destined for recycling.

In spite of huge volumes, there are enough Action Networks to monitor illegal activities. One of the cases reported in 2006 was the Clemenceau—a defunct aircraft carrier laden with asbestos—being exported by the French Government to India. It was recalled, however, after a French Court ruled that France was not abiding by the established rules under the Basel Convention. The International Maritime Organization is also developing a new convention on "International Convention for Safe and Environmentally Sound Recycling of Ships," and it is felt that it should be further strengthened to be at least as strict as the Basel Convention.

Basin

A BASIN IS an area of land that is lower than the surrounding land. Many basins form lakes because water flows down into the lower land; however, this does not always happen. When the basin occurs underwater, for example in sea floors, then it makes little difference—as is also the case for the Kalahari Desert basin, around which all of the land receives too little precipitation or river flow to create a lake. In other cases, the flow of water is accompanied by sediment of different types and, eventually, this can cause significant filling up of the depression. In any case, the long-term changes in climate and terrain mean that any particular configuration will not be permanent. Many hydrocarbon resources are formed as the result of the presence of basins.

Basins were created principally through tectonic activity in the distant past. The interaction of tectonic plates causes some areas of land to rise and some to fall. Pressure caused by plates causes unevenness in other plates, and thus basins are formed. These can be very large. The Aral Sea and the Black Seas are examples of basins, as too are some of the lakes of central Africa and the Great Basin on South Australia.

The science of limnology is used to help classify the different types of basins. This is necessary because tectonic interactions can form basins in a number of different ways, for example by damming valleys, uplifting some surrounding area, or forcing a lower plate against a higher one. Basins may be distinguished from depressions, which are a broader group of phenomena that includes lower ground caused by meteor impact and crater formation, wind erosion, and other weathering effects. They may also be formed by volcanic activity and lava flows. Multiple factors may of course work together to create complex basin-like configurations.

Those basins into which water flows create standing bodies of water forming as lakes. As the water flows, it collects dissolved salts and small pieces of rock in suspension. These are known collectively as sediment, which are deposited in the lakes as their final destinations of the rivers. The weight of the combined sediment may cause additional subsidence of the original basin floor and may be associated with the formation of geological faults giving rise to earthquakes. Under certain circumstances, sedimentation may lead to conditions that give rise to the creation of complex chemical products, notably hydrocarbons such as oil and natural gas. Sedimentation also has an impact on the quality of soil in an area, and hence, the agricultural value of the land.

Beaches

A BEACH IS a sloping accumulation of sediment, usually sand or gravel, that is a result of wave action at the edge of a water body, such as an ocean or lake. The presence of a uniform surface adjacent to water provides a prime location for recreational activities that, in turn, often drive regional economies. Beaches also hold great environmental value and provide habitat for a variety of important species. Because of the environmental, social, and economic value of beaches, societies have long grappled with how best to manage these landforms. Questions of beach replenishment, the protection of endangered species, and the public's right of access all complicate society's relationship to its beaches.

Beaches are not static features. They represent a balance between the size and regularity of waves and the availability of sediment. The action of waves reworks and sorts the sediment, washing away smaller particles and leaving larger ones, like sand or gravel. If a water body has little to no wave action, no beach will form. Similarly, the supply of sediment available to the waves must be sufficient to create a beach—too little sediment supply, and the beach will decrease in size. The supply of sediment commonly comes from nearby bluffs, a river mouth, or a reef offshore. Waves approaching the shore at an angle move the sediment and sand along the beach, which becomes important when considering how society alters beaches.

A common way humans interrupt the sediment supply is through the construction of groins—rock jetties perpendicular to the shoreline. These structures are designed to trap sand moving along the beach to produce a wider beach. Unfortunately, this trapped sediment is prevented from moving further along the shore, resulting in erosion downdrift of the groin. Similarly, homes built above an eroding bluff may be protected in the short term by the construction of a sea wall that removes the bluff as a sediment source for a nearby beach. Dams on rivers also trap sediment and prevent it from being carried by the river to the coast where it nourishes beaches. All three of these modifications—groins, sea walls, and dams—are built with good short-term intentions, but have unaccounted costs to society in the form of accelerated beach erosion. In some cases, society pays for these costs through beach replenishment, the importing of sediment from an offshore or land-based source at great expense. Artificial beach replenishment has to be repeated as long as the cause of the sediment supply reduction remains in place.

The physical dynamics of a beach are just one set of factors influencing society's use of beach environments. The public's right to beach access can be limited due to health concerns or property rights. Along many populated coasts, beach closures are common due to elevated levels of bacteria in the water, particularly after rain events that wash polluted storm water to the coast or cause sewer systems to overflow. Beaches also provide breeding habitat for a variety of species (such as horseshoe crabs and sea turtles) and, in many cases, society has chosen to restrict access to beaches during breeding times for these species.

The broader question of who has the right to access a particular beach is complex in a beach landscape that is both desirable and dynamic. Landowners adjacent to beaches are interested in protecting their privacy, while the public has an interest in preserving equal access to the beach. Laws outlining public and private rights vary by region, but many are based on some definition of the shoreline boundary, such as the mean high water line. The situation is exacerbated by global sea level rise that, in most cases, is moving the mean high water line farther ashore and narrowing the distance between the water line and private property.

The intensity of society-nature interactions is proportional to the environmental and economic value of the landscape in question. Only through acknowledgment of the processes that form beaches can society ensure its beaches will be accessible and available for future generations.

Belarus

THE TERRITORY OF Belarus covers 207,600 square kilometers, and it has a population of 10.2 million people. The country was declared an independent republic in September 1991, after the collapse of the Soviet Union. Subsequent reforms were slow and did not indicate rapid economic change. The first president of the independent Belarus, Alexander Lukashenko, was elected in 1994 and has aimed to create a dictatorship; his politics have been criticized by the international community, especially by the European Union (EU). The outcome of the presidential elections in 2006, when Lukashenko won around 85 percent of the votes, was not approved by the international community, except Russia. Following the election, the EU banned Belarusian leaders to enter the territory of the EU.

One of the most important environmental issues is radioactivity due to the destruction at the Chernobyl Nuclear Power Plant in the Ukraine on April 26, 1986. Radio nuclides are deposited very heterogeneously due to weather and wind over Belarusian territory. To date, about 135,000 persons have been resettled or evacuated. Some of them have moved back to these areas with or without the right to resettle, which poses significant health problems. It is hard to estimate the total environmental toll of the nuclear catastrophe in Belarus, but a very significant share of the Belarusian flora and fauna has been affected by the deposit of Chernobyl plume.

Environmental quality in Belarus has improved since the early 1990s, but this was largely the result of a decline in economic activity. Only a little can be accredited to new production technologies and to the shift from industrial to postindustrial production. Water quality in general has been poor, and hygienic standards have not been met since the late 1980s. Water quality problems are even more serious in rural areas served by shallow wells, where the level of microbe pollution is high. High nitrate and iron content in groundwater has reported in the early 1990s, and remains a major environmental issue. Air is relatively clean in Belarus, even compared to EU countries or to the United States. Urban air pollution is low, due to the low number of vehicles.

Central institutions have played an important role in environmental issues in Belarus. National and international non governmental organizations (NGOs) have to face several difficulties posed by the central government. Complex regulation, occasional intervention from authorities, and the lack of central financial support has created difficult situation for most of the NGOs. Furthermore, their information can be distributed only if the material is registered by the authorities. Complex taxation has cut off donations significantly to environmental NGOs, therefore only a very limited sources of aid are available. In addition, collaboration with NGOs and media is not encouraged. As a result, public participation is only limited in environmental issues. Due to the increasing isolation of Belarus, that trend is likely to continue into the future.

Belgium

THE KINGDOM OF Belgium is known as the “crossroads of Western Europe” because most other western European capitals are located within 1,000 kilometers of the capital city of Brussels. Bordering on the North Sea, the climate of Belgium is temperate with mild winters and wet, cool summers. The topography of Belgium varies from the flat coastal plains of the northwest to hills in the central part of the country to the mountains of the Ardennes Forest in the southeast. Belgium has protected large areas of land, particularly in the Ardennes, which is home to many of the 191 species of birds and the 58 mammal species endemic to Belgium. Close attention is also paid to the peat bogs of the Hautes Fagnes Reserve. Flooding is a constant threat on the coast, and the government has created a protective system of concrete dikes along the 200 square miles of reclaimed coastal land. Belgium's natural resources are somewhat limited, consisting of construction materials, silica sand, and carbonates. With a per capita income of $31,800, the quality of life in Belgium is among the highest in the world, and the United Nations Development Project (UNDP) Human Development Reports place Belgium in ninth place.

CONSEQUENCES OF INDUSTRIALIZATION

Long a leading industrial nation, Belgium continues to be heavily industrialized, particularly in Flanders. As a result, the environment has suffered from intense urbanization, transportation and agricultural contamination, and industrial pollution. The Ministry of Public Health and Environment works closely with provincial and local governments to implement environmental policies derived from the Mature Development Plan, the Environmental Policy Plan, and the Waste Plan. In 2006, a study by Yale University ranked Belgium 39 among 132 nations on environmental performance. Belgium's chief environmental concerns are acidification and air, water, and soil pollution. Pollutants include nuclear radiation, mercury, pesticides, phosphorous, and other metals. Because of intense urbanization, Belgium is also a major emitter of carbon dioxide.

Less than 3 percent of the Belgian population live in rural areas, and only 1.3 percent of the labor force are involved in agriculture. Intensive use of the pesticide mirex (Dechlorane), which was used as a fire retardant in plastics, rubber, paint, paper, and electric goods, and as a method of controlling fire ants, was common from the 1950s to the 1970s, and residues of mirex have been identified in water emissions and rain water. Belgium subsequently became more environmentally responsible; and since the 1990s, acidifying and eutrophying emissions have dropped by 35 percent due to a decrease in the number of livestock and to more responsible use of fertilizers and nutrients.

Because Belgium is one of the most urbanized countries in the world, household waste has presented major environmental problems. Since 2000, however, much progress has been made in other areas. Energy consumption has begun falling, and a water purification policy has led to lower levels of pollution in ground water. Increased attention to reducing acidification has resulted in decreased rates of DenOx and DeSox units and to a rise in the use of low-sulfur fuels. Additionally, rates of heavy metals identified in wastewater have continued to decrease.

Because Belgium is a federal system, much of the responsibility for environmental policy lies with local governments. In response to the 1992 United Nations Conference on Environment and Development, provincial and local governments began generating action plans for environmental protection and sustainable development. Belgium has expressed its commitment to the environment by signing the following agreements: Air Pollution, Air Pollution–Nitrogen Oxides, Air Pollution–Sulfur 85, Air Pollution–Sulfur 94, Air Pollution–Volatile Organic Compounds, Antarctic–Environmental Protocol, Antarctic–Marine Living Resources, Antarctic Seals, Antarctic Treaty, Biodiversity, Climate Change, Kyoto Protocol, Desertification, Endangered Species, Environmental Modification, Hazardous Wastes, Law of the Sea, Marine Dumping, Marine Life Conservation, Ozone Layer Protection, Ship Pollution, Tropical Timber 83, Tropical Timber 94, Wetlands. The agreement to control Air Pollution–Persistent Organic Pollutants has been signed but not yet ratified.

Belize

BELIZE IS LOCATED on the eastern coast of Central America, bordered by Mexico to the north, Guatemala to the west and south, and the Caribbean Sea to the east. Covering 22,806 square kilometers (8,805 square miles), Belize is the second smallest nation in Central America and the only one without a Pacific coastline. Belize is also the only English-speaking country in Central America, and with approximately 291,800 people, the least densely populated. Known as "British Honduras" until 1973, Belize was a British colony for more than a century before gaining independence on September 21, 1981.

Belize's landscape is marked by diverse topography. The northern region is primarily tableland covered by scrub vegetation and hardwood tropical forest. A narrow coastal plain, much of it covered with mangrove swamp, stretches along the Caribbean coast. Inland, the Maya Mountains, Cockscomb Range, and the Mountain Pine Ridge form the backbone of the southern half of the country, the highest point being Doyle's Delight at 1,124 meters (3,688 feet) above sea level. This region is covered primarily by tropical rain forest. Belize's coast is bordered by the second longest coral reef system in the world, spanning approximately 322 kilometers (200 miles) with over 450 islets and cays.

Belize is one of the world's most biologically diverse countries with over 2,894 species of plants and 877 known species of amphibians, birds, mammals, and reptiles. Belize is home to more jaguars than any other Central American country and hosts the world's only reserve for these felines, the Cockscomb Basin Wildlife Sanctuary and Jaguar Preserve.

The livelihoods of many Belizeans are tied to the land. Sugar and citrus fruits are Belize's main sources of export revenue, while the banana industry is the country's largest employer. Until the 1950s, timber

Cayes Ecotourism

This former British colony in Central America has recently developed into a center for ecotourism with its small islands, or "cayes."

Traditionally, Belize has been regarded as unsafe for tourists and was not visited by many wealthier tourists, who were worried about robberies and drug dealing in Belize City. However, the country has undergone great changes, and with a warm climate, a relatively low cost of living, and unspoiled beaches, tourism to Belize increased in the 1990s.

The most popular caye in Belize remains Caye Caulker, which has attracted tourists since the 1980s. In the pirate era, the caye had a small fishing settlement, and derived its name from boats arriving to the port for repair or caulking. It soon became important during the War of the Castes, which took place between 1847 and 1901. In 1870, Luciano Reyes bought the land and left some to descendants, many of whom still live there. The beaches and the jetties are on the Caribbean side of the peninsula, and is accessed from Belize City by light aircraft or boat.

St. George's Caye, near Belize City, was the site of the Battle of St. George's Caye, which was fought on September 10, 1798. The bigger Spanish boats found themselves unable to maneuver, whereas the baymen from Belize had ships with shallow drafts. It was the last Spanish attempt to take British possession, and September 10 is now a public holiday. Mythology surrounding the battle suggests that freemen and slaves fought side by side, with the slaves eager to support their masters rather than be ruled by the Spanish.

dominated the economy. Timber was selectively logged, leaving much of the canopy intact, and until recently much of the country had little road access and relatively light development. As a result, nearly 75 percent of Belize is still under forest cover, although the transfer of land from forest to agriculture continues to accelerate.

The Belizean government and citizens have largely embraced environmental conservation for protecting the landscape and attracting tourism and foreign investment. The creation of the Ministry of Tourism and the Environment and the passage of major environmental legislation, including the Belize Environmental Protection Act of 1992, have further strengthened this rhetoric of conservation. Consequently, 42 percent of Belize is under a form of legal protection, the greatest proportion of any country in the western hemisphere.

However, these laws are limited by a lack of financial support. In response, the government has developed partnerships with nonprofit environmental groups, for-profit groups, and local community associations in order to support the institution and enforcement of these protections. Recently, these conservation efforts have been criticized as being "ecocolonialist," favoring the management of the environment at the expense of the economic and cultural needs of the Belizean people. The greatest challenge in Belize remains balancing the needs of the human population with conservation programs.

Beneficial Use Doctrine

THE BENEFICIAL USE Doctrine refers to the principle of water management adopted by the western United States during a period of expansion during the 19th century. The California Gold Rush and other stimuli led to a rapid population increase in the western states that was plagued by little standing groundwater, among other features. The Beneficial Use Doctrine stipulates that land rights, which may be transferred or bought, are also accompanied by a right to water that exists on that property, insofar as any use of the water is beneficial and not wasted in any way, with the risk of forfeiture of those rights for individuals who fail to comply with that stipulation.

CHALLENGES

The concept of beneficial use has remained in practice, although it has been challenged on a number of grounds since its introduction. One set of challenges has centered on practical issues related to the implementation of laws based on the doctrine and as expressed in the legislation of the separate states. This has included the comparative weakness of the laws when it comes to monitoring and prosecution. However, a more persistent set of challenges has arisen on a more fundamental, ideological basis. Many people believe that market-based allocation of resources would be equal or even superior to the Beneficial Use Doctrine, and that the latter should, therefore, be phased out of the legislation.

Much has changed over the past century in terms of the demand for water resources, which has grown enormously, as well as the ability to use technology to efficiently manage water, route it, and recycle it to an extent previously unimagined. The purpose of the original doctrine was to hinder the seizing of a monopoly and concomitant speculation and price gouging in water resources. This does not necessarily encourage the most efficient and parsimonious use of water, but simply deters its use in ways that openly flout the regulations. Modern requirements have changed, and it may be that adjustment of the doctrine will better reflect these requirements. In any case, it will be important to ensure that any such adjustment is the result of genuine public consultation and is not hijacked by corporate interests.

Benin

ARISING OUT OF the 15th-century kingdom of Dahomey, the Republic of Benin won its independence from France in 1960. In the early 1990s, Benin became the first African nation to successfully transform itself from a Marxist-Leninist government to a multi-party democracy, though local elections were not actually held until 2002. With a per capita income of only $1,100, Benin is the 27th poorest country in the world. One-third of the people live in poverty, and a fifth of them are seriously undernourished. Benin's economy is generally underdeveloped and is chiefly dependent on subsistence agriculture. Less than 45 percent of the people live in urban areas. In addition to small offshore deposits of oil, Benin's natural resources include limestone, marble, and timber.

Bordering on the Bight of Benin in the Atlantic Ocean, this West African country has a coastline of 121 kilometers and shares land borders with Nigeria, Niger, Togo, and Burkina Faso. Because the coast of Benin has no natural harbors, river mouths, or islands, sandbanks limit coastal access in some areas. The land is mostly flat with a few hills and low mountains. Elevations range from sea level to 658 meters at Mont Sokbaro. Benin's climate is tropical, varying from hot and humid in the south to semiarid in the north. From December to March, northern areas may experience the harmattan, a hot, dry, and dusty wind that accelerates soil degradation. Cotonou, which is the economic capital, experiences frequent flooding and may become even more vulnerable in response to global warming.

HEALTH AND ENVIRONMENT

Benin's population of 7,460,025 is seriously threatened by a 1.9 percent HIV/AIDS rate that caused 5,800 deaths by 2003. Another 68,000 Beninese have been diagnosed with the disease. Benin has a shortage of potable water. Some 32 percent of the population lacks sustained access to safe drinking water, and 68 of Beninese do not have access to improved sanitation (12 percent in rural areas). This lack of safe water and basic sanitation has created a very high risk of contracting food and waterborne diseases, including typhoid fever and hepatitis A. Beninese are also at risk for contracting meningococcal meningitis, a respiratory disease. In some areas, the risk of contracting vectorborne diseases such as malaria and yellow fever is also high.

Because of the high disease rate, the Beninese experience low life expectancy (53.04 years) and high infant mortality (79.56 deaths per 1,000 live births) and death rates (12.22/1,000). Thus, the population grows at a rate of only 2.73 percent. The Benin fertility rate is extremely high at 5.9 children per female. Low literacy rates (46.4 percent for males and 22.6 percent for females) make the dissemination of health and environmental information difficult. The United Nations Development Project (UNDP) Human Development Reports rank Benin 162 of 232 countries on overall quality-of-life issues.

In 2006, scientists at Yale University ranked Benin 84 of 132 countries on environmental performance, slightly above the comparable income and geographic groups. Desertification is spreading in Benin, and deforestation occurs at a rate of 2.3 percent each year. Approximately 247,000 acres of forest have been cleared to provide fuel, as there is no other source of energy for cooking and heating. These problems are particularly severe in the arid areas of the north. The government has protected 11.4 percent of land area. Of 188 mammal species identified in Benin, eight are endangered, as are two of 112 bird species. Wildlife populations are at great risk from poaching.

Coastal erosion in Benin that has resulted from decades of dam building and the practice of removing a million meters of sand each year for construction have led to loss of land for development and to the destruction of existing buildings. For instance, in the cities of Grand Popo and Finagnon, hundreds of houses have vanished, along with the expensive Palm Beach Hotel that was built along the Atlantic coast of Benin in 1982. Approximately 20 meters of coastal land per year is being reclaimed by the sea. Such losses not only produce massive human displacement and environmental degradation, they also damage the already fragile Beninese economy.

In 1990, Benin's Constitution declared that a clean environment was the right and responsibility of all Beninese. Two years later, the Ministry of Environment, Housing, and Urban Development was created and charged with the implementation and monitoring of Benin's environmental laws. The following year, an environmental framework was set out in the Environmental Plan, which operates on the principle that polluters pay for the damage they create. Modeled after international and regional plans, Benin's environmental policies seek to promote sustainable development while dealing with issues that range from improving the quality of water and waste disposal to severe coastal erosion.

Checking coastal erosion is considered a major priority in environmental planning, and the government has begun constructing groins, a system of levees that are built at right angles to the sea, to check the damage created by ocean currents. The ultimate success of this project will depend on obtaining the roughly $60 million necessary for full implementation. Benin participates in the following international agreements on the environment: Biodiversity, Climate Change, Kyoto Protocol, Desertification, Endangered Species, Environmental Modification, Hazardous Wastes, Law of the Sea, Ozone Layer Protection, Ship Pollution, and Wetlands.

Berry, Wendell (1934–)

POET, NOVELIST, ESSAYIST, social critic, and small farmer, Wendell Erdman Berry was born August 5, 1934, in rural Henry County, Kentucky. The years after World War II witnessed large farms replacing small ones, machines replacing horses, and internecine, debt-ridden, assistance-dependent farmers replacing a tight-knit, largely self-sufficient rural community. This agri*cultural* transition that took place in Henry County (and more broadly, the rural United States) during Berry's formative years would have a lasting impact on his values, livelihood, and ultimately his writing. After completing the creative writing graduate program at Stanford University as a Wallace Stegner fellow, Berry spent one year in Europe as a Guggenheim fellow and two years teaching at New York University, finally to return home to Kentucky in 1964. For over a decade, he split time between teaching at the University of Kentucky in Lexington and farming in Henry County. With the exception of another short teaching stint in the late 1980s, he has farmed and written from his small farm in Henry County since 1977.

To summarize Berry's work is nearly impossible; even to label him an "environmental writer" is almost unfair. His earliest works were novels of rural life in Kentucky, and his more recent writings include overtly political essays with little central focus on things natural. In all, Berry has published 15 novels and short story collections, and over 30 volumes of poetry. It is perhaps in his agrarian essays, however, that Berry has received his widest readership, highest critical acclaim, and forged what will be his most lasting influence.

Berry's first collection of nonfiction essays was 1972's *A Continuous Harmony: Essays Cultural and Agricultural*. His Jeffersonian agrarian ideals shine through in countless passages, such as the following taken from the essay "Think Little":

> What we are up against in this country, in any attempt to invoke private responsibility, is that we have nearly destroyed private life. Our people have given up their independence in return for the cheap seductions of 'affluence.'

Most tragically, for Berry, is that rural Americans—even its farmers—have followed this urban trend. The fallout is a rural landscape that is at once depopulated, environmentally degraded, and devoid of the sense of community that held these once ecologically and culturally rich, if always (relatively) monetarily poor, places together.

These themes are most forcefully expressed in his 1977 collection *The Unsettling of America: Culture and Agriculture*. Here Berry makes his first focused attacks on the irredeemably unjust U.S. agricultural-policy/agribusiness-corporation nexus. Often echoing the sentiments of Aldo Leopold, but always more bitter and pessimistic, *The Unsettling of America* exposes the modern, corporate farm as a wasteful, unnatural, antiecological, profit-driven use of the land. Berry argues that unless small landholders—self-sufficient, community-minded growers and makers—return to an appropriate scale and method of practice, the landscape of natural and human communities will continue to suffer the increasingly toxic effects of modernity. A good starting place for Berry's biting but crystal-clear and prescient critique is the 2002 collection *The Art of the Commonplace: The Agrarian Essays of Wendell Berry*.

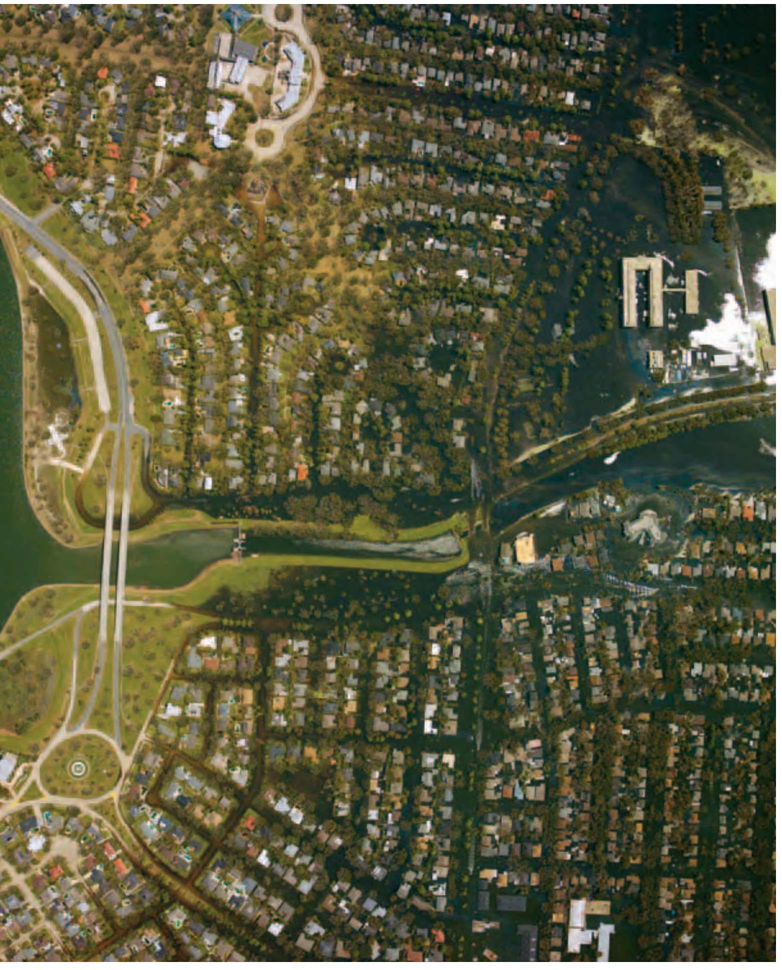
Best Available Technology (BAT)

BEST AVAILABLE TECHNOLOGY (BAT) refers to a doctrine, sometimes adopted in enforcement of environmental policy, to pursue only the most state-of-the-art, technological solutions and processes, regardless of efficiency or expense. For permitting of industrial effluents under the Clean Water Act, for example, levels of allowed toxic pollutants have been set as matching those that might be reached with the "Best Available Technology." The doctrine of BAT differs significantly from cost-benefit decision-making, as employed by the U.S. Corps of Engineers, for example, in balancing the costs of a project against the potential gains or losses.

The difference between the two can be seen in the strength of the levee system in New Orleans, Louisiana prior to Hurricane Katrina on August 29, 2005. When the levees broke, catastrophic damage occurred. The Corps of Engineers had used state-of-the-art technology in their cost-benefit studies, including the likelihood of a great hurricane striking the city. The cost of rebuilding New Orleans will probably be more than the cost if the BAT doctrine had been applied. If the levees of New Orleans had been protected by the BAT doctrine, it would have appeared excessively expensive; however the decision to use BAT would have had a different environmental impact.

Many future-oriented businesses have adopted a BAT strategy in order to beat competition in the struggle for market share. Environmental issues can also benefit from the BAT approach if the situation is an emergency like an oil spill, or the survival of a species. Congress has mandated BAT be used to control air pollution in the Clear Air Act.



When the levees broke in New Orleans during Hurricane Katrina in August of 2005, catastrophic damage followed.

Both state laws and other federal laws related to the Clean Air Act have mandated the use of BAT. The courts are in the process of applying BAT to cases as a legal doctrine.

In the area of pollution control, a modified form of BAT is the Best Available Control Technology (BACT) approach. Using BACT means that the best technology for controlling pollution, such as nuclear waste, is accomplished by whatever means at any cost. BACT is used in contrast to the most economical pollutions-control approach to environmental problems, which runs the risk of failures that will result in major ecological disasters. The policy decision to avoid risk in order to save money is a decision more concerned with excellent results than with costs. Under the Clean Air Act, a polluter must show that pollution emissions cannot be controlled by BAT. Usually, whichever technology produces the greatest reduction of air pollutants is the technology that must be used by a polluter regardless of the cost.

Bhopal Gas Tragedy

ON DECEMBER 3, 1984, one of the worst industrial disasters of the 20th century occurred in Bhopal, India, a city located in Central India's state of Madhya Pradesh. Here, at about 1 a.m., a highly poisonous vapor (methyl isocyanate, or MIC) leaked from the Union Carbide pesticide plant. This incident not only left about 300,000 people injured and about 2,000 dead immediately (it is reported that later about 15,000 people died), but also had an impact on local plants and animals. The majority of deaths and serious injuries were related to pulmonary edema, but the gas caused other ailments such as cough, dyspnea, chest pain, eyelid edema, and unconsciousness leading to acute lung injury, cardiac arrest, and death. Other problems included partial or complete blindness, gastrointestinal disorders, impaired immune systems, and post-traumatic stress disorders. After this tragedy in Bhopal there was a rise in spontaneous abortions and stillbirths; offspring with genetic defects were also noted.

There are a few reasons for leakage of MIC. Water accidentally entered the tank where MIC was stored, which started the exothermic reaction of excessive heat and eventual bursting of the tank's safety valve. The pressure of this burst even broke the concrete of the tank, releasing MIC. With a chimney height of just 30 meters and high moisture content in the discharge, the heavy gas sank to the ground. The weak winter wind changed direction quickly, which contributed to the spread of the gas and covered a large area in a short period of time. But the main reason for the tragedy is a combination of human factors and the faulty design of the safety system. According to some reports, part of the safety equipment was faulty, and by the time the alarm was sounded, an hour had elapsed since the gas was released into the atmosphere. Some other causes have been debated, but there seems to be a combination of human and technical fault—the same plant experienced six accidents between 1981 and 1984. These accidents should have alerted the authorities, but were neglected. India, a poor nation with a need for pesticides, did not raise any concern.

The Indian government sued Union Carbide for $3 billion, and the case was settled in 1989 for $470 million, but very little money reached the victims of the tragedy. Even more than two decades after the accident, due to lack of political will and resources, the environment surrounding the plant are still laced with toxic wastes. The plant and the surrounding areas are still contaminated, causing slow poisoning and diseases in humans, destroying the local biodiversity, and affecting the ecosystem. The contamination of groundwater (the main source of drinking water) in the neighboring areas of Union Carbide was a serious problem even before the tragedy hit Bhopal. The condition has worsened since then because the area has not been cleaned.

The Bhopal gas tragedy is one of the worst industrial disasters in history, but it did start a public debate on the hazards of the chemical industry, which led the Chemical Manufacturing Association to start the Responsible Care Program. The main goal of the Responsible Care Program is to improve community awareness, emergency response, and employee health and safety. The tragedy also started an environmental movement in India and has made the general public more aware of the impacts of industrial accidents. Following this tragic event, Indian Environmental legislations have also undergone drastic changes. The Ministry of Environment and Forests has been created to administer and enforce environmental laws and policies, and an Environment Protection Act was passed in 1986. The ministry was established to integrate environmental strategies into all industrial development plans for the country, but in spite of all these commitments to the environment and public health, development has taken precedence.

Bhutan

IN THE EARLY 20th century, Bhutan was a Protectorate of Great Britain, who took responsibility for directing Bhutan's foreign affairs, theoretically leaving internal affairs to the Bhutanese government. They ceded that role to India in 1947, with the relationship formally defined in 1949. Bhutan has one of the smallest and least-developed economies in the world. Some 93 percent of the population is engaged in agriculture, chiefly in subsistence farming and animal husbandry, and there is a substantial lack of modern technology. Only 8.5 percent of Bhutanese are urbanized.

One-fourth of the workforce is engaged in industries, and employers are faced with a massive labor shortage. The economy is highly dependent on regular subsidies from India. With a per capita income of $1,400, Bhutan is ranked 197th of 232 nations in world incomes. A current and ongoing political crisis revolves around the issue of 100,000 Bhutanese refugees of Nepali ethnicity, expelled by Bhutan in the early 1990s, who remain in camps under the administration of the United Nations Office of the High Commissioner for Refugees.

Population estimates for Bhutan vary from 810,000 to 2,200,00. Life is harsh in Bhutan, and life expectancy is low at only 54.39 years. On the other hand, infant mortality is high (100.44 deaths per 1,000 live births). Partly for this reason, the fertility rate is also abnormally high at 4.81 children per female. Low literacy rates contribute to the labor shortage. Less than half of the adult population can read and write, and the literacy rate for females is abysmally low (28.1 percent). About 38 percent of Bhutanese lack access to safe drinking water, and 30 percent have no access to improved sanitation. The United Nations Development Project (UNDP) Human Development Reports rank Bhutan 134th in the world in overall quality-of-life issues.

Nestled between China and India, Bhutan controls some of the major passes through the Himalayas. The country is landlocked and has no freshwater resources. The climate is diverse, ranging from tropical in the southern plains to cool winters and hot summers in the central valleys to severe winters and cool summers in the Himalayas. The Kingdom of Bhutan received its name, the "Land of the Thunder Dragon," from the frequent thunderstorms that occur during the rainy season. Bhutan is also subject to landslides. The terrain is mostly mountainous, interspersed with fertile valleys and savanna. Due to a lack of roads, transportation is difficult.

HEALTH AND ENVIRONMENT

In addition to the lack of potable water, soil erosion and land degradation are the major environmental problem for Bhutan. Other problems include air and water pollution, overgrazing, uncontrolled fires, road construction, solid waste management, and poaching. The Glacial Lake Outburst Floods, which are composed of 24 glacial lakes, are in danger of bursting due to climate change. Bhutan ranks in the top 10 countries of the world in species density. To protect these important resources, the National Assembly issued a mandate that forest cover must be maintained at least 60 percent at all times. Bhutan is home to some 200 mammal species that include the golden langur and the clouded leopard. More than 700 bird species and 800-900 butterfly species are also found in Bhutan. Twelve bird species and 22 mammal species are in danger of extinction.

In 1969, the Bhutanese government passed the Bhutan Forest Act and followed it up five years later with the National Forest Policy. It was not until 1998, however, that the government set up a comprehensive framework for environmental policy by strengthening the National Environment Commission and the Nature Conservation Division, which share the responsibility for environmental planning, assessment, and enforcement in Bhutan. The 1998 legislation also established the National Biodiversity Centre. A number of nongovernmental organizations are also active in protecting the environment. Bhutan has signed the following international agreements: Biodiversity, Climate Change, Kyoto Protocol, Endangered Species, and Hazardous Wastes. The Law of the Sea agreement has been signed but not ratified.

Bicycle

THE BICYCLE IS a two-wheeled, human-powered mode of personal transportation that transforms muscle power with chain-driven gears into motive force. Numbering perhaps one billion today, bicycles and analogous tricycle rickshaws accomplish a significant component of the world's commuting and light transport. Bicycle ownership and use is globally very uneven. Western European countries have the most bikes per capita, and in the Netherlands and Denmark, as many as one-third of commuting trips are by bicycle. Japan, Australia, and the United States have about the same number of bicycles per capita, but Japanese commuters use bicycles far more. In some south and southeast Asian cities rickshaws haul more goods and passengers than motorized vehicles. The world's preeminent cycling society is China, with at least 300 million machines and high rates of urban and rural use.

Bicycles are an efficient and relatively cheap means of transportation. Energy use in cycling averages 35 kilocalories per mile, three times more efficient than walking and 53 times more than an automobile getting 20 mpg. In 1975 dollars, cycling costs for a U.S. commuter covering 2,500 miles per year were (including road construction and maintenance costs) 10 cents per mile, compared to 56 cents for cars, 27cents for trains, and 18cents for buses.

WHEELS OF CHANGE

Despite its reputation as a green alternative to the automobile, the bicycle is an artifact of the same modernity that spawned the car. The cycling boom in Europe and the United States in the 1890s contributed to and was affected by a belief in scientific and social progress liberating the individual from the constraints of Victorian life. The changes to women's dress and mobility brought on by cycling articulated with feminism, and the bicycle's democratization of access to peri-urban parklands allowed more leisure time in the countryside.

At the same time, the boom presaged contradictions of automobile culture like dependence on neocolonial resource economies and the engineering of cities around personal vehicles over pedestrians or public transit. The demand for bicycles contributed to the scramble for rubber, which motivated the savage variety of European colonialism seen in the Belgian Congo. The political action of bicyclists in the United States in the 1890s centered on improving urban roads and reducing the street presence of trolley car lines. This put bicycles at odds with mass transit, and defined fast roads designed for private vehicles as the epitome of progress, an ideology of personal mobility amplified in the automobile age.

The bicycle was embraced by the European working classes for utilitarian purposes in the inter-war decades, but lost out to automobiles in the 1960s. At the same time, cycling rebounded in China, booming especially in the economic liberalization of the 1980s. Mass use of bicycles was a transport solution for rapid urbanization and industrialization without heavy investments in infrastructure, vehicles, or petroleum that the government encouraged through street engineering and support for domestic bike manufacturing. The rickshaw, a Japanese innovation influenced by European carriages, became the cycle rickshaw when fused with Western bicycle gearing and pedals. Human-powered urban transport fueled Asian urban economies with limited animal power or motorized vehicles, and created working class political power through paralyzing rickshawmens' strikes.

The *Critical Mass* phenomenon, where cyclists ride together to occupy street space typically given over to cars, began in San Francisco in 1992 and has since diffused to cities the world over. Celebratory and oppositional, *Critical Mass* challenges automobile culture and its connections to oil wars, global climate change, and the privatization of urban space. The term was coined by American cycling activists visiting China who observed Chinese bike commuters' tactics of negotiating street space with cars. The recent explosion in Chinese automobile use poses a unique question: What happens when the world's largest bicycling culture runs into the world's fastest growing car culture?

Bikini Atoll

BIKINI ATOLL IS located in the North Pacific at 11 degrees 30' North Latitude and 165 degrees 25' East Longitude, and comprises one of 29 atolls in the

Marshall Islands. The atoll consists of 36 islets that surround a lagoon of 594 square kilometers in area. Culturally part of the Micronesian region, archeologists place their best estimates of human colonization of the Marshall Islands between 3,000 – 2,000 years before present, with Bikini being settled more toward the recent portion of this date range. One controversial assessment of Bikini's settlement, based on carbon dating of charcoal, pushes that date back to between 4,000 – 3,600 years ago, although this date range supersedes geologic estimates of the Atoll's formation by 600 – 1,000 years (it is possible that the charcoal could have drifted in from elsewhere). Bikini Atoll is currently part of the Republic of the Marshall Islands, an independent state since 1979; a Compact of Free Association was signed with the United States since 1986, and its independence was formally recognized internationally in 1990 after the United State's trusteeship of the region was formally terminated by the United Nations.

BOMB TESTING AND RELOCATION

Bikini Atoll is best known as the site of U.S. nuclear testing between 1946 and 1958, during which 23 nuclear devices were detonated on the atoll, including the 15 megaton "Bravo" hydrogen bomb. As such, Bikini Atoll is often remembered as a symbol of U.S. imperialism in the Pacific Region, primarily for the forced relocation of the atoll's inhabitants, the destruction of the atoll and lingering effects of the radiation that prevent the peoples' return.

For its Project Crossroads, the U.S. military needed a large, remote test site that protected the U.S. population from radiation, in order to test the effectiveness of nuclear weapons against naval fleets as well as serve as a demonstration of military and technological prowess. Bikini Atoll was considered an ideal location for these and other reasons, except that it was inhabited.

The U.S. military characterized Bikini Atoll as a marginal environment incapable of providing a healthy standard of living for its inhabitants, and sought to move them to nearby Rongerik Atoll amid considerable fanfare. Although the U.S. military indicated that Rongerik was essentially identical to Bikini, their assessments ran counter to the perceptions of the Bikinians themselves. Contrary to the claims of the military, the people of Bikini atoll had strong cultural ties to the Atoll, having lived there for over 1,000 years. They viewed the area as a rich resource where their ancestors were buried, in contrast to the considerably smaller Rongerik that was viewed as inhabited by a maleficent spirit that had poisoned the food resources and consequently remained uninhabited over the same timespan. Indeed, within two months after relocation to Rongerik in early 1946, the Bikinians complained of inadequate food and water resources and were requesting repatriation to Bikini Atoll. Their plight was ignored by the military until 1948, after an anthropologist revealed that the Bikinians had been suffering from starvation and ciguatera poisoning (resulting from the consumption of fish that have fed upon toxic marine algae). The military relocated the Bikinians first to a camp on Kwajalein, and then to the island of Kili, which was smaller than Rongerik. Today, roughly one-third of the 3,100 Bikinians live on Kili, and the rest are scattered through the Marshall Islands.

The people of Bikini remain expatriated, despite being allowed to return, over lingering fears of radioactive contamination. The 23 nuclear detonations inundated the atoll with radiation, with the Bravo blast being especially destructive in vaporizing two islets, leaving a large crater in the lagoon and causing thyroid disorders from the radiation in nearby Rongelap Atoll to this day. The U.S. government declared Bikini Atoll safe for repatriation after 1960, but the Bikinians themselves opted not to return until they felt more certain of their safety. Some began to return after 1970, but after five years exhibited concentrations of radioactive caesium and strontium in their bodies over ten times the safe levels (from eating contaminated local foods), and were forced to leave again in 1978. Recent assessments suggest that permanent settlement is currently possible, provided certain remediation efforts are undertaken, such as applying potassium fertilizer that the crops will take up more readily than caesium. Bikinians are nevertheless skeptical of the scientific assessments, having been falsely reassured of the atoll's safety before, and have yet to resettle. Bikini Atoll is currently being developed as a tourist destination, with scuba diving among the sunken ships used in the nuclear testing as a primary attraction.

Nuclear testing in the Pacific remains a sore point in geopolitical relations between Pacific Island citizens, and the United States and France in particular. New Zealand emphasizes this fact in its Nuclear Free Pacific policy, which it uses as a diplomatic tool to maintain friendly relations with the various Pacific Island Countries. Most recently, France resumed its nuclear testing at Mururoa Atoll (French Polynesia) in 1995, despite vociferous opposition from the citizenry of French Polynesia; this move sparked regional protests and renewed calls for independence from France from some factions within French Polynesia. Comparisons with Bikini were made during these protests, with the United States and France being vilified for their historical lack of respect for Pacific Island peoples. New Zealand opposed the testing under its Nuclear Free Pacific policy, and strengthened its diplomatic ties with many Pacific Island Countries.

Biocentrism

DERIVING FROM FAMOUS precursors such as Aristotle and his work, *Virtue Ethics,* which stresses the importance of character traits and the inherent value of all life, *biocentrism* is a whole of life—a centered, environmental ethic that positions the environment and all living things as equal to human beings.

The interconnectedness of humans to nature is emphasized, as is the idea that all living things have an equal right to life, and are each unique in their own right. As a concept, it is best understood in relation to its opposite, *anthropocentrism,* which positions humanity at the center of the world, uniquely different from and superior to all other life forms.

The notion of "biotic justice" underpins biocentrism, which posits that moral values should not only be attributed to humans but a whole range of other entities. P.W. Taylor argues that a biocentric perspective morally obliges humans to consider the impacts of their actions, insofar as they might negatively impact on or harm nature. Taylor further argues that we are obliged to other living things in their own right, a principle based on the notion of "inherent worth," which is a concept he identifies as *species impartiality*. This intrinsic well-being, or good of each species, is identified as a "teleological-center-of-life."

In application to decision-making processes, proponents of the "biocentrist" theory argue that there are limits to what humans can do with the environment; and they emphasize the need for the development of systems and processes that promote stability, conservation and the interdependency and connectedness of all life systems.

Allocation of resources within a biocentric paradigm would be on the basis of a decision-making system that ascribes all organisms—humans included—equal values and rights. As such, biocentrism advocates an approach to environmental decision-making based on the precautionary principle, and the recognition that environmental systems need to be protected in the short and long term.

MORALITY OF BIOCENTRISM

Consequently, the animal rights, Gaia, and deep ecology movements stem from a biocentrist foundation, that human society is but part of a wide number and scope of organisms and systems. For example, key tenets of deep ecological theory reflect biocentric principles, that: 1) all human and non—human life on earth has value in itself and equal rights to flourish and experience quality of life and well—being; 2) the richness and diversity of all life forms contribute to the realization of these values and are also of value in themselves; and 3) that humans have no right to reduce this richness and diversity except to satisfy vital needs.

Peter Singer, an environmental ethicist who focuses on animal rights, takes the view that we share with other species a relationship to earth; that we are but one species amongst others; and that the integrity of the entire biosphere is related to the welfare of both human and nonhuman communities of life. He argues for the adoption of three other principles to guide ethical human action: that animals have the ability to reason; are sentient; and that the capacity to experience pleasure or pain is not limited to humans, nor can it be applied as arbitrary criteria for moral consideration.

Biocentrism has been criticized in that its moral concerns are directed toward the responsibility of the individual, rather than to ecological life forms and systems. While the protection of such collective entities is of major concern, none qualify as being sentient, a "subject-of-a-life," or a "teleological-center-of-life." Advocacy by biocentrists of the notion of well-being and worth has also been critiqued for being descriptive rather than prescriptive and therefore difficult to apply.

Biocentrism offers an alternative way of thinking about the world, and describes an ethical system that prioritizes a moral duty of human beings to place limits on human population, development, technology, and all other negative environmental impacts that diminish the welfare of life systems overall.

Biodiversity

BIODIVERSITY IS GENERALLY used to refer to all aspects of variability evident within the living world, including diversity within and between individuals, populations, species, communities, and ecosystems. Differences in pest resistance among rice varieties, the range of habitats within a forest ecosystem, or the global extinction of species of lake fish all illustrate different aspects of biological diversity. Biodiversity therefore embraces the whole of the incredible variety of life found on earth.

Globally, about 1.75 million species have been described and formally named, and it is believed that millions more species are yet to be discovered and described. In general, biodiversity is highest in and around the equator and continuously decreases toward the poles. The highest terrestrial biodiversity is found in tropical lowland rainforests. They cover only 6–7 percent of the earth's total land area, but contain probably more than 50 percent of all species. Seasonal variation in climate and any environmental extreme are some other important factors causing a decrease in diversity of plants and animals.

DEFINITIONS AND APPROACHES

Biodiversity is often described in hierarchical terms including genetic diversity, species diversity, and ecosystem diversity. Genetic diversity refers to the genetic differences between populations of a single species and between individuals within a single population; species diversity refers to the frequency and variety of species within a geographical area; and ecosystem diversity refers to the variety of habitats, the dynamic complexes of plant, animal, and microorganism communities and their nonliving environment, which interact as a functional unit and their change over time.

Varieties of rice, number of plants and animal species coexisting in a geographical area, and number of ecosystems in a forest area exemplify genetic, species, and ecosystem diversity, respectively.

Species diversity can be further distinguished into three types: *alpha*, *beta*, and *gamma* diversities. Alpha diversity refers the diversity at one site, i.e., the number of species coexisting within a single biological community. Beta diversity is species turnover across an environmental or geographical gradient, and gamma diversity refers to the total number of species in all habitats within a region. The "region" means a geographical area that includes no significant barriers to dispersal of organisms.

Some scientists have argued for the necessity of making distinctions between "functional" and "compositional" perspectives in approaching biodiversity, rather than using hierarchical terms. The functional approach is primarily concerned with ecosystem and evolutionary processes, while the compositional approach sees organisms as aggregated into populations, species, higher taxa, communities, and other categories.

Despite a wide range of definitions, biodiversity emerges as a concept linked primarily to the idea of biological variation that is largely unknown in its extent, and its future values.

WHY DOES BIODIVERSITY MATTER?

Biodiversity is important for human beings in a number of ways. First, species have utilitarian (subsistence and commercial) value to humans. Diversity of biological organisms is a crucial component in the livelihood of many poor people, as they often depend on the diversified plants and animals to meet their nutritional, medicinal, and energy needs. Different cultures and societies use, value, and protect these resources and services in a variety of ways. Moreover, there are huge prospects of benefiting from unknown genetic and species diversity. Second, biodiversity represents the natural balance within an ecosystem. Detoxification and decomposition of wastes by biological communities (particularly bacteria and fungi); generation and renewal of soil fertility, including nutrient cycling; and pollination of plants are just a few examples of ecological services associated with biological diversity. As biodiversity is reduced, internal and natural controls must be replaced by more artificial controls (in the form of management and resources), which may not be successful to the same extent. Third, species have intrinsic value. Many argue that protecting them from the terrible finality of extinction by saving their habitats is an ethical responsibility.

THE RAPID LOSS OF BIODIVERSITY

Highly valuable biodiversity is being lost at a great rate, and extinction of species is the most serious aspect of this loss. It is estimated that every hour we are losing one species forever; this rate is about 10,000 times higher than the natural rate of extinction. One million species have been estimated to

Tropical lowland rainforests contain the highest terrestrial biodiversity, with more than 50 percent of all species.

have been lost, and scientists working in this field generally agree that several more million will be lost in the first few decades of the 21st century, unless we have effective measures to control the current rate of species extinction.

The causes of species extinction can be natural as well as human activities. The causes in prehistoric times were mainly natural, whereas the extinctions in historic and present times are mainly human-caused. Our concern today is related to human-caused extinctions that result from human activities such as destruction, degradation, and fragmentation of natural habitats (e.g., agricultural clearance of forest land); exploitation of species for human use (such as commercial logging); introduction of invasive exotic species, such as certain species of fish; pollution (e.g., pesticides and industrial wastes, particularly sulfur and nitrogen oxides); international trade of wild animals and animal body parts; and increased spread of diseases. Climate change could become the main threat in the future.

These direct or proximate causes of biodiversity loss are considered to be the results of underlying causes, including rapid growth of human population, drive to globalization, and inequality of ownership and property rights. Globalization, for example, has increased reliance on a small number of crop species that can be traded in the global market; for example, demands in industrialized countries encouraged conversion of tropical rainforests into rubber or cocoa plantations, and mangroves into shrimp farms. Overconsumption by developed countries, which acts as a driving force to exploit resources from developing countries for a short-term gain, exemplifies the inequality of ownership and property rights. Governmental and international support for industrial forestry, agriculture, and energy programs over and above traditional usage patterns, and state subsidies for the cattle industry (e.g., in the Amazon region) and agribusiness (e.g., to grow export crops in Brazil) are some other examples of underlying economic and political causes of the loss of biodiversity.

Concerns are also being expressed in some quarters that the introduction of intellectual property rights, under the aegis of World Trade Organization (WTO) in the biological resources—including agriculture—may lead to erosion of biological diversity in many bioresource zones. The underlying disparity between the private and social costs and benefits of biodiversity use and conservation can be considered as another main reason for the decline of biodiversity. Private costs and benefits refer to losses and gains as perceived by the immediate user, such as the farmer or the industrialist, while social costs and benefits refer to losses and gains that accrue to society (the local area, country, or world). These two interests often do not coincide.

The high rate of biodiversity loss has been a matter of great concern among conservation scientists, especially since the late 1980s. The concern has been increased by our incomplete knowledge of biodiversity: We don't know the exact number of species on earth, nor do we fully understand the relationships that bind them. The loss of even one species can ruin an entire forest ecosystem of plants and animals because the animals that depended on this vanished species as prey have now lost their food source. In turn, the animals that it fed on have lost a predator, and these species often undergo population explosions that are devastating for the plants or animals that they feed on. The entire ecosystem can collapse in this manner, and will therefore be prevented from performing its usual "ecosystem services" (a utilitarian term for the natural processes that provide rich soil, clean water, and the air we breathe). The seriousness of the problem also lies in the fact that it takes millions of years for new species to evolve in the place of the species that have gone extinct.

ADDRESSING LOSS OF BIODIVERSITY

The major issue for biodiversity is how its conservation may be integrated with other needs of society. This has become an important issue in the world especially after the Earth Summit held in Rio de Janeiro in 1992. In that summit, more than 150 states signed the Convention on Biological Diversity, acknowledging the sustainable management of the world's biological resources to be one of the most urgent issues of the modern era, and expressed their commitment to address this collectively. Since then, around 180 countries have ratified the convention. The convention recognizes the need for a multisectoral approach to ensure that biological diversity is conserved and used sustainably, the importance of sharing information and critical technologies, and the benefits that can accrue from use of biological resources. The treaty is considered a landmark in the international community's approach to environment and development. It has increased the coordination of cross-sectoral action within and between countries for biodiversity conservation, and has also led to the release of substantial international funds to support developing countries. Some international nongovernmental organizations, such as the World Conservation Union (IUCN) and World Wildlife Fund (WWF), are also actively involved in conservation of biodiversity on a global scale.

Investments in public education and awareness, increased stakeholder involvement in decision making, effective implementation of the national biodiversity strategies and action plans, improvement in sectoral and cross-sectoral integration, and strengthening protected area networks are some of the most important priority areas for further action by countries as identified by the *Global Biodiversity Outlook 2002*. Moreover, it is essential to take a holistic view of biodiversity and address the interactions that species have with each other and their nonliving environment to increase the efficiency of management interventions.

Bioenergy

USING WOOD BIOMASS for energy started since creation to provide heating under harsh winter conditions. Biomass energy is still used to provide cooking fuel, heat, and electricity to many communities, homes, and industries globally. Using wood biomass for energy can help mitigate global warming effects and improve water and air quality.

Using forest-related biomass for energy has become the subject of many international mandates, such as the International protocol to the United Nations Framework Convention on Climate Change (UNFCCC). Also, the International Energy Agency has dedicated offices that research biomass energy potentials. Many international, governmental, academic and private institutions are developing fast-growing woody crop species for a higher yield of biomass per unit acre. Efforts are also directed toward improving machinery that can handle dispersed wood biomass in an efficient manner.

Many scientists believe that trees sequester carbon, and therefore reduce Greenhouse Gas Emissions. However, when biomass is burned, this carbon is released again into the atmosphere. Therefore, by growing more trees, this emitted carbon is sequestered again. Growing trees for energy makes this source a renewable one.

The term *biomass* in forestry is used in conjunction with the production of energy from trees. Biomass is derived from plant photosynthesis, and is formed from the storage of solar energy in the form of carbon, hydrogen, and oxygen. Biomass can be obtained as a direct outcome or as a joint production from forest operations. Usually, forest biomass energy is derived as a joint product from timber harvesting and management operations. In this case, the term normally refers to forest residue, such as treetops and branches. Nonmerchantable stems and dead, diseased, and downed trees are a source for forest biomass energy. Wood biomass also includes short-rotation woody crops, such as fast-growing hybrid poplars, willows, and eucalyptus plantations.

The world's largest biomass power generation facility is the Alholmens plant in Pietarsaari, Finland. Finland has invested in improving biomass-handling technology, with the aim of having biomass energy, which is more cost and energy efficient. Countries such as Sweden and Brazil grow short-rotation, intensive cultures from willows and eucalyptus for energy.

One way to make forest biomass less expensive is to cofire it with other nonrenewable sources, such as coal. However, if wood biomass is burned alone, wood ash can return to soils as a nutrient that replaces the wood removed for energy. However, if wood is cofired with coal biomass, then it cannot be used as a soils nutrient. Other soil-fertilization options need to be considered to avoid soil nutrient depletion.

The ability to have a sustainable supply of biomass to generate heat and electricity is another concern attached to biomass harvesting. Unlike many other industries, the more biomass that is required for energy, the more expensive it becomes. This is because biomass procurers need to collect biomass material from longer distances. Therefore, more road construction, energy, and costs are involved. Growing dedicated plantations for energy can reduce these factors, since only one site is accessed for a significant number of years, with already-prepared roads for harvesting.

In addition, biomass energy industries offer job opportunities to local communities. Many research and development projects are underway to offer a cheaper, more energy- and cost-efficient methods for biomass utilization and collection from forests.

Biogeochemical Cycle

A BIOGEOCHEMICAL CYCLE refers to the cycling and transport of a chemical element or compound, usually in multiple forms and physical states, through the biotic (living) and abiotic (nonliving) components of the earth system. Some of the most commonly examined biogeochemical cycles include carbon, nitrogen, oxygen, water, and phosphorous, which are highly interdependent and connected to both the physical environment and human activity. Biogeochemical processes include cycling to and from living organisms in the biosphere, rock minerals in the lithosphere, hydrological processes in the hydrosphere, and air circulation in the atmosphere, making the spatial and temporal variability of biogeochemical cycles quite complex. Biogeochemistry attempts to understand the physical processes that control and make up these cycles, as well as the natural and anthropogenically-induced variation in these cycles, including potentially harmful alterations. Humans depend upon biogeochemical cycles for, among other things, food production, water supplies, and oxygen, so the dynamics and disturbances of these processes are a major concern for environmental scientists and policymakers. Similarly, concerns related to global warming, air pollution, and biodiversity also require an understanding of biogeochemical cycles, as well as their interaction with humans and human activity across the world.

Biogeochemistry is an interdisciplinary science because it requires knowledge of living and nonliving processes that occur at various temporal and spatial scales in all components of the earth system, including the world's oceans, forests, and urban areas. A biogeochemical cycle may include the occurrence of pools or sinks (where an element or compound is stored for longer periods) and sources (where an element or compound is freed from a sink, often in a short time and in relatively large quantities). Both human and nonhuman processes and activities (such as fire) may alter the spatial and temporal cycling of elements such as carbon and oxygen from sources and sinks, which can make it difficult to clearly distinguish "natural" and "human" perturbations of biogeochemical cycles. Furthermore, biogeochemical cycles occur and can be altered at a range scale from molecular to global, making it challenging to study entire biogeochemical cycles at one time. As a result, biogeochemistry examines past, current, and future time scales though the use of paleo-ecology, physical science, and statistical modeling.

CARBON AND NITROGEN

Biogeochemistry attempts to determine the interrelated and multidirectional connections and feedback loops that make up the physical environment. Biogeochemical cycles interact with other chemicals and compounds, human and nonhuman processes, and various components of the earth's spheres. The carbon and nitrogen cycles are provided as examples of the complex interactions that constitute biogeochemistry.

Carbon is one of the most studied elements in biogeochemistry because it is the primary element of living tissue, is essential for plant photosynthesis, and is an important greenhouse gas (as carbon dioxide and methane) in the earth's atmosphere. Carbon cycles through plants, animals, oceans, vegetation, the atmosphere, and lithosphere, and is driven largely by photosynthesis and respiration in plants, animals, and other living organisms. This cycle has been dramatically altered through human activity, such as the burning of fossil fuels, cement production, urban development, and grazing, all of which can release carbon dioxide into the atmosphere. Higher concentrations of carbon dioxide since the industrial revolution have been shown to contribute to global warming by increasing the atmosphere's greenhouse effect, which may raise global temperatures, cause a rise in sea level due to the melting of sea ice, alter precipitation patterns around the world, and change storm frequency and intensity.

HUMAN ACTIVITY

At the same time, however, human activities that increase atmospheric CO_2 have also been shown to alter the rate at which plants take up carbon through photosynthesis. Specifically, some studies have shown that higher carbon dioxide levels in the atmosphere may increase the rate at which some plants photosynthesize, offsetting some carbon dioxide emissions (in what has been called CO_2 fertilization). These spatial and temporal changes, however, must be understood within the complete biogeochemical cycling of carbon, because the potential for short-lived increases in CO_2 uptake during increased photosynthesis is unlikely to offset decades of human increases of atmospheric CO_2.

Similarly, human activity has been shown to alter the nitrogen cycle through the application of fertilizers, production of power, combustion engines, and increases in human and animal waste. In an attempt to increase plant growth and photosynthesis, humans have applied fertilizers containing nitrogen and phosphorous to agricultural lands worldwide. Though productivity rates may be temporarily improved, the excess nitrogen released into the biosphere has damaged certain aquatic habitats through eutrophication, where the excessive growth of particular organisms can deplete the water of oxygen. Acid rain has also been attributed to increases in certain forms of nitrogen, which can disturb water systems and aquatic life, leach important nutrients from soils, and damage plants and buildings. The biogeochemistry of both carbon and nitrogen reveal the connections between various processes and components of the earth system, both human and nonhuman.

Biogeochemical cycles are of incredible significance to society because the science related to the biogeochemical cycling of chemicals becomes the basis for various policies, programs, and actions by individuals, states, and corporations. For example, climate policy is based upon the understanding of changes in carbon sources and sequestration, while interactions of the land and atmosphere with hydrological systems become the basis for water quality measures. Because biogeochemistry examines multiple elements and systems, it is essential to understand the spatial and temporal variability of biogeochemical cycles and the complex connections between human activity and physical responses. Isolating any one particular part of a biogeochemical cycle may not accurately characterize the complete interaction between the physical environment and human activity. Biogeochemistry works to uncover and more fully understand the connections between various elements, parts of the earth system, and biotic and abiotic processes.

Biological Oxygen Demand

BIOLOGICAL OXYGEN DEMAND (BOD), or biochemical oxygen demand, is an index or measure of the concentration of biodegradable organic matter in a body or quantity of water. BOD is a natural phenomenon, but is also a test used to determine the condition of water for maintaining natural ecological processes of human use. Oxygen dissolved in water is a naturally occurring resource, provided by waterfalls, rapids, winds, and waves, without which organic materials would build up beyond the capacity of water bodies to sustain life. BOD occurs naturally as organic debris wash into streams, rivers, and lakes. These organic materials are oxidized by bacteria and other microorganisms, which decompose organic wastes (e.g., dead leaves, fish, plants, manure, sewage), consuming oxygen in the process. Should oxidation outpace the availability of oxygen, the water can become anoxic (depleted of oxygen). The lack of oxygen in water will render a lake or a sea dead. For example, most of the water of the Black Sea is anoxic water.

Pollutants in water in high levels—nitrates, phosphates, or manure—cause the rate of oxygen consumption to increase as the available bacteria consumes the waste and grows in number. Rises in water temperature can also contribute to a reduction in the oxygenation of water, which promotes the growth of algae and other plants. They also die more rapidly, which increases the amount of organic material in the water, and thus, the food supply for bacteria. If the BOD is high, the levels of dissolved oxygen will decrease, threatening the water quality. Human pollution deprives water of oxygen, and is a threat to both natural and human life.

The greater the organic matter in the water, the greater will be the oxygen consumption by the microorganisms laboring to dispose of the waste. The Royal Commission on River Pollution first used BOD as a way of measuring water pollution in England in 1865. After the work of the Royal Commission on Sewage Disposal in 1898, BOD tests were developed to define the amount of pollution in rivers. The test took five days, the length of time for water in English rivers to travel from the source to an estuary. An additional element of 30 ppm (parts per million) was added in 1912 as the maximum concentration of organic material that a sewage system could discharge into a river. The test was later refined.

Direct measurement of BOD is used to report the amount of oxygen that a biological process is consuming as it reduces organic material in water. BOD can also be used to describe an indirect measurement of the amount of waste in a solution by measuring the concentration of the biologically degradable organic material in a given unit of water. The term then applies to the amount of oxygen needed in five days if a biological process is to break down a quantity of organic waste. From the results, the quality of the water may be inferred. If the water quality is rated as poor because the level of organic material in the water is high, then the water may be considered polluted, and unsafe for humans to drink or swim in.

Biomagnification

BIOMAGNIFICATION REFERS TO the tendency of some chemicals to concentrate in living organisms and to pass up the food chain as they are consumed. Especially pernicious are those chemicals that are easily absorbed, not easily metabolized or excreted, have long half-lives, and an affinity for fat. These include methyl mercury; polychlorinated biphenyls (PCBs); and the chlorinated hydrocarbon pesticides such as DDT, aldrin, dieldrin, lindane, and heptachlor. Substances that are water-soluble and biodegradable are not generally subject to biomagnification.

The loads of these chemicals increase in small, ostensibly harmless increments, but are concentrated in higher trophic levels, as organisms eat and in turn are eaten. Over time, the repeated consumption of contaminated prey ultimately results in the accumulation of high and possibly toxic levels within the consumer, compared with ambient levels of the contaminant in air, soil, and water that may be quite low. Additionally, since predators may preferentially select prey with the highest levels of contaminants (that is, those experiencing sublethal symptoms of chemical poisoning), predators may be exposed—not to average pollutant concentrations—but to maximum levels.

Because of the slow and incremental nature of biomagnification, there is often no indication that poisoning has occurred until toxic levels are reached. Poisoning at high levels can be lethal; while at lower doses, neurological, developmental, reproductive, and behavioral disorders—among other problems—may arise.

SPECIES AT RISK

Biomagnification is a special concern for species that occupy the higher trophic levels and those that have long average life spans. Particularly at risk are terrestrial mammalian carnivores, marine mammals, birds of prey, and predator fish species. Studies have demonstrated that the degree of biomagnification, however, is not merely related to the trophic levels of the consumer, but also to the species' bioenergetic conversion efficiency, which relates activity and energy expenditures to growth and bioaccumulation rates. It is also associated with the species' physiological ability to detoxify the chemical.

Predatory birds are especially vulnerable to biomagnification because their detoxification capability is poor. In fish-eating birds—such as the bald eagle and osprey—the biomagnification of DDT created toxic levels of DDE, a metabolic product of DDT that interferes with calcium absorption. This led to the thinning of eggshells and caused eggs to crack under the weight of the roosting parent, leading to plummeting numbers of these species. In the decades following the prohibition of DDT use in the United States in the 1970s, some of these populations have recovered.

As a high trophic level feeder, humans are not excluded from the process of biomagnification. A tragic example of this occurred in Minamata, Japan, in the 1950s. Mercury was released into a nearby river by a factory and then methylated by bacteria. The methyl mercury was bioconcentrated by organisms and subject to biomagnification, eventually poisoning the humans who consumed contaminated fish. This resulted in a host of health disorders and deaths, creating health problems even for successive human generations.

Mobile and migratory organisms have the capacity to move chemical contaminants in their bodies from one ecosystem to another. Global air and ocean circulatory patterns, in addition to transport by rivers, can move contaminants long distances. Thus, biomagnification of toxins occurs in organisms living in ecosystems far removed from the original sources of contamination.

Salmon are high trophic level feeders, relatively large, and have high lipid content. As such, they may accumulate a high concentration of toxins over their life span. Because of their anadromous life history, they can transport toxins from marine to freshwater systems. In the Great Lakes, salmon transport contaminants from the lakes to small tributaries. After spawning in freshwater tributaries, salmon die. Many species, both aquatic and terrestrial, consume their carcasses and take on their burden of toxins, thereby passing them to terrestrial food webs.

In aquatic environments, biomagnification occurs at every trophic level and toxins are ingested not only through the consumption of food, but also through the intake of water and sediments containing contaminants. As a result of the global transport of pollutants, the amplified process of biomagnification in aquatic systems, and the impact of cold climates on processes of chemical transformation, elevated levels of persistent organic pollutants (POPs) have been found in the arctic—far from their place of origin—in arctic-dwelling species of fish, birds, and mammals, including polar bears and marine mammals. With diets high in these species, humans living in arctic communities, such as the Inuit, have been found to have high levels of POPs in their bodies. The breast milk of Inuit women has been found to have DDT and PCB concentrations many times higher than that of women in more temperate latitudes. In a final step of biomagnification, these toxins are passed via breast milk to infants. The implications of this on the health and development of these infants is not yet completely understood.

Biomes

BIOMES ARE COMPRISED of the major, regionally distinct biotic communities. They are the largest ecosystem units, delineated at a global scale. Biomes are not distinguished by the taxonomic identities of the organisms they contain, but rather on the basis of the life forms of these organisms, their structure, life history, and responses to environmental change. Although specific plant and animal species differ among continents, the same biomes with similar structure, seasonality, productivity, niches and uses by humans exist in different regions. For example, northern conifer forests exist in North America and Asia, and tropical rain forests are found in Africa, Central and South America, and south and southeast Asia. Biomes are usually associated with their climax community vegetation; however, they encompass successional and subclimax community species and animal species, as well as soils. Generally, they are not divided by sharp boundaries; rather, adjacent biomes grade into each other, interact, and function as interdependent parts of the biosphere as a whole.

Classifying the earth into major biome types is a useful approach that allows the development of a common framework and mapping system for these large-scale systems. This facilitates communication among scientists, comparative analyses, and the development of resource and environmental management strategies. However, it is important to note that maps of biomes are human constructions and not usually drawn to reflect a current reality. Rather, they tend to depict an imagined world devoid of human impacts and influence, and one in which processes of succession have reached a climax end-state.

Biomes are delineated by a combination of ecological gradients, including temperature, precipitation, altitude/depth, latitude, longitude, proximity to various features such as oceans and mountains, soil type, salinity, and range of tidal activity. These factors determine the assemblage of animals and plants that live in the biome, and their biological productivity.

HUMAN IMPACT ON BIOME CLASSES

Various classification systems have been developed to organize biomes. Some scientists apply the biome concept exclusively to terrestrial systems because their structure and connections to other aquatic environments differ from terrestrial systems, and they are perceived to be less responsive to climatic cues. Other scientists, however, include freshwater and marine systems in their biome classifications. Whittaker provides a classification system that is more detailed than some, with 36 discrete biome types. Cox and Moore identify ten terrestrial and four aquatic biomes. These encompass the arctic tundra, northern coniferous forest, temperate forest, tropical rain forest, tropical seasonal forest, temperate grassland, tropical savanna grassland and scrub, desert, chaparral, mountains, freshwater, oceans, rocky shores, and muddy or sandy shores.

Desert biomes are arid, with low and often irregular precipitation coupled with high evaporation. They have relatively low productivity and are one of the harshest environments on earth. Human activities, such as animal grazing, have actually extended the range of deserts in the world through the process of desertification. Tundra is identified with low temperatures and permafrost, and is predominantly found in northern polar regions with less occurring in the southern hemisphere. Many animal populations in the tundra are migratory and/or have large cyclic changes in abundance. Significant human impacts on the tundra include those associated with fossil fuel and mineral extraction, military operations, and the exploitation of both marine and terrestrial animal resources.

The northern coniferous forest (or taiga) occurs adjacent to the tundra region, encircling the northern latitudes of continents, and is also found in high-altitude regions in lower latitudes. It is comprised primarily of evergreen conifers and represents one of the world's largest, most intact biomes. Logging coupled with large-scale mining, however, are degrading this biome. This degradation is exacerbated by the impacts of acid rain (caused by emissions of air pollutants primarily from mid-latitudes) on terrestrial and freshwater aquatic systems. In the mid-latitudes, temperate forests have a seasonal climate distinguished by warm summers, cold winters, and deciduous treed land cover. A large extent of these biomes has been converted to human settlements and boasts large agricultural, urban, and industrial areas with concomitant deforestation, habitat fragmentation, and production of waste and air pollution.

Tropical rainforests occupy the equatorial region between the Tropics of Cancer and Capricorn, and are characterized by high solar radiation, temperature precipitation, species diversity, and nutrient-poor soils. Intense logging, especially in the Amazon region of South America, coupled with land conversion for agricultural operations—particularly animal grazing—are of special concern. Cox and Moore estimate that at the current projected rates of destruction, the tropical rainforest biome could be eradicated completely within this century.

Temperate grasslands have precipitation levels greater than those found in deserts, but too low to support forest vegetation. They are characterized by grasses, large herds of grazing mammals, and soil rich in organic matter. These biomes have been altered by development of animal and plant agricultural operations and by the introduction, both purposeful and accidental, of new plant species. This has changed the ecological balance and made soils vulnerable to moisture loss and erosion, and as a result, intact examples of this biome are quite rare. Tropical savannas have warm climates with significant dry seasons and generally poor soils. They are comprised of grasslands, shrubs, and woodlands with significant grasses as well as a diverse fauna, including large herds of grazing mammals. Fire is an important abiotic aspect of this biome. Chaparral or sclerophyll ecosystems are characterized by a Mediterranean climate of wet, mild winters and dry, hot summers. The short trees and shrubs found in these areas are adapted to withstand summer droughts. These areas support large human settlements and, as a result, have been degraded by urbanization, pollution, and introduced species.

Overarching all of these human impacts is the impact of greenhouse gas pollution on the earth's atmosphere and its climate system. All of the world's biomes are affected by climate change, with the arctic tundra and ice-covered regions experiencing the

The arctic tundra and ice-covered regions experience the most serious impacts of climate change.

most serious and visible impacts. Future impacts of climate change pose arguably the greatest threat to the stability of the world's biomes.

Biophilia

COINED BY EDWARD O. Wilson, the *biophilia* hypothesis suggests that humans have an "innate tendency to focus on life and life-like processes." With "innate" meaning "hereditary and hence part of ultimate human nature," Wilson claims a biological basis for humans' attraction to living things and to nature at large, and argues that such an affinity was selected evolutionarily; not only does being "biophilic" confer a competitive advantage, it also provides the key to our achieving meaningful and fulfilling existences. The biophilia hypothesis is rooted in sociobiology, a discipline popularized by Wilson and Richard Dawkins in the 1970s to examine the genetic bases of social behavior within different species. Sociobiology has been critiqued, perhaps most notably by Richard Lewontin and Stephen Jay Gould, for being biologically deterministic, undervaluing the effects of culture and learning and, significantly, drawing the majority of its claims from research conducted on insects and other nonhuman animals. Sociobiology has been somewhat reworked through evolutionary psychology and human behavioral ecology, and it has enjoyed resurgence in light of the Human Genome Project.

Wilson and other proponents describe biophilia not as a single instinct, but rather as a "complex of learning rules that can be teased apart and analyzed individually." The learning rules mold feelings, or types of emotional response, that can range from attraction to aversion and from serenity to fear. These "multiple strands of emotional response" together form symbols that constitute a large part of culture. Spread by natural selection within a cultural context, genes prescribe the learning propensities that influenced cultural elaborations. This process is called biocultural evolution: According to Wilson, "a certain genotype makes a behavioral response more likely, the response enhances survival and reproductive fitness, the genotype consequently spreads through the population, and the behavioral response grows more frequent." Human tendencies to make meaning from these feelings—to explain, depict, and dream—have led to our cultural elaborations of art, worldview, and more.

A classic example would be what has been called the "maternal instinct," but should accordingly be described as a complexity of behaviors within many species that arguably confers advantages to the protected offspring, who would then survive to reproduce additional individuals as well as protective behaviors. Another example would be the readily observed behaviors supporting the claim that many species have evolved to be genetically averse to snakes. Such a tendency to aversion, called biophobia, fulfills the premises of the biophilia hypothesis.

Proponents of the biophilia hypothesis argue that the natural environment—that which defined much of our evolutionary experience—has been increasingly degraded. What happens to the human psyche as we become further separated from nature? In his book *Last Child in the Woods*, Richard Louv tracks what he calls "nature deficit disorder" among American children. Louv defines nature deficit disorder as the cumulative effect of withdrawing nature from people's experiences, which leads to increased stress, decreased attentiveness, and feelings of "not being rooted in the world." Nature deficit disorder is not biophobia; rather, it is the kind of disengagement from the natural environment that alarms supporters of the biophilia hypothesis and its attendant biophobic manifestations. Nature deficit disorder has become a societal disorder, Louv suggests. Children are victimized by it through the mutually reinforcing patterns of being increasingly confined to rigid, artificial environments; labeled ADHD; and not encouraged to exercise via unstructured play, such as the emphasis on team sports and fixed schedules.

The biophilia hypothesis suggests that humans benefit from exploring and trying to understand other life forms and processes. Wilson, a self-identifying conservationist, actively promotes the protection of biodiversity for its vast material wealth, ecosystem services, information value (including ecological and evolutionary processes), and spiritual value. He argues that our emotional bonds with the natural world can lead to a meaningful environmental ethic that overcomes the constraints of resource economics (where plants, animals, and other so-called natural resources are assigned prices and thus exchange values), as well as the aprioristic species-rights approach. Wilson argues it is best to state that we need biodiversity in order to remain human—an anthropocentric agenda that, by extension, protects other species and accords them value without necessarily being reductionist.

Biopiracy

BIOPIRACY IS THE practice whereby pharmaceutical companies or research scientists collect and remove biological specimens and related indigenous knowledge, without authorization, acknowledgment, and/or due compensation, in order to develop commercial products, such as modern medicines, for profit. The term *biopiracy* is highly controversial and has emerged as a critique of bioprospecting. In this highly polarized debate, cases regarding the research and development of biological resources are generally characterized in one of two ways: as bioprospecting, which is the acceptable practice of research and development of medicinal plants and believed to result in win-win scenarios for local communities and international actors; or as biopiracy, in which villains and victims are seen as perpetuating the sustained history of colonial exploitation of developing nations. One of history's most notorious biopirates was Henry Wickham, an Englishman who smuggled 70,000 rubber tree (*Hevea brasiliensis*) seeds from the Manuas region of Brazil in 1876. With Wickham's seeds, British-owned rubber plantations in Asia quickly outproduced those in Brazil, resulting in the collapse of the Amazon rubber boom.

CRITICS OF BIOPIRACY

The biopiracy narrative, critiquing the win-win scenarios championed by supporters of bioprospecting, draws on the solidarity of farmers, rural poor, and indigenous people, and suggests that the activities of scientists and pharmaceutical companies result in the plunder of the poor and the exploitation of their resources for economic gain.

Vandana Shiva, a vocal author and antibiopiracy activist, argues that biological resources should not be removed from the realm of public good to private property rights. In this view, all external attempts to patent biological resources are acts of piracy. For Shiva, the ability to patent life forms is seen as a classic case of bio-colonialism, in which the Western system of intellectual property rights and neoliberal economics jeopardizes the cultural rights and natural resource practices of local peoples.

A recent victory for opponents of biopiracy was won in 2005, when the European Patent Office revoked a patent based on the fungicidal properties of the neem tree (Azadirachta *indica*). Opponents to the patent argued that the neem tree's fungicidal properties have been known about and used in

India for centuries. This case signals to researchers that they can not equate indigenous knowledge with free and public information. For those questioning the patenting of life forms based on traditional knowledge, this case presents a clear victory in the struggle of indigenous rights against global commercial interests.

Bioprospecting

WHEN PRIVATE COMPANIES that produce pharmaceuticals, agrochemicals, cosmetics, flavoring, fragrances, and industrial enzymes seek plant material to integrate into their commercial products, their undertaking is often termed *bioprospecting*. Bioprospecting is usually conducted by private companies that search in a variety of ecosystems for certain parts of plants, ranging from barks to genetic material. Although the task of bioprospecting seems to be beneficial in terms of producing important products such as medicines, it is an activity engulfed in politics between the global north (the "developed" world) and the south (or "underdeveloped" world).

There have been several cases in which northern-based private companies have bioprospected in southern ecosystems for particular plants. However, such companies have neglected to share profits with those in the south who are the custodians of the plant, such as indigenous peoples. Additionally, claims have been made in which bioprospectors have patented indigenous knowledge regarding a particular plant, while failing to protect or compensate intellectual property rights of traditional knowledge of those in the south. These claims are known as biopiracy, which is a result of unfair or inequitable bioprospecting.

Bioprospecting, as an acceptable practice of research and development of medicinal plants, is legally supported by two international treaties. The 2002 Convention on Biodiversity (CBD), which many countries have ratified, provides those nations that recognize CBD with the legal and regulatory means to protect citizens who own plant material that is in demand through the Access and Benefit Sharing (ABS) mechanism. The ABS creates economic incentives to conserve biodiversity and traditional knowledge while building equitable commercial partnerships between private companies and citizens who claim their rights over natural resources. The CBD's actions were further strengthened by the Trade Agreement on Trade-Related Aspects of Intellectual Property Rights (TRIPs), which institutionalized a modern intellectual property rights system that allows for the patenting of life forms.

SHARING ACCESS AND BENEFITS

In addition to sharing profits and protecting intellectual property rights, countries in the south may also be able to benefit from the transfer of technology, training, and infrastructure development once a resource has been identified during the process of bioprospecting. However, the extent to which bioprospecting has occurred, has helped to conserve biodiversity, and increased profits for extractors and guardians of the resource is difficult to assess, especially because what is the highly subjective concepts of "fair" or "equitable" are difficult to define.

The most well-known positive case study of bioprospecting comes from a partnership between Costa Rica's Instituto Nacional de Biodiversidad (InBio) and the U.S. pharmaceutical giant Merck and Company. InBio was designed to identity and find ways to sustainably use natural resources. In 1991, InBio made an agreement with Merck to provide natural resources from protected areas for scientific evaluation. In exchange, Merck provided $1,000,000 over two years and $135,000 worth of equipment and training to Costa Ricans involved in this partnership. The agreement also involved profit sharing between these two parties, if commercial products resulted from scientific evaluation. Although this partnership may seem equitable and fair, questions been raised regarding how fair Merck's payments are.

A more negative incident occurred between Shaman Pharmaceuticals, which desired access to the croton tree to produce antivirals, and the Pan American Indigenous Peoples Federation (COICA) of Amazonian South America who would harvest this plant for the private company. Critics of this partnership question the compensation Shaman provided COICA and how Shaman has claimed exclusive monopoly over this plant. Shaman has also been criticized for patenting this plant and claiming "novelty" over the product, when knowledge about this plant has been held in the public domain by COICA, which is the custodian of this plant.

The extent to which bioprospecting has occurred is debatable, however. Some have claimed the media has created an "alarmist" perception that exaggerates the occurrence of bioprospecting. Because bioprospecting is expensive, time consuming, and uncovers resources that are of low or at least unpredictable value, many private companies have not invested in it, thereby forestalling what V. Bolsvert and F.D. Vivien call a "green gold rush." It is also unclear if bioprospecting will lead to greater conservation of species because of the potential health and economic benefits they could bring or greater exploitation of ecosystems when genetic resources become dispensable. Nevertheless, bioprospecting is an activity that will remain in the spotlight because of the various ethical and political debates associated with it, such as fair trade, intellectual property rights, and access and benefit sharing.

Bioregionalism

ECOLOGICAL WRITERS AND thinkers Allen Van Newkirk, Peter Berg, Jim Dodge, Raymond Dasmann, and Gary Snyder developed the concept of *bioregionalism* in the mid–1970s. It is a framework for the organization of society, based on the idea of an ecological area or "bioregion" defined by a local pattern of ecological and social characteristics, rather than static political boundaries. In the words of Peter Berg, bioregionalism is both a geographic terrain or place, and a terrain of consciousness, a way of thinking about how local communities can produce a sustainable future. Bioregionalism research looks specifically at the experiences of local social and ecological organization based on an understanding of community and shared identity as embedded in local ecology, geography, history, and social and cultural context.

A bioregion is defined according to the main ecological features found in a continuous geographical terrain, such as climate, soils, watersheds, and distribution of native species, including humans. For example, the Cascadia Bioregion in the Pacific Northwest of the United States and Canada includes the Alaskan panhandle, British Columbia, Washington, Oregon, Idaho, northern California and western Montana. Geographically, it includes the Columbia River Watershed and the area around the Cascade Mountain Range. The region is historically defined as the "land of the Chinook Jargon speakers," a trade language used for communication at the end of the 18th century between Native American tribes and white traders.

The primary objectives of bioregionalist thinkers and activists are to restore and maintain natural ecosystems, practice sustainable livelihoods by establishing local systems of trade and food provisioning to satisfy basic human needs, and support the work of re-habitation. Re-habitation refers to the restoration of degraded areas and the subsequent development of a relationship between people and nature that involves a sustainable way of life. For example, residents of the Cascadia bioregion work to restore salmon runs and develop ways to use plant-based fuels as a renewable energy source.

PROPONENTS AND CRITICS

While bioregionalists are mainly concerned with the relationship between local communities, environmental habitats, and local forms of democratic governance, recent works by bioregionalist thinkers also consider the relationship between local bioregions and global environmental and economic contexts. Bioregionalists critique the state governance system by arguing that artificial political boundaries are unable to effectively address ecological problems. Instead, they envision a confederation of local and bioregional communities that acknowledge the connections between diverse ecological communities and bioregions, and work together to preserve local cultures and diversities that comprise the larger global whole. Bioregionalists recognize the relationship between local communities and global environmental problems; for example, they view global warming as the consequence of local activities and practices that are linked in a global political economy.

Critics of bioregionalism point out that the approach "naturalizes" human life in a way that recalls environmental determinism, that regions are not actual or given but historically and culturally constructed, that all earth processes (including human social and economic practice for millennia) are multi-scaled and never isolated in convenient regions, and that "blood and soil" discourses like bioregionalism recall the grim ideologies of fascism. Nevertheless, recent scholarly interest in the concept of place within a variety of disciplines including sociology, anthropology, geography, and philosophy includes a discussion of bioregionalist thinkers as pioneers in the development of new conceptions of place. In this sense, bioregionalists prioritize the construction and analysis of place from the ground up, with the development of new social systems by local residents based on the material limitations of local ecological places and regions.

Biosphere

THE TERM *BIOSPHERE* refers to the totality of life on earth and its interdependency on abiotic environmental factors. It encompasses the interactions between the atmosphere, hydrosphere, and lithosphere to support the entirety of earth's organism through climate (temperature and precipitation), soil formation, hydrology (surface water, ground water, and soil moisture storage), solar energy input (variation in intensity and daily and seasonal accumulation with latitude), and the cycling of energy and nutrients through food webs. The biosphere is the highest level of the ecological hierarchy.

The lowest level of the ecological hierarchy focuses on individual species, with a single individual of a species at the lowest level of classification, and moving upward to a population of that species (the total number of individuals of a species in a given area) and metapopulations (the total number of individuals of a species across the total number of disjunctly distributed populations). Above the species level of classification is the community, which is concerned with the number of species co-occurring in a given location. Emphasis is placed strictly upon the species that are present and the nature of their competitive or mutualistic interactions in creating stable or unstable species compositions.

Above the community level, the ecosystem level is concerned with both the specific community composition in addition to environmental factors of nutrient and energy input as well as the cycling of these nutrients through food webs. At this level, both biotic and abiotic factors are considered to be components. At broader spatial scales, the abiotic inputs are grouped according to climatic patterns and their support of terrestrial ecosystems whose vegetation have similar physiognomic structure, giving the biome level of classification. For example, the tropical rainforest biome is characterized by high biomass and broadleaf evergreen trees forming multiple canopy layers, although the actual species composition and nutrient cycling specifics (i.e., ecosystems) will differ between the tropics of the various continents. Above the biome level is the globally inclusive classification of the biosphere, in which the interconnectedness of global climatic systems forms a principal analytical focus.

HUMAN–BIOSPHERE INTERACTION

Environmental concerns at the biosphere level focus on human–environment interactions, especially as these interactions contribute to global climate change and mass extinction of species. Ecologists consider the contemporary period of history, especially after the mid-20th century, to be unique in the history of the planet, in that human activity is altering the environment on a global scale. Furthermore, environmental management efforts are being targeted at the biosphere level as well.

Current extinction rates of known species exceed the background extinction rate by 40 times, but could be as high as 400 times the background rate based on estimates of total species. For this reason, many biologists consider these extinctions to be the beginning of a major extinction event. Ecologists have identified habitat loss as being the primary cause of these extinctions, as extractive activities (forest clearing for timber and agriculture, urban sprawl), with the introduction of nonnative species (either by direct human introduction or accidentally through transportation networks), pollution, and direct exploitation of species contributing greatly to these extinction rates. Regions of the world with highly specialized species and endemics are particularly at risk of extinctions, and identified as "biodiversity hotspots." Due to high rates of endemism, many islands environments and Mediterranean shrubland ecosystems have been identified as biodiversity hotspots.

Global climate change is also a human-driven aspect of environmental change that affects the entire biosphere. Although scientists debated for years whether observed warming trends were normal climatic variations or the result of interglacial warming as opposed to being anthropogenically driven, by 2001 the persistence of increasing carbon dioxide levels in the atmosphere, in conjunction with results from analyzing the dissolved gas content in ice core samples taken from Antarctica and Greenland, have settled the debate in favor of human causes for the phenomenon. The data from the ice cores provide a record of environmental change extending back 900,000 years, and indicate that the rate of carbon dioxide accumulation since the beginning of the Industrial Revolution has been at an unprecedented high. Carbon dioxide concentrations in the atmosphere currently have reached their highest levels during this 900,000 year period, and temperatures are expected to rapidly follow. The polar regions have been warming more rapidly than models have predicted, causing many arctic species to be threatened with extinction.

If climatic conditions change more rapidly than species can adapt or disperse, then climate change could have severely adverse effects on the entire biosphere. The solutions require coordinated political action between international governments, but multilateral cooperation has proven difficult to achieve. Industrialized nations invariably consume the greatest amount of the worlds' resources, especially fossil fuels that produce greenhouse gases, while many of the world's developing nations do not, but view increased consumption of fossil fuels as being necessary for economic development.

For example, the newly industrializing countries of south and east Asia, in conjunction with their high populations and rates of growth, are expected to consume more fossil fuels in the near future. Political tensions have thus arisen around perceived inequalities in both consumption and economic impacts to emissions reductions. The Kyoto Protocols, an international agreement setting goals for reductions of greenhouse gas emissions, became international law in March of 2005, despite the United States and Australian delegations not participating.

Habitat loss tends to occur on a more local scale, but is greatly affected by social, political, and economic linkages in the global economy. The articulation of precapitalist modes of production with market economies tends to increase the amount of cultivated land required to meet a household's needs, as well as exacerbate gender and age differences within the household mode of production. Developing countries rely heavily on primary production of agricultural and timber products, driving deforestation and often putting various social groups into conflict.

Biosphere Reserves

BIOSPHERE RESERVES ARE areas of natural significance that are designated under the United Nations Educational, Scientific, and Cultural Organization's (UNESCO) Man and the Biosphere Program. A reserve may comprise a terrestrial or coastal ecosystem or, in some cases, encompass multiple types of ecosystems. A biosphere reserve may be a national park or other type of protected area that is recognized either nationally or internationally. Biosphere reserves collectively form a World Network, the purpose of which is to share information relating to conservation, development, and logistics.

Biosphere reserves are different from other protected areas in three ways. First, they are part of the designated UNESCO Man and the Biosphere Program. Second, the outer boundary is more flexible than legally defined. Third, the water and land contained in a biosphere reserve may be managed by more than one owner or agency. In practice, however, the main binding concept is the first designation as part of the World Network of the Man and the Biosphere Program.

A national committee nominates an area to be designated by UNESCO as a biosphere reserve. Funding for the biosphere reserve comes from various sources such as national or local municipalities, nongovernmental organizations, tour operators, and other such sources. UNESCO does not provide funding except occasionally to fund pilot projects at the local level. Each biosphere reserve has its own management system.

INTENTS AND ORIGINS

Biosphere reserves were originally intended as places for scientists and public agencies to conduct scientific research together in order to meet the changing needs of the environment on a global scale. The biosphere reserve network established through the Man and the Biosphere Program was intended to facilitate the compilation and international sharing of information, especially for ecosystems that were heavily impacted by human activities.

The origin of biosphere reserves dates to the Biosphere Conference, which was organized by UNESCO in 1968. It was the first intergovernmental conference of its kind to address both the themes of conservation and use of natural resources, which were the precursor to present-day notions of sustainable development.

The primary result of the Biosphere Conference was the establishment in 1970 of the Man and the

Biosphere Program. Within this program is the World Network of biosphere sites, which sought to have the main ecosystems of the world protected and monitored, with some scope for training. The term *biosphere reserve* was in reference to the overall UNESCO Man and the Biosphere Program.

Biosphere reserves were seen in the 1970s as sites of natural excellence in the areas of science, conservation, and natural resource education, and were intended as model places from which lessons could be learned and applied more widely to other protected areas. Plants and animals within the biosphere reserves were to be protected, particularly in regard to genetic diversity. Environmental and ecological research was to take place within biosphere reserves, and facilities for training and education were to be provided.

In the early 1980s, emphasis shifted as key links between conservation and development were made more widely in the world. Partly as a result of experience from the first decade of biosphere reserves, local people were increasingly regarded as critical to the success of a biosphere reserve. This is reflected in the expansion of purpose of a biosphere reserve, which moved beyond the original concept of conservation, monitoring, and training. Indeed, the concept of biosphere reserves is an evolving one. In addition to conservation, biosphere reserves are also intended to provide logistical support for the research, education, monitoring, and exchange of information made possible through the activities within the biosphere reserve. Both human and economic developments are to be fostered in a socioculturally and ecologically sustainable manner.

The 1990s forwarded the concepts of conservation and sustainable development. One of the most important events during this time was the International Conference on Biosphere Reserves in Seville in March 1995. The resulting Seville Strategy proposed that the original concept of research and monitoring comprised only two of ten key directions. Subsequent actions have evaluated the Seville Strategy and show it to be of varying impact, depending upon local and national circumstance.

One of the benefits of a biosphere reserve designation is the potential economic benefit through tourism or other forms of external funding. Another benefit is that some biosphere reserves are located on the boundaries of more than one country and, as such, are ideal ways to develop long-term cooperation. Finally, one of the most important benefits is to promote awareness about sustainable development and conservation among local people, governmental authorities, and other stakeholders.

The model biosphere reserve area comprises a core zone, buffer area, and transition area. The core zone is the strictly protected area, and the buffer area is for limited public access, research, and education. Activities such as low-impact farming, settlement, and recreation may take place in the outer transition area. The boundaries of the protected area may be quite fixed, with the transition area as more flexible and changing. In fact, the entire zonation scheme is, like the biosphere reserve concept itself, subject to evolution and revision according to local and global concerns.

Biotechnology

BIOTECHNOLOGY HAS RECENTLY emerged as a technology of promise and peril in the lexicon of environmental controversies. The Organization for Economic Cooperation and Development (OECD) defines biotechnology as "The application of Science and Technology to living organisms as well as parts, products and models thereof, to alter living or nonliving materials for the production of knowledge,

With genetic engineering, biotechnology became negatively associated with for-profit development.

goods and services." The Convention on Biodiversity defines biotechnology in similar terms in regard to its biosafety protocol and its revenue-sharing agreements for genetic resources.

Early applications in biotechnology promised significant improvements in society roughly corresponding with the enthusiasm for the project of modernism. The vision of putting life processes to work for humans was naturally an extension of the high modernism of dead engineering. The Baconian ideal of controlling nature was in many ways a reproduction of Enlightenment ideas. For example, early in this century it was suggested that bioreactors could produce single-cell proteins that could be a food source for developing countries. Even today biotechnology enthusiasts describe genetic solutions to hunger, environmental degradation, and cancer that can be solved by the technology. However, with the advent of genetic engineering, biotechnology became associated in some circles with the negative consequences of industrialism and capitalist-led research and development. Activists and scientists who were concerned with the uncontrollability and irreversibility of some manipulations of life's processes questioned the technology.

Some suggest that the earliest products of biotechnology were plants domesticated through human selection. Others date the beginnings of biotechnology to Egyptian beer brewing and the use of yeast to bake bread. The work of Louis Pasteur on microbial origins of fermentation is often described as the earliest scientific work in biotechnology with significant implications for industry. The work of Pasteur led to the widespread adoption of pasteurization. In *The Uses of Life*, Robert Bud takes this broad definition for biotechnology to mean any technology that directs life processes toward production or product development. He bases his definition on the language commonly used to describe fermentation reactors in the early to mid 20th century.

In the 20th century, biotechnology emerged out of chemical engineering and its marriage to biochemistry, bacteriology, and industrial microbiology. Zymotechnology, a discipline that harnesses life processes for industrial processes such as fermentation, was an early precedent. Again influenced by the work of Pasteur, zymotechnologists understood how to industrially produce alcohol through fermentation. It was at this time that Karl Ereky, a Hungarian agricultural scientist, coined the term *Biotechnologie*.

By World War I, biotechnology was being used to produce lactic, citric, and butyric acids; industrial alcohols; treated sewage; and isoprene to make rubber. With the war cutting off grain supplies to Germany, where zymotechnology was at its zenith, 60% of the fodder protein needs of the nation were provided by yeast cultivation on molasses, preventing widespread wartime famine.

By the World War II, biotechnology became well known for the industrial production of antibiotics and research on the threat of biological warfare. The production of penicillin is regarded by historians of technology as a major feat of engineering because of the complications of producing the living organisms at considerably larger scales. This era of industrial microbiology saw the scaling-up of biological production of acetic acid, penicillin, and enzymes, ushering in a pharmaceutical industry based on microbiology. Some of the world largest chemical companies, Pfizer, BASF, and Dow, were among the first commercial producers of the products of biotechnology.

Because of cheaper alternatives from synthetic chemistry, based on inexpensive fossil fuels, many of the promises of biotechnology in these early years remained unfulfilled. Other major chemical companies preferred stocks derived from petroleum and coal. However, popular writers like Aldous Huxley continued to write about the utopian vision and aesthetic of biotechnology. Even social critic Lewis Mumford adopts the historical category he labels the *Biotechnic* to describe a utopian epoch of production that was good for both the worker and the consumer.

PROMISES AND PITFALLS

The increasing support for molecular biology in universities also played a large role in the development of biotechnology. MIT (1939) and UCLA (1947) had units in biological engineering and biotechnology. Together with private sector support, universities helped initiate the development of continuous process fermentation, as opposed to batch fermentation, which significantly shaped the industrial production of living organisms. The National Institutes of Health saw dramatic increases in funding availability in biomedicines in the postwar period, which help spur growth in areas like the Santa Clara Valley in California and Cambridge, MA.

By the 1970s, with decreasing support for university research and incentives for private-public research partnerships, biotechnology in universities came under significant scrutiny. It was asserted that the quest for patents in the public sector was contrary to the public mission of the university, and would affect both the free flow of information and materials in the university. Yet, many universities today have patent offices explicitly to deal with the products of biotechnology.

Much like nuclear power, the public discourse about biotechnology remained benign and an efficient answer to the effects of industrialization. It was particularly in the context of the famines of the 1960s that biotechnology was viewed with great promise. Biotechnology would produce plants that could fix nitrogen and eliminate the need for synthetic fertilizers, and its fermentation vats would provide low-cost industrial foodstuff to the world's poor. Likewise, with the energy crisis of 1973, biotechnological products like biogas and gasohol were seen as viable alternatives to fossil fuels—and still are, particularly in places like Cuba and Brazil.

But beginning in the 1980s, biotechnology was discussed in the context of potential nefarious social and environmental consequences of industrialization. Critics of biotechnology often describe the wider implications of technological change as well as the direct consequences. In particular, genetic engineering, genetically modified organisms, and agricultural biotechnology has raised the ire of activists.

The controversies associated with the new biotechnologies are both political and in part a consequence of the scale of scientific intervention. Beer, bread, and penicillin all intervene as the level of the organism. New techniques characterized as biotechnology move to smaller scales such as the molecular or cellular scale, or as with nanotechnology, at the atomic scale. The new biotechnologies include recombinant DNA transfer, protoplast fusion, and tissue culture, all techniques that are widely used in the sciences today.

Today the private firms that engage with the commercial development of biotechnology are known as the life sciences industries, which are politically and commercially represented by The Biotechnology Industry Organization. With the life sciences industries emerging out of the much-disdained chemical industry, great skepticism was associated with biotechnology. Much of today's controversy stems from questions about intellectual property rights. A key Supreme Court decision, *Diamond v. Chakrabarty*, ruled that living organisms were subject to patents after a General Electric biologist developed a microorganism to eat crude oil, an environmental application that could be applied to oil spills. Central to the question about patenting organisms is what exactly constitutes an improvement worthy of patenting, as well as many of the other questions attributed to the process of commodification. For example, farmers have improved plants through selection for eons, yet their work falls into the domain of common heritage. However, scientific improvements using genetic engineering fall under the auspices of patentable subject matter, implying a labor theory of value that favors modern science and the developed world.

Developments in cloning have also raised many ethical and political questions. The cloned sheep known as Dolly introduced much of the world to the implications of new biotechnological interventions at the cellular level. Because cloning often involves significant numbers of miscarriages, birth deformations, and clinical failures, human cloning is quite controversial beyond questions about social justice and reproductive technologies, but about the direct loss of human life consequent to the cloning process itself.

While biotechnology still holds much promise, the controversies around genetic engineering and genetically modified organisms continue to take center stage. Today, the promising tools coming out of biotechnology include the development of biosensors as well as plant breeding techniques that could help breed perennial crops. But until questions about property rights, economic concentration, the shape of the research trajectory, and any social consequences of biotechnology are sorted out, the promises of biotechnology will remain embattled in the realm of discourse.

Birth Control

BELIEFS, RESEARCH, AND debate about birth control have been present in societies since Ancient Rome. People have had more efficient means available (such as the latex condom and the anovulant pill) since the 1950s. With the advent of these widely available types of birth control has come increased ethical, religious, social, and familial debates. The Catholic Church, in particular, has maintained a position of only approving natural family planning via the calendar method.

On a personal level, birth control enables people to plan for or against pregnancy within their own timeframes. However, birth control can also be a matter of public policy to manipulate population growth. For instance, governments like Israel created noncoercive pronatalist measures that reward bigger families with tax reductions and other incentives. In other cases, the state may have provisions for giving financial help to couples who face infertility problems. From a business standpoint, some corporations provide pay while employees are on adoption leave, particularly when couples are going abroad for international adoptions.

At the other end of the spectrum are governments that have established antinatalist efforts, which are policies to inhibit big families. The most notable example is the one-child policy in China, which has created an imbalance of boys and girls, as many families prefer to have a boy. This imbalance has exacerbated social issues such as prostitution, sex tourism, homosexuality, and forced migration.

In the early 21st century, the world population was more than 6 billion, compared to a worldwide population of 1 billion in the early 19th century. Countries like India and China alone have more than 1 billion citizens. These numbers raise questions and concerns about prosperity, poverty, the limits of growth, and the future.

Overpopulation is regarded as a contributing factor to problems like environmental pressures, global warming, the food crisis in the developing countries, poverty, starvation, and megacities. The overpopulation issue is not new—two centuries ago, economist Thomas Robert Malthus (1766-1834) published *An Essay on the Principle of Population, as It Affects the Future Improvement of Society* in 1798. Malthus argued that "population must always be kept down to the level of the means of subsistence." Concerns related to overpopulation and limited food supplies have visited almost every generation.

The issue of overpopulation has had many prophets and followers. Paul Ehrlich's bestseller *The Population Bomb* was published in 1968, when the U.S. population reached 200 million. The book sold three million copies and was so influential that even the title remained a popular catchphrase. As we now know, many of Ehrlich's overly pessimistic scenarios did not come to pass, and some were even removed in subsequent editions. Still, many people who were influenced by the book opted to have sterilization surgery. Other authors also cashed in with predictions related to overpopulation and the food supply. Donnella Meadows's book *Limits to Growth* in 1972 sold 10 million copies in 30 languages. An updated version titled *Limits to Growth: The 30-Year Update* was released in 2004. Most recently is Lester Brown's apocalyptic book, *Plan B 2.0: Rescuing a Planet Under Stress and a Civilization in Trouble* (2006).

Despite statistics that confirm the increased number of people on earth, overpopulation is not really a fact. It is better understood as a worldview that is part of a complex debate regarding issues such as global warming. Politicians, decision makers, and the population in general must rely on experts's interpretations of existing research. While some find grounds for concern, others do not. Economist Julian Simon, for example, wrote *The Ultimate Resource*, which has been reissued twice since 1981. Simon argues that overpopulation is a myth; with new technologies, nuclear plants, and resourcefulness, humans have proven that they can adapt to challenging situations and find new ways to face global issues. Therefore, the main cause for starvation in emerging countries is often corruption, and not lack of resources.

Economics professor Jacqueline Kasun, of Humboldt State University in California, also challenges the seriousness of overpopulation. She argues that overpopulation is an ideology and often a means of propaganda. She criticizes Ehrlich's *The Population Bomb*, maintaining that there is still room on the planet, except in megacities and some autodependent suburbs.

After the baby boom generation (those born between 1946 and 1964), subsequent generations seem to have adopted the two-child model as a standard in many Western countries. But this is not the norm worldwide. Peter Berger found that women in India refused to use oral contraceptives, even when given for free by nurses, because most Indian women did not see big families as a problem. Similarly, many African males refuse to use condoms. In sum, population control is quite different from birth control, although the two concepts are often linked.

Mechai Viravaidya

Mechai Viravaidya (b. 1941) is a politician and activist in Thailand who has become well-known for popularizing of the use of condoms in Thailand. The son of a Thai father with connections to the Thai Royal Family, and a Scottish mother, he was educated at Geelong Grammar School in Australia. Returning to Thailand, he started to work on population control. He quickly became nicknamed "Mr Condom" for his promotion of the use of condoms for birth control, and later for the prevention of the spread of venereal diseases. He also supported vasectomies and other methods of contraception. In 1973 he left the government; in the following year he formed his own Population and Community Development Association, and also runs a restaurant called "Cabbages and Condoms" in Bangkok. For many years, condoms in Thailand were often known colloquially as "mechais."

Mechai was deputy minister of industry from 1985 until 1986, and senator from 1987 until 1991, and again from 2004. During the mid-1980s, when AIDS appeared in Thailand, Mechai urged the use of condoms to prevent its spread, conducting public awareness campaigns in schools, universities, and among sex workers in Bangkok and elsewhere in Thailand. In 1991, the new military government gave their backing to his campaign, appointing Mechai as Minister of the Prime Minister's Office, responsible for Tourism, Information, Sports, Economic Cooperation, Zoological Gardens, and AIDS Prevention Coordination. His role in both birth control and AIDS awareness is known around the world, and he has been given many awards by international institutions.

Birth Rate

THE BIRTH RATE, or the crude birth rate (CBR) as it is sometimes referred, refers to the number of childbirths per 1,000 of the population per year. When combined with the crude death rate (the total number of deaths per 1,000 of the population per year) the rate of natural population growth or decrease is calculated. However, for a more complete and accurate picture of population growth or shrinkage, patterns of migration must also be considered.

The levels of birth rate are affected by numerous factors. Of significant impact is government policies, which can either stimulate or depress the level of fertility and the number of births within a nation. For example, China has a relatively low birth rate (about 13 per 1,000 people) due to the Chinese national government advocating a policy of one child per family. Birth rate can also be affected by socio-religious beliefs, especially in regards to the use of contraception, as well as a country's age-sex structure, economic prosperity, and levels of poverty. In relatively wealthy nations, the birth rate is usually low, even though families can adequately afford to have large families if they desired.

In wealthier regions of the world, such as Europe, North America, and parts of Asia, it is commonplace to find small family sizes and low birth rates. The birth rates in some affluent nations are so low that the total population level is approaching a point of decline, as in Japan. On the other hand, within societies where poverty is prevalent, it is not unusual to find that the birth rate is high; the level of the birth rate can be further exacerbated when the age-sex structure of a nation is relatively young, that is, at a sexually active age. When societies are less economically developed, their fertility rates will be higher than nations that have already undergone economic advancement. At present, the global birth rate is about 20 per 1,000, yet in some economically developing nations it is higher than 50 per 1,000, as in Niger and Mali. In contrast, affluent parts of the world like Hong Kong, Monaco, and Singapore have rates of less than 10 per 1,000.

Regardless of the influence of culture, economics, or politics, where the infant mortality level (the number of children dying under one year of age divided by the number of live births annually) is high, it is also common to find a high birth rate. This is partly a behavioral response of families, which may have more children given their knowledge some might die in childhood. In African nations like Angola, where the child mortality rate is 192 per 1,000, and in Asian nations like Afghanistan, with an infant mortality rate of 166 per 1,000, the birth rate is in excess of 45 per 1,000, some of the world's highest.

Bison

ONCE FOUND THROUGHOUT most of the Northern Hemisphere, bison are now found only in limited areas of North America and Europe. Large herbivores, bison typically move in herds composed of cows, calves, and adolescent or elderly males. Bulls of mating age are somewhat more solitary, staying at the fringes of the herd except during the rut, when they compete to mate with the most fecund cows in the herd. The bison's size has protected it from all but the largest natural predators—grizzly bears, wolves, and cougars. The American bison has more commonly been known as the American buffalo, even though bison are a distinct species from buffalo. The American bison once roamed in huge herds from Alaska and northern Canada to northern Mexico, as well as from the Rocky Mountains to the Appalachians. Although the largest herds were found on the open plains, smaller numbers spread into the woodlands. When Europeans first arrived in the Americas, there were an estimated 60 million bison in North America. The Native American tribes of the Central and Great Plains not only depended on the bison for food, clothing, and shelter, but also created a vibrant culture around their seasonal migrations with the herds.

In the 19th century, when Anglo-Americans began to build railroads across the continent to the Pacific coast, companies hired professional hunters to provide meat to the large work crews. The most famous of these hunters was William "Buffalo Bill" Cody, who sometimes shot several hundred bison on a single day. The hunters and those passengers who shot bison for "sport" from the moving trains contributed to a casual attitude toward killing buffalo. The herds were so immense that they seemed impervious to any culling, no matter how destructive. Nonetheless, in the decade following the Civil War, political and commercial pressures soon led to the rapid destruction of the great bison herds of the plains. The U.S. military recognized that as long as the herds sustained the plains tribes' way of life, they would be reluctant to move onto reservations. The government thus sanctioned the destruction of the herds as a way to bring the tribes under control and to open their lands to development. At the same time, coats made from buffalo hides became as popular as hats made from beaver pelts had been several decades earlier.

Organized companies of hunters moved first out onto the southern plains, killing almost four million bison in less than two years. Hunters such as Josiah Wright Mooar, James White, John Webb, Frank Mayer, Steele Frazier, and Billy Dixon each killed many more bison than Cody ever did, but there was no romance in this slaughter. They used long rifles that they rested on tripods and poured water over the barrels to keep them from overheating. Their hide men moved among the carcasses, heaping the hides and tongues onto wagons, and leaving everything else to rot. The hides sold for $3.50 apiece, and the tongues were salted and sold in hundred-pound bundles. The last herds on the Staked Plains of west Texas disappeared after the defeat of the Comanche at Adobe Wells and Palo Duro Canyon. The northern herds lasted about a half-decade longer. By the time the Ghost Dancers were massacred at Wounded Knee, those herds were as much a memory of a lost time as Crazy Horse and Sitting Bull. Only a few hundred bison remained in a few pockets of Western wilderness.

REBUILDING THE HERDS

Over the last half-century, efforts have been initiated to expand the bison herds, especially on public lands such as national parks. These efforts have been opposed by most ranchers, who have argued that the bison cannot be contained on public lands, that their cattle will have to compete with the bison for already limited range land, and that bison carry diseases that can decimate their herds. Ironically, some ranchers have either developed commercial bison herds or have inter-bred bison and cattle, marketing the meat as a lower-fat alternative to beef. Of the approximately 250,000 bison in the United States, only 16,000 live in wilderness areas. As farming communities on the Great Plains have declined and in many instances simply disappeared, serious proposals have been made to return the depopulated areas back to their pre-settlement state as prairie. Beyond the environmental implications, such proposals envision sustainable economic benefits from eco-tourism and managed commercial exploitation of the reintroduced bison herds.

Black Death

BLACK DEATH WAS an epidemic that spread to Western Europe and Britain in 1347–50. It caused havoc because about one-third of the European population died from the disease. The plague was weather related, because temperature and humidity were associated with multiplication of the carrier insects—Oriental rat fleas—which transmitted the bacteria from rats to human beings. After a flea fed on blood from the skin of an infected rodent, the ingested plague bacteria (*Yersinia pestis*) multiplied in the flea's upper digestive tract, blocking the flea's stomach. When the flea fed again on a human or another rodent, the blockage caused the freshly ingested blood to be regurgitated back into the bite, along with the plague bacteria. The infected human beings then carried these bacteria throughout their circulatory system. The first signs of illness in humans appeared within about a week. The plague caused a high fever, and the lymph nodes throughout the body, especially those in the groin and the thigh, become swollen and extremely painful. The enlarged lymph nodes, called buboes, become filled with pus, and the disease spread through the infected bloodstream and the lymphatic system. The disease also caused spots on the skin that were initially red and then turned black, which some believe inspired the name Black Death. In 60–90 percent of untreated victims, the inflection became overwhelming, leading to death within a few days.

The Peasants' Revolt

Following the Black Death in England, the labor force throughout the country was massively reduced with the result that agricultural laborers could demand higher wages and better conditions. To get around this, the government enacted the Statue of Labourers in 1351. This stopped wage increases and also restricted peasants from freely moving about the country. This was highly unpopular, especially with the artisans and some peasants. With the need to raise more money for the Hundred Years' War in France, the government in 1381 decided to raise a poll tax (or "head tax") of one shilling on everyone in the country. In 1377, taxes were at a quarter of the 1381 level.

Many people throughout the country objected to this and protests started. In Kent and Essex, men gathered and decided to march on London. This became known as the Peasants' Revolt of 1381, or Wat Tyler's Rebellion (after one of the leaders of the revolt) or the "Great Rising of 1381."

When the peasants arrived in London, they stormed the Tower of London and killed the Archbishop of Canterbury and the Lord Treasurer. They then sacked the Savoy Palace of John of Gaunt, uncle of King Richard II. This forced Richard II to agree to meet the rebels at Smithfield. He paid tribute to the rebels and told them of concessions he had made, giving his supporters time to raise a militia that later put down the rebellion with ferocity. Large numbers of rebels were arrested and executed for their role in the Peasants' Revolt.

Pneumonic plague is caused by the same bacteria, as in the case of bubonic and septicemic plague. It is acquired when plague bacilli, discharged into the atmosphere via infected droplets during coughing or heavy breathing, is inhaled by the victim. This form of plague is highly contagious; the largest epidemic occurred in Manchuria in 1910 and 1911, when 60,000 people died.

This urban community plague, originating in China, first spread with the movement of the Mongol armies and traders. In the beginning, Caffa—a Crimean port on the Black Sea—was afflicted by the disease in Europe in 1346. The Italian traders from Genoa brought the disease to the western European soil, from where sea traders and caravans carried the disease to France, Germany, Denmark, Poland, Finland, and Greenland. From its central Asian foci it diffused southward to Africa, eastward to China, and northwestward to Russia. Within three years, the disease reached the British Isles, and the first afflicted ports were Bristol and Southampton.

The impact of Black Death in England was not only immediate; it also lasted for at least two centuries. About half of the English population died during the bubonic form of plague that first appeared in the summer of 1348 in England. The bacteria also mutated into a dreadful pneumonic form in the winter, and London was attacked by both pneumonic and bubonic plague. The Parliament was prorogued; three archbishops of Canterbury died in quick succession.

Plague, which killed both rich and poor alike, could not be treated by the physicians. The monks were also of no help. Many blamed the disease to be a curse of the God. As a result, a group of people, *Flagellant Brahren*, inflicted punishment on themselves. Others tried to find a scapegoat, such as the Jews, who were in turn persecuted; many were forced to move from western Europe to eastern Germany, Poland, and western Russia.

The effect on economy was staggering. Large numbers of farmers who tilled and harvested the land died. There was a tremendous dearth of working people, and an acute shortage of skilled craftsmen of any kind. Many building programs were abandoned. The feudal society that had created serfs started to crumble; domesticated animals roamed unattended. As there was a shortage of law enforcement personnel, lawlessness prevailed. People had witnessed so much death that even funeral processions became subjects of jokes. The mass death changed the nature of art. Coffins bore the pictures of corpses on the cover. Sculptures displayed worms and snails; paintings contained skeletons. Christian-based idealistic paintings were replaced by paintings of sad and dead people.

A mass of Yersinia pestis bacteria (the cause of bubonic plague) in the foregut of the flea vector.

The first episode of the Black Death plague epidemic died out by 1350. The second episode occurred in 1361–64, the third in 1368–69, and the fourth in 1371–75. The later episodes were less destructive. Eventually, by the 15th century, incidents of plague declined and virtually disappeared from Europe. The reasons attributed are the replacement of the black rats by brown rats (the former were associated with human beings as they preferred to live in homes), and the fact that such devastating plagues occur in a time span gap of between six hundred to one thousand years. Thus, this pandemic had its own cycle.

The causative organism, *Pasteurella pestis,* was discovered by a Japanese, Shiramiro Kitasato, and a Swede, Alexander Yersin, during an outbreak in Hong Kong in 1884. Prevention of plague is achieved by inoculation with a killed vaccine; antibiotics cure infected patients. Rats and fleas can be killed with pesticides. The possibility of a Black Death-type of pandemic reoccurrence is remote, because the scientific knowledge has advanced to the level that plague can be prevented and cured.

Black Sea

THE BOSPHORUS AND the Dardanelles, the narrow straits into the Black Sea, have long been the division between Europe and Asia. Istanbul, founded as Constantinople on these straits, has long been a rival with Rome and Jerusalem as the center of the world. Ever since Jason and the Argonaut's legendary journey to the region, the Black Sea has been a corridor between North and South and Europe and Asia, and an ancient place of trade, culture, and cross-fertilization of ideas. That vigorous trade continues today with about 50,000 cargo ships and 1,500 tankers crossing in and out of the Black Sea annually.

Six different countries—Romania, Bulgaria, Ukraine, Russia, Turkey, and Georgia—along with a narrow access for Moldova, all share the Black Sea coastline. With so many claims to the Black Sea's resources from countries with different religious and cultural values, the environmental consequences of the Black Sea region's economic development are difficult to manage.

The Black Sea was formed only some six or seven thousand years ago, when the rising Mediterranean breached into a freshwater lake basin. Some have connected this incident with legendary accounts of the great flood encountered in several different religious traditions. Although most of the sea is quite deep, the northwestern section of the sea is relatively shallow, and provides a flourishing ecosystem for red algae and animals dependent on the algae as a food source. Although the Black Sea ecosystem was generally quite strong, the recent introduction of alien species such as the Rapana snail has devastated some native populations.

Shipping, industry, and especially tourism have transformed the Black Sea coastal region with large numbers of artificial structures to protect beaches from erosion, causing the buildup of pollution and toxins. During the 1960s, the advent of the Green Revolution in agriculture led to the massive inflow of fertilizers into the sea, creating an overabundance of nutrients and crowding out of native red algae, the foundation of the Black Sea's ecosystem.

Tons of plant and animal life washed up onto the shores as the sea became starved of oxygen. The introduction of the alien comb jelly in the 1980s, which ate fish larvae, led to a massive decline in fish. The fall of the Soviet Union led to a respite in fertilizer and waste dumping into the Black Sea, leading to a partial recovery of the red algae habitat. Nevertheless, the recent development of oil fields and pipelines may lead to serious negative, environmental consequences for the region.

Blaut, James (1921–2000)

JAMES M. BLAUT was an historian and geographer. His intellectual contribution was centered on what he considered to be the Eurocentrism of much existing thought, and which has come to be accepted as the best available explanation of the past. This Eurocentrism was initially expounded by Max Weber and has been restated by subsequent historians of repute, including modern exponents such as Jared Diamond and David Landes. Blaut challenged the exceptionalist view of European expansion and the so-called European Miracle, which ascribed the massive expansion of European interests and power to superior ideology, technology, and cultural expression.

In *The Colonizer's Model of the World,* Blaut argued that the transformation of the global economy between 1492-1688 could be explained by the comparative proximity of European states to the Americas and the resources they provided, which subsequently enabled colonial states to accumulate surpluses to fuel their further colonization of Africa and Asia.

The subsequent work, *Eight Eurocentric Historians,* further developed his arguments that the reality of the past had been, and was continuing to be, distorted by historians. The result of this distortion was to malign the actions and histories of developing world people and institutions who are considered to be necessarily inferior to the colonists. This way of thinking is linked to the World Systems Theory of History and the Structural Dependency view of economic history. Blaut died before he was due to write and publish the third part of his projected trilogy to complete his argument. However, he did foreshadow in papers such as "The Theory of Cultural Racism" the ways in which he believed that Eurocentrism had become embedded in modern thought patterns:

> …the dominant racist theory of the early 19th century was a biblical argument, grounded in religion; the dominant racist theory of the period from about 1850 to 1950 was a biological argument, grounded in natural science; the racist theory of today is mainly a historical argument, grounded in the idea of culture history or simply culture.

Today's racism is "cultural racism." In other words, the sense of European superiority, which had been obtained through geographical accident and capitalist accumulation, was justified first by those who believed that following Christian beliefs in some prescribed way were privileged by God over other people; this belief was succeeded by biological and scientific arguments purporting to show the mental superiority of Caucasians (a school of thought that still occasionally recurs) and then by the belief that one culture offered benefits to its people above others. In the 1970s, some speculated that since so many Catholic countries were controlled by dictators, then Catholicism may be culturally inferior to Protestantism. At the beginning of the 21st century, similar arguments are made about Islamic cultures.

Blizzards

BLIZZARDS ARE THE most severe winter storm, with blowing snow, high winds, and low temperatures. Different countries have different classification systems for blizzards. The U.S. National Weather Service categorizes a blizzard as a winter storm with sustained winds or frequent gusts of 35 miles per hour or greater, and enough falling or blowing snow to frequently reduce visibility to less than a quarter of a mile. Temperatures are 20 degrees F or lower. These conditions prevail for at least three hours. A "severe" blizzard has winds of 45 miles per hour or greater and temperatures at 10 degrees F or below.

Blizzards are caused by extra-tropical storms that originate outside the tropics and dominate the weather in the mid-latitudes of the world from autumn to spring. A mid-latitude cyclone, an area of low atmospheric pressure surrounded by winds that blow counter-clockwise in the Northern Hemisphere and clockwise in the Southern Hemisphere, is at the center of these storms. Cyclones are large-scale rotating weather systems that pull cold air toward the equator from the poles and carry warmer, humid air in the direction of the polar regions. The clash between these warm and cold air masses produces precipitation along a wide front. In winter, this can generate freezing rain, heavy snowfall, and blizzards. The normal lifetime of a winter cyclone is about three to five days, and generally tends to move across continents and oceans from west to east.

A significant proportion of the world's population live in the mid-latitude regions, which can expect blizzards in winter along with the severe disruption and economic loss they may cause. A wide range of countries in the Northern Hemisphere may experience blizzards, from Canada to northern regions of Europe and Asia. In the Southern Hemisphere, recent blizzards have occurred in the Chilean Andes, southern Peru, and Patagonia in Argentina. Both Arctic and Antarctic regions experience intensely cold blizzards.

In the United States, about 60 million people live in areas with a high risk of snowstorms. From 1960 to 2000, there were 438 blizzards in the United States, or an average of just over ten blizzards a year. On average, a blizzard event affected an area of over 150,000 square kilometers and over 2.4 million people. The highest incidence of blizzards occurred in the blizzard zone of North Dakota, South Dakota, and western Minnesota.

Blizzards create several risks. Blowing and drifting snow can create whiteouts, in which it is impossible to distinguish ground from air, making aviation and land transportation extremely hazardous. Cold temperatures combined with strong winds also create severe wind chills, which can result in frostbite or hypothermia. Power outages may occur, and livestock may die due to heavy snow and high winds. The deadliest blizzard in the world in the 20th century occurred in Iran in February 1972, when a week-long storm caused approximately 4,000 fatalities.

Some observers have predicted that the greater moisture in the atmosphere caused by global warming will intensify the number and strength of blizzards. However, the polar air masses, which are the second ingredient in making a blizzard, are not likely to become colder due to global warming. A recent study shows that blizzards are a less common occurrence on the Canadian prairies during the past 45 years. This may be an early indicator of a reduc-

Captain Oates

Many people associate going into a blizzard with the remark by Captain Oates in 1912: "I am just going outside and may be some time." This immortal phrase was recorded in the diary of a fellow expedition member of Captain Lawrence Edward Grace Oates.

Oates, who had served in the Second Anglo-Boer War as an officer in the Dragoons, wanted to go on the Terra Nova Expedition in 1910, which was organized by Robert Falcon Scott with the intention of being the first men to reach the South Pole. He was good at handling horses, and Scott initially liked him, although they were later to have bitter arguments over the management of the expedition.

When the party of five men reached the South Pole, they found that the Norwegian Roald Amundsen had beaten them to it. Oates by this time was suffering from scurvy and also aggravations to an old war wound. On their way back from the South Pole, the five men found themselves in serious trouble, and having difficulties in reaching their supply dumps. One of the party, Edgar Evans, died, and Oates was suffering from frostbite. On the night of March 17, 1912, when the four were trapped in a tent and supplies were low—they did not realize that they were only eleven miles from the next supply dump—Oates, on his 32nd birthday, uttered his famous remark and went out of the tent into the blizzard and died. Unfortunately, the other three men were trapped in their tent during the blizzard, and they perished soon afterward.

Oates's body was never found; it lies somewhere under a deep burial of snow and ice.

tion in the number of Northern Hemisphere mid-latitude cyclones due to global warming.

Body, Human

THE HUMAN BODY is a very complex set of systems that can withstand enormous challenges as well as accomplish dramatic feats. It can be described chemically, biologically, physically, and in terms of its functions. Chemically, the body is mostly water with additional elements including calcium, nitrogen, oxygen, sodium chloride, iron, phosphorus, potassium, trace minerals, and carbon. The human body is composed of a number of organic compounds that include carbohydrates, lipids, nucleic acids, and proteins.

The carbohydrates supply energy to the body's cells. The body is maintained by energy derived from chemical reactions with carbohydrates. Lipids are fats that store energy for future use. Some lipids are the material used by the body to make the living cells of the body. Nucleic acids supply cells with instructions to perform their jobs. Proteins also serve as building blocks for cells. Some proteins are enzymes, which perform a variety of functions such as speeding chemical reactions within the body.

Biologically, the human body is composed of cells, which is the basic unit of living things. Cells are mostly composed of proteins and nucleic acids in addition to water. The cells in the human body perform many functions such as providing food and oxygen, eliminating wastes, defending against disease organisms, and regulating body temperature. They stimulate growth and other activities as well. Each cell, such at blood cells, muscle cells, or brain cells, have unique features.

There are four major kinds of tissue cells. Connective tissue cells join together various parts of the body and also provide support. Most of the connective tissues, such as those attaching bones to muscles, are very strong and can withstand rugged use. The elastic connective tissues attach muscles to bones, or in the case of cartilage, support bones and act as support for motion.

Muscle tissue is fibrous and threadlike, and can contract or stretch in actions that enable a variety of motions, such as work or play. Nervous tissue transmits electro-chemical impulses that act as signals to the brain, muscles, sensory organs, and to other parts of the body. The epithelial tissue covers the body with skin and orifices such as the mouth and throat with a lining. The epithelial tissues protect the body from invasive organisms or from harmful substances.

Some of the tissues in the human body are organized into organs, which perform specialized functions. Groups of organs create networks to perform major functions in the body, such as the digestive system and the nervous system. Organs are composed of two or more types of tissue. The heart is an organ composed of muscle tissue, nervous tissue, and connective tissue.

The human body can be compared to a complex process organized into systems. The major systems include the skeletal, muscular, nervous, respiratory, circulatory, digestive, lymphatic, urinary, endocrine, reproductive, and epidermis (integumentary).

The skeletal system is the body's framework. It supports the body, protects its vital organs, and enables it to do activities. The skeletal system is composed of 206 bones. Marrow forms the inside of bones and serves as an intricate microstructure fed by the blood. Bones also make red blood cells.

The muscular system consists of 600 muscles of three types that enable the body to move. Skeletal muscles are attached to the bone and are voluntary, meaning they can usually be controlled by the mind. The body's internal organs have smooth muscles which, unlike skeletal muscles, do not have striations. Smooth muscles are involuntary muscles; they move automatically. Cardiac muscles in the heart are like both smooth and skeletal muscles. They have striations, but operate like smooth muscles with continuous, automatic, rhythmic actions. The heart beats, on average, 70-80 times per minute.

The respiratory system supplies oxygen to the body and removes carbon dioxide, which is a waste gas produced by respiration. The respiratory system includes the trachea (windpipe) and the lungs. Oxygen is needed by the cells of the body to release the energy supplied by food.

The circulatory system is composed of the heart, blood vessels, blood, and the lymphatic system. The heart is a four-chambered hollow muscle that pumps blood throughout the body. The right side receives the oxygen-poor blood and sends it to the lungs. The lungs then return blood to two chambers in the left side of the heart, which then send the oxygen-rich blood out to the brain and the body. The lymphatic system uses lymph, a milky liquid drawn from watery fluids collected around cells. Taken from blood vessels, lymph move slowly into the lymph system running throughout the body. The lymph collects wastes from cell activities, carries nutrients, and delivers white blood cells to various parts of the body. The thymus gland in the upper chest and the spleen are the main glands involved in the lymph system.

Another system that cleanses the body is the urinary system. The kidneys are the pair of organs that do most of the work in the urinary system; they are composed of millions of tiny filtering *nephrons* that filter salt, urea, and other wastes and water to be removed in the form of urine.

The glands in the endocrine system regulate growth, reproduction, digestion, and other hormonal functions. The major glands are the pineal gland, the hypothalamus, pituitary gland, thyroid gland, adrenal gland, the pancreas, the ovaries or testes, and the placenta during pregnancy. The body produces over 50 hormones that act as messengers to stimulate certain tissues.

The nervous system manages the activities of the other systems with chemical messages. These are

The human body is a very complex set of systems that can withstand enormous challenges as well as accomplish dramatic feats. It can be described chemically, biologically, physically, and in terms of its functions.

transmitted through nerve cells (neurons). The central nervous system, the brain and spinal cord, controls the actions of the body. It receives information from the peripheral nervous system, which is composed of the eyes, ears, nose and other sense organs. The autonomic nervous system communicates messages from the brain's subconscious to the involuntary muscles and to other automatic bodily functions.

The digestive system enables food and water to be used for the health of the body. Food taken into the mouth is passed down the esophagus into the stomach, where it is converted into *chime*. This thick liquid passes into the first part of the small intestines, where enzymes from the liver and the pancreas finish the digestion. The second part of the small intestines absorbs substances that can be used by the body. The remainder is passed to the large intestines, which extract water and minerals. What is left is eventually expelled as waste.

The reproductive system ensures the continuation of the species by bringing together the male sperm and the egg for growth in the uterus to produce a baby. Human gestation is nine months.

The skin or integumentary system has three layers. The outer layer, the epidermis, is tough and constantly shedding dead cells as new ones are replaced every several weeks. The skin protects the body from invasive bacteria, viruses, chemicals, and the sun. The middle layer is the dermis. It regulates body temperature; sweat glands are part of the dermis layer. The third later contains subcutaneous tissues that provide storage for fat, act as a cushion, and aid in the retention of heat.

Bolivia

THE HISTORY OF Bolivia has been one of resource extraction by outside powers, revolution, and countercoups. As a result of persistent instability and exploitation, the nation is one of the poorest and least developed in Latin America. Some 64 percent of the 8,857,870 live in poverty. Life expectancy (65.5 years) is low and the fertility rate is high (2.94 children per woman). With a per capita income of $2,700, Bolivia is ranked 164th of 232 nations in world incomes. The United Nations Development Project (UNDP) Human Development Reports rank Bolivia 113th of 232 countries on general quality-of-life issues. Although Bolivia is rich in natural resources, including tin, natural gas, petroleum, zinc, tungsten, antimony, silver, iron, lead, gold, timber, and hydropower, the benefits of resource development have predominantly flowed to a handful of corporations and important ruling families. Prices have been volatile for many resources, making sustained investment difficult. The controversial move to nationalize valuable natural gas fields is welcomed by most Bolivians as a effort to keep a higher share of profits in-country, though it is seen by foreign investors and free-trade advocates as serious error. Consequently, foreign aid is essential to Bolivia's economic survival.

Over 60 percent of the population lives in urban areas. Elsewhere, desperation often propels farmers into the business of illicit drugs. Currently, Bolivia is the third largest cultivator of coca in the world, and the number of hectares under cultivation increases regularly. Farming and raising livestock are often left to women and small children, who manage farms while males migrate to cities to seek employment. Overburdened and overworked, environmental protection is not a high priority for Bolivian farm women. Since the land is used year-round in order to survive, massive soil degradation occurs. Consequently, more land is needed to grow the same amount of crops. This practice, in turn, contributes to perpetual land shortage. Livestock, particularly goats that browse on trees and shrubs, also cause considerable environmental damage, stripping the land of essential vegetation.

Although landlocked, Bolivia has 8,817 square kilometers (14,190 square miles) of inland water, including Lake Titicaca. Located along the borders of Bolivia and Peru, Lake Titicaca is the world's highest navigable lake (6,122 kilometers [3,805 miles]). It is also the largest lake in South America (9,064 square kilometers [5,632 square miles]). Elevations in Bolivia vary from 145 kilometers (90 miles) at Rio Paraguay to 10,526 kilometers (6,542 miles) at Nevado Sajama. The climate varies according to altitude, ranging from humid and topical in the lowlands to cold and semiarid in the highlands. The terrain is also varied. The Andes Mountains are rugged with a highland plateau that gives way to hills. The Amazon Basin is made up of lowland plains. During March and April, northeastern Bolivia is prone to flooding. Droughts are also a threat. In 1983, for instance, a drought began that lasted into the 1990s, forcing many Bolivians from their homes.

A FRAGILE ENVIRONMENT

Much of Bolivia's environment is fragile. Forests have been stripped for their high-value timber, and slash-and-burn tactics have been employed to clear land. Such practices have also led to widespread deforestation and substantial soil erosion. Due to industrial pollution, Bolivia also suffers from a lack of fresh water for drinking, cooking, and irrigation. Some 28 percent of Bolivians have no sustained access to fresh drinking water, and 55 percent lack access to improved sanitation.

Other environmental problems include loss of biodiversity and desertification. The Bolivian government has protected 13.4 percent of the country's biologically diverse areas, such as the Chimán Forest and the Santa Cruz White and Black Rivers Wildlife Reserve. Of 316 endemic mammal species, 24 species are endangered, and 28 of the 504 endemic bird species are threatened with extinction. In 2006, a study at Yale University ranked Bolivia 71st of 132 nations on environmental performance. While Bolivia's ranking was above the relevant income group average, it was considerably lower than the average for the relevant geographic group. Bolivia's lowest scores were in the areas of air quality and environmental health.

Bolivia's current environmental policy is chiefly concerned with sustainable development. Policies are designed to ensure a healthier environment for all living things while promoting the economic growth that is essential to fighting poverty. Key objectives have been identified as improving environmental management, more responsible use of resources, forests, and ecosystems, and improving and monitoring environmental quality. The Institutional Network of Environmental Quality has been established to promote environmental quality, and the Unit of Social and Policy Analysis has been charged with evaluating and monitoring the rules and policies of the Strategy for Sustainable Development.

Bolivia has participated in the following international agreements: Biodiversity, Climate Change, Kyoto Protocol, Desertification, Endangered Species, Hazardous Wastes, Law of the Sea, Marine Dumping, Ozone Layer Protection, Ship Pollution, Tropical Timber 83, Tropical Timber 94, and Wetlands. The government has signed but not ratified the Environmental Modification, Marine Life Conservation, and Ozone Layer Protection agreements.

Boll Weevil

IN 1892, NEAR Brownsville, Texas, a small beetle, identified by local agricultural authorities as the Boll Weevil, or *Anthonomus grandis,* made its first appearance in the United States. For the next century, the tiny insect would radically alter the South's agricultural economy by attacking the region's major crop—cotton. Many believe that the weevil was one of the most important agents of social change in the South, second only to the Civil War. The beetle's destructive wrath, coupled with a backwards agricultural system known as sharecropping, impoverished the southern states and prompted Franklin D. Roosevelt during the 1930s to label the South as the "nation's number one economic problem."

Although the boll weevil is indigenous to Mexico and Central America, it is an invasive species in the United States. At the time of its arrival, most of the South's agricultural lands were cultivated in cotton. Over the next 30 years, the ravenous beetle migrated eastward. By 1915, it was bearing down on Georgia. At the time of the beetle's entry into Georgia, approximately 5.2 million acres of the state's land was cultivated in cotton. The weevil's impact on the state could be observed eight years later when it was reported that only 2.6 million acres were devoted to cotton. The decline in cultivated acreage corresponded with a drastic reduction in yield. In 1914, for example, Georgia produced 2.8 million bales of cotton. By 1923, these numbers had been reduced to 600,000 bales, primarily due to the weevil. The story was the same across the Cotton Belt. In 1907, Mississippi produced 191,790 bales of cotton. Within only five years of the weevil's arrival, Mississippi farmers could barely generate 30,000 bales. During the height of the Great Depression in the 1930s, the South's estimates of damage due to the insect exceeded $200,000 annually. In 1950, the Cotton Belt set a historical record with losses topping over $750 million. By the end of the 20th century, the weevil had cost the region's cotton farmers an estimated $22 billion in losses and control efforts.

In order to survive, the boll weevil must have access to cotton. Adult weevils impact young cotton bolls (or squares) by feeding upon them and using them as a place to deposit their eggs. Actually, the damage done by feeding is minimal. It is the larval stage of the insect that is most devastating to cotton. Male weevils, after locating a cotton field, release a special pheromone to attract females. Thus, the presence of cotton is necessary to ensure the insect's propagation. Upon mating, females seek out a cotton boll in which to deposit an egg. Meanwhile, both males and females use their long snout to puncture the bolls and feed.

After mating, the female lays an egg (usually one per boll) in an abandoned feeding tube and covers it with a dark, sticky substance known as frass. Within the week, the egg hatches and a small, legless larva, or grub, emerges. For the next few days, the larva consumes the boll's internal tissues, after which it enters a pupation stage that lasts for about a week. At the end of the pupation period, an adult weevil emerges from the boll and immediately begins to seek out cotton and a mate.

The damaged boll yellows, withers, and drops. The entire life cycle (egg, larva, pupa, and adult) requires around three weeks to complete. A typical season may produce as many as eight to ten generations of weevils. To ensure the survival of the species, adult weevils over-winter in or adjacent to cotton fields, only to reemerge in the spring.

For most of the 20th century, the fight against the boll weevil produced only limited results. The struggle compelled many farmers to give up cotton and pursue other cash crops, like peanuts, tobacco, and vegetables. During the 1970s, however, scientists discovered ways to attack the insect through its own biology by developing pheromone lures and detection traps. The use of chemicals, particularly Malathion, has also been effective. Cultural practices, too, like the destruction of cotton stalks after harvest to deprive weevils of a winter habitat, have also been successful.

WINNING THE BATTLE

Today, cotton-producing states participate in the Boll Weevil Eradication Program (BWEP), which was first tried in North Carolina during the late 1970s. Basically, BWEP applies a three-pronged approach to weevil eradication: the spraying of Malathion, the use of pheromone lures and traps, and the destruction of cotton stalks. The early successes with the program prompted other states to participate. BWEP has had enormous success in eliminating the weevil from several states and some, like Georgia, Alabama, South Carolina, and North Carolina have declared themselves free of the insect. BWEP also boasts an environmental benefit. With the eradication of the weevil, the need for insecticides is greatly reduced, allowing farmers to rely more heavily on beneficial insects to control cotton pests.

Bookchin, Murray (1921–2006)

MURRAY BOOKCHIN (1921–2006) is best known as the founding figure of social ecology, a political and philosophical approach to radical environmentalism. As the author of dozens of books and countless articles, as a prolific public speaker, and as the founder of the Institute for Social Ecology, Bookchin's sphere of influence encompassed green political theory and environmental activism internationally.

Raised in the New York City in the 1930s, Bookchin grew up amongst radical politics and the labor movement; these working-class roots continued to inform his politics and philosophy for years to come. From the 1950s forward, Bookchin worked to bring together the cohesive political vision of the traditional Left with the new concerns of ecology, toxics, and biodiversity. His contribution mainly took the form of an immense body of writing, but he was also an active figure in grassroots anti-war, anti-nuclear, and environmental social movements since the 1960s. His influence was particularly important for various European Green parties, as well as the anti-nuclear movement known as the American Clamshell Alliance. Even during the retirement period before his death, Bookchin continued to write prolifically.

BOOKCHIN'S MAJOR WORKS

Bookchin's first major work, *Our Synthetic Environment* (1962), published under the pseudonym Lewis Herber, outlined a comprehensive critique of industrial capitalism's relation to the natural world. While Rachel Carson's *Silent Spring*, published at the same time, is often credited with sparking the nascent ecology movement in the United States, it was Bookchin's work that provided the seminal ideas that would eventually become radical ecology. *Post-Scarcity Anarchism* and *The Modern Crisis*, among other works, served as responses to the way the traditional Left movements in the United States had attempted to understand ecology and natural value. Bookchin emphasizes that the destruction of the natural environment stems from the same political and economic systems that oppress the working class, the developing world, and so on.

These ideas are developed further in *The Ecology of Freedom* and *The Philosophy of Social Ecology*, where Bookchin laid out the teleological philosophy behind social ecology. He argued that human sociality emerges directly from evolution's tendency toward increasing complexity and consciousness. In the context of Bookchin's leftist politics, this argument suggests that an objective basis for a free and just society can be found in nature itself. In practical terms, Bookchin advocated an approach to political organization he called *libertarian municipalism*.

As described in *From Urbanization to Cities and Remaking Society: Pathways to a Green Future*, this approach is based on a radical decentralization of power, allowing citizens direct access to all forms of political decision-making. Bookchin modeled this strategy on classic Greek democratic forms and New England town meetings, updated with an understanding of global environmental problems and appropriate technologies like solar energy and public transportation.

Since the 1980s, Bookchin frequently became entangled in sectarian controversies with other leftists and radical ecologists. In particular, he has taken a hard line against the philosophy and practice of deep ecology, associated with earth spirituality and the militant biocentric environmentalism of groups like Earth First! While these debates generated significant bitterness and divisiveness, Bookchin's ideas remain an important legacy for green political theory and practice.

Boreal Forest

IN CONVENTIONAL GEOGRAPHIC terms, the boreal forest is a terrestrial biome encircling nearly the entire subarctic. In North America, the boreal forest lies predominantly within Canada, where it occupies a contiguous zone from the province of Newfoundland to the Mackenzie River delta in the Northwest Territories, extending as far south as central Ontario and Québec. Significant portions of boreal forest are also found in central Alaska. In Europe and North Asia, the boreal forest—or taiga forest—is equally impressive in size, spanning northern Scandinavia, northern Russia and Siberia, and the Kamchatka Peninsula. Although frequently represented as a vast wilderness, millions of people reside in the boreal forest. In Canada alone, just fewer than 4 million people are estimated to reside within the boreal forest, including well over 500 hundred First Nations communities and several large resource-dependent municipalities. The taiga in Eurasia is also very heavily populated.

RICH IN NATURAL RESOURCES

The boreal forest consists of mainly coniferous tree species, including fir, spruce, and tamarack. There are also deciduous tree species, such as trembling aspen and poplar, and large expanses of peat bog, especially in the northern latitudes. Sizeable herds of woodland caribou (reindeer in Eurasia) migrate throughout the boreal forest, as do large populations of black bears, grizzly bears, and timber wolves. Recent estimates suggest that in North America alone, over 4 billion migratory landbirds inhabit the boreal forest at the height of the summer breeding season. Topographically, the boreal forest varies from flat, lowland expanses in central and northern Canada and the Siberian lowland, to mountainous regions in western Canada and west-central Russia.

The boreal forest is among the world's most important sources of natural resources, and for this reason has become an object of environmental concern over the last few decades. Since roughly the early 1990s, environmental and conservation organizations have argued that excessive industrial resource extraction throughout the boreal forest is having a detrimental effect on the forest's capacity to deliver environmental services such as biodiversity, potable water and carbon storage. In 1997, these concerns were given additional gravitas when the World Resources Institute declared that the boreal forest comprises 50 percent of the world's remaining "frontier forest" and urged governments, civil society and industry to collectively halt the pace of boreal forest destruction. Subsequently, many North American and European conservation organizations began drawing public attention to the boreal forest through media campaigns and consensus-building activities. Similarly, many indigenous peoples' groups—including the Sámi people, the Lubicon Cree, James Bay Cree, and Deh Cho First Nations—have argued that excessive resource extraction in the boreal forest poses a significant threat to their cultural survival, since such activities are frequently carried out on their traditional territories and often infringe on their legal rights.

One noteworthy feature of boreal forest politics is that the forest is represented politically in different terms depending on the region in question. In Canada, many conservation groups recognize the importance of the Canadian boreal forest's carbon storage capacity, echoing the Intergovernmental Panel on Climate Change, which says that the global boreal forest contains 25 percent of the world's terrestrial carbon. They also place heavy emphasis on the protection of mammalian and avian biodiversity. In seeking some degree of boreal forest conservation, these groups have embraced an anthropocentric ideology that places an economic value on the ecosystem goods and services provided by the boreal forest. According to one recent estimate, the total value of ecosystem goods and services supplied by Canada's boreal forest in 2002 was $93.2 billion, while the total value of carbon stored in the boreal forest was valued at $3.7 trillion. These groups hope that policymakers will factor these figures into long-term land use planning decisions that affect the boreal forest, and as such, contribute to ecologically benign future development. In Canada, this approach to boreal forest conservation has resulted in an environmental political culture that emphasizes consensus building among numerous stakeholder groups. The Canadian Boreal Initiative, for instance, is currently brokering a social consensus that brings together First Nations, conservation groups and industry to negotiate a sustainable future for the boreal forest.

In Europe and North Asia, environmental groups articulate the taiga forest in somewhat different terms. While such "green developmentalism" is an important goal for many of these groups, they argue that taiga conservation cannot be implemented without addressing the underlying causes of taiga deforestation, such as illegal forest activity and government corruption. These groups seek to ensure that taiga forest products imported into the European Union conform to the highest environmental, social and governance standards.

Boserup, Ester (1910–99)

ESTER BOSERUP WAS a Danish economist who studied economic and agricultural development. Her most notable work is *The Conditions of Agricultural Growth: The Economics of Agrarian Change under Population Pressure* (1965). Boserup presented her work as a "framework for a dynamic analysis embracing all types of primitive agriculture." She posited the theory that instead of agricultural output determining population size, population pressure was a precondition for the emergence and development of agricultural innovation and intensification, primarily among subsistence and peasant producers. Boserup described how societies with moderate population growth can increase agricultural productivity by investing additional labor and applying innovations to their farming systems, such as digging irrigation channels or building terraces. Her theory that population pressure stimulates agricultural innovations directly contradicted Thomas Malthus (1766–1834). Malthus, an English political economist, argued that increased food production triggered population growth, and that population growth would always outpace the food supply because population grows geometrically while the food supply grows linearly. Thus, population growth would outstrip agricultural output, eventually resulting in famine and population crash. This cycle was labeled the "Malthusian catastrophe."

CHALLENGING MALTHUS

Malthus's theory held sway for over a century until Ester Boserup's provocative thesis challenged his ideas. Drawing on Boserup's work, social scientists intensified their research into agricultural change. Anthropologists and geographers, most notably those studying swidden agriculture (closely related to shifting cultivation), sought evidence to test Boserup's thesis. Many scientists found that at low population densities, swidden agriculture was the most efficient way to produce food, in terms of workload and productivity. Following Boserup's model, it was demonstrated that with population growth, the swidden fallowing periods often became too short, fields became less fertile, and the workload increased, while productivity decreased. At this point, rather than collapsing into famine, societies developed ways to intensify agricultural production through innovation. In many cases, the innovations that supported increased populations came in the form of inputs, such as fertilizers, pesticides, and high-yielding crop varieties, technologies that Malthus could not have imagined in 18th-century England.

Many of the current debates on population and the environment trace their intellectual roots to Malthus or Boserup. For neo-Malthusians like Paul Erlich, author of *The Population Bomb* (1968), societies become mired in a cycle of high population growth, resulting in an inability to produce enough food. Ecological degradation inevitably follows this scenario. Boserup provided an alternative viewpoint in the current population–environment debate by arguing that population growth may stimulate agricultural intensification, thereby suggesting that population growth can ultimately have a benign or possibly even a positive effect on the environment.

Although Boserup's theory is generally considered oversimplified and too general, it has been supported by research on agricultural societies that are not fully integrated into market economies. However, in some of the world's poorest regions, such as sub-Saharan Africa, population pressures have outstripped food production, resulting in famines. Boserup's theory was not fully developed and cannot explain these contradictions. Geographers such as David Carr who examine the evolution of thought on population–environment theories believe that further research is necessary to understand under what conditions population pressure will lead to agricultural intensification, and whether or not this intensification will result in more or less environmental degradation.

Bosnia and Herzegovina

IN 1992, BOSNIA and Herzegovina declared independence when the former Federation of Yugoslavia broke up into smaller nations. The move was followed by an extended period of ethnic conflicts among the new countries. Peace efforts in 1994 led to the creation of the Federation of Bosnia and Herzegovina. With a total land area of 51,129 square kilometers, Bosnia and Herzegovina supports a population of 4,025,476 people.

Most areas experience hot summers and cold winters; but in higher elevations, the summers are short and cool while the winters are severe. Rain is frequent along the 20 kilometers of Adriatic coastline. The most common environmental problems include air pollution from the numerous metallurgical plants, a shortage of urban waste disposal sites, deforestation through illegal logging, water shortages, and destruction of the infrastructure. Destructive earthquakes are not uncommon. Protracted war and conflict has also left hazards behind, including an estimated 1,000,000 land mines that dot the landscape.

Bosnia and Herzegovina is rich in natural resources that include coal, iron ore, bauxite, copper, lead, zinc, chromite, cobalt, manganese, nickel, clay, gypsum, salt, sand, and hydropower. With over 40 percent of the land area of Bosnia and Herzegovina forested, the nation has the third-largest forest reserve in Europe. However, large areas of forests are steadily being lost to illegal logging and other forms of uncontrolled exploitation. Such disturbances to the environment have led to massive landslides that have changed the course of the Bosna River and to soil erosion and fire destruction. Little is being done to counteract this destruction because of a weak infrastructure, even though the forests of Bosnia and Herzegovina are home to the majority of the 72 species of mammals that are endemic to the area. As a result, 10 species are threatened with extinction. Likewise, three species of the 206 bird species endemic to the area are threatened.

Despite potential for growth, Bosnia and Herzegovina is the second poorest nation among the former Yugoslav countries, outranked only by Macedonia. Agricultural output contributes 14.2 percent of the Gross Domestic Product, but farms tend to

Stari Most

The Stari Most ("Old Bridge") across the river Neretva in Mostar, Bosnia, was built between 1557 and 1568 by the Turks after having been commissioned by Suleiman the Magnificent to replace a wooden suspension bridge. The first span of the stone bridge collapsed, and the Sultan told Mimar Hayruddin, the architect and a student of the famous architect Sinan, that he would lose his head if the next span also collapsed. As no time limit was given, the architect decided to stall. However, the architect was worried that the new span might collapse when the scaffolding was removed, so he fled and was found digging his own grave when the locals went to look for him. On its completion, the bridge was said to have been the largest single span arch bridge.

The bridge is 4 meters wide, 30 meters long, and 24 meters above the river. It did not have any foundations, but has abutments made from limestone, which are against the cliffs on either side of the river. There has been some academic debate over how the scaffolding across the river was erected in the first place, how it was possible to have the tenelija stone transported from one bank of the river to the other, and how the scaffolding survived during the long period before it was removed.

The bridge remained one of the most famous sites of Bosnia-Herzegovina, appearing on many postcards from the 1890s onward. Each year men jumped from the bridge into the cold Neretva River, and tourists visited it regularly from the 1930s. During the war in Bosnia-Herzegovina from 1992–1995, Croat militia were keen on taking control of Mostar and blew up the bridge with artillery fire in order to split the Bosnian-held left bank from territory they held on the right bank. The bridge was rebuilt in 2004 and reopened on July 22, 2004, looking much like its predecessor but strengthened with a reinforced concrete core.

be small and inefficient. Therefore, most food is imported. With a 45.5 percent unemployment rate and a poverty rate of 25 percent, environmentalism often takes a back seat to economic concerns. At present, around 44.4 percent of the population is urbanized, but that percentage is expected to rise over the next decade. Two percent of the population lacks access to safe drinking water, and seven percent lack access to improved sanitation. The United Nations Development Project (UNDP) Human Development Reports rank Bosnia and Herzegovina 68th in quality-of-life indicators.

Because of its recent history of strife, Bosnia and Herzegovina is still establishing institutions, and the country is only slowly finding its path to a consciousness of environmentalism. This is reflected in the lack of a legal framework to regulate the use and protection of natural resources. Additionally, the government lacks funding for programs that promote environmental responsibility and for oversight. Bosnia and Herzegovina has no water treatment plants, and waste treatment plants are inefficient.

The drafting of environmental laws is now underway, and some international groups have stepped in to promote environmentalism. For instance, Project Highlight, sponsored by PM, a multinational project and construction management company, is working with the Ministries of Environment on developing environmental policies that are cost effective and in enacting environmental legislation that meets European Union standards. PM is also involved in raising public awareness, training officials, and providing technical support for environmental policies and programs. For its part, the government of Bosnia and Herzegovina has announced its commitment to the environment through participation in the following international agreements: Air Pollution, Biodiversity, Climate Change, Hazardous Wastes, Law of the Sea, Marine Life Conservation, Ozone Layer Protection, and Wetlands.

Botany

BOTANY IS THE study of plants. Botanists study all aspects of plants, including their environment and how they grow. It is closely associated with agriculture, horticulture, and pharmacology. Botany is one of the oldest of sciences. From early human history, people have gathered plants for medicine or food. Folklore in the earliest of human societies was passed on for generations. Medicine men or women practiced the development of remedies for diseases and injuries, as well as intoxicants. With the development of farming about 12,000 years ago, horticultural plant knowledge also began to move toward a body of knowledge. Ancient civilizations of the Egyptians, Indians, and Babylonians coined names for the plants they knew. The Greeks added descriptions to plant names. Aristotle, his student Theophrastus (*An Inquiry into Plants*), and Galen the physician gave descriptions to the names. Aristotle sought for the unique form or idea that is found in each plant. This basis would eventually aid the development of taxonomy of plants.

There are hundreds of thousands of plants around the world. They vary widely, even when related.

Because of this variation, it was necessary to develop a standardized nomenclature to aid a precise science. Latin, the language of scholarship until the 20th century, was used for the taxonomy to assign a universal name to plants with different common names or national names in the many European languages. The use of Latin, a dead language, prevents changes in names that would occur in a living language, thereby creating lasting scientific precision. The scientific naming has a fixed pattern in which the first name identifies the genus to which a plant belongs. The second name is the species name, which denominates precisely in which one of the subgroups it is a member. Each genus is a unique class with each of its species also a unique group. The commonly named orange tree has a scientific name of *Citrus sinensis*, of which naval and Valencia oranges are varieties. Field guides for a particular region may include common names to aid in identification.

Other features of plants not only aid it identification and naming, but also are studied in order to understand the nature and possible uses of plants. These features of plants studied by botanists include plant physiology, cytology and histology; morphology; genetics; pathology; plant ecology; and economic botany.

Physiology in botany is the study of plant survival activities, such as how plants make and use food, how the cells of a plant enable it to grow, how the plant reproduces, and how the plant is influenced by heat, light, and moisture. The way that plants metabolize materials as food in order to grow is a central part of botany. For example, trees breathe in carbon dioxide and exhale oxygen, which in turn is breathed by humans and animals. Photosynthesis is the process used by plants to make green chlorophyll, which animals and humans eat.

Botanists also study how plants make chemicals. Alfalfa, clover, peanuts, and other plants produce nitrogen compounds that aid plant growth and ultimately also fertilize the soil. Their symbiotic relationship with Rhizobia bacteria are similar to other types of symbiotic relationships plants have. Histology is the study of the different kinds of cells and how they are arranged in different plants, and cytology focuses on the specific nature of plant cells.

Plants range from single-cell, very complex arrangements of cells into soft green leaves, seaweed, or into very hard tropical trees like mahogany. Cytology and histology are subdisciplines of plant morphology, which is the study of the form and structure of plants. Morphology is organized around the taxonomy of plants. This part of botany seeks to understand how a plant grows and lives. The goal is to place new plants into an organized taxonomy.

Many gardeners seek to breed a flower with a unique beauty, new color, or some other characteristic.

Plant genetics focuses on the laws of genetic reproduction to describe how plants transmit their characteristics to their offspring. Many gardeners seek to breed a rose that may be an ideal beauty, or a flower with a new color or some other characteristic. University botanists may be seeking to selectively breed a more productive type of tomato or corn plant using genetic knowledge of each plant.

Plant pathology has a number of causes. The most damaging pathogens are viruses, bacteria, fungi, and molds. Other causes may be exhaustion of the soil or weather. Plant pathogens may also be toxic to humans if the infected plants are eaten. To prevent crop loss, plant pathology includes the study of ways to fight or prevent plant diseases. Genetics may be used to develop strains of plants resistant to infection, or medicinal fungicides or other treatments may be used. Some botanists seek to apply their knowledge to all segments of agriculture. They specialize in making rapid, accurate, and scientifically sound diagnoses and management strategies for all types of plant health problems.

Plant ecology studies the relationship between plants and their spatial location. Also important to plant ecology are studies of how plants grow (or do not grow) together in different climates or regions such as mountains, deserts, swamps, seashores, river bottoms, or under the sea. Knowledge of plant ecology can be very helpful in aiding recovery of the natural health of an area. For example, the nutria (*Myocastor coypus*), a large fur-bearing rodent that has become an invasive species in Louisiana, Maryland, and elsewhere, destroy wide areas of marshland by eating the roots of marsh grasses. Promoting the marsh grass recovery is important, because the marshes are vital sea life breeding areas.

Economic botany is the application of botanical knowledge. It involves research to adapt plants to human use for food, fertilizer, medicine, or for other benefits such as grass on golf courses. It also seeks to develop practical knowledge of all aspects of plants. Botany is also related to many other sciences such as soil science, chemistry, geography, mathematics, and physics. All the sciences and businesses that use botanical knowledge benefit from pure botanical research.

Botkin, Daniel B.

THE ECOLOGIST DANIEL B. Botkin has worked and published on forest and wildlife ecology for many decades, and developed one of the first computer simulation models in ecology. His best known work is *Discordant Harmonies: A New Ecology for the 21st Century* (1990). Botkin forcefully argues against the myth of the balance of nature, which he claims has permeated environmental thinking since antiquity. Illustrated by many case studies, Botkin shows that this balance has never existed, and that "wherever we seek to find constancy we discover change." It is not only impossible to preserve unchanging "natural" landscapes, but attempts to do so can actually have disastrous consequences. Thus at Tsavo National Park in Kenya, the elephant population first grew to completely destroy the existing tree population, then collapsed itself after a devastating drought.

Botkin does not argue that all environmental management should be abandoned, or that all environmental change is desirable. Rather, "the key to a new but wise management of nature is to accept changes that are natural in kind and in frequency, to pick out the melodies from the noise." This, he believes, will be possible through more careful data collection and more sophisticated analysis and modeling that take complexity into account.

Disequilibrium ideas are further explored in all of Botkin's subsequent writings, including historical studies of Lewis, Clark, and Thoreau's nature observations as well as a series of consultancy reports. They also influence his thinking on climate change. While deeply concerned about the effects of climate change on biodiversity, Botkin has pointed out that predictions about these effects may be misleading if based on assumptions of otherwise stable conditions.

Botkin's accessible writing and many other activities have played a key role in spreading disequilibrium ecology beyond the science of ecology, amongst both social scientists concerned with the environment and environmental management practitioners. In the social sciences, where popular equilibrium thinking has been quite persistent, many different authors are beginning to draw on Botkin and new ecology ideas, in particular in political ecology and environmental history. In environmental management, there are several hurdles that make the translation of disequilibrium theory into practice difficult. For one, conservation continues to be dominated by territorial approaches, the preservation of whole landscapes, which hinder a radical reorientation. If there is no longer a given "natural" landscape, decisions over what should be preserved become even more political. Moreover, there is, in most places, simply not the kind of long-term data available that would be necessary for proper disequilibrium management—in fact, as Botkin himself has frequently pointed out, there is often astonishingly little ecological data altogether used in environmental management.

Having said this, Botkin's suggestions for a different kind of ecological science and management are now widely discussed in the conservation world and have been integrated into practice in some instances. One example is the adoption of let-burn policies on natural fire disturbances, in which Botkin's work has been very influential. Another is Botkin's own study on salmon in Oregon, which led to the adoption of a different management approach.

Botswana

THE REPUBLIC OF Botswana is located in southern Africa, between South Africa, Namibia, Zimbabwe, and Zambia. Botswana covers 600,370 square kilometers (231,803 square miles), equivalent to an area twice the size of Arizona. Formerly the British protectorate of Bechuanaland, Botswana adopted its new name upon independence on September 30, 1966. The country is named after the dominant ethnic group, the Tswana. Botswana has a population of 1,765,000 people, with 195,000 living in Gaborone, the capital city.

Botswana is the oldest democracy in Africa, with four decades of civilian leadership, a pluriform multiparty system, progressive social policies, and significant capital investment. As one of the Frontline States, Botswana played an influential role in countering the former apartheid government of South Africa.

Botswana has one of the most dynamic economies in Africa, characterized by the most rapid growth in per capita income in the world since 1966. The economy is strong, with one of the highest credit ratings of any African country. Botswana has a proven record of good economic governance and is ranked the least corrupt country in Africa. The economy is dominated by the mining sector, with Botswana being the largest exporter of gemstone diamonds in the world. Other minerals, including copper, nickel, salt, soda, ash, and potash, are also extracted. Livestock production is also an important part of the economy, as Botswana is the largest exporter of beef to the European community. Only 0.6 percent of the land in Botswana is farmed, and major crops include sorghum, maize, millet, and groundnuts. Another source of revenue is tourism, which is a growing sector due to the abundant number of large game that are protected in parks and reserves that cover 15 percent of the country.

Botswana has the second-highest rate of HIV/AIDS infection in the world (after Swaziland) with 37.5 percent of the total population infected. This has resulted in a decline in the average life expectancy to 33.7 years (the lowest in the world) as well as a nonexistent growth rate in population. However, Botswana also has one of Africa's most progressive and comprehensive programs for dealing with the disease. While English is the official language, there are several local dialects reflecting various ethnic groups, including Setswana (spoken by the Tswana, who make up 79 percent of the population), Kalanga (11 percent), and Basarwa (3 percent). Half of the country has indigenous religious beliefs, while 30 percent are Christian, and the remaining 20 percent observe other religions. Literacy rate is 80 percent.

GREAT WILDERNESS AREAS

Two of Africa's great wildernesses, the Kalahari Desert and the Okavango Delta, are found in Botswana. The Kalahari covers nearly 70 percent of the country. While Botswana is landlocked, 2.5 percent of the country is covered in water with most of it in the Okavango Delta, the world's largest inland delta. In addition to the desert and delta, there is a large saltpan in the north (the Makgadikgadi) while the rest of the country is covered in rolling hills of grasslands and savanna. These diverse habitats are one reason for the rich fauna in the country, including the Blue Wildebeest and antelope. Three environmental issues facing the country are desertification, overgrazing, and limited sources of fresh water.

Bovine Growth Hormone

BOVINE GROWTH HORMONE (also referred to as recombinant bovine growth hormone, rbGH, or recombinant bovine somatotropin, rbST) is a genetically engineered version of a hormone that occurs naturally in cows. When injected into cows, it can increase milk production by between 15 and 25 percent. Consumer organizations, animal welfare groups, environmental groups, and small farmers' organizations have opposed the use of bovine growth hormone due to its potential threats to food safety, cow health, and the economic viability of small farms.

The Monsanto corporation began experimenting with rbGH in the 1980s. Their rbGH product, Prosilac, was approved by the U.S. Food and Drug Administration for commercial sale and use on November 5, 1993. But the approval process and subsequent use of rbGH have been surrounded by controversy. Studies have shown that the use of rbGH can cause a number of health problems in cows including lameness, diminished fertility, and an increased risk of mastitis (udder inflammation). Mastitis is usually treated with antibiotics, which can make their way into dairy products, thus increasing health risks for consumers. Concerns have also been raised about the relationship between rbGH use and increases in another hormone found in cows, insulin growth factor or IGF-1, which, while naturally found in milk and beneficial to human health, has also been linked to certain forms of cancer. Scientific reports have yielded conflicting conclusions about the broader health impacts of rbGH use.

Consumer organizations such as the Center for Food Safety and the Organic Consumers Association have charged that there was inadequate testing of the drug prior to its approval and that health consequences, including cancer risks, have been underestimated. Some charge that Monsanto used political influence to usher through the approval of the growth hormone in the United States, and that the corporation covered up evidence of its dangers. A major controversy erupted, and a series of lawsuits were filed over a Fox News report on bovine growth hormone (BGH) that Monsanto sought to suppress.

Political conflicts have also erupted over the labeling of products made from cows treated with

BGH. In an industry victory in 1997, a federal court struck down a Vermont law that required labeling for dairy products made with milk from BGH-treated cows. Voluntary labeling is still allowed in most states, and some dairy producers indicate on labels that their products were produced from cows that have not been treated with the hormone.

Resistance to BGH and genetic engineering in general has been even stronger in Europe and Canada than in the United States. The European Union placed a moratorium on the use and marketing of rbST in 1990, and in 1999 imposed a permanent ban. Health agencies in Europe and Canada place more weight on the evidence suggesting human health risks of the growth hormone. Public opinion in Europe is also strongly against genetically modified products. The United States sought to overturn the European ban for the purposes of marketing U.S. goods. However, when Codex, an international organization that sets food standards, failed to reach consensus on the safety of BST in 1999, the United States backed off on its efforts to force these goods onto the European market.

Concern about the implications of the use of growth hormones for small farms is also significant in Europe and America. There is no shortage of milk, thus increased production resulting from the use of synthetic hormones threatens to lower milk prices and harm small producers. Resistance to rBGH has been particularly strong in dairy farm states such as Wisconsin and Vermont.

There is no shortage of milk, so increased production due to synthetic hormones threatens to lower milk prices.

Bovine Spongiform Encephalopathy

BOVINE SPONGIFORM ENCEPHALOPATHY (BSE) is a communicable, chronic, degenerative, and fatal disease that predominantly affects the central nervous system of cattle. Affected animals' brain tissue becomes increasingly damaged by lesions of sponge-like holes that commonly cause animals to exhibit behavioral symptoms such as dementia, aggression, lack of balance, and excessive salivation. As a result, BSE has become more popularly known as "mad cow disease." During the early 1990s, a "mad cow" epidemic emerged in the United Kingdom (UK) and then spread throughout Europe, decimating beef industries in affected nations and terrifying populaces. While it is believed that the disease has presently leveled off considerably due to stricter livestock testing and policy changes designed to limit BSE's contagious viability, new cases of BSE continue to appear in nations previously unaffected by the disease, such as the United States.

BSE is one of a class of brain diseases classified as Transmissible Spongiform Encephalopathies (TSEs) that are contracted by human and non-human animals. Non-human TSEs also include Chronic Wasting Disease in deer and elk, Transmissible Mink Encephalopathy, Feline Spongiform Encephalopathy, and Scrapie found in goats and sheep. Human TSEs include Kuru, Gerstmann-Straussler-Scheinker Syndrome, Fatal Familial Insomnia, and Creutzfeldt-Jakob disease. Notably, in 1996, a new variant of Creutzfeldt-Jakob disease (vCJD) was diagnosed, and while it has never been proven that BSE directly causes vCJD, many experts now believe that vCJD results when BSE crosses the species barrier and achieves human transmission. Unlike many other infectious diseases that are transmitted by virus or bacteria, TSEs are believed to be caused by misshapen, self-replicating body proteins called prions, and TSEs are spread through contact with prion-infected tissue or fluids, particularly through consumption. Unlike most bacteria and viruses, however, prions are believed to survive normal refrigeration and cooking procedures. Thus, it is believed that vCJD generally occurs after persons have eaten meat infected with BSE.

PROPAGATION AND ORIGINS

BSE has been greatly propagated due to the widespread adoption of controversial factory farm feeding practices, in which slaughterhouse waste by-products, often described as "meat and bone meal" (MBM), are incorporated into cattle feed as a protein additive in order to generate weight gain in livestock. This practice resulted in the mass propagation of the disease when MBM from infected herds was utilized as feed. Technically, such feeding practices have existed since the early 20th century, but it is only over the last few decades with the rise of factory farms as agro-industry standards that MBM feeding became truly ubiquitous for millions of animals. Thus, while it is possible that BSE has been transferred between individual animals for some time via MBM, it is only since the 1970s that agricultural conditions have existed that would allow for the development of a BSE epidemic on national and global levels.

The origins of BSE remain mysterious. One leading theory purports that BSE originated when sheep infected with Scrapie were fed to cattle, which were in turn rendered and then fed to other cattle, thereby resulting in a mutated BSE prion. However, a competing theory claims that the disease developed spontaneously. The British government, for instance, maintains that BSE arose spontaneously in a small number of UK cattle sometime during the 1970s. Those favoring the theory of spontaneous origin also point to the discovery in Italy during 2003, and in countries such as France and the United States, of an apparently new form of BSE-causing prion. The disease associated with this prion has been named Bovine Amyloidotic Spongiform Encephalopathy (BASE), but scientists note that, except for the different mutations between the BASE and BSE prions, the two diseases are largely equivalent in terms of their prognosis. This has led some to believe that BASE is a spontaneous strain of BSE that developed outside of the United Kingdom.

While BSE has been discovered in some 35 countries, it is perhaps most closely linked to the UK. Authorities in the UK first officially identified BSE during 1986. Over the next 15 years, more than 180,000 animals contracted the disease, and billions of dollars in damage was done to the British cattle industry as international bans on the importation of British beef products ensued. The resulting public alarm led to a mass cull of over four million head of asymptomatic cattle in an attempt to ensure safety, and in 1988 the British government became the first of many nations to ban the use of ruminant proteins in the manufacture of animal feed. A year later, they enacted a ban of specified bovine offals, such as ruminant brain, spinal, and intestinal meat, for human consumption. By 1993, the worst of the epidemic was over in the UK, but the export of British cattle and MBM had begun to seed BSE in many other countries. Then, beginning in 1995, the first of about 160 people began to die of vCJD, and studies began to predict the emergence over time of thousands of additional cases. As the British government had repeatedly promoted the safety and quality of British beef throughout the preceding decade's crisis, sometimes in opposition to its own scientific findings, critics charged that the government consciously put public health in jeopardy in order to stabilize the large economic losses suffered by the beef industry.

TESTING AND PREVENTION

In the United States, consumer groups argue that the government uses inaccurate tests and small testing samples, as well as lax MBM regulation policies and enforcement practices. Stanley Prusiner, who won a Nobel Prize in 1997 for his work on BSE, has called for U.S. testing to mirror standards achieved by Japan and the European Union (EU). Japan tests all cattle slaughtered for human consumption and every suspect farm animal, totaling some 1.2 million cattle annually at a cost of over $30 million. Likewise, the EU tests all slaughtered cattle older than 30 months and all nonambulatory livestock older than two years, involving more than 10 million animals annually at a yearly cost of $300 million. Meanwhile, the United States seeks only random testing of sick and nonambulatory cattle, which would involve a mere 20,000 animals at a cost of around $500,000 per year. Considering that monetary losses to a nation's beef industry often run into the billions when BSE is discovered, stringent testing standards may prove prudent. Many nations may lack the political will to create such policy, though, especially when BSE and vCJD epidemics no longer dominate the headlines. Still, the disease continues to evolve, and the conditions that gave rise to an epidemic may continue to exist.

Braudel, Fernand (1902–85)

FRENCH HISTORIAN Fernand Braudel taught in Algeria and Brazil, and from 1937 at the École Practique d'Hautes Études of Paris. In 1947 he entered as faculty in the College de France and became one of the most relevant figures of the so-called French Annales School of History, named for the journal *Annales d'Histoire Économique et Sociale,* continuing the tradition pioneered by Marc Bloch and Lucien Febvre, who together founded the journal in 1929.

Braudel's most important work is *The Mediterranean and the Mediterranean World in the Age of Philip II* (first published in French in 1949 and considerably expanded in the second edition of 1966). *The Mediterranean* (written while Braudel was in a German prisoner-of-war camp) offers an innovative view of history articulated in three movements, characterized by different evolutionary rhythms. First, in what he called the *Longue Durée,* was the history of the slowly unfolding relationships between the humans and their geographical environment. This part owed much to the world on French regional geography of Vidal de la Blache that had come to Braudel through the work of Lucien Febvre and was profusely illustrated by maps. On top of this "geohistory," Braudel placed an economic and social history of people and their relationships (mostly based on circulation and not on production), and finally, he situated political history, in which individual figures acquired more protagonism. Braudel thus reunited Vidal de la Blache with Durkheim and Weber, and with the more conventional history of great individuals.

The first part of *The Mediterranean* offers a prime example of a classical interpretation of the geography of this sea and its peoples, emphasizing the common elements (physical and human) of a

Mediterranean environment, especially the relationships between mountains, valleys, islands, and the people inhabiting them. Braudel shows how on some occasions, the Mediterranean islands are insular, but on others, they open up to foreign influence and actively participate in the progress of commerce and politics.

Braudel's approach and that of the Annales School in general had wide appeal because it represented a well-articulated alternative to historical materialism. In fact, Braudel was highly critical of Marx and Marxist historians, whom he defined as determinists. For Marx, Braudel would say that history is flat, whereas for Braudel, history has a temporal and geographical thickness. However, Braudel always refused to enter into the study of economic relationships.

Between 1967 and 1969, Braudel published another ambitious work, the three-volume *Material Civilization, Economy and Capitalism: 15–18th Centuries*. The first volume, *The Structure of Everyday Life,* focused on demography and the conditions of livelihood. The second centered upon *The Wheels of Commerce* and the third on *The Perspective of the World,* or the time in which Europe unified the world to its profit. The concept of the world economy was later developed by Braudel's disciple Immanuel Wallerstein. His final work was *The Identity of France* (published posthumously in three volumes). The first volume, titled *History and Environment,* uses again the geohistorical approach of *The Mediterranean,* and geography is brought in to explain the French identity.

Brazil

BRAZIL IS THE largest country in South America, covering an area of 8.5 million square kilometers and with a population of approximately 170 million people, according to the 2000 census. Brazil encompasses several distinct biomes, notably some 4 million square kilometers of the Amazon basin, as well as the Atlantic forest (which once covered some 1.4 million square kilometers) and the Pantanal, the world's largest interior wetland (110,000 square kilometers).

Human occupation in what is now Brazil appears to have begun at least 11,500 years ago, based on pottery shards found in the Amazon. Estimates of the indigenous population of Brazil upon European contact in 1500 have ranged widely, and recent estimates have been higher, up to 5 million. The higher estimates are based on growing evidence of greater pre-Columbian environmental alterations than previously recognized.

The Portuguese discovery of Brazil led to colonization efforts beginning in the 16th century. This led to a series of boom-bust economic cycles, each featuring a specific natural resource exported to Europe by the colonizers. The first product was Brazilwood, used for dye; this went into decline by 1600. Sugar plantations had emerged along the Atlantic coast by then, and this stimulated forest clearing and conflicts and enslavement of indigenous peoples. In the late 19th century, coffee became the preeminent export product.

Consequently, railways spread across São Paulo and other states of southern Brazil, enabling expansion of the agricultural frontier. This facilitated forest clearing in the Brazilian interior, which provided fuelwood for coastal Brazilian industry in the early 20th century. Interior colonization and incipient industrialization thus greatly reduced Brazil's indigenous population, as well as the Atlantic forest.

After World War II, new medical technologies facilitated population growth by reducing mortality, prompting rural-urban migration and the expansion of an industrial workforce. Brazil's urban populations, especially in its largest cities, grew rapidly. This proceeded via unplanned construction of new housing in the peripheries of many towns, resulting in considerable pollution via untreated disposal of raw human waste as well as accumulation or burning of garbage. A notable exception to this pattern is the city of Curitiba, which beginning in the 1960s planned its urban expansion via zoning measures and waste management.

Brazil's military took control of the government in 1964 and embarked on policies of "authoritarian capitalism" that paired repression of labor unions with incentives for industrial development and frontier expansion into the Amazon. Brazil's economic growth accelerated in the late 1960s, called The Brazilian Miracle, but industrial pollution also rapidly increased. The industrial town of Cubatão subsequently became infamous for its extremely polluted air and water, as well as its high rates of cancer and birth defects.

By the late 1970s, economic growth slowed and Brazil's financial status worsened, eventually leading to democratic elections in the 1980s. However, growing environmental problems were overshadowed by Brazil's economic crisis. Civilian politicians focused primarily on national development rather than environmental protection. Large projects, such as the Carajás iron mine in the Amazon and the hydroelectric dam at Iguaú Falls, were given priority.

Nonetheless, 1988 proved to be a bellwether year, as demonstrations and lobbying in the national capital of Brasília led to recognition of environmental patrimony and indigenous rights in Brazil's new constitution. On Christmas day that year, the rubber tapper Chico Mendes was assassinated by ranchers for defending the forest, ending a year of record deforestation and burning in the Amazon, which placed the deforestation issue before the international community. Brazil's government responded with the "Our Nature" program and voiced concerns about foreign intervention in the Amazon as a threat to Brazil's national sovereignty.

By the early 1990s, environmental issues gained more attention. Brazilian environmental organizations had proliferated, including SOS Atlantic Forest, and Brazil created a new Ministry of the Environment. In response to land conflicts in the Amazon, Brazil also instituted the concept of "extractive reserves," where communities earn livelihoods via sustainable use of forest products, rather than clearing forest for agriculture.

Bertha Lutz

Bertha Maria Júlia Lutz (1894–1976) was a prominent Brazilian zoologist and scientist, as well as a feminist and campaigner for women's rights in Brazil. Her father, Adolfo Lutz (1855–1940), originally from Switzerland, was a pioneer of tropical medicine. Settling in Sao Paulo, he worked as a microbiologist and specialized in the link between sanitation and epidemics, especially the plague, malaria, and yellow fever, and became head of the Bacteriological Institute of Sao Paulo. Bertha Lutz studied at the University of Paris (Sorbonne), and became intensely interested in amphibians. She later gave her name to a frog: Paratelmatobius lutzii ("Lutz Rapids Frog"). In 1919, having returned to Brazil, she started work at the Museu Nacional in Rio de Janeiro, then the capital of Brazil. She became the second woman to hold a job in the Brazilian public service, and later became a naturalist at the Botany section of the museum.

From her time in Paris, Bertha Lutz had been heavily influenced by French and British feminist ideas, and started agitating for the women's right to vote in Brazil, attending several international meetings, notably the Pan-American Conference on Women in 1922. Women were allowed to vote from 1932, and Lutz was briefly a member of parliament. With the death of her father in 1940, Bertha decided to work on cataloguing his papers, and spent the next 30 years of her life working on this, publishing several papers. In 1948 she was a signatory to the United Nations' Universal Declaration of Human Rights, one of only four women who signed it. The Bertha Lutz Foundation was established in her honor; its symbol is a green butterfly.

In 1992, Brazil hosted the United Nations Conference on Environment and Development in Rio de Janeiro. This conference led to drafting of international conventions on climate, biodiversity, and numerous other environmental issues of global concern. This in turn led to formulation of "Agenda 21," Brazil's response to the conventions drafted at "Rio-92." Brazil has since signed and ratified nearly all of these conventions, including the Kyoto Protocol on Climate Change.

Consequently, Brazilian environmental law progressed considerably during the 1990s. However, implementation of many of those laws has been inadequate, largely due to their complexity and the lack of resources allocated to the Ministry of Environment. Deforestation in both the Amazon and Atlantic forests has continued, accelerating somewhat since 2000. Air pollution in metropolitan São Paulo also worsened, leading to restrictions on the use of automobiles to certain days of the week. While Brazil has been less dependent than many countries on fossil fuels, its network of hydroelectric dams has generated environmental problems and public protest, and prompted Brazil to develop fossil fuel energy sources. Biodiversity is high but not adequately documented in Brazil, prompting the expansion of a system of national parks, forests, and biological and indigenous reserves. However, they require more resources for enforcement of conservation regulations, for there remains considerable trade in illegal wildlife and timber from Brazil.

Brazil's environmental record in the new millennium is mixed. Basic sanitation in urban areas, including waste disposal and water treatment, have both improved. Large Brazilian companies are increasingly adopting international standards of conduct and environmental quality, due in part to international demand for corporate accountability. But tensions between Ministries over questions of development and the environment have led the government to favor continued expansion of soybeans and other agricultural exports into the Amazon and other fragile environments, in order to help Brazil pay its national debt via economic growth.

Brockovich, Erin (1960–)

WHEN ERIN ELIZABETH Pattee was growing up in Kansas, she seemed an unlikely prospect for becoming a high-profile advocate for victims of industrial poisoning. She suffered from a learning disability, panic attacks, anorexia, and low self-esteem. Nevertheless, she developed the strong sense of right and wrong that gave her the motivation to become the voice for silenced and exploited victims. In 1991, as a broke, divorced parent recovering from an automobile accident, Brockovich became a receptionist in the law office of Masry and Vititoe in Westlake Village, CA.

By chance, she was asked to open a file on a pro bono real estate case involving Pacific Gas and Electric (PG&E). Brockovich noticed that the file contained the result of blood tests performed on residents of Hinkley, California, and asked permission to pursue the case. This move changed her life.

As Erin Brockovich pursued the story behind mysterious illnesses in Hinkley, she discovered that PG&E had released more than 370 million gallons of Chromium VI in the water of Hinkley over a 30-year period. Studies have shown that repeated exposure to high levels of Chromium VI may cause headaches and nosebleeds. Acute toxicity from Chromium VI may also lead to allergic contact dermatitis, skin ulcers, nasal rhinitis, liver damage, edema, nephritis, and various pulmonary conditions and cancers.

In 1962, the Public Health Service established a cap of 50 UG/L in drinking water. By 1975, the Environmental Protection Agency (EPA) had mandated that cap through the National Interim Primary Drinking Water Regulations. The samples that Brockovich took from Hinkley contained Chromium VI at 10 times the acceptable level. In 1976, Congress passed the Resource Conservation and Recovery Act (PL 94-580), which provided the EPA with the authority to identify hazardous wastes such as those containing chromium and to establish standards for generating and transporting hazardous materials.

Residents of Hinkley had not only drunk the chromium-polluted water; they had also swam and bathed in it and irrigated their crops with it. As a result, they suffered from the classic symptoms of chromium poisoning. Brochovich's lack of professional position and authority allowed her to become friends with the residents of the small town and win their trust. Using unorthodox methods, she also gained access to files that irrevocably incriminated PG&E in the contamination.

When 634 residents of Hinkley hired Masry and Vititoe to handle their suit against PG&E, the law firm paid Brochovich's friend, George Halibee, to serve as her nanny so that she could devote more time to the case. Ultimately, Erin Brockovich and Ed Masry were able to assemble such overwhelming evidence against PG&E that after four years of arbitration, the company agreed to pay $333 million to the victims. It was the largest settlement in a direct lawsuit in American history. Masry and Vititoe paid Brockovich a bonus of $2.5 million for her work on the case.

In 2000, Steven Soderbergh brought Brockovich's story to the public in the motion picture *Erin Brockovich*, with Julia Roberts in the title role. Brockovich was paid $30,000 for the rights to her life story, and Roberts won an Academy Award for Best Actress for her portrayal of the blowsy, feisty Brockovich. She has continued to serve as an environmental activist in her position as director of environmental research at Masry and Vititoe. In 2001, Brockovich published the inspirational *New York Times* best-seller, *Take It from Me: Life's a Struggle, but You Can Win*. Brockovich also hosts *Final Justice* for Lifetime Television.

Brower, David (1912–2000)

DAVID BROWER (1912-2000) was an environmentalist who lived the phrase "In the beginning was the act!" He battled fiercely for the protection of the earth and he had a profound influence on America's wilderness areas. Brower's credits in environmental protection and advocacy are legendary in their volume and significance. He worked on the creation of national parks in the Pacific Northwest, Alaska, and New England. Along with other staunch environmentalists, he was instrumental in blocking the building of dams in Dinosaur National Park, the Grand Canyon, and Canada's Yukon Territory. Brower's own words portray the man and his passion: "Polite conservationists leave no mark save the scars upon the Earth that could have been prevented had they stood their ground."

David Brower served as executive director of the Sierra Club from 1952 to 1969, where he continued to serve in various capacities until 1998, two years before his death at the age of 88. In 1982, David Brower founded the Earth Island Institute (EII), an organization dedicated to the conversation, preservation, and restoration of the environment. The EII provides support for enterprising environmentalists to develop projects and to support them in the implementation of their work. EII environmentalists have been active in projects worldwide to protect the fast-disappearing rainforests, promote organic and sustainable agriculture, the reduction of pollution in the world's oceans, and the development of environmental programs to protect urban areas. The latter effort resulted in the formation of the Urban Habitat project, addressing environmental issue in metropolitan areas.

BATTLES AND COMPROMISES

Brower's battle over Glen Canyon Dam in 1956 was perhaps one of the defining moments (and setbacks) of the preservation movement in the United States. Following a rafting trip down the Colorado river with Floyd Dominy, the chief dam builder of the Bureau of Reclamation, Brower struck a deal to allow the flooding of Glen Canyon in exchange for preservation of the Green River in northern Utah. These events are recorded in detail in John McPhee's classic book, *Encounters with the Archdruid*. Brower lived to regret the decision, but the struggle helped to place the Sierra Club in the public consciousness and fueled Brower's no-compromise work in his later years.

Up to his death in 2000, Brower remained active in nature preservation. In Lake Baikal in Siberia, for example, he led teams of scientists in search of ways to protect Lake Baikal and ensure its full restoration during the 1980s and 1990s. On three occasions (1978, 1979, 1998), Brower was nominated for the Nobel Peace Prize for his profound accomplishments in stewardship of the global environment. He received the coveted Blue Planet Prize in 1998, a highly prestigious award given each year by the Asahi Glass Foundation. David Brower had a profound influence on the environmental and conservation movements in the United States and globally.

Brownfields Properties

BROWNFIELDS PROPERTIES, DEFINED as "real property, the expansion, redevelopment, or reuse of which may be complicated by the presence or potential presence of a hazardous substance, pollutant, or contaminant" exist in virtually every urban and rural community across the United States and internationally. Although the exact number of brownfields properties in the United States is unknown, the U.S. Environmental Protection Agency (EPA) estimates more than 450,000 sites exist, ranging in size from less than one acre to several thousand acres.

Brownfields properties may be abandoned, vacant, or underutilized, ranging in size, form, and degree of contamination with former uses such as gas stations, manufacturing plants, dry cleaning facilities, railroads, and residential buildings with asbestos. Some sites have low to moderate levels of contamination. In the United States, properties classified as Superfund sites contain higher levels of environmental contamination, pose significantly greater health and safety risks, and require more extensive remediation. As of February 2006, more than 1,200 contaminated properties in the United States were listed on the EPA's Superfund National Priorities List.

Brownfields can have negative economic and societal impacts on communities. In addition to the actual or potential health and safety ramifications, brownfields are often considered eyesores due to deteriorated structures, vandalism, and lack of grounds maintenance. These properties reduce property values of surrounding real estate. Many local public officials, however, now see beyond brownfields as liabilities and recognize them as potential assets in comprehensive local development strategies.

Likewise, in the United States, state government agencies regularly work with local officials through a variety of rehabilitation and redevelopment programs. The National Governors Association stated: "There is a compelling economic case for state spending on brownfields. A dollar of state spending produces about 10 times to 100 times more dollars in economic benefits. Expanding the mission of brownfields justifies greater state spending."

Remediation and redevelopment of brownfields properties results in benefits such as job creation,

Brownfields are often considered eyesores due to deteriorated structures and vandalism.

tax revenue increases, neighborhood revitalization, crime reduction, environmental improvement, and urban sprawl reduction. In many industrialized nations, brownfields redevelopment is considered a vital component to sustainable development. A study by George Washington University for the U.S. Council of Environmental Quality shows that one acre of redeveloped brownfields property saves 4.5 acres of greenfields property—undeveloped lands outside of core urban areas that can be preserved from the offset of development. Likewise, rehabilitation and redevelopment of brownfields sites can create substantial employment and return to state or city investment. A 1999 study by the Council for Urban Economic Development (CUED), for instance, shows that $1 invested by the public sector in brownfields redevelopment generated $3.41 in private investment. In 2005, an Illinois study of 37 brownfields projects reported that every $1 invested by the city resulted in $4.17 in private investment and 66 jobs created or retained.

Many environmental remediation methods exist, and the specific process used depends on several factors: type and location of contamination, concentration of the contaminant, planned future use of the property, and cleanup standards required by regulatory programs. For instance, property planned for residential use requires higher cleanup standards than property intended for industrial or commercial uses.

Remediation techniques take several forms: physical, chemical, biological, thermal, solidification/stabilization, encapsulation, and monitoring. Innovative techniques including in-place oxidation, bioremediation, and phytoremediation are becoming more common. These methods involve the use of agents, live organisms, or plants to decompose, degrade, or otherwise transform the state of the hazardous material, rendering it less harmful or eliminating it completely. On-site (in situ) treatments such as these are less disruptive to the environment and avoid the risks associated with the removal and transportation of contaminants to waste disposal locations (ex situ or off-site remediation). Increasing attention is being paid to incorporating brownfields properties into environment-friendly programs in cities located in the industrialized world. Innovative, environmentally sound practices were implemented in the remediation and site redevelopment of Chicago's highly acclaimed Center for Green Technology, constructed on a former brownfields site.

Brownfields site preparation, planning, assessment, cleanup, and redevelopment is facilitated through assorted federal, state, and local level initiatives. The level of assistance offered through brownfields policies and programs varies widely among industrialized nations. In the United States, at the federal level, the financial and technical assistance for brownfields is offered mainly through Environmental Protection Agency (EPA) assessment and cleanup programs, and the Housing and Urban Development (HUD) Brownfields Economic Development Initiative (BEDI).

Other U.S. federal programs, however, also fund brownfields rehabilitation and redevelopment projects that fit within specific program guidelines. State and local governments offer direct financial assistance such as loans and grants, and indirect assistance through various financial tools such as tax abatements, credits and refunds, low-cost environmental insurance, infrastructure upgrades, job training, and tax increment financing. Brownfields redevelopment projects can involve public investment, private investment, or a combination of the two.

Despite the availability of programs and resources to encourage remediation and redevelopment, many brownfields sites remain undeveloped for several reasons, including shortage of funds, potential liability, and environmental regulations. Contamination can exist in the soil, surface water, groundwater, and/or structures. The extent of contamination, related costs, and resources are often not known until the project is well under way. Potential stakeholders are often reluctant to initiate the redevelopment process because of uncertainty associated with brownfields. By contrast, previously undeveloped land, or greenfields, located on the periphery of development, are often more attractive to developers because of lower risks and costs.

Brucellosis

BRUCELLOSIS, WHICH PRIMARILY affects mammals such as deer and elk, cattle, pigs, dogs, sheep, and goats, is an infectious disease caused by Brucella bacteria. Human cases of brucellosis are rare, but are more common in places where public health efforts are limited; unpasteurized milk and dairy products account for the most common route of infection.

Brucella abortis, a strain of the bacteria that generally affects cattle and bison, causes decreases in milk production and spontaneous abortions in infected individuals. In the United States, this is the most common agent causing brucellosis infections. Transmission of the bacteria is typically accomplished through direct exposure to infected animals, although cases of contamination through affected food and water sources have been documented. Contemporary losses to farmers, in the form of decreased milk production and aborted fetuses, are estimated at less than $1 million annually, compared to $400 million in 1952.

CONTROL AND PREVENTION

Prior to 1934, control of brucellosis in the United States was limited to individual herds and livestock owners. Since the mid-1930s, the Cooperative State Federal Brucellosis Eradication Program has eliminated occurrence of brucellosis in 44 states, with the other six states charting infection rates of less than 0.25 percent. Yellowstone National Park (YNP), which is comprised of land in Montana, Wyoming, and Idaho, is home to the last remaining free-range bison herds in North America, some of which carry brucellosis; about 50 percent of Yellowstone bison are estimated to carry the brucella abortis bacteria. Reintroduction of brucellosis from free-range herds could enormously economic impact the livestock industry, and potentially jeopardize export markets for American beef.

Because brucellosis prevention was historically focused on private herds nationwide, the YNP bison herds were controlled through border control activities and shot upon leaving the park. Problems arose during the winter of 1996–97, when record snowfalls limited forage for YNP bison. Some 1,079 bison that departed YNP in search of food were shot or sent to slaughter, while an additional 1,300 bison starved to death within the park. The winter of 2005 saw another 900 bison shot or slaughtered by the National Park Service. Concerns with this style of management include a potential reduction in genetic diversity and population viability of YNP bison. Environmental groups discount the theoretical risk to domestic livestock posed by bison and elk, and suggest that less heavy-handed management of wildlife in the YNP area could still protect livestock health.

Current management plans focus on managing a free-range bison herd, while also attempting to control brucellosis. To this end, a strain RB51 vaccine is being tested for use in bison, although delivery of the vaccine is often difficult, and would have to be delivered ballistically or to bison captured outside the YNP boundary. Another delivery option under study is microcapsules of oral vaccine that could be distributed in feeding areas in the park. If the YNP bison and elk herds were to become brucellosis-free, they could presumably be allowed unfettered access to the North American continent once again.

Brundtland Report

THE BRUNDTLAND REPORT, *Our Common Future*, is so named for having been authored (in 1987) by a United Nations (UN) commission chaired by the former prime minister of Norway, Gro Harlem Brundtland. The United Nations established the World Commission on Environment and Development, and charged it with articulating a long-term vision for development to the year 2000 and beyond that would afford avenues of cooperation among countries at differing stages of economic and social development. One broad aim of the commission was to reconcile two fundamental political dilemmas posed by development that had taken hold by the mid-late 1980s: one emanating from the tension between economic development and environmental preservation, and the other embodying the disparate states, rates and priorities of development in the global north vs. south.

In presenting its proposal for bridging the two gaps (between environment and development, and between developed and developing countries), the Brundtland Commission tapped the concept of sustainable development. Sustainable development had previously been defined and recommended by the former International Union for the Conservation of Nature (IUCN) in its *World Conservation Strategy,* published in 1980. It was a trajectory for developing countries that would enable them to avoid the environmental costs incurred by developed nations in the course of their own processes of industrialization and economic development. This vision of sustainable development focused primarily on the concept of inter-generational equity; in other words, the focus was on preserving the environment for the future in order to enable future generations to meet their own development needs. The Brundtland Commission, while reiterating the IUCN's general linking of environment and development, also placed a stronger emphasis on the needs of developing nations and on concerns of poverty alleviation and equity, particularly intra-generational equity. *Our Common Future* defined sustainable development as a process that:

> …meets the needs of the present without compromising the ability of future generations to meet their own needs… It contains within it two key concepts: the concept of 'needs,' in particular, the essential needs of the world's poor, to which overriding priority should be given, and the idea of limitations imposed by the state of technology and social organization on the environment's ability to meet present and future needs.

The commission thus laid out an alternative vision for sustainable development, tying inter-generational equity predicated on sustaining the environment for future generations, to intra-generational equity that hinged on poverty alleviation and reducing the gap between developed and developing nations. In other words, it linked economic development to environmental conservation as well as social justice. The report implied that sustainable development could be achieved by changing the quality rather than the quantitative aspects of development; in so doing, it diverged fundamentally from the former Limits to Growth model popularized in the 1970s by environmentalists in the developed world. In most interpretations of the concept of sustainable development as defined by the Brundtland Report, disproportionate emphasis continues to be placed on inter-generational equity (environment–development goals) at the expense of the intra-generational equity (development–social justice goals).

SPHERE OF INFLUENCE

The Brundtland report's timeliness in addressing these political schisms on development partly explains the visibility and influence it has come to wield in development and policy arenas. Perhaps the greatest reason for its success on the international stage, however, lies in what is also its fundamental weakness: its ambiguity in defining sustainable development, and its concomitant inability (or unwillingness) to specify how such development could be attained. The challenges of realizing the tripartite goals of economic development, social justice, and environmental conservation outlined by the Brundtland Commission are complex and manifold, and nowhere as palpable as in the developing world. In the spaces allowed by the concept's ambiguity, however, could be accommodated the panoply of perspectives from the developed world, focusing on *environmental* sustainability; and from the governments of the lesser developed nations, concentrating on sustaining their *economic development* and the reduction of poverty. The common ground that the Brundtland Commission cleared in 1987 laid the foundation for the subsequent conference of nations at Rio de Janeiro's Earth Summit in 1992, a forum where both developed and developing nations converged to further discuss their visions, priorities and specific agendas for national and international environment–development issues. After Rio de Janeiro, the discourse on sustainable development switched to a discussion of rights rather than needs, and has come to reflect several parallel trains rather than a consensus. The report continues to be the source of lively debate over the definitions and principles of sustainable development, and has generated the development of numerous indicator variables capturing sustainability from the social as well as environmental sciences.

Bt (Bacillus thuringiensis)

BACILLUS THURINGIENSIS (BT) is a bacterium that naturally occurs in soil and on both wild and domesticated plant species. Some varieties of this bacterium produce a protein that acts as a natural insecticide, toxic to certain classes of insect larvae, including moth and butterfly as well as some varieties of beetle and fly larvae. As a result, Bt is a natural insecticide used in traditional agricultural production systems, as well as applied in higher-intensity modern agriculture, usually sprayed directly on crops. In the latter form, the bacterium is a product marketed as an insecticide under numerous trade names. Because the toxins break down quickly when exposed to ultraviolet light and other environmental factors, Bt is considered an attractive, organic, and environmentally friendly form of pesticide, especially when

Some varieties of Bt produce a protein that acts as a natural insecticide, toxic to certain insect larvae.

compared to more persistent compounds that have the tendency to bioaccumulate (such as chlorinated hydrocarbons), and nerve-based substances (e.g., organophosphates).

Far more controversially, Bt toxins have become widely used in transgenic crops, where genetic modification creates new crop plant breeds (especially corn, cotton, and potatoes) that produce Bt. Critics warn that although Bt itself is a relatively safe insecticide, the new breeds present human and environmental risks. Specifically, they raise concerns about human health exposure, resistance of insect species over time, and the possible transfer of the gene through crosspollination to wild relatives that may result in the creation of new, especially persistent super-weeds, whose new genetic advantages make them immune to healthy predation by pests.

Industry has responded by suggesting that since commerical Bt is already safely applied, the new genetic applications pose a minimal risk. While it is true that the scientific evidence on Bt as applied in spray form is well developed, the broader ecosystemic effects of the Bt transgene are essentially unknown. Nevertheless, the acreage of Bt crops has expanded rapidly in the last several years, making Bt crop acreage roughly one fifth of the global total of transgenic crops, demonstrating a violation of the precautionary principle.

BT Toxoid

BT TOXOID IS shorthand for *Botulinum* toxoid (BT) vaccine. It has been used for over 25 years to protect industry and laboratory workers from occupational exposure. The BT toxoid vaccine immunizes against *Clostridium botulinum* bacteria toxin. Vaccines use the toxin produced by *Clostridium botulinum* bacteria to stimulate the body's production of antibodies or antitoxins against the threat of infection by the bacteria. Pharmaceutical companies have found ways to nullify the highly toxic poisons produced by the disease. The toxin protein is treated with either chemicals or heat to neutralize its poisonous property. These methods allow toxoids to be administered in large quantities to quickly stimulate immunization; however, adverse reactions have occurred in a number of those receiving it.

Botulinum neurotoxis (BT) is a protein produced by the soil bacteria *Clostridium botulinum*. The bacteria are rod-shaped and flourish best in anaerobic conditions. The spores of the bacteria survive in a dormant condition until they are exposed to conditions favorable to growth. There are seven different strains of the *Clostridium botulinum* bacteria; each strain produces a different toxin. The letters A through G identify the seven known kinds of BT. Four of these strains (A, B, E, and F) cause human botulism. The toxicity of BT is very high. An average adult can be killed by 70 one-millionths of a gram. Contracting botulism can cause serious paralysis because the *Clostridium botulinum* bacteria's toxin, botulin, is a nerve toxin.

There are three main type of botulism. All can be fatal and must be treated as a medical emergency. Eating food contaminated with *Clostridium botulinum* bacteria causes foodborne botulism. This form of botulism is very dangerous because it can affect a large number of people; however, only a quarter of cases each year are this form of botulism. Toxins produced in a wound infected with *Clostridium botulinum* bacteria cause wound botulism. This form of botulism is a danger for farm workers and combat soldiers, and produces a few cases each year. Infant botulism develops in an underdeveloped baby's intestines, where the toxins are released. Honey contaminated with *Clostridium botulinum* bacteria is the most common cause of infant botulism. Isolated cases of aerosol botulism have occurred among researchers. This condition is rare and also unnatural.

When a botulism infection occurs, the first symptoms occur within less than one to two days. In more severe cases, vision may be doubled or blurred, speech slurred, breathing will be shallow, and swallowing will be difficult with the mouth dry. The effects of the toxin move from the upper to the lower extremities in the body symmetrically. The toxin reduces muscles reflexes, paralyzes the limbs, and in deadly cases, destroys the nerves that fire the diaphragm and the muscles required for breathing. *Clostridium botulinum* has also attracted the attention of governments and terrorists for its potential as a biological weapon. Aum Shinrikyo, the Japanese terrorist group, tried to use a weaponized aerosol botulinun toxin on three separate occasions with little success. For some years until the First Gulf War in 1991, Iraq had a biological weapons program that included botulism.

Buffalo Commons

IN THE DECEMBER 1987 issue of *Planning* magazine, Deborah Popper, a geography graduate student at Rutgers University, and Frank Popper, chair of the Rutgers urban studies department, published an article proposing that the U.S. Great Plains be transformed into the world's largest historic preservation region. The Poppers suggested that the vast area be called the Buffalo Commons, and that the federal government would inherit the task of bringing the region back to its 19th-century condition. The Poppers proposed that an extensive area of the Great Plains be taken out of the private property category as part of roughly 20 million acres of native grassland. Initially, landowners in the Great Plains spoke out harshly against the Popper's ideas. There was the belief among residents that their land would simply be taken from them by federal mandate.

However, this was not the idea. In one plan, farmers and landowners would enter into contracts with federal agencies and be compensated for their estimated financial loss over a 15-year period. The landowner agreed to the planting of native grasses for the transition to the new era.

The Poppers contended that modern human settlement and agriculture on the Great Plains were not environmentally sustainable. The Dust Bowl era saw thousands of settlers leave the region as the winds blew away what little topsoil existed. John Steinbeck's *The Grapes of Wrath* is a vivid account of the drought's devastation. As a result of this natural disaster and the aridity of the region, the Great Plains lost over a third of its population between the 1920s and the 1980s. As late as the 2000 census, some counties registered population densities below two people per square mile, a figure used by Frederick Jackson Turner in 1983 to proclaim the end of the frontier era. Declining population densities in the Great Plains belie Turner's pronouncement. Along with low population densities and remote communities comes a paucity of essential services, such as full-service hospitals and shopping centers. Schools in the Great Plains regions are either closing or yielding to consolidation with other districts. The loss of a school in a small community can spell its demise. The smaller the community, the greater the influence of the school. It may very well be the largest employer in the community, and will open its doors to community members during after-school hours.

Water availability in the Great Plains is also a serious problem. The region relies to a large degree on the vast Ogallala Aquifer, an extensive underground source of fresh water extending from Texas north to South Dakota. The aquifer at its highest volume was estimated to hold an amount of water equal to that of Lake Michigan. Over the years, the level of water has declined dramatically as more and more wells have been put in place and the amount of water taken out of the ground has far exceeded that gained through natural recharge. Adding to the problem, recharge occurs primarily at the northern terminus of the aquifer in an arid area. Thousands of farms in the Great Plains have ceased operations because of the inability to reach the lowered water level of the aquifer.

Invoking the frontier notion has given rise to the acceptance in the U.S. House of Representatives of a formal definition of a *frontier county:* one that has a critically low population density, does not have medical facilities readily available, and is significantly distanced from other essential services. Hundreds of counties, primarily in the western United States, are officially classified as frontier counties. As provocative as the Popper's initial proposals seemed, it appears that the era of the Buffalo Commons may occur in some parts of the Great Plains in a de facto sense, and not as a federal program.

Buffer Areas

BUFFER AREAS SURROUND or abut core protected areas. The activities that take place in buffer areas depend largely upon local circumstances and national or international legislation. Buffer areas may be privately owned or owned by governments, and in some cases, ownership is a combination of the two. Buffer areas, like the core zone, may be otherwise recognized through international treaties. The level of protection may, however, be less in the buffer area than in the core zone. Buffer areas may also be referred to as buffer zones or managed-use areas.

If the core zone's purpose is to protect the environment through restricting human use of the area, more wide-ranging activities may occur in the buffer area. These activities need to be of low impact upon the core area. Some examples are ecotourism, low-impact recreation, environmental education, and research.

The core zone and buffer area often occur as part of the United Nations Educational, Scientific, and Cultural Organization's (UNESCO) Man and Biosphere Reserves, which had strict concentric zonation in its original design. At the center of the zonation was the core zone, which, as stated, was a place where the natural ecosystems were protected and monitored. Surrounding the core zone was the buffer area, which was intended to shield the core zone from wider human impacts.

ORIGINS OF BUFFER MODELS

The original model conceived in the 1970s intended that the buffer area would comprise two separate areas. The inner buffer area was to be strictly limited in terms of public access, with the main activities to be education and research. In the outer buffer area, wider-ranging activities such as recreation could take place. Later, in the 1980s, the outer buffer area was renamed the *transition zone*. Subsequently, this outer zone has sometimes been called an *area of cooperation*. Agriculture, settlement, and other activities that sustainably develop the area may occur in the area of cooperation.

In fact, the original concentric design for the core, buffer, and transition areas has not always been followed, and this in some ways reflects the flexibility of the biosphere reserve concept. For instance, the Gouraya Biosphere Reserve in Algeria is a national park by the same name. It contains uplands, one wetland, and a marine area. The forests and marine areas contain important flora and fauna. The core zone is strictly protected. There are two buffer areas that abut the core zones in order to protect them from the activities in the transition area. The transition area comprises about 4.7 square miles (1157.6 hectares), with the two buffer areas totaling 0.6 square miles (162.7 hectares) and the core zone comprising 2.6 square miles (680.2 hectares).

Buffer areas can on occasion be absent from a biosphere reserve. Such is the case in the Taï Biosphere Reserve in the southwest Côte d'Ivoire. This primary tropical forest has a core area of 2,007.8 square miles (520,000 hectares) with a transition area of 386 square miles (100,000 hectares). 160,000 people were counted as living within the core zone of the biosphere reserve in 1998. This shows how flexible the biosphere reserve concept is in its application as the original ideal model depicted the core zone as being devoid of human occupation. Yet there are problems within this biosphere reserve include logging, farming, poaching, and illegal gold mining. Given these activities and the human settlements, this biosphere reserve's core zone is followed directly by a transition zone, with no buffer zone.

Bulgaria

FROM 1946 TO 1990, Bulgaria was part of the Soviet bloc of nations. After the breakup of the bloc, Bulgaria held its first multiparty election of the post–World War II era and began its transformation into a market economy. This nation of 7,450,349 people covers 110,910 square kilometers, with the Black Sea forming its eastern border. Because of the temperate climate, Bulgarian summers are dry and winters are cold and damp. Bulgarian industry utilizes large deposits of coal, copper, and zinc. Other natural resources include bauxite, lead, timber, and arable land. The mountainous terrain makes the country vulnerable to landslides, and earthquakes are a constant threat.

Environmentally, Bulgaria faces problems with air pollution caused by industrial emissions and with rivers polluted by raw sewage, detergents, and heavy metals. Additionally, Bulgarian forests have been damaged by air pollution and acid rain, and the soil has been contaminated by heavy metals and other industrial wastes. Around 4.5 percent of Bulgaria's land area is protected. Among the 81 species of mammals endemic to the country, 14 species are threatened, as are 10 species of the 248 endemic bird species. A study conducted by Yale University in 2006 ranked Bulgaria 50th of 132 countries on environmental performance; however, Bulgaria outranks most other countries in its income and geographic groups. Concerning overall quality-of-life issues, The United Nations Development Project (UNDP) Human Development Reports rank Bulgaria 55th.

ENVIRONMENTAL PROS AND CONS

Bulgaria's labor force is heavily dependent on services (56.3 percent) and industry (32.7 percent). And while almost 70 percent of the population lives in urban areas and only 11 percent of the labor force is engaged in agriculture, the per capita income of $9,000, unemployment rate of 11.5 percent, and poverty rate of 13.4 percent mean that backyard gardening, canning, and informal urban agriculture are crucial components of livelihoods throughout the country. All Bulgarians have access to safe drinking water and improved sanitation.

Indiscriminate usage of pesticides in the past continues to create environmental problems for Bulgaria. In 1996, for instance, an inventory revealed that large quantities of organochlorine pesticides, which have been banned by the government, are still stockpiled. High concentrations of hydrocarbons (HCBs) have been found in the Danube, Dnieper, and Dniester Rivers. HCB residues dropped extensively in Bulgaria between the 1970s and the 1990s. On the other hand, lindane continued to show up in the Bulgarian waters of the Danube. Pollution has also been found in estuaries in areas of Bulgaria where oil production refineries are located.

Offering a more positive view of Bulgaria's environment than that presented by the Regional Environmental Center, the Bulgarian Council of Ministers has identified Bulgaria's environmental strengths as low air, water, and soil pollution, overall cleanliness, rich biological diversity, legislation and programs to promote environmentalism, a high percent of nuclear power use, and a well developed pollution monitoring system. Nevertheless, the study also identified environmental weaknesses in Bulgaria that include a shortage of funding for environmental programs, water shortages, inefficient water usage, high noise pollution, high levels of transportation pollution, a lack of administrative oversight capacity, persistent "hot spots" of pollution in large cities, and continued problems of waste disposal.

Local governments have been given responsibility for dealing with pollution in their own areas, and Bulgaria has pledged a commitment to global environmentalism by participating in the following international agreements: Air Pollution, Air Pollution–Nitrogen Oxides, Air Pollution–Persistent Organic Pollutants, Air Pollution—Sulfur 85, Air Pollution–Volatile Organic Compounds, Antarctic–Environmental Protocol, Antarctic–Marine Living Resources, Antarctic Treaty, Biodiversity, Climate Change, Kyoto Protocol, Desertification, Endangered Species, Environmental Modification, Hazardous Wastes, Law of the Sea, Ozone Layer Protection, Ship Pollution, and Wetlands. Bulgaria has ratified but not signed the agreement on Air Pollution–Sulfur 94.

Bullard, Robert

ROBERT BULLARD IS an activist and academic who has been one of the leading voices of the environmental justice movement. While working as an environmental sociologist in the 1970s, Bullard wrote a study called "Solid Waste Sites and the Black Houston Community" that identified a systematic pattern of siting garbage dumps in black neighborhoods. His research documenting the unjust connection between toxic siting and communities of color led to the first lawsuit (*Bean v. Southwestern Waste Management*) that used civil rights law to challenge environmental discrimination.

Bullard documented this research in *Dumping in Dixie: Race, Class, and Environmental Quality* (1990), which is widely regarded as the first book to fully articulate the concept of environmental justice. In *Dumping in Dixie,* Bullard reports that African Americans in the South bear a disproportionate burden in the siting of hazardous-waste landfills and incinerators, lead smelters, petrochemical plants, and many other toxic facilities. Bullard's study, in conjunction with a 1987 report issued by the Commission for Racial Justice of the United Church of Christ, proved to be crucial documents for establishing the momentum of the environmental justice movement. His later research extends to include all people of color, as well as working-class and low-income communities that are disproportionately affected by garbage and pollution, going beyond individual cases to demonstrate the institutional racism that propels this type of inequality.

Bullard was an instrumental planner of the First National People of Color Environmental Leadership Summit in 1991, which brought together a network of grassroots activists concerned with environment justice. This summit not only drafted organizing principles of the modern environmental justice movement, but also identified a new kind of environmental politics that challenged environmentalism to become more than a white, upper-middle-class movement. Later, Bullard was influential in working with the Clinton Administration to enact an executive order that required all federal agencies to consider environmental justice in their programs. In Bullard's 2003 book, *Just Sustainabilities: Development in an Unequal World,* he argues that social equity must be addressed in all decisions of economics and environment for any true sustainability to be achieved.

CURRENT RESEARCH

Bullard's current research focuses on how U.S. government response to emergencies (including flood, drought, hurricane, and accidents) has consistently endangered the health and welfare of African Americans. He states, for example, that the inadequate response to Hurricane Katrina in Louisiana fits a historical pattern of institutional racism. He argues that the response to Hurricane Katrina was not an aberration, nor was it solely due to the incompetence on the part of a particular agency or administration. Rather, natural disasters are made worse by the way society differentiates between race and class. He also extends this logic globally, suggesting that the framework of the environmental justice movement can resonate across many environmental and social issues facing developing countries.

For the past 25 years, Bullard has maintained a leading role in advocating for environmental justice. His academic research and dedicated activism have significantly influenced the environmental movement by introducing class and race into the analysis of how environment and society interact. Bullard is currently the director of the Environmental Justice Resource Center at Clark Atlanta University.

Bureau of Land Management, (U.S.)

FOUR FEDERAL AGENCIES administer most of the 671.8 million acres of land in the United States owned by the federal government (as of 2004, 29.6 percent of the total): the Bureau of Land Management (BLM), the National Park Service, the Fish and Wildlife Service in the Department of the Interior, and the Forest Service in the Department of Agriculture. The BLM manages the largest proportion, 261.5 million acres (12.5 percent of the total land in the United States) and is responsible for managing subsurface mineral resources on an additional 300 million acres. Most of the lands the BLM manages are located in ten western states and Alaska and are dominated by rangelands and deserts and, in Alaska, by forests, high mountains, and arctic tundra. The BLM manages a wide variety of resources and uses, including energy and minerals; timber; forage; wild horse and burro populations; fish and wildlife habitat; wilderness areas; archaeological, paleontological, and historical sites; and other natural heritage values.

The BLM came into its role almost by default. In the late 19th century, the creation of the first national parks and forests reserves signaled a shift from a congressional policy of transferring the ownership of lands from public to federal. Formed last among the land management units, the BLM came to manage land unclaimed—and considered less valuable—by the Parks and Forest Service. The BLM was created in 1946 through the merger of two agencies: the General Land Office and the Grazing Service. The General Land Office was created by Congress in 1812 to oversee the survey and disposal of public domain lands ceded to the federal government by the 13 original colonies or acquired through treaty or purchase. The Grazing Service, initially known as the Division of Grazing, was established in accordance with the 1934 Taylor Grazing Act to manage those public domain lands deemed chiefly valuable for grazing, pending their final disposal. This act delegated much decision-making power to local grazing boards, and the Grazing Service was intended to resemble more of a temporary custodian of the public rangelands than a powerful agency. Its existence was characterized by conflict with the Forest Service over control of grazing on the public domain and with Congress and the western cattle industry over the setting of grazing fees. In addition, because it was formed through an executive reorganization, the BLM operated on insecure foundations and under a maze of confusing and sometimes conflicting regulations, until 1976 when Congress passed the Federal Land Policy and Management Act (FLPMA), sometimes called the BLM Organic Act. The BLM is still hampered by these initial weaknesses and a per-acre budget much lower than the other federal land management agencies.

EQUIPPING THE BLM

FLPMA declared that the public lands would be retained in federal ownership; superceded and rationalized many existing public land laws and regulations; officially gave authority and direction for managing the public lands to the BLM; and gave the agency its multiple-use, sustained-yield mandate. It eliminated the grazing boards and set up a system of federal grazing regulations, 43 CFR 4100, to provide uniform guidance for administration of grazing on the public lands exclusive of Alaska; this strengthened BLM's ability to regulate grazing and placed greater emphasis on maintaining or improving the ecological health of public rangelands. It also directed the BLM to inventory the lands it managed for wilderness characteristics, as the 1964 Wilderness Act had directed the National Park Service and the Forest Service. With this mandate, the BLM was finally equipped to manage the public lands. Even so, controversy follows agency management decisions, especially in ongoing debates about the role of grazing on public lands versus conservation, recreation, and other land uses. Critics continue to argue that the agency remains subject to "capture" by narrow interests, though the increasingly enlarged mandate of BLM has made such controversies more complex and multi-sided.

The BLM has organized into a Washington office with a politically appointed director and 12 state offices, each with a state director. Each state is organized into field offices, whose managers report to the state directors. In 2001, the BLM created a National Landscape Conservation System to administer the national monuments, National Conservation Areas, Wilderness Areas, Wilderness Study Areas, National Historic Trails, and Wild and Scenic Rivers under its jurisdiction.

Bureau of Reclamation (U.S.)

IN THE LATE 19th century, insufficient rainfall caused western settlers in the United States to use irrigation for farming, and pressure escalated for the federal government to create and manage irrigation and reservoir storage projects. The U.S. Congress was already investing in the nation's growing infrastructure: Roads, navigable rivers, harbors, canals, and railroads were being built, maintained, and/or developed. Westerners especially needed the government to invest in regional irrigation projects, and this movement showed its strength when irrigation platforms were debated during the presidential election in 1900. It was therefore only two years later that the Bureau of U.S. Reclamation Service would be created.

In 1924, Congress authorized the building of the Hoover Dam in Boulder Canyon, Nevada, using federal funding.

On July 17, 1902, Congress passed the Reclamation Act, which required that water users repay construction costs from which they received benefits, and was created to study the need for and institute water development projects in federal lands across the western states. Secretary of the Interior Ethan Allen Hitchcock then established the U.S. Reclamation Service within the U.S. Geological Survey (USGS) to operate solely on the revenue from federal land sales, but since Texas had no federal land, it was not included in any reclamation projects until 1906, when Congress passed a special act to include it. In 1903, the Roosevelt Dam and the Salt River Project was the first major project under this new Act, and ultimately made Phoenix, Arizona, a thriving agricultural and urban site.

In 1907, the Secretary of the Interior separated the Reclamation Service from the USGS, and created an independent bureau within the Department of the Interior with Frederick Haynes Newell appointed as its first director. These first years have been called the Irrigation Age; however, many of the bureau's early water projects were fraught with problems—land was purchased that was unfeasible for irrigation; many early settlers were inexperienced in the use of irrigation; some lands were over-irrigated, requiring expensive drainage plans; irrigation customers were unable to repay their loans from exorbitant preparation and construction costs; settlements were abandoned; shady land dealings and speculation created an atmosphere of mistrust; and many projects were created in farmlands only suitable for low-value crops.

In 1923, the agency was renamed the Bureau of Reclamation, and one year later, Congress authorized building of the Hoover Dam in Boulder Canyon, Nevada. This monumental project required large appropriations; and for the first time, the Bureau began to receive substantial federal funding, but only after a lengthy public debate about supporting public power versus its private-sector creation and supervision. Called the Multi-Purpose Era, huge projects followed one after another including Boulder Dam, the Columbia Basin, the Colorado–Big Thompson, and the California Central Valley Projects. These largest water facilities started during the Great Depression and lasted until the decades after World War II. From 1941–47, civilian public service labor was used for extensive western water projects that had been interrupted by the war.

GRASSROOTS OPPOSITION

The last major construction projects occurred in the 1960s, when the American environmental movement gained influence to develop considerable grassroots groups opposed to the water development projects. In 1976, when the Teton Dam failed as it was filled for the first time, it barely tarnished the Bureau's international status; however, it was America's growing environmental movement, in addition to President Carter's criticism of water projects, that many believe most affected the Bureau of Reclamation's direction and planned projects across the western United States. During the late 1980s, the bureau reorganized all plans for projects planned up to 40 years before stating that "the arid West essentially has been reclaimed."

The Bureau of Reclamation is now a division of the U.S. Department of the Interior, and administers and oversees all water development projects in the western United States (180 projects in 17 western states) and provides agricultural, household, and industrial water to about one-third of the population in that region. In 1992, roughly 5 percent of western lands were irrigated, and the bureau supplied water to about 20 percent of the region, or about nine million acres. Also, dams constructed by the Bureau of Reclamation are major electricity generators, with 56 power plants online, generating 35,000 megawatt hours of electricity in 1996.

Burkina Faso

BURKINA FASO IS a landlocked country in West Africa, north of Ghana, Togo, and Côte D'Ivoire, formerly known as Haute Volta (Upper Volta). Despite its relative international obscurity, it is known for three things: its people, particularly its rural population's struggle against poverty in a sometimes harsh and unyielding physical milieu; a legacy of recent political populism; and the presence of extensive and sometimes innovative international development assistance. Most of the country lies in the Sahelian and Sudano-Sahelian climatic zone. It is wetter and thus more productive in the south than the north, where rainfed cropping gives way to herding. A unimodal rainfall pattern allows the cultivation of dryland crops, particularly millet and sorghum, on ferruginous and sandy soils in summer. Sugar and cotton are also grown, primarily in the wetter southwest.

Population growth is rapid in Burkina (to approximately 13 million in 2006), and parts of the rural hinterland have median densities (50 persons/square kilometer) and intensive cultivation systems. Some 90% are primarily engaged in subsistence farming or herding, and urban growth is concentrated in Ouagadougou (the capital) and Bobo-Dioulassou. The primary exports, gold, cotton, and livestock, are vulnerable to price fluctuations. The country lacks reserves of natural resources and imports its fuel, some food, and other essentials. It is one of the world's poorest five countries with a Gross National Income per capita of approximately $350 per year.

HISTORY OF THE REGION

This region was occupied by hunter-gathers for at least 12,000 years, and was first farmed 5,000 years ago. The Mossi people, warrior-farmers from northern Ghana, conquered and intermingled with indigenous inhabitants since at least the 1400s, establishing several kingdoms. Several other ethnic groups are found in the west, and Fulani herders to the north. Burkina became a colony of France in 1896, and through several colonial configurations, the administration used forced and voluntary labor for work on plantations and other projects across its regional territories, because other economic options were so limited. The country achieved independence peacefully in 1960.

From 1983–87, Burkina was led by Capt. Thomas Sankara, one of Africa's most charismatic leaders. Sankara challenged gender inequality, nepotism, the power of chiefs and pervasive post-colonial domination by France, and launched major campaigns to provide rural health care and infrastructure. Blaise Compaoré, who has ruled since 1987 before and after national elections, has overseen the embrace of neoliberalism, privatization, and less-discriminate aid flows. Decentralization is also being pursued.

Despite persistent drought, Burkina's farmers are masters of their milieu. They have adapted to climatic uncertainties through intensive micro-management of soil, water, labor, and crop varieties. Unpredictable conditions means livelihood diversification is the norm: the "bricolage" of locally-based and more distant activities, the latter including a significant economic migration stream to the West African coast and beyond. Migration to the plantation and urban economy of Côte D'Ivoire has traditionally been huge, but has fallen since 2001 with the xenophobia that preceded civil war in that country.

Major famines across the Sahel in the 1970s and 1980s were sparked by a succession of poor rainy seasons, and magnified by poor institutional capacity. Strong international humanitarian support to Burkina dates from this period. It has included numerous bilateral and nongovernmental programs, including assistance for health, food security, and sustainable production. For example, there has been great innovation in soil and water conservation supported by Oxfam, GTZ, Six-S and other organizations. Semi-permeable rock bunds (walls), built by locals across contours in hundreds of communities, captured summer rains on slopes and increased infiltration rates and crop yields. This "miracle" conservation strategy attracted international attention and support, because its success depended on a combination of appropriate technology, Sankariste local communitarianism, and social cohesiveness among Mossi and other peoples.

Burundi

IN THE EARLY 1990s, the Republic of Burundi experienced the assassination of its first democratically elected president after only 100 days in office. The ethnic conflict between the Hutu majority (85 percent) and the Tutsi minority (14 percent) that followed the assassination lasted for almost 12 years and led to the deaths of 200,000 Burundians. Hundreds of thousands more fled to other areas in Burundi and to neighboring countries, chiefly Tanzania. In 2003, international groups engineered a peace agreement; and in 2005, the Hutu elected a new president. However, rebel groups continue to threaten political and economic stability.

With a per capita income of only $600, Burundi is the sixth poorest country in the world. Nearly 70 percent of the population lives in extreme poverty. Income is unevenly distributed, with the richest 10 percent of the population holding almost a third of all resources and the poorest 10 percent sharing 1.8 percent of income. Burundi's largely undeveloped natural resources include nickel, uranium, rare earth oxides, peat, cobalt, copper, platinum, vanadium, hydropower, niobium, tantalum, gold, tin, tungsten, kaolin, and limestone. More than 35 percent of Burundi is arable, and 93.6 percent of the workforce is engaged in subsistence agriculture. Together, tea and coffee exports furnish 90 percent of Burundi's foreign exchange revenues. Depressed prices on these markets in recent years have led to declining revenue and efforts at increasingly intensive cultivation.

Burundi, which is situated at the crest of the Nile-Congo watershed in central Africa, shares borders with the Democratic Republic of the Congo, Rwanda, and Tanzania. The climate of Burundi is equatorial, and altitudes vary from 772 meters at Lake Tanganyika along the western border to 2,670 meters at Heha in west central Burundi. The mostly moderate temperatures vary according to altitude. Around 150 centimeters of rain falls on Burundi during the wet seasons that occur between February and May and between September and November. Most of Burundi's terrain is hilly and mountainous, with interspersing plains and a plateau in the east. Burundi experiences both flooding and drought, and landslides are common.

With one out of every 10 adults in Burundi living with HIV/AIDS, the country is experiencing a major health crisis. Some 25,000 individuals had died of this disease by 2003. Around 21 percent of Burundians lack sustained access to safe drinking water, and 64 percent lack access to improved sanitation. Consequently, the population faces a very high risk of contracting food and waterborne diseases such as bacterial diarrhea, hepatitis A, typhoid fever, and malaria, a vectorborne disease. High incidences of disease result in low life expectancy (50.81 years), population growth (3.7 percent), high infant mortality (63.13 deaths per 1,000 live births), and death rates (4.22/1,000). Burundian women bear an average of 6.8 children. Since only one of every two children attends school and only 45.2 percent of females and 58.8 percent of males are literate, it is extremely difficult to disseminate essential information on health and the environment.

CRIPPLED ENVIRONMENT

Soil erosion is accelerating in Burundi in response to overgrazing and the encroachment of agricultural development into marginal lands. The loss of large areas of forest for fuel use has produced an annual deforestation rate of 9 percent. Because of declining rainfall and the destruction of forests, water catchments, and ecosystems, northeastern Burundi, where many refuges fled during the civil war, is experiencing major food shortages. This destruction motivated by attempts to survive has spread to the Murehe Nature Reserve, depleting the bamboo and aquatic grasses and threatening biodiversity. Of 107 endemic mammal species, six are threatened, as are seven of 145 bird species. While laws have been enacted to prevent illegal hunting and poaching, they are rarely enforced.

In 2006, scientists at Yale University ranked Burundi 108 of 132 countries in environmental performance, slightly above the comparable geographic and income groups. The lowest scores were received in the areas of environmental health, biodiversity and habitat, and production of natural resources. The Ministry for Land, Environment, and Tourism is responsible for implementing environmental laws in Burundi, which focus on sustainable development and eradicating poverty. The Burundi government participates in the following international environmental agreements: Biodiversity, Climate Change, Kyoto Protocol, Desertification, Endangered Species, Hazardous Wastes, and Ozone Layer Protection. The Law of the Sea agreement has been signed but was never ratified.

Bush, George H. W. Administration

ON NOVEMBER 15, 1990, President George H. W. Bush signed amendments of the Clear Air Act—an act written by congressional Democrats—into law, and declared in the East Wing of the White House that "polluters must pay." While campaigning against democrat Michael Dukakis of Massachusetts, Bush accused his opponent of being lax on pollution in Boston Harbor, declaring that Dukakis delayed and caused the harbor to get "dirtier and dirtier." President Bush also declared in 1988, "I am an environmentalist; always have been and always will be." Bush claimed he would aggressively enforce environmental laws and standards. In many ways, Bush realized this campaign promise. Recognizing their vital, long-term importance in sustainable development, he created a "no net loss" policy toward wetlands and development that required the protection of wetlands or the creation of new ones. President Bush attended the Rio Environmental Summit in Brazil in 1992, but did not ultimately sign its final provisions. The famous summit introduced the term *sustainable development* into common speech, which means creating conditions for economic development that do not leave developing countries worse off environmentally than when they began.

HESITATIONS ON POLICY

Even as he strongly advocated for environmental protections and seemed to have a personal interest in the environment, President Bush also had reservations about the possible negative consequences of environmental policies that could be implemented too quickly. He claimed in 1992, "We cannot keep some of the extremes of the environmental movement happy because I believe that a sound environment can go hand-in-hand with reasonable growth." President Bush was particularly concerned about how strict environmental provisions might affect jobs, especially in the lumber industries of the northwest where "40,000 people could be thrown out of work." When asked about the environment in a presidential debate, he refused to "burden the automobile industry with the kind of costs the Europeans wanted us to put on the industry." He also mentioned the American families who would be affected by overly protective policies toward the Spotted Owl, a symbol of the environmental movement as well as popular resistance to some environmental policies that affected jobs. Bush seemed determined to protect the environment in principle; but he was wary of the political consequences of signing international agreements and enforcing policies that might—in the short term—risk the jobs of American voters.

Bush, George W. Administration

WHILE IT IS far too early to judge the legacy of a sitting president, many have called George W. Bush the weakest environmental president in history; even Republicans have criticized President Bush for his environmental record. In addition, much of the public does not support Bush's environmental initiatives. A USA Today/CNN/Gallup poll taken in 2004 found those who disapprove of Bush's environmental record had risen to 45 percent. Another 2004 poll found 65 percent of Americans did not believe the Bush administration would make environmental progress in the next term.

In keeping with the governing philosophy of the administration, several controversial policies of the administration have sought to reconcile environmental protection with issues of economic growth. Specifically, the Bush administration has pushed to open the Arctic National Wildlife Refuge (ANWR) for oil and gas development, asserting the minimal risk that modern extraction represents to native wildlife and stressing the problem of dependence on foreign oil. Critics suggest that the artic ecosystem is especially fragile and that the limited reserves in ANWR represent a limited benefit for the risk. The administration has also advanced a forest fire control policy for National Forests, the Healthy Forests Restoration Act of 2003 (or Healthy Forests Initiative), which seeks to thin forest stands through contracts to private timber companies. Critics maintain that these efforts at "thinning" represent unwarranted subsidized access for loggers to pristine forest areas that do not represent a serious fire hazard.

The administration also has withdrawn United States support, committed under the previous administration, for the Kyoto Protocol, an international attempt to reduce greenhouse gas emissions. The administration argues that, as currently written, Kyoto exempts large countries like China and India from immediate action, producing an unfair trade advantage for these growing industrial powers. Critics maintain that lack of leadership on this crucial problem further marginalizes the United States in key issues of global governance.

The Bush administration has also sought to exempt the Department of Defense, one of the nation's worst polluters, from critical environmental laws. The Natural Resources Defense Council (NRDC) released their report of Bush's first term in 2004, citing over 150 destructive policy actions in just the previous year. They claimed the worst offenses to be the amount of toxic releases from industrial facilities, worsened mercury contamination, sewage contamination, and air pollution. Equally controversial, on the inauguration day of his first term, President Bush mandated that all federal agencies halt pending regulations established by the Clinton administration, including at least a dozen regulations dealing with the environment.

President Bush has also made a number of controversial decisions in filling key environmental positions. These include the posting of a former timber lobbyist to Undersecretary for Natural Resources and Environment with the Department of Agriculture; a former lobbyist for power companies and major electricity users to the post of Chairman for the Council on Environmental Quality (CEQ); an attorney who formerly represented mining interests to Assistant Secretary for Land and Minerals Management; and an attorney who previously represented clients in cases against the Environmental Protection Agency (EPA) regarding chemical and air pollution to the helm of the administration's overhaul of the Clean Air Act, governing industrial plants pollution controls.

The Bush administration defends their record. They cite continued progress in regard to access to clean water, cleanup of hazardous wastes, land conservation and stewardship, increased aid and cooperation for conservation efforts, improving air quality, and addressing global climate change.

A nondiesel road rule is aimed at reducing air pollution from diesel-powered bulldozers, tractors, boats, and other off-road engines.

Nevertheless, the administration's strategies for managing their environmental image point to continued problems. Critics point to euphemistic names for policies that slacken regulatory authority in ways that make them more appealing, such as "Healthy Forests Initiative." The final evaluation of the administration's environmental record will be judged in the future, but current controversy remains pronounced.

Butterfly Effect

THE *BUTTERFLY EFFECT* is colloquial language used to describe the idea within chaos theory called *sensitive dependence on initial conditions*. This principle became the cornerstone to the science of chaos theory. Scientists interested in the butterfly effect and chaos theory are concerned about initial conditions, determinism, uncertainty of measurement, dynamic instabilities, manifestations of chaos, and perceiving new order.

It is because of the constant butterfly effect that the world's weather forecasts remain very imperfect. They are accurate for a few days, but beyond six or seven they become speculative. This is the butterfly effect in action. Tiny pieces of weather cascade into bigger and bigger effects. Likewise, mistakes and uncertainties in calculations create false assertions that, when expanded millions of times, result in false predictions.

Chaos theory, originating within mathematics and meteorology, posits that all systems, including complex and seemingly chaotic ones, are determined by underlying order, and tiny movements in a system can build to large events (the butterfly effect). The term *chaos theory*, however, can be misleading because the theory attempts to describe phenomena that appear to be random, periodic, and chaotic, but actually evolve in complex systems and interactions among systems according to exact and predictable rules.

Chaos theory is sometimes presented as esoteric knowledge, but many researchers illustrate the principles with very simple examples like swinging pendulums, bouncing balls, and pinball machines. Slightly different inputs can determine very different results.

Chaos theory posits that even tiny movements in a system can build to large events (the butterfly effect).

Chaos theory is both a challenge to and an extension of the deterministic view of science. Determinism is historically a central belief in modern science. Newton thought scientists could know the future of the physical universe by measuring initial conditions and applying the physical laws determining its development. Newtonian science assumes that more precise measurements of a phenomenon will yield more accurate predictions about future events. The assumption was that an inability to make accurate predictions was related to problems in making accurate enough measurements. Discoveries in astronomical science, however, reveal that tiny errors in the measurement of initial states yield large and unpredictable outcomes. Two or more nearly identical states can yield vastly different outcomes. Even if measurements could be made thousands of times more accurately, the uncertainty of the outcome doesn't decrease along with the refined starting measurement.

Edward Lorenz arrived at his chaos observations during his attempts to to create better meteorological predictions with early computers, which had the capacity to conduct vast mathematical problems with slight iterations. He observed in his models that changing the values in numeric systems at the level of the thousandths decimal led to different weather phenomena after many iterations. Slight differences in initial conditions created large differences in outcome. At the time, it was not believed such small differences were significant. Yet, the instruments used to measure weather were not even as accurate as Lorenz's hypothetical models. Because perfect measurements of initial conditions, especially in large systems with many variables, are impossible, predictability is extremely problematic.

Initial conditions are also problematic to define, because one researcher's initial conditions may be another's conditions of midstream. Additionally, measuring initial conditions in any given moment will not give a full picture of the current processes, directions, and causes of the initial condition.

Sensitive dependence is also empirically difficult to measure, as it implies more than a relationship between two states. It implies that there are deterministic, dynamical systems. Dynamical systems have moments of near balance and instability, and small influences can have large consequences. Initial differences of one unit may increase a hundred times in one system and a million times in another, and the variable of time will differentiate systems even more.

Chaos theory maintains that things that appear chaotic are actually not chaotic at all. The central goal in chaos theory is development of a science and perception that can detect a pattern in a seemingly chaotic system. According to James Gleick, author of *Chaos: Making a New Science*, chaos theory is "a revolution not of technology, like the laser revolution or the computer revolution, but a revolution of ideas." Chaos is actually orderly disorder, and the task is to perceive the order.

Many physicists claim chaos theory is about a description of process rather than a being or state. Chaos theory breaks across academic disciplines because it is interested in the holistic nature of systems. Mathematicians, physicists, chemists, biologists, ecologists, and economists are all interested in irregularity. Advocates of chaos theory say chaos theory and the recognition of the butterfly effect have turned back the reductionistic trend in science. The environmentally oriented philosophy known as deep ecology embraces the butterfly effect as it illustrates well the fragile dynamic relationship between seemingly disparate elements.

Cacao

PRECOLONIAL MAYAS OF Central America described cocoa, the main ingredient of chocolate, cocoa butter, and cocoa powder, as the "food of the gods." But since the early to mid-19th century, when Europeans developed milk chocolate and solid chocolate, cocoa has certainly become a culinary delight for humans. Cacao (*Theobroma cacao*) is the tree that produces the cocoa beans from which cocoa is derived. The crop's origin is the Amazon Basin, and today 75 percent of cacao is cultivated in broadly similar humid lowland tropical forest environments, within 8 degrees of the equator.

SWEEPING CHANGES IN PRODUCTION

The history of cacao production for markets is a history of remarkable changes—socioeconomic, cultural, and ecological. Globally, cacao production levels tell a story of change that shows a historical trend of significantly rising output. The collective output of the four largest producers of cocoa beans—Côte d'Ivoire, Ghana, Indonesia, and Brazil (in order of rank from the largest producer)—expanded in recent decades by over 650 percent, from 381, 000 metric tons in 1951 to 2,889,774 metric tons in 2005 (which is 81 percent of the 2005 global cocoa bean output of 3,552,586 metric tons). Nationally, cocoa products have made sizeable contributions to government tax revenues, foreign exchange earnings, national income, and employment. For instance, in Ghana, the cocoa economy has established itself as a major component of the national economy since the late 19th century, when cocoa exports began. While the relative economic contributions of cocoa have declined as Ghana's economic activities have expanded, the cocoa sector remains important, contributing a fifth of total export income of about $1.9 billion in 2001. The 23 percent of rural households involved in cacao production are the source of 83 percent of Ghana's cocoa income.

The story of change associated with cacao production is also a local story. Locally, the commercial production of cacao has been historically a vehicle of modernization and social change that brought increased trade and other economic activities, as well as greater access to transportation and formal education. Also, social differentiation and gender relations in cacao producing societies have been influenced by access to income and wealth from cocoa sales. In West Africa, a region that produces over 70 percent of global cocoa beans, cacao production

The impact of cacao production has been global, from indulgence in chocolate to the impact on biodiversity.

increasingly drew rural dwellers into commercial activity that transformed relations of production, changed land and labor relations, and modified processes of access to land and labor. Within the rural settings where cacao is produced, land transactions have become more commercialized and land rights more exclusive (to provide land tenure security for cacao farmers), compared to pre–cacao production customary practices and rights. Changes have also occurred in the types of labor employed by the rural cacao farmers. For instance, the use of hired labor increased with cacao production, but so did problems of labor motivation and control in this labor-intensive enterprise. And since 2000, a more troubling observation in Côte d'Ivoire is the reemergence of an early 20th-century practice of increasing use of forced child labor on cacao plantations. As in all capitalist enterprises, keeping costs of labor and other cacao production costs low is a key to profit making. And keeping costs of production low at all levels of the cocoa supply chain—from the cultivation of cacao to its manufacture into other value-added cocoa products—is what ultimately translates into the cheap chocolate consumed in ever larger quantities in Europe and North America.

IMPACT ON ENVIRONMENT

The impacts of changes in the environment–society relations associated with cacao production are garnering increased attention. Cacao production marks a shift in the way societies managed their environment. Prior to the introduction of export crops, the bush fallow/shifting cultivation agroforestry system of agriculture, involving the recycling of land between cultivation and forest fallow, had little permanent effects on farmlands. The soils and forest vegetation had enough time to regenerate after a short period of cropping. Also, the scale of ecological disturbance was small, as much of the production was for subsistence.

The fact that cacao trees are widely cultivated under the shade cover of natural indigenous canopy trees that are left standing as farms are made, or cultivated under a planted canopy of trees, would intuitively suggest that the ecological impacts of cacao production in tropical forests would be minimal. However, cacao production simplifies a complex ecosystem. The under-story vegetation of forests is drastically suppressed, and the density of the upper-story canopy trees is severely altered to make room for cacao trees. And an increasing number of farmers are completely eliminating shade trees on monospecies cacao farms to boost their yields in high-chemical input farms. Biodiversity is thus endangered and threatened over time, and so are a variety of ecological processes, whose absence depletes soil nutrients and increase pests and fungal and viral diseases on cacao farms. A further environmental issue is the use of agrochemicals to sustain short-run cacao yields and its implications for environmental contamination and human health.

Declining yields (often after 20 to 25 years of cultivation) in the old cacao producing frontiers, as soils decline in fertility and as cacao pests and diseases proliferate, make production unsustainable and have led to the search for richer soils and exploitation of new forests, in a cycle of destruction in which the biotic and edaphic components of the environment deteriorate over time. In just 20 years (1984–2004), the size of the area from which cocoa beans were harvested within tropical forests increased by 2.2 to 7 million hectares, and much of this 47 percent increase came from the four leading cocoa bean producers, particularly from Indonesia.

The impact of cacao production has been truly global in scope; from the global indulgence in chocolate treats to the role of cacao production as a major threat to global biodiversity. Cacao production has yet another potential global impact: the potential of ameliorating biodiversity decline and global warming through well-managed cacao farms that grow cacao under a wide variety of planted shade vegetation species and that retain an array of natural vegetation life forms in the tropical forests.

Cadastral Maps

CADASTRAL MAPS ARE maps of properties. They identify plot boundaries, and so generally are very large-scale (covering a relatively small area in great detail), and identify the owner(s) and/or user(s) of each property, usually by linking plots on a map to a written register that records ownership and use, and often other details such as the area of the plot. Before maps were used for these purposes, written registers recorded each plot's owner(s) and/or user(s), and a description of plot location and boundaries. The change from written to mapped cadasters started about 1570 and continued primarily through 1900, in tandem with a move to capitalist property relations and market-orientated agriculture. England was an early leader, probably because capitalist economic relations emerged so early there. Sometimes the written textual descriptions remained the authoritative legal documents proving ownership, the maps being merely descriptive accompaniments. Cadastral maps, called *estate maps*, record the property owned in one area by one person, family, or body such as a college. Such maps usually remained in manuscript, being of interest to only a few people who commissioned the maps to help them manage their estates.

Publicly commissioned cadastral maps record the plots of all the property owners and/or users in one administrative unit, and may be commissioned by government at all levels. Publicly commissioned cadastral mapping, which was practiced by the Romans at least as early as the second century B.C.E., began again in the early 17th century in the Netherlands and Sweden and continues today. The public authority might order such mapping for several reasons: to impose taxation, to reallocate land, as an inventory of national resources, to distribute plots on land to be settled, or as a public legal record to aid property transactions. Such projects almost invariably aroused opposition, either for the general reason that they absorbed time, personnel, and money that others thought might be better spent elsewhere, or from those who would suffer from the particular measure being effected by the maps. Nobles resented taxation surveys, which threatened their traditional immunity from taxation; peasants resented land redistribution schemes, which threatened their precarious livelihoods; and local people resented imperial surveys, which would allow central authorities more control over their lives. Publicly commissioned cadastral mapping did not always represent a threat: some of the earliest occurred in polder areas of the Netherlands, where people knew they must work together to raise money for dikes to keep their lands dry.

Because each publicly commissioned cadastral map was used by relatively few people, they generally remained in manuscript and in government archives. A few, such as those advertising plots for sale in newly laid out towns, were printed. Between the private estate maps and the publicly commissioned cadastral maps lie maps of crown estates (land over which the crown, or later in some countries the state, has rights, but which may include plots of land held by others). Where the estate in question was small and the purpose of the map was land management, the maps often resemble estate maps. There are many beautiful examples of such maps, made for display by the prince and perhaps showing his hunting grounds. Where such estates covered huge tracts of land or had many tenants, they resemble government cadastral maps and could have a connected purpose, because the more money raised by the crown through effective administration of crown estates, the less pressure for taxation to fund government. Government cadastral maps gradually changed from being used to effect one particular measure to being a body of information useful for a variety of government needs. Cadastral maps today are mostly publicly commissioned, and many use geographical information systems accurately and comprehensively to record information for many purposes.

Cairo Guidelines on Waste Trading (UN)

THE UNITED NATIONS Environment Program (UNEP) adopted the Cairo Guidelines and Principles for the Environmentally Sound Management of Hazardous Wastes, or Cairo Guidelines on Waste Trading, in 1987. The guidelines dealt with the nature and transport of hazardous wastes, primarily by sea, and the informed consent to be given by states through whose territory the waste passed and the prior notification that states were to receive. These guidelines were necessary to regulate the increasing flows of such wastes and their often-toxic nature. Maritime trade had also become an almost entirely globalized industry with regulations almost impossible to enforce. Concern had been raised in 1981 at the Ad Hoc Meeting of Senior Government Officials Expert in Environmental Law that was held in Montevideo, and gave rise to an Ad Hoc Working Group that provided the guidelines that were ultimately adopted.

The process of negotiation was controversial because of the unclear nature of what exactly defines waste and other technical issues. However, the continuing stream of problematic shipping accidents galvanized the discussions. Even so, a variety of political arguments meant that it took several years before ratification could take place, even though it required the signatures of only 20 countries. One of the most significant areas of controversy focused on the nature of the guidelines, which provided a basis for continued transportation of waste and not the complete ban preferred by many interests. Ultimately, the guidelines were ratified as the Basel Convention in 1987.

Some conflict has centered on what qualifies as hazardous waste. Since regulations inevitably add some cost to transportation of such items and by protecting people from them and their effects, commercial firms seek ways to minimize those costs. As a result, they have lobbied to have different categories of hazardous waste downgraded in status. The importance of the Cairo Guidelines has been to provide a reasonably comprehensive set of regulations that serve as a legal basis for all aspects of a complex, widely distributed industry with significant implications for the environment. Even so, this listing approach is problematic; it is difficult to create a fully comprehensive listing that is up to date with the latest technologies and techniques for dealing with hazards.

Cambodia

THROUGHOUT MOST OF its recent history, Cambodia has been beset by political strife. After gaining independence from France in 1953, the country was dragged by global politics into a period of profound violence. In 1975, the Communist Khmer Rouge captured Phnom Penh and evacuated all cities and towns, causing the deaths of around 1.5 million Cambodians through execution, starvation, and hardship. Cambodia fared somewhat better during the 10-year Vietnamese occupation that followed. In 1991, the Paris Peace Accords led to a ceasefire and eventually to free elections. However, the long years of political strife left Cambodia struggling economically and environmentally.

Bordering on the Gulf of Thailand, Cambodia has a coastline of 443 kilometers. The climate is tropical with seasonal variations. The rainy season generally lasts from May to November and is followed by a five-month dry season. Monsoons are common between June and November, and flooding and occasional droughts threaten the stability of life. Though the government created flood protection sleeves, many migrants have made their homes in these structures, limiting ability to control water flow. Most of the terrain is flat with interspersing paddies and forests. In the southwest and north, the land is mountainous. Cambodia's most distinct geographic features and the ones perhaps most important to its history, are the Mekong River and Tonle Sap, a lake in the western part of the country. During the dry season, the Tonle Sap drains to the Mekong. But this flow is reversed on an enormous scale during the rainy season, which increases the size of the lake by more than three times, ensuring a flow of fresh water into the Mekong delta to support agriculture,

Land Mines

During the war in Cambodia from December 1978 until the Paris International Conference on Cambodia in October 1991, millions of landmines were laid by various military factions. The government, the Vietnamese-backed People's Republic of Kampuchea (P.R.K.), planted many mines around their friendly bases and villages to prevent surprise attacks. The resistance groups, the hard-line Maoist Khmer Rouge, and the pro-Western Non-Communist Resistance of the right-wing Khmer People's National Liberation Front and the royalist F.U.N.C.I.N.P.E.C. also laid mines around P.R.K. bases to prevent attack. Many are long-lasting plastic mines; and because they are light, during the monsoons many float to new places.

During the war, many thousands of people have been maimed each year, and it is estimated that there were some 40,000 victims of land mines in Cambodia, with the mines still claiming 40 to 50 victims each month. There are now many groups clearing mines in known trouble spots, with the Cambodian government agency, the Cambodian Mine Action Centre (C.M.A.C.), operating with support from foreign countries. In addition, the Hazardous Areas Life (Support) Organization (H.A.L.O.) and the British-funded Mines Advisory Group (M.A.G.) are both active, the latter being involved in the training of many Cambodians in mine clearance.

Many of the areas in Siem Reap province, around the temples of Angkor—the major tourist attractions in the country—have been cleared, but other regions along the Thai-Cambodian border, where much of the fighting from 1978 until 1991 took place, are still littered with hundreds of thousands of unexploded mines. Most areas thought to have unexploded mines are marked, with education programs to rural families and children helping reduce the toll.

and producing a unique and enormous fishery that supplies most of the country's protein. Other natural resources include oil and gas, timber, gemstones, small deposits of iron ore, manganese, phosphates, and the potential for developing hydropower.

In 1999, an agreement with the United States and a guaranteed quota of textile imports paved the way for economic growth, but competition has since slowed economic recovery. Three-fourths of the workforce is involved in subsistence farming. Forty percent of the population lives below the poverty line, and one-third of Cambodians are chronically undernourished. Rice, the staple food for most Cambodians, is often destroyed by flooding and drought. The per capita income of $2,100 places Cambodia 173rd in world incomes.

PRESSING ENVIRONMENTAL ISSUES

Cambodia's population of 13,600,000 people is threatened by a number of health factors, including a high HIV/AIDS rate (2.6 percent) that produces lower life expectancy (59.29 years), growth rates (1.81 percent), high infant mortality (68.78 deaths per 1,000 live births), and death rates (8.97 deaths/1,000 population). It is difficult to disseminate health and environmental information because of educational deficiencies. Eighty percent of the population lives in rural areas where there is a serious lack of potable water; around 66 percent of Cambodians do not have access to safe drinking water. Only 16 percent of the total population has access to improved sanitation. Consequently, food and waterborne diseases are common, including cholera, bacterial and protozoal diarrhea, hepatitis A, and typhoid fever. Some locations are also vulnerable to vectorborne diseases such as dengue fever, malaria, and Japanese encephalitis. The United Nations Development Program (UNDP) Human Development Reports rank Cambodia 130th of 232 nations in overall quality of life.

One of Cambodia's most pressing environmental problems is waste management. Domestic and industrial effluents and solid wastes have cause extensive pollution of surface and groundwater. Hazardous wastes released by industries are frequently burned in open dumpsites. Extensive deforestation has occurred from illegal logging, and gem strip mining along the Thai border has created vast wastelands. The loss of large areas of mangrove swamps and overfishing are threatening the fisheries that are essential to Cambodian survival.

Widespread soil erosion is a by-product of natural disasters and human mismanagement. River and coastal sedimentation from logging has degraded coastal, marine, and freshwater resources. Water samples reveal residue from toxic pesticides. In 2006, a study by Yale University ranked Cambodia 110 of 132 countries in environmental performance, well below the relevant income and geographic groups. The lowest ranking was in the field of environmental health. Although estimates vary, it is generally believed that a little over half of Cambodia has some forest cover remaining. The government has protected 18.5 percent of the land. Of 123 endemic mammal species, 24 are threatened with extinction, and 19 of 183 endemic bird species are similarly endangered.

After peace was restored in 1991, the Cambodian government launched a recovery effort by passing a body of environmental legislation. The Ministry of Environment was charged with environmental protection and conservation of natural resources and instructed to work with the Ministry of Agriculture, Forestry, and Fisheries to promote sustainable development. This task is made more difficult by overlapping responsibilities, the shortage of skilled staff, and chronic funding shortages. Cambodia has signed the following international agreements: Biodiversity, Climate Change, Kyoto Protocol, Desertification, Endangered Species, Hazardous Wastes, Marine Life Conservation, Ozone Layer Protection, Ship Pollution, Tropical Timber 94, and Wetlands. The Law of the Sea agreement has been signed but not ratified.

Cameroon

THE PRESENT-DAY REPUBLIC of Cameroon was formed in 1961 when the former French Cameroon joined part of British Cameroon to create a new government. In response to continued political stability, Cameroon has created a strong infrastructure while developing the agricultural, petroleum, and transportation sectors. The Chad–Cameroon Pipeline has caused much controversy and concern among environmentalists but has been lauded as an important economic project for both countries. Funding from the World Bank and the International Monetary Fund have fueled development and structural reform in Cameroon; however, the high level of national debt has been an anchor on local prosperity and equitable growth. Democratic reform has also continued at a slower pace than development, in part because of widespread government corruption. The prospect of debt relief from multi-lateral funding agencies represents a promising development.

With a per capita income of $1,900, Cameroon is ranked 183rd of 232 countries in world incomes. Approximately 70 percent of the labor force is engaged in agriculture, chiefly at the subsistence level. Nearly half of Cameroonians live below the national poverty line, and one-fourth of the people are undernourished. Some 30 percent are unemployed. Just over half the population lives in urban areas. Income is unevenly distributed, with the richest 10 percent possessing 36.6 percent of income as compared to 1.9 percent for the poorest 10 percent. The United Nations Development Program (UNDP) Human Development Reports rank Cameroon 158th of 232 countries on overall quality-of-life issues.

Bordering the Bight of Biafra, Cameroon has a coastline of 402 kilometers and shares land borders with the Central African Republic, Chad, the Republic of the Congo, Equatorial Guinea, Gabon, and Nigeria. Cameroon also has 6,000 square kilometers of inland water resources. The terrain of Cameroon varies from the coastal plains of the southwest and north to mountains in the west and a dissected plateau in the central region of the country. Elevations range from sea level to 4,095 meters at Fako on Mount Cameroon. This mountain, the highest in sub-saharan West Africa, is an active volcano. The climate of Cameroon is also varied, with the coast enjoying a tropical climate while the north is semiarid and hot. Cameroon experiences a good deal of volcanic activity, and volcanoes on Lake Nyos and Lake Monoun periodically release poisonous gases into the atmosphere. Cameroon's natural resources include petroleum, bauxite, iron ore, timber, and hydropower. Nearly 13 percent of the land area is arable.

The population of 17,340,702 Cameroonians experiences an HIV/AIDS rate of 6.9 percent. Some 49,000 people have died from this disease since 2003, and it is estimated that 560,000 others are living with it. Some 37 percent of Cameroonians lack sustained access to safe drinking water, and 52 percent do not have access to improved sanitation. As a result, the population has a very high risk of contracting food and waterborne diseases that include bacterial diarrhea, hepatitis A, and typhoid fever and the water contact disease schistosomiasis. In some areas, chances for contracting vectorborne diseases such as malaria and yellow fever are also high. High incidences of disease in Cameroon result in low population growth (2.04 percent) and life expectancy (51.16 years) and high infant mortality (63.52 deaths per 1,000 live births) and death (13.47/1,000) rates. Cameroonian women bear an average of 4.39 children, and 26.6 percent of the adult female population is illiterate as compared to 15.3 percent of adult males.

Most environmental problems in Cameroon are a result of uncontrolled economic activities. Part of the Congo Basin Forest, the second-largest rain forest in the world, lies within Cameroon. However, only 4.5 percent of land area is under national protection. Deforestation is occurring at a rate of nine percent as ecologically valuable tropical forests are cut down for export. The rate of desertification in the Congo Basin Forest has accelerated in response to agricultural mismanagement, overgrazing, and deforestation. The countries that host the rain forest have joined together with international groups to form the Congo Basin Forest Partnership designed to prevent further damage. With a $35 million grant from the United Nations Conference on Environment and Development, Cameroon introduced the Forest and Environmental Policy Development Program in 2006 under the leadership of the Ministry of Environment and Forests. The program targets enhancement of sustainable development and the promotion of biodiversity. Local and international environmental groups also play a major role in protecting the environment of the rain forest.

Overfishing has threatened marine ecosystems and placed the Cameroonian food supply in danger. Poaching as well as destruction of habitats has also placed wildlife at risk. Of 409 mammal species that have been identified in Cameroon, 40 are endangered, as are 15 of 165 known bird species. In a 2006 study conducted by scientists at Yale University, Cameroon was ranked 100th of 132 countries on environmental performance, in line with the comparable income group and slightly above the comparable geographic group. The overall score was reduced because of the low ranking in environmental health. The Cameroonian government participates in the following international agreements on the environment: Biodiversity, Climate Change, Kyoto Protocol, Desertification, Endangered Species, Hazardous Wastes, Law of the Sea, Ozone Layer Protection, Tropical Timber 83, and Tropical Timber 94.

Canada

CANADA IS THE world's second-largest country with a population of 33 million (July 2006 estimate). On July 1, 1867, the Constitution Act created the Canadian federation, which originally consisted of four provinces: Ontario, Quebec, New Brunswick, and Nova Scotia. Canada today is a parliamentary democracy with elected legislatures at the federal, provincial, and territorial level. The federal government is made up of an executive branch, consisting of the governor general, prime minister and cabinet.

Canada is divided into 10 provinces and three territories, each with its own legislature and administration. The central government maintains jurisdiction over such areas as national defense, banking, navigation, fisheries, commerce, indigenous peoples' affairs, and international relations. The provinces have jurisdiction over social services such as education and health, land and natural resources, and the regulation of economic activity. Both levels of government have extensive taxation powers. Each territory has legislative powers similar to those of the provinces, although the federal government retains controls over most of the territories' land and natural resources.

Canada's economy is dominated by the services sector (68.7 percent of Gross Domestic Product, or GDP), followed by industry (29.1 percent) and agriculture (2.2 percent). Its key industries reflect the country's rich natural resource base and include transportation equipment, chemicals, processed and unprocessed minerals, food products, wood and paper products, fish products, and petroleum and natural gas. Canada's GDP reached U.S. $934 billion in 2002, positioning it as the world's 12th largest economy. Canada's GDP per capita of $29,300 is the 9th highest in the world, and its GDP growth rate of 3.3 percent compares well to other Organization for Economic Co-operation and Development (OECD) countries. Canada's labor force comprises 16.3 million people (49 percent of the total population) and is distributed among occupations in the services (75 percent), manufacturing (14 percent), construction (5 percent), agriculture (2 percent), and other sectors (3 percent). Canada is highly integrated into the global economy through trade, with 33.6 percent of its GDP dedicated to exports. Despite Canada's strong ties to both Britain and France, Canadian culture and its economy are heavily influenced by the United States, the destination for over 85 percent of Canada's exports and with trade arrangements that include the 1989 United States–Canada Free Trade Agreement (FTA) and the 1994 North American Free Trade Agreement (NAFTA).

Female Bighorn sheep in the Canadian Rockies. Expanding industrial areas are encroaching on wildlands.

Canada's human development index (HDI), which is a comparative, worldwide measure of poverty, literacy, education, life expectancy, childbirth, and other factors, is 0.949. While this gives Canada the 5th highest HDI in the world, its world ranking has slipped relative to other countries over the past decade. High cultural diversity is evidenced by the 71.1 percent of its population in 2001with ethnic origins other than English, French, or Canadian. Although its rural population is declining, Canada's total rural population was 20.6 percent in 2001. Those residing in rural and small town regions are greatest in the Atlantic provinces, Manitoba, Saskatchewan, the Northwest Territories, and Nunavut. Canada compares favorably to other countries with respect to violent crime, as evidenced by its relatively low homicide rate of 1.6 per 100,000 (vs. 9.9 in the United States and 17.2 in Mexico).

With a geographical space of over 2.1 million square kilometers, Canada accounts for a relatively large share of the planet's natural resources, including about 10 percent of the world's forests and renewable fresh water supply. Most of the forestland is owned and managed by the provincial and federal governments (about 71 percent and 23 percent, respectively). While the limits to resource availability have generally not been reached (key exceptions include the Atlantic cod fisheries which collapsed in the early 1990s), resource sustainability remains a serious concern in the long run. Its proximity to the United States also means that both countries must work collaboratively in addressing cross-border environmental issues, such as air and water pollution, and the management of shared wildlife species.

Canada has made significant progress toward achieving its environmental domestic objectives and international commitments since 1995. For example, Canada is a signatory to the Kyoto Protocol. As an Annex I country, Canada has pledged to reduce its carbon dioxide emissions to six percent below

1990 levels by 2012. The Canadian government plans to spend over CA $6 billion to meet the Kyoto requirements, chiefly by purchasing over CA $1 billion worth of emissions credits, greater investment in green technologies, and tax credits for industrial reductions in carbon dioxide emissions.

On the other side, Canada faces some significant environmental challenges. Industrial emissions to air, water, and land represent significant sources of pollution in spite of pollution control advances. Canada is the worst among OECD countries for scaling back on emissions of carbon dioxide, a contributor to global climate change. Over the period from 1990 to 2000, Canada's carbon emissions for each citizen rose by 10.1 percent, more than double the OECD average of 4.8 percent. Expanding urban environments and industrial development are encroaching on wildlands and contributing to increases in energy use and air and water pollution. Urban and agricultural runoff also threatens water quality in several areas. Three provincial capitals—Victoria, Halifax, and St. John's—continue to pump raw sewage directly into the ocean. Currently 487 plant and animal species are classified as being at risk in Canada.

Canada also has the third-largest ecological footprint per person in the world after the United Arab Emirates and the United States. If everyone in the world consumed at Canada's rate, it would take four more earths to support humanity. It takes 7.25 hectares of land and sea to support each Canadian. Municipal footprints range from as low as 6.87 hectares/person in Greater Sudbury to a high of 9.86 for Calgary. In addition, Canada has the second-highest rate of energy consumption per person in the world, behind only the United States.

While many of its environment challenges need to be seriously addressed, Canada is still considered a world leader in many ways—for example, in global security, social service programs, and human rights.

Cancer Alley

THE LAND KNOWN to the Louisiana environmental justice movement as Cancer Alley follows the Mississippi River from Baton Rouge to New Orleans. Otherwise known as the chemical corridor, this area is home to facilities producing gasoline, fertilizers, plastics, and numerous other petrochemical products.

This high ground along the river was settled by Europeans who, with slave labor, created sugar cane plantations. After emancipation, many freed men remained in the region but sought to establish independent African-American towns in the interstices between plantation properties. These "freetowns" dotted the landscape of parishes along the river.

The discovery of petroleum in Louisiana in 1901 led eight years later to the building of the massive Standard Oil refinery in Baton Rouge. New oil fields were opened up in and around the Gulf of Mexico from the 1930s and on. Combined with convenient access to the ocean, abundant fresh water from the Mississippi and nearby deposits of other feedstock materials like sulfur and salt, Louisiana was well-suited for the emerging chemical industry. A compliant state government that imposed little in the way of taxes or regulations and the availability of large tracts of undivided land on the river—the plantations—made for an even better location for rapid industrialization.

The chemical plant boom started in the early 1960s, as plantation owners sold out to industries and towns and villages found themselves the neighbors of, and sometimes almost surrounded by, the new facilities. Local residents received few jobs from the new industries, which were highly capital-intensive and have only become more automated over time. Since locals owned homes and land—even though most saw few benefits from industrialization—they stayed where they were. This brought about an increasingly strained relationship between people living on the fencelines of those industries.

The modern industrial corridor has grown to 156 facilities and generates one-sixteenth of the entire toxic emissions of the United States. In 1988, one-third of the nation's underground injections of hazardous waste were in Louisiana. In 1991, Louisiana generated 16,280 pounds of toxic pollution per chemical industry job, compared with Texas at 8,997 and New Jersey at 1,084. Because of Louisiana's industrial tax exemption, the most expansive of any in the country, local school boards lost an estimated $129 million statewide in 1995.

The environmental justice movement in Louisiana cannot be separated from the Civil Rights movement. African Americans, who organized in the 1960s to get access to education, voting rights, employment in industry, became the backbone of environmental justice in the 1980s. Driven by personal experiences of strange smells and gas clouds drifting through their neighborhoods, explosions and chemical leaks that left people to close their doors and windows and hope for the best, and illnesses and deaths of family and friends, a number of local environmental justice fights began at this time.

These local campaigns came out of places like the community of Alsen, just north of Baton Rouge. Surrounded by industrial zoned property, Alsen's neighbors include a disposal facility and injection wells for hazardous waste and several chemical plants. Residents of Alsen and other communities have been able to stop expansions of some facilities and link up to statewide and national organizations to conduct actions like the Great Louisiana Toxics March in 1988. In the mid-1990s, the Shintech Corporation attempted to build a polyvinyl chloride plant in St. James parish. The accumulated experience and infrastructure of the Louisiana environmental justice movement helped these campaigns to win victories such as Shintech's decision not to locate in St. James, and the relocation of the community of Diamond—sandwiched between a chemical plant, an oil refinery, train tracks full of carloads of chemicals, and the Mississippi River.

Disposing of the debris left by Hurricane Katrina poses difficult questions for Louisiana. The Agriculture Street landfill in New Orleans was used to dump debris from Hurricane Betsy in 1965; the mostly African-American neighborhood that was built on top of it subsequently became a Superfund site, and a still-unresolved cleanup or relocation. Progress toward environmental justice in Cancer Alley has come slowly and at great cost to those who have suffered for industrial development.

Cane Toad

NATIVE TO THE broader Caribbean region between southern Florida and northern South America, but purposely introduced into Australia and other regions, cane toads have provided a pointed

The cane toad has pronounced parotoid glands on its shoulder, from which it releases a very toxic poison.

illustration of the dangers of introducing species to a new environment, even for very well-intentioned reasons. Large toads with almost omnivorous appetites, cane toads breed prolifically and have proven adaptable to a fairly broad range of environments from coastal mangrove swamps to rainforests, from grasslands to marginal woodlands, and from agricultural areas to urban lots. On its shoulders, the cane toad has pronounced parotoid glands, from which it releases a very toxic poison. Although some predators such as keelback snakes, wolf spiders, freshwater crayfish, saltwater crocodiles, crows, several other types of birds, and several types of rats can tolerate the toad's poison, it is fatal to most mammals, lizards, and snakes that try to kill and eat the toad. Thus, under most conditions, the population of cane toads is almost impossible to control.

The cane toad has become a pest of monstrous proportions in Australia, where, ironically, scientists introduced it to control other pests. In the mid-1930s, the larva of two types of beetles, the French's Cane Beetle and the Greyback Cane Beetle, were devastating Queensland's main cash crop, sugar cane, by attacking the plant's roots. The Australian Bureau of Sugar Experimental Stations introduced various predators to control the beetle larvae, and in 1935, 100 cane toads were imported from Hawaii to the Meringa Experimental Station located near Cairns. The toads proved extraordinarily effective against the beetle larvae, and the operators of the station received permission to release about 3,000 toads into the fields of several local sugar cane plantations. Protests by some leading entomologists caused a moratorium on further releases of the toads, but the commercial pressure to protect the sugar cane crop ultimately outweighed opponents' evidence that the cane toad might very well become a worse pest than the beetle larvae. By the late 1930s, the toads were being released across Queensland.

There are now millions of cane toads in Australia, and their range has extended beyond Queensland and into the Northern Territory. In addition to the beetle larvae, cane toads will eat almost any insect, other amphibians, most small reptiles, some small mammals, and even cat and dog food. In their native range, the toad population is controlled by several snakes, for which they have become the primary food source. But Australians, from specialists to the general public, are naturally skeptical about the introduction of any more non-native species. They have proven a bane to domestic pets with which they have increasingly come into contact and to native species with whom they compete voraciously for food sources. More broadly, the cane toads have become a sort of grim national joke, with canny entrepreneurs creating all sorts of souvenir items featuring the toads for sale to tourists, both from other Australian states and from overseas.

Despite its almost universal vilification, the cane toad has some potential benefits. It is widely used in schools and universities for dissection lessons because of its size and the ease with its tissues can be incised. Its hide has proven to be commercially viable material for making attractive "leather" items such as purses, belts, and shoes. And, lastly, its venom is being studied because it contains many chemical compounds with a broad range of possible pharmacological applications.

Cape Verde

IN THE 15TH century, the Portuguese discovered the uninhabited Cape Verde archipelago in the North Atlantic and developed in into a major trading center for African slaves and a resupply station for whaling and transatlantic shipping. Today, two major island groups make up the Republic of Cape Verde. The Barlavento (Windward) Islands are composed of Santo Antão, Boa Vista, São Nicolau, São Vicente, Sal, and Santa Luzia. The Sotavento (Leeward) island group includes São Tiago, Fogo, Maio, and Brava. Ever since achieving independence in 1975, Cape Verde has flourished as a stable democracy, but its economic progress has been negatively affected by a number of factors, especially environmental conditions, like drought and seismic activity.

Natural resources on the islands include salt, basalt rock, limestone, kaolin, fish, clay, and gypsum, but none of these resources provides substantial revenue. Less than 10 percent of the land area of Cape Verde is arable, and agriculture provides just over 10 percent of the Gross Domestic Product. Approximately 82 percent of Cape Verde's food supply is imported. Close to 70 percent of the population lives in rural areas. Because of prolonged droughts, the island experiences a chronic shortage of fresh water. Some 20 percent of the population lack sustained access to safe drinking water, and 42 percent lack access to improved sanitation. With a per capita income of $6,200, Cape Verde is ranked 119th in world incomes. A third of the 418,224 people lives in poverty, and over a fifth of Cape Verdeans are unemployed. The United Nations Development Program (UNDP) Human Development Reports rank Cape Verde 105 of 232 countries in overall quality-of-life issues.

Surrounded entirely by the Atlantic Ocean, Cape Verde has a coastline of 965 kilometers. These volcanic islands are steep, rugged, and rocky. Elevations range from sea level to 2,829 meters at Mount Fogo, a volcano located on Fogo Island. The temperate climate generally produces warm, dry summers. Little precipitation falls on the islands, and there is no predictable pattern to its occurrence. Seismic activity is a constant threat on Cape Verde, and droughts became so common in the latter half of the 20th century that most of the population suffered hardship, and large groups of people fled the islands. The harmattan, a hot, dry, and dusty seasonal wind, releases large amounts of dust into the atmosphere and accelerates soil degradation. Cyclones and insect infestations also contribute to environmental degradation on Cape Verde.

In addition to soil erosion and desertification that are consequences of both human and climatic activity, deforestation is expanding as forests are cut down for use in cooking and heating. As habitats are damaged, survival rates of wildlife become problematic. Endangered mammals include the Mediterranean monk seal, the northern bald ibis, the green sea turtle, and the hawksbill turtle. Three of 103 bird species are also threatened with extinction, as are 14 of 659 plant species. Overfishing has damaged marine ecosystems and further reduced available food supplies. The practice of removing large amounts of sand from the beaches to use in construction projects has resulted in coastal erosion.

The Minister of Agriculture, Food, and Environment is responsible for implementing environmental laws in Cape Verde and for monitoring compliance with existing laws. The Minister works with regional and international groups to promote sustainable development of the islands. In 2003, the Cape Verde government joined with three United Nations organizations to involve unemployed youth in reconstructing damaged environmental resources.

The Cape Verde government participates in the following international agreements: Biodiversity, Climate Change, Desertification, Environmental Modification, Hazardous Wastes, Law of the Sea, Marine Dumping, and Ozone Layer Protection.

Capitalism

CAPITALISM IS DESCRIBED in *Webster's College Dictionary* as "an economic system in which investment in and ownership of the means of production, distribution, and exchange of wealth is made and maintained chiefly by private individuals or corporations." This is in contrast to the main alternative to capitalism—socialism—that is defined as "a theory or system of social organization in which the means of production and distribution of goods are owned and controlled collectively or by the government." There are many variations or types of capitalism and socialism both in theory and practice, and most countries in the world have mixed economies that have some elements of both production systems. These systems produce both public and private goods and services.

Capitalism can be described as a system: generally as a private sector, market economy regulated by a public sector government. Capitalism can exist as a global system, where exchange transactions that travel over national boundaries are defined as international trade and international finance. Nations can be classified and rank-ordered according to the types of capitalism practiced. One type of ranking would compare levels of taxation and regulation, while another might look at the most dominant formats of business organization.

Capitalism can also be couched as a philosophy. Major philosophical tenets include: emphasis of individual rights over social rights; the right to purchase, own, and sell private property, including real estate; the use of price as a mechanism that guides the demand and supply of goods and services; the reward to entrepreneurs by the earning of profits derived from business operations; and the retention of capital gains resulting from the selling of privately owned assets.

Capitalism also can be experienced as a lifestyle. A capitalist is a person who practices capitalism in a number of roles. These include the entrepreneur, a person who works alone or in partnership to convert an invented idea, product or process to a marketable good or service. A capitalist can also be an investor who provides monetary resources to entrepreneurs, in exchange for a percentage ownership of their organization. A capitalist might be a manager, who seeks higher income and profit sharing associated with a growing business.

A capitalist is also a significant consumer. Income derived from capital gains, business profits, interest earned from renting capital, and salaries is used to acquire assets such as houses, automobiles, and computers, or more general retail consumption of a myriad of goods and services.

Corporate employees can also play the role of capitalist, to the extent they can save a portion of earned wages and invest them to start small-scale businesses; in many cases, home-based and requiring part-time work. In some societies, the majority of residents might be active in business formation of various sizes and scopes. In other societies, the capitalist might be a rare individual, possibly viewed as an opportunistic nonconformist.

In general, a capitalist economy can be described as having a private sector, with the power to produce and distribute goods and services; and a smaller, public sector, which partially taxes and regulates the private sector. The private sector is made up of a myriad set of activities by individuals, partnerships, and corporations, involving investors, entrepreneurs, employers and employees, vendors, and customers. A large volume of transactions occur in thousands of spatially diverse markets.

Capitalism is correlated with science and technology, and is a process where discoveries lead to innovations in how people organize space. These innovations are then packaged and marketed. If successful, new goods or services will diffuse across space as they are utilized by related producers and end consumers. For example, cellular communications towers allow for the use of small and portable communications devices. The diffusion of this technology has been rapid, and many countries now count more cell phones than fixed-line phones.

LEGAL STRUCTURES AND PROCESS

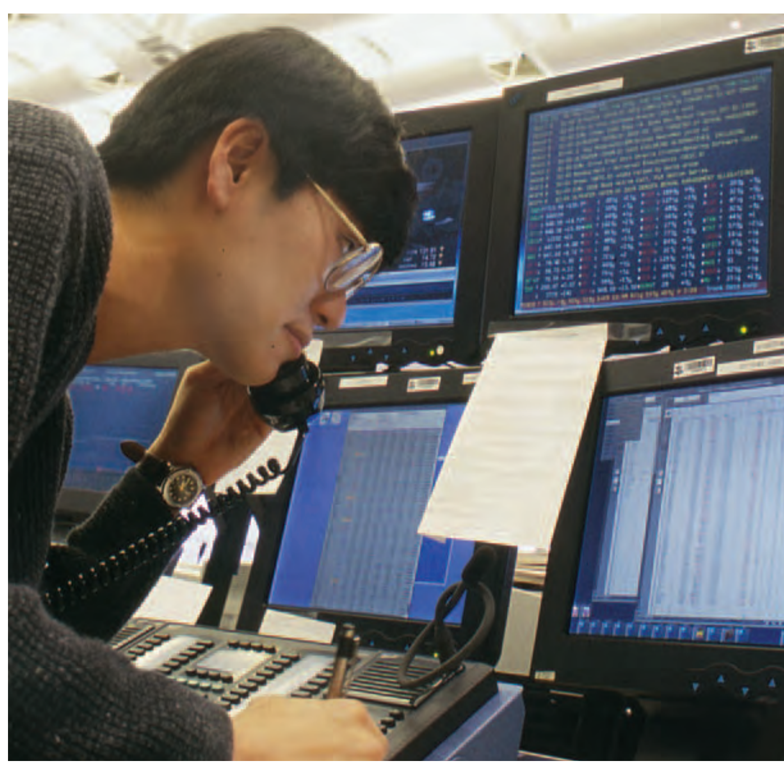
Capitalism will generate a legal structure that constructs a legal process. It is dependent on a public legal system to enforce noncompliance with written contracts, which is a legally binding agreement between two businesses (which themselves are legal entities). Three major legal forms are the sole proprietorship, which is a business is owned by a single individual; the partnership, which is is a contract that defines ownership percentage for two or more individuals; and the corporation, which has a more formal structure, where ownership can be traded between two unaffiliated parties, generally via stock markets. The corporation has the advantage of allowing ownership to shift over time, which means there is no inherent life expectancy or temporal limitation. In addition, corporations tend to have limited liability, related to the potential loss of direct investment, and not personal loss of property or liberty except in cases of gross or criminal negligence. A corporation's life is limited by the decreasing demand from its consumers. This flexible structure has allowed for corporations to become relatively large, in some cases employing upwards of one million employees, having thousands of owners, and supplying goods and services to millions of customers. Corporations that take full advantage of the span of transportation and communications system networks can operate in many locations and thus become global or multi-national.

A corporation is formed by a multi-step process of idea generation, acquisition of investors and capital, the entrepreneur's stock ownership of the newly formed corporation, hiring of organizational and technical managers to develop the good or service, identification of vendors, hiring of employees, marketing to identify and secure customers, and securing a customer service and accounting process.

If unsuccessful, the investment is lost, and the entrepreneur's reputation is damaged. If successful, however, a return on investment is made and a profit is earned, and a business enterprise is able to scale up in size, earning higher revenue and employing more workers. This expansion will be limited by competing firms. Generally, a portion of the profits will be taxed; and to varying extent, government will regulate the firm, especially if there are identified byproducts of the production process, such as air, water and land pollution, and/or safety issues for consumers.

With millions of corporations and thousands of governments in existence, there are numerous interactions between the two entities. Many of these interactions are complementary, and assist in relatively efficient economic activity that has resulted in economic growth. Some of the interactions are contentious, resulting from a disagreement about the level of taxation or the volume of regulations. This can result in firms relocating their business activities to places with lower taxes and regulations.

Corporate ownership can be traded between two unaffiliated parties, generally via stock markets.



There are many environmental impacts resulting from capitalist economic activity. First, there are the land use and land cover changes associated with the raw materials needed for the production, such as the water supply, food, fiber, metals, construction and building materials, and energy. This can involve large areas of land used for cropland, pastureland, plantation timber or selective forest harvesting, and energy and mineral extraction. Second, there are pollution byproducts, which can take gaseous, liquid or solid forms. Pollution impact can be on-site and affect production workers, or migrate across space and affect larger areas. Third, goods and services are consumed in buildings and houses, which in turn are the result of extensive construction. Over time, the area used in clusters of housing and buildings form a set of urban places that convert land from natural or primary production into urban related development.

The mitigation of negative environmental changes takes a number of forms. In many cases, new technologies and markets evolve, including pollution control devices and more efficient production methods. In other cases, the public sector regulates or taxes the private sector to reduce the volume of pollution. An incentive is created to minimize pollution outputs, and thus the burden of pollution-related tax and regulation. Technological changes take place over time, resulting in reduced pollution levels, which may be offset with increased pollution associated with greater economic activity. Spatial changes may occur where pollution is avoided by moving from degraded landscapes to healthier landscapes.

From 2001–2006, the global economy has expanded at an average rate of about four percent per year. Most of this economic expansion has been the result of successful investment in capitalistic activities. In contrast to the period 1800–2000—where some places became economically successful relative to their neighbors, resulting in divergence in per capita incomes—the 21st century begins with strong evidence of convergence, with a set of emerging economies growing at twice the economic growth rates as developed economies. These emerging economies include China and India, and as a group of about 30 nations, contain the majority of the world's population.

The Rise of Capitalism

Capitalism is a process closely related to the industrial revolution, starting in a limited geography in the early part of the 19th century, including the northern United States and Great Britain, and initially expanding and networking slowly outward. At the start of the 20th century, the global economy encompassed approximately $3 trillion in annual economic activity. Most of this monetary value resulted from urban- or city-based capitalistic processes, while most of the world's population was engaged in rural-based subsistence agriculture. The result of the 20th-century set of economic processes is a global scale economic activity estimated at about $60 trillion in 2006, comprised of trillions of individual transactions where goods and services are exchanged.

The system has a base infrastructure that is largely public provision; a network of millions of kilometers of paved roads, railroads, airports and water ports. An interconnected network allows for the completion of a spatial transaction: an order is placed for a good or service using a communications network, which is then delivered using the transportation network. The public infrastructure connects a private infrastructure, consisting of billions of housing units and millions of commercial buildings. Capitalism operates on a public infrastructure, and uses this network to obtain primary produced resources of timber, crops and ranged domesticated animals, ore and energy.

The future implication of continued economic growth at these rates is a mid-century global economy growing from $60 trillion to about $300 trillion. Combined with a demographic transition, which may result in a stabilized global population of about 8 billion persons, there is a potential for the global economy to have a per capita income of about $40,000 per person. This is a level currently enjoyed by countries including the United States, United Arab Emirates, and Norway. Capitalism is characterized by competition and varied outcomes, so there is a range of observed incomes. The potential exists, however, for the large reduction in poverty and even elimination of extreme poverty, and a human condition that, overall, is better than in prior history.

The environmental challenges are how an economic system of this size will obtain sufficient energy that is efficient and sustainable in the long-term, with less environmental problems than the current energy mix that is dominated by oil, coal, and natural gas. Also, there is the future relationship of primary production of food, in an efficient process that provides bountiful per capita caloric needs, while also expanding and maintaining a global network of wild lands, wild vegetation, and animal life.

A capitalist might view the environmentalist as faced with two important challenges. First, to use comprehensive scientific monitoring of the earth to identify new problems to which a wider audience will need to be alerted, and refine the relative relationships of the current set of problems, whose parameters may be shifting. Second, to play a complementary role—as both outside observers and participants of both the public and private sectors of the global capitalist economy—so that the trillions of economic transactions occurring in a global trading system incorporate environmental attributes.

Car Corporate Average Fuel Economy (CAFE) Standards

CORPORATE AVERAGE FUEL Economy (CAFE) Standards are gas mileage standards applied to automobile manufacturers. The standards were developed as part of the Energy Policy and Conservation Act passed by Congress in 1975. The act was designed to conserve energy following the 1973–74 Arab oil embargo, when restricted oil imports led to long lines at gas stations and contributed to economic recession. The measure is calculated by averaging the miles per gallon (mpg) of each vehicle manufactured by a given firm for sale in the United States in a given model year. Since the standard is based on the average of a firm's entire fleet of vehicles, some models may exceed the standard if others fall below it. There are separate standards for passenger cars and light-duty trucks, a category that includes most pickup trucks, vans, and sport utility vehicles (SUVs).

The original goal of the legislation was to double new passenger car fuel economy within 10 years to a corporate average of 27.5 mpg in 1985. The standards, which gradually increased fuel economy requirements, were designed to push technological innovation toward greater fuel efficiency. That goal was met, but the standard was then briefly lowered between 1986 and 1989. The 27.5 mpg standard was then reinstated in 1990, where it remained. Light trucks, originally defined as trucks weighing 6,000 pounds or less, and later redefined as trucks weighing up to 8,500 pounds, have a different CAFE standard.

There are no standards for vehicles that exceed 8,500 pounds. Standards for light trucks were originally set in 1979 at 15.8 mpg for two-wheel-drive vehicles and 17.2 for four-wheel-drive vehicles (the two-wheel/four wheel drive distinction was later eliminated). The National Highway Traffic Safety Administration (NHTSA), the federal government agency that has been empowered by Congress to set the CAFE standards when specific goals were not included in legislation, has raised the light truck standard in several years since its implementation.

The NHTSA has set a light truck standard of 22.2 mpg for model year 2007. The U.S. Environmental Protection Agency (EPA) monitors firms and enforces the standards for both classes of vehicles. Firms that do not meet the CAFE standard are required to pay a fine based on the amount by which their fleet fails to meet the requirements. Due to the low mileage vehicles they tend to manufacture, many European firms have been required to pay these fines, while no Asian or American firms have had to pay this civil penalty.

CONFLICTS AND CONTROVERSY

CAFE standards have been the subject of much political debate. Most economists agree that the standards have served their purpose of increasing fuel efficiency, although some argue that alternative measures, such as increased gas taxes, would be more effective for achieving these goals. Environmental organizations support the use of CAFE standards as a means to reduce air pollution, greenhouse gas emissions, and natural resource extraction.

Yet many environmental groups, such as the Sierra Club, believe that the standards need to be increased. Environmentalists also see the existing standard as flawed given the dramatic rise in the use of pickup trucks and SUVs for traditional passenger car purposes. When the policy was enacted, the separate light truck standard was justified given the need for hauling construction and farm materials. These vehicles made up roughly 20 percent of the market at that time. Today, almost half of all new vehicles sold fall in the light truck category, most of which are used for the same purpose as conventional passenger cars. The result has been that overall vehicle fuel efficiency has actually decreased in recent years.

Automobile manufacturers oppose the legislation of higher fuel economy standards. They believe that such mandates increase production costs, raise the price that consumers will have to pay, and lower sales. Makers of SUVs are especially concerned, given that these less-fuel-efficient vehicles are more profitable than most passenger cars. The Alliance of Automobile Manufacturers, a trade organization that includes manufacturers such as Ford and General Motors, lobbies against legislated standards and advocates instead for tax incentives for consumers who purchase fuel-efficient vehicles. Some auto manufacturers have also suggested higher gas taxes as a means to encourage greater fuel conservation.

In 2002, legislation was introduced in the U.S. Senate to raise CAFE standards in order to improve fuel efficiency by almost 30 percent over a 10-year period. Environmentalists supported the bill for the effect it would have on reducing greenhouse gas emissions. The auto industry opposed it and enlisted organized labor to generate popular opposition. They argued that higher vehicle prices resulting from the new standards would dampen auto sales and result in significant job loss. A number of Democrats joined the majority of Republican senators opposing the bill and it was defeated.

Carbon Cycle

THE CARBON CYCLE describes the movement and storage of carbon on earth. Knowledge of the carbon cycle helps us to understand the impacts of anthropogenic additions of carbon to the atmosphere on the storage and movement of carbon.

Places where carbon is stored are called pools or reservoirs. The five pools of carbon are sedimentary rock, terrestrial soils, the atmosphere, land vegetation, and oceans.

By far, the largest amount of carbon is buried in sedimentary rock, and this quantity is considered inactive in the carbon cycle. The active (or surface) pools constitute less than 1 percent of the carbon on earth, and they contain 40 x 10^{18} g C. Within this active carbon, the oceans constitute the largest pool (38,000 x 10^{15} g C, or 38,000 gigatons of carbon [GtC]). Movement (or fluxes) of carbon to and from the ocean happen primarily with the atmosphere, and the input and output of carbon to the ocean are almost balanced. Oceans take up carbon dioxide through diffusion, which is then used by photosynthetic plankton to produce sugars, or is taken up by organisms to produce shells. Some of the carbon, particularly from shell-producing organisms, sinks to the ocean floor and is buried in the sediments, which can eventually become part of the inactive carbon pool. The largest flux of carbon out of the ocean is back into the atmosphere, and this occurs via respiration of ocean organisms.

Terrestrial soils make up the second-largest pool of active carbon (1,500 GtC). Inputs of carbon (made up mostly of sugars) to soils occur when terrestrial vegetation sheds litter or dies. This organic matter is decomposed by organisms within the soil and becomes part of the soil carbon pool. Output of carbon from soils happens through the respiration of carbon dioxide from soil organisms, which, together with the respiration of land plants, generally equals the amount of carbon taken up by land plants, thus balancing the carbon budget for terrestrial systems. Land plants constitute the smallest pool of carbon (560 GtC). Vegetation takes up carbon dioxide from the atmosphere to make sugars and other carbon-based compounds. Such carbon compounds are either used within the plant for storage, reproduction, or respiration or they are transferred to the soil through litterfall or when plants die. This process, like any other that removes carbon from the atmosphere is an example of carbon sequestration.

The atmosphere is the third-largest pool of carbon (750 GtC), and the only two forms of carbon found here are methane and carbon dioxide. As we have seen, the atmosphere exchanges carbon with the ocean and land plants and receives carbon from soils. In addition, the atmosphere is the only pool known to be increasing with anthropogenic additions to the carbon cycle. Fossil fuel emissions and land clearing constitute an additional flux to the atmosphere of about 7 GtC/year. The combustion of fossil fuels and the burning of forests emit carbon dioxide, while the draining and clearing of wetlands release methane. It is known that half of this additional flux (about 3.2 GtC/year) remains in the atmosphere, slowly increasing the concentrations of carbon dioxide and methane. The fate of the other half of this additional flux (or carbon "sink"), however, is not fully known. It is possible that the oceans are absorbing some of the extra carbon.

UNDERSTANDING THE CARBON CYCLE

General knowledge of how the carbon cycle works improved as scientists developed an understanding of anthropogenic forces on the cycle. The idea that addition of carbon to the atmosphere could affect the climate was first described by a Swedish chemist, Svante Arrhenius, in 1896. He understood that carbon dioxide could trap heat reradiating from the earth's surface and predicted that an increase in atmospheric carbon dioxide would result in a warmer climate. Actual atmospheric concentrations of carbon dioxide were measured by Charles Keeling on Mauna Loa in Hawaii beginning in the 1950s. At that time, the carbon dioxide concentration was about 315 ppm (parts per million), up from 280 ppm in preindustrial times. This recording of carbon dioxide concentration continues on Mauna Loa, and today it records 381 ppm. In the summer, there is a slight decrease in atmospheric carbon dioxide concentration as land plants become active and perform photosynthesis (the majority of photosynthesis takes place in the northern hemisphere). In the winter, carbon dioxide concentration rises slightly as plants respire carbon during their nonphotosynthetic period. Such measurements of atmospheric carbon dioxide concentration will be essential as humans continue to burn fossil fuels and emit greenhouse gases to the atmosphere.

Carbon Dioxide (CO_2)

CARBON DIOXIDE (CO_2) is a chemical compound made up of one carbon atom and two oxygen atoms. While it is a trace gas in the atmosphere in terms of volume, it is of central interest to atmospheric chemistry due to its capacity to trap incoming solar radiation in the atmosphere. For this reason, it has become known as a greenhouse gas, where increases of carbon dioxide into the atmosphere cause climate changes, which include global warming. Other greenhouse gases include methane (CH_4), nitrous oxide (N_2O), tropospheric ozone (O_3), halocarbons (CFCs, HFCs, HCFCs), and water vapor (H_2O_v). Carbon dioxide is the principle greenhouse gas that contributes to climate change and global warming, as increases in carbon dioxide have contributed most to climate change compared to other greenhouse gases over time.

Carbon dioxide is part of larger carbon cycles on Earth. All living things are composed primarily of carbon, so the cycling of carbon through the various spheres can provide indications of the health of the planet. Unlike other greenhouse gases, carbon dioxide is not broken down or destroyed through chemical reactions. Aside from time spent in the atmosphere mainly as carbon dioxide, carbon also moves through the biosphere, hydrosphere and lithosphere. For example, atmospheric carbon dioxide is taken out of the atmosphere and up into the biosphere through photosynthesis. The carbon can then stay in this "reservoir" until the forest dies and decomposes, is cut down, or is burned. At this time, carbon is then released again to the atmosphere mainly as carbon dioxide.

There are many reasons why carbon dioxide is so influential in climate change. Among them, carbon dioxide has a long "residence time:" emissions can stay in the atmosphere for up to 200 years. For instance, emissions from a 1911 Model T Ford are potentially in the atmosphere today. This also means that even if all carbon dioxide emissions were halted today, declines in atmospheric carbon dioxide would only begin after the carbon dioxide cycled out of the atmosphere into another reservoir. Furthermore, carbon dioxide is the greenhouse gas most directly responsible for climate change by way of human activities (called *anthropogenic* climate change). This is also called the *enhanced greenhouse effect*. In the climate science community, there is overwhelming consensus that human activity has significantly driven climate changes in the past two centuries.

It is important to understand that there are also natural sources of carbon dioxide emissions. These include plant decomposition and volcanic activity, which contribute to a baseline *natural greenhouse effect* that makes the world habitable. Without them, the earth would on average be about 60 degrees F cooler and the planet would be covered with ice. With this natural greenhouse effect, humans have been able to live and enjoy benefits such as forest and food growth.

Looking more carefully at this distinction in sources of carbon dioxide emissions, climate research has shown that three quarters of atmospheric warming since 1850—the beginning of the Industrial Revolution—has been attributed to anthropogenic sources. These anthropogenic sources include fossil fuel burning (primarily coal, gas, and oil) and land use change. In the United States, roughly a quarter of anthropogenic climate changes can be attributed each to transportation, industry, household use/infrastructure, and land use and land-cover changes.

Current heavy reliance on carbon-based sources for energy has led to significant human contributions of carbon dioxide.

Thus, increases in concentrations of atmospheric carbon dioxide and associated climate changes critically permeate economic, environmental, political, cultural, and societal aspects of life on the planet.

Current heavy reliance on carbon-based sources for energy in industry and society has led to significant human contributions of carbon dioxide, and thus further changes in the climate, such as sea level rise. This particular period of time has been referred to as the Anthropocene Era, or the Age of the Hydrocarbon Human. Measurements over time show that atmospheric carbon dioxide concentrations have now risen to approximately 381 parts per million (ppm), a 36 percent increase from preindustrial levels (around 280 ppm). These data have been aggregated with other climate proxy data—such as ice cores, tree rings, and archaeological information—that help to understand past atmospheric concentrations of carbon dioxide. Together, these have shown that the recent increase in atmospheric carbon dioxide exceeds the bounds of natural variability experienced during the preceding 650,000 years.

Within carbon-based industry and society there are uneven patterns of consumption and consequent carbon dioxide emissions. One way to consider anthropogenic carbon dioxide emissions is on the country level. At this scale, the United States is the world leader, accounting for approximately 25 percent of global carbon dioxide emissions. Related to this, the United States is also the world leader in oil consumption, where 20 million barrels are consumed every day. China follows second, as a large consumer of coal, accounting for about 14 percent of global carbon dioxide emissions. Russia (7 percent), Japan (5 percent), and India (5 percent) are the third-, fourth-, and fifth-largest carbon dioxide emitters, respectively. These five countries are then followed in order by Germany, the UK, Canada, Italy, and South Korea. Emissions are increasing at a faster rate in the global south; left unchecked, many predict that Chinese emissions will surpass those of the United States by 2030. Another way this is considered is through per capita—or individual—carbon dioxide emissions. The United States leads the planet in per capita emissions, with 19.1 metric tons per year.

While China ranks as the second-largest emitter of carbon dioxide emissions, the individual emissions of a typical citizen in China are less than 1/8th that of the United States. The individual emissions of a citizen of Russia or Japan are both about one-half that of a U.S. citizen, while a citizen of India emits less than 1/20th that of a U.S. citizen. This per capita approach provides a much different picture of carbon dioxide emissions. Different perspectives like these can serve to reshape and broaden views on current and future plans for carbon dioxide emissions reductions policies and programs.

Carbon Sequestration

CARBON SEQUESTRATION OCCURS when carbon is removed from the atmosphere, or captured directly from industrial emission sources, and then stored (sequestered) where it cannot readily reenter the atmosphere. Most atmospheric carbon is present in the form of carbon dioxide (CO_2) and methane. Although these gases constitute a minor component of the total atmosphere (less than 0.1 percent of all atmospheric gases), they are among the primary greenhouse gases and contribute directly to global warming.

Burning fossil fuels and converting forest lands to agriculture release large amounts of carbon to the atmosphere and are leading to a rise in atmospheric CO_2 and methane levels. Stabilizing atmospheric greenhouse gas concentrations will require either a reduction in the amount of carbon being released or an increase in the rate of carbon sequestration. Many countries are pursuing both strategies.

There are two different approaches to carbon sequestration: Biological and technological. Both focus on CO_2, which is removed either directly from the atmosphere or at the point of emission and sequestered in a form or location where it is not radiatively active (that is, where it will not contribute to global warming). In some cases, sequestered carbon remains out of the atmosphere for hundreds or thousands of years, while in others the period of sequestration may be relatively short (years to decades).

Biological carbon sequestration takes advantage of the natural carbon cycle, and is primarily concerned with the uptake of atmospheric CO_2 and its storage as organic matter. Whenever photosynthesis (CO_2 uptake) is greater than respiration (CO_2 release), the result is carbon storage.

On land, green plants take up CO_2 through photosynthesis and store that carbon in leaves, stems, and roots. When leaves are shed or a plant dies, that stored carbon is either released back into the atmosphere relatively quickly through the process of decomposition, or it may be sequestered for much longer periods; for example, undecomposed tree trunks, wood products such as lumber, or soil organic matter. The longer the sequestration time, the more valuable the process is for climate change mitigation.

In the ocean, most photosynthesis is done by single-celled algae called phytoplankton, floating near the surface. Phytoplankton grows and dies quickly and much of the stored carbon is released back into the atmosphere when the algal cells decompose. If dead algae sink below the depth where decomposition occurs, however, their stored carbon can be sequestered for long periods as organic matter in marine sediments.

MEASUREMENTS AND PREDICTION

To predict changes in atmospheric greenhouse gas concentrations as a result of fossil fuel burning and deforestation, we need accurate measurements of global biological carbon sequestration. The greater the rate of carbon sequestration, the less rapid the expected rise in atmospheric CO_2. For individual countries and municipalities, quantifying biological carbon sequestration may be important for negotiating carbon emission standards or for validating carbon trading schemes. A variety of methods are used to calculate rates of biological carbon sequestration; these include measurements of carbon in wood, soil, and ocean sediments, measurements of CO_2 concentrations in the air and water, and computer simulations of the carbon cycle.

Strategies to increase biological carbon sequestration by land plants usually focus on increasing the amount of carbon in organic matter that decays slowly. Allowing forests to regrow or planting new forests results in carbon sequestration in wood and in soil. In agricultural lands, conservation tillage (or no-till soil) management practices result in higher amounts of soil carbon. The amounts of carbon that might be sequestered through improved forestry and agricultural practices are potentially quite large, with estimates for the United States of up to 50 percent of its annual fossil fuel emissions. Biotechnology also may play a role in efforts to enhance biological carbon sequestration. For example, the chemical structure of wood can be bioengineered to slow the natural process of decomposition, thereby lengthening the time carbon may remain sequestered in this form.

Technological carbon sequestration involves capture of CO_2 at the point of emission (its conversion to a form that can be transported in pipelines) and its long-term storage underground or under water. Much of the CO_2 emitted through fossil fuel burning comes from stationary sources such as power plants, oil refineries, and other energy intensive industries. Existing technology can be used to remove CO_2 from industrial flue gases and prevent it from entering the atmosphere. Chemical or physical solvents are used to trap CO_2, and CO_2 can also be separated from other gases cryogenically by cooling and condensation. Most CO_2 capture technologies now in place work best with high CO_2 concentration flue gases, however, and may need to be modified to work with the more dilute flue gases from many CO_2 emission sources.

Long-term sequestration of CO_2 captured in this way can be achieved via injection into underground geological formations or into the ocean. Candidate sites for geological sequestration are deep saline aquifers, old oil and gas fields, and coal beds. The potential CO_2 storage capacity of these geological formations worldwide is very large. Due to the costs involved in transporting captured CO_2, however, it is important that potential geological sequestration sites be relatively close to emission sources. Studies suggest that these conditions are common enough that carbon sequestration through capture and storage underground can be an important CO_2 emissions mitigation strategy. Carbon sequestration in ocean waters is theoretically possible, either by piping highly concentrated CO_2 below 1,000 meters where it would remain trapped by the overlying salt water, or by piping it into shallower waters where it would dissolve and disperse. In either case, possible impacts on marine life would be an important concern. For both biological and technological carbon sequestration, the feasibility of any particular approach rests on a complete accounting of the costs (monetary, energetic, and environmental) and benefits (amount of carbon stored and its sequestration time).

Carbon Tax

A CARBON TAX is a market-based instrument (MBI) designed to reduce the severity of climate change. It does so by discouraging the use of energy sources that emit carbon dioxide (CO_2) by making their use more expensive, through economic rather than government regulation. A carbon tax increases the price of CO_2–emitting energy sources, making investments in cleaner, alternative energy generation a more competitive and financially attractive way of generating power.

Many countries around the world have introduced a carbon tax, including Denmark, Switzerland, Sweden, Norway, Holland, Finland, Austria, Italy, and Germany. The German government introduced a carbon tax in 1999 as part of a wider ecological policy initiative that aimed to reduce CO_2 emissions, encourage investment in energy-efficient technology, and provide an economic boost to the German green-goods market. The revenue collected from the carbon tax in Germany has been used to reduce the pressure on other parts of the German economy by lowering the burden of income-related costs such as pension contributions. Socially, this has been particularly important for Germany. Since reunification in 1990, the German economy has endured long periods of recession and high levels of unemployment.

The European Union (EU) plans to introduce an industry-specific carbon tax on airlines in 2008 as part of a strategy to meet targets set by the Kyoto Protocol. Carbon dioxide pollution from aircraft presently accounts for 3 percent of the EU total, and in Britain (where there has been a rapid increase in the availability of cheap air fares), air travel is predicted to account for 25 percent of emissions by 2030.

The Tyndall Centre for Climate Change Research suggests that, unless the United Kingdom drastically reduces the amount of emissions caused by air travel, all householders, motorists, and businesses will have to reduce their CO_2 pollution levels to zero. Otherwise, it is argued that the British government climate change targets will not be met. The EU hopes a carbon tax on airlines will increase the price of air travel sufficiently to discourage its use and encourage people to use alternative forms of transportation.

FAIRNESS OF USE

A carbon tax is a regressive tax, however, which means people on low incomes pay more than those on high incomes because a greater percentage of their wage is consumed by energy and travel costs. The United Nations argues that a carbon tax is an inefficient way of reducing CO_2 emissions in poorer countries because they do not have the capacity to set, monitor, or enforce such schemes.

New Zealand was to implement a carbon tax in 2007, but after the 2005 general election the government abandoned the plan because it was determined to be too costly to implement, and greater cuts in CO_2 emissions could be gained through other schemes, such as carbon sinks.

Carbon Trading

CARBON TRADING DESCRIBES an economic market trading scheme that will encourage a reduction in emissions of the climate-changing gases caused by anthropogenic activities such as the burning of fossil fuels for energy generation. Unlike a carbon tax, which is a rigid market-based instrument that simply increases the cost of emitting carbon dioxide (CO_2), carbon trading allows a more flexible approach.

The most common form of carbon trading occurs within a cap-and-trade environment. A government sets an overall cap on the level of emissions and issues emitters with allowances that can be bought and sold amongst members of the scheme. The scheme works by allowing a company that produces too many emissions to purchase allowances from an emitter that has produced less than their entitlement, thus ensuring the overall emission targets set by a government are met.

Trading in gases that pollute the atmosphere was first trialed in the United States under provisions in the Clean Air Act in 1990 (United States). Known as the Acid Rain Program, the U.S. government imposed a cap on sulphur dioxide (SO_2) emissions from power plants, distributed allowances and the permission of the owners to meet targets by installing new technologies, burning fuels with a lower sulphur dioxide content, engaging in projects that reduced SO_2 emissions from other parts of the economy, or through the trading of allowances between other participants in the scheme. Between the late 1980s and 2000, sulphur dioxide emissions from U.S. industry had been reduced by 5 million tons per year.

The success of the Acid Rain Program provided the United States with a strong argument that trading schemes could successfully reduce carbon emissions and should therefore be employed as a mechanism to reduce CO_2 emissions under the terms of the Kyoto Protocol. Although the United States pulled out of the Kyoto Protocol in 2001, Articles 6 and 17 provide mechanisms that enable member nations to trade greenhouse gases. The Kyoto Protocol allows all greenhouse gases to be traded either directly through the transfer of allowances or through the Clean Development Mechanism. This mechanism primarily allows polluters in the developed world to earn credits for investing either in technologies that lower emissions in developing nations, or through investment in carbon sinks.

BIG PLAYERS IN CARBON TRADING

The United Kingdom (UK) launched the world's first economy-wide carbon trading scheme in March 2002 to help it meet emission targets set by the Kyoto Protocol. Over the first three years of the scheme, CO_2 emissions were reduced by 5.9 million tons. The UK is now part of the European Union Emissions Trading Scheme, which was launched in January 2005. This is by far the world's most ambitious trading scheme, and when fully operational, 12,700 industrial organizations will be able to trade carbon allowances.

Carbon trading also operates at a voluntary level, either directly through company endeavors or through programs such as the Chicago Climate Exchange. In 2000, Canada's second-largest greenhouse gas emitter, TransAlta, released voluntary plans to reduce their emissions of CO_2 to zero by 2024, primarily through carbon trading. The Chicago Climate Exchange is a pilot project that trades CO_2 in a stock market-like environment. Companies trading on the exchange include Rolls-Royce, Ford, New Belgian Brewing Company, Dupont, Motorola, and IBM. Each company trading on the Chicago Climate Exchange has set voluntary targets to reduce emissions by 4 percent of their 1998 to 2000 average by 2006.

Critics argue that carbon trading will not significantly reduce climate gas emissions and will further reinforce social inequalities between the developed and developing world. Carbon trading does not encourage a significant change in polluting behavior by developed nations and excludes most poor countries because they produce very few emissions and thus have little to trade.

The European trading scheme, moreover, does not include emissions from transport or the aviation industry, which together account for 50 percent of their emissions. Russia has also been singled out as a potential problem. Kyoto Protocol targets were set to 1990 levels, and at that time Russia was still part of the Soviet Union and producing massive amounts of climate-changing emissions through energy production in decrepit, coal-fired power stations. Since the collapse of the Soviet Union, Russia now possesses significant carbon credits. Because many of the old coal-fired power stations have been decommissioned, there are fears that if Russia was to trade all of its credits, there could be a significant increase in CO_2 emissions.

Trading via carbon sinks is also seen as problematic. Establishing a carbon sink—such as replanting areas of cleared tropical rainforest—would provide significant biodiversity benefits. There is no sound scientific method of determining precisely how much carbon is sequestered during the growing phase, however, or any political guarantee that the sink will remain in place for the life of the project it was designed to offset.

Carcinogens

CARCINOGENS CAN BE defined as potential cancer-causing agents that are found within our natural (air, water, soil), social (lifestyle and dietary choices, voluntary vs. involuntary exposures), and built (synthetic chemicals, pharmaceuticals, radioactive substances) environments. Carcinogens can induce cancer in an organism and as such, the biological environment (genetics, aging, sex) plays a role in the degree of vulnerability to the carcinogen(s) in question. Bacteria, parasites, and viruses have also been implicated for their role in cancer causation; their impact varies depending on the biological environment.

The most direct method to evaluate the effect(s) of a carcinogen is through the use of animal models.

According to the International Agency for Research on Cancer (IARC), the most recent description of the *categories of agents* includes “both ‘specific’ as well as ‘groups’ of related chemicals, complex mixtures, occupational or environmental exposures, cultural or behavioural practices, biological organisms, and physical agents.” The IARC Monographs provide a complete listing of all of the carcinogens assessed to date.

In an attempt to better understand, potentially lessen, and possibly eliminate human exposure to carcinogens, testing and evaluation of carcinogenic agents are frequently conducted within the field of science. Numerous carcinogens have been assessed by organizations such as the IARC and the U.S. Environmental Protection Agency (EPA). According to J.B. King, there are three main methods for directly testing an agent’s carcinogenic potential in an ethical manner (i.e., not knowingly putting humans at risk of being exposed to carcinogenic agents for experimental purposes). As with any method, each of these tests has its own advantages and disadvantages.

METHODS OF TESTING

The first method of testing is conducted with cultured cells. In order to minimize species variation, human cells can be used. However, when an agent is evaluated in the absence of the complex nature of an entire biological system—as in the case with cultured cells—the metabolic activation of the test agent may not occur, which can result in false negatives. The main objective for using cultured cells is to test compounds by monitoring their effects on the cell functions that are involved in the process of transforming normal cells into cancer cells (i.e., DNA damage).

The second method includes testing on microorganisms. Using this method, scientists can examine the carcinogen’s ability to generate mutations. The Ames test—developed by Bruce Ames in 1975—was the first method to use the bacterium *Salmonella typhimurium*. This bacterium was genetically altered so that it could detect chemically induced mutations. The Ames test is relatively simple to administer and can quickly examine a large number of agents. A limitation with this method is the frequent occurrence of false positive and false negative results. Such inaccuracies can occur because the premise behind this test is that carcinogens are also mutagens. However, this is not always the case. Therefore, the Ames test has been used by many researchers as a screening test for carcinogens prior to testing on animals.

The third and most direct method to evaluate the effect(s) of a carcinogen is through the use of animal models. These tests are conducted primarily to examine the ability of the carcinogenic agent(s) to induce cancer(s) and/or to damage the DNA of animals. However, because humans have different genetic predispositions and are not confined to various controlled environments, they often experience multiple and varied exposures to carcinogens at different doses for various durations and at different points in time throughout their lifetimes. As Curtis D. Klaassen notes, the route of exposure (ingestion, inhalation, absorption, or parenteral), as well as the carcinogen's ability to metabolize in the body, plays a role in the effect the agent has on the body. These factors make it difficult to draw parallel comparisons among humans, let alone between animals and humans.

Nevertheless, animal experiments are the best available method for testing carcinogens to date. Because different strains of the same species vary in their reaction(s) to carcinogens, it has been suggested by King that different species should be used in animal tests in order to fully understand and more accurately classify carcinogens.

To date, the best available approach for understanding human carcinogenic exposure are those methods used in the field of epidemiology. The association between human exposures to occupational carcinogens and cancer can be traced back to the late 1700s, when Sir Percivall Pott recognized the association between exposure to soot among chimney sweepers (which was later identified as benzo[a]pyrene) and the occurrence of scrotum cancer. Since then, numerous occupational epidemiological studies have been conducted in an attempt to better understand human exposure to specific carcinogens. Research has been undertaken using occupational and health records in conjunction with the testing of blood, serum, and other biological samples.

HURDLES TO INVESTIGATION

Nevertheless, there are limitations with these types of studies, because the examination of several exposures (such as those found in the natural, social, and built environments) over one's lifetime are difficult to isolate, despite their critical role in cancer causation. There is also the possibility of delayed effects—or a latency period—between carcinogenic exposure and the manifestation of cancer. This creates further difficulties in the identification of causative agents. Additionally, as Jack Siemiatycki and his associates note, several earmarked "occupational carcinogens" (i.e., asbestos, radon gas, and benzene) are not strictly monitored or measured in the general environment; therefore, one cannot be certain that these presumed occupational carcinogens are in fact solely the result of workplace exposures. This gives rise to concerns on a micro level, such as deciphering the totality of study findings. It also raises concerns on a macro level such as the implementation of stringent policies and regulatory measures as well as social responsibility.

Other epidemiological studies have been conducted in contaminated sites, such as the Hiroshima and Nagasaki atomic World War II bomb sites and the nuclear fallout accident at Chernobyl in 1986. These sites gave rise to an increase of certain cancers, and these populations became of interest to epidemiologists around the world. Numerous human observational studies have been conducted with the populations of these regions in order to better understand deleterious health outcomes as a result of carcinogenic exposures.

Epidemiological studies have been successful at implicating some cultural practices for their role in cancer causation. For instance, Parviz Ghadirian and associates found that in certain regions of Iran, the custom of eating opium dross, as well as the consumption of contaminated bread containing large quantities of silica fibers originating from extraneous seeds used in the bread, have been suspected as the "initiating" carcinogenic factors for esophageal cancer. Additionally, some cooking practices (including inhalation-exposure to cooking fumes, the consumption of charred meat, the consumption of pickled or moldy foods) have been associated with certain cancers.

The use of epidemiological studies to understand carcinogenic agents is not limited to occupational and/or environmental agents. Several viruses and bacteria have also been implicated in cancer causation. For instance, the bacteria helicobacter pylori (h-pylori) has been found to be associated with stomach cancer. Likewise, some studies have linked the human papillomavirus (hpv) to cervical cancer.

Based on a number of different types of studies that examine carcinogenicity, in addition to other relevant data presented, the IARC assesses carcinogenic agents on an ongoing basis. These carcinogens fall into one of four groups, and can move up and down the ranks as new information becomes available. Carcinogens are categorized as "Group 1 when the agent is *carcinogenic to humans*; Group 2A when the agent is *probably carcinogenic to humans*; Group 2B when the agent is *possibly carcinogenic to humans*; Group 3 when the agent *is not classifiable as to its carcinogenicity to humans*; and Group 4 when the agent is *probably not carcinogenic to humans*." The IARC has reviewed almost 900 agents since 1972. In 2002–03, there was some controversy in the literature among several scholars and researchers regarding possible industry influence in the decision-making process concerning some of the carcinogens reviewed. Notwithstanding, there are numerous carcinogens that are yet to be reviewed that we are voluntarily and involuntary exposed to in our environments every day.

Caribbean Sea

LOCATED ADJACENT TO the Atlantic Ocean, the Caribbean Sea covers the majority of the Caribbean Plate. With an area of approximately 1,710,000 square kilometers (1,063,000 square miles), the Caribbean Sea surrounds dozens of islands of different sizes, with Cuba being the largest. Cuba is part of a group of islands known as the Greater Antilles, along with the Dominican Republic, Haiti, Jamaica, and Puerto Rico. The Lesser Antilles includes two arcs of small islands known as the Windward and Leeward Islands. The Caribbean is a mix of independent states, such as Barbados and Trinidad and Tobago, as well as various dependent territories, such as Aruba, Martinique, and the Virgin Islands.

The Caribbean Sea borders a total of approximately 40 nations, depending on how its limits are defined. Mexico's Yucatan Peninsula and the eastern coasts of Belize, Costa Rica, Guatemala, Honduras, Nicaragua, and Panama border the sea on its western edge. South American coasts are found in Colombia, the Guianas (French Guiana, Guyana, and Suriname), and Venezuela. English, Spanish, French, and Dutch are spoken in the Greater Caribbean, as well as Amerindian languages.

The origin of the name *Caribbean* (pronounced kar-*uh*-**bee**-*uh*n) can be traced to the Carib Indians, skilled boat builders and sailors who navigated the sea. The Caribs once lived throughout the Lesser Antilles, but their numbers were greatly reduced in the colonial period. Starting in the late 1400s, the Caribbean islands served as ports for colonial expeditions from various European nations. With the arrival of Europeans, the indigenous populations, such as the Arawak and Caribs, were decimated by introduced diseases such as smallpox. Colonial empires then turned to African slaves to work in plantation agriculture for crops such as sugarcane and bananas until the end of slavery in the 1800s. In modern times, the Caribbean region makes up an important African diaspora.

Since the mid-1950s, there has been a transition from a primary focus on agricultural production to economies oriented around tourism, services, and manufacturing. There is currently an emphasis on the development of ecotourism and improvements to community involvement in existing tourism programs. Tourism in the Caribbean has historically been based from isolated resorts, beaches, or cruise ships, which limits benefit to local people.

Economic assistance from the United States to the Caribbean region was reduced after the Cold War, and European preferential purchases of bananas and sugar are being phased out. These products are central to the economies of several islands. Bilateral and multilateral trade pacts involving the Caribbean are increasingly common as leaders look to improve economic cooperation among the islands and strengthen ties with Latin American countries considered part of the Greater Caribbean. Although the creation of the Caribbean Community (Caricom) began over 30 years ago, with the aim to integrate states of the region, progress toward a Caribbean Single Market and Economy (CSME) has been slow. CSME finally entered into force on January 3, 2006. The Association of Caribbean States, created in 1994, covers a larger area than Caricom. Its goals are to strengthen economic cooperation, preserve the environmental integrity of the Caribbean Sea, and promote sustainable development throughout the region.

The Caribbean faces many challenges. A central problem is an increase in crime, often linked to drug and gun trafficking. The Caribbean Sea lies in a trafficking corridor between South America and the United States. A significant portion of cocaine passing though various ports is distributed and used

Martinique 1902

At 7.50 a.m., on the morning of May 8, 1902, the volcano of Mt. Pelée on the Caribbean island of Martinique erupted. A deadly cloud of poisonous gas descended on the town of St. Pierre. A wealthy planter who was watching the scene, Fernand Clerc, managed to get his wife and children into a carriage and escape into the hills as the final eruption took place and hot ash showered the whole of St. Pierre. This totally devastated the entire town, burning the largely wooden buildings, and killing about 30,000 people who lived there.

Off the coast of Martinique, the *Roraima* from the Quebec Line was moored in the bay, about half a mile from the town. The vessel was showered with volcanic debris and started to burn. Scalding hot ash covered the passengers and crew. Of the 68 passengers and crew, only about 20 survived.

By contrast, most of the people in the town died immediately. When the air cleared, Clerc returned and found only two survivors. One of them was a young shoemaker, Léon Comprer-Léandre, who had, miraculously, managed to find shelter. The other was Auguste Ciparis (of Ludger Sylbaris), a prisoner held on a charge of murder whose lonely cell had only a narrow vent, away from the volcano. He was badly burned, but was released and became “the man who lived through Doomsday” at Barnum’s Traveling Circus in the United States. He was the first black man ever to star in the segregated performances. Some accounts have a girl, Havivra da Ilfrile, surviving, and there was also a woman who survived the eruption but died soon after giving a description of the event. All around the world, French colonies collected money to pay for the rebuilding of St. Pierre. However, the administrative capital of Martinique was moved to Fort-de-France.

domestically. Another problem is extreme poverty in both rural and urban areas. There are wide gaps between rich and poor within and among Caribbean states and territories.

VULNERABLE COASTS AND ISLANDS

A large portion of the Caribbean population lives in the coastal zone, which is prone to damage from hurricanes and tropical storms. Vulnerability in low-lying areas creates concern over climate change, with the potential for rising sea levels. Caribbean islands share several additional environmental problems, such as increased sedimentation in rivers due to deforestation, dredging, and mining. Fluvial sediments often deposit in coastal waters. Water pollution originates from industrial waste, untreated sewage, landfills, and pesticide use. Solid waste in the form of plastic, glass, and metal also harms marine life, such as sea turtles. Caribbean biodiversity loss has led to the creation of new marine and terrestrial protected areas in recent years, but many precious natural resources remain at risk. An unprecedented loss of coral colonies has been attributed to sea temperature increase in combination with disease. Overextraction of fish is another widespread problem.

Carpooling

CARPOOLING OCCURS WHEN a group of people, who live and work near each other and share the same approximate work hours, share a ride to their place of employment. There are a number of environmental, health, economic, and social advantages to carpooling.

Carpooling is an overall effective means of reducing the amount of automobile emissions into the atmosphere, which is a major source of air pollution, particularly in wealthier nations. Automobiles emit five gases linked to global warming (carbon monoxide, carbon dioxide, nitrous oxide, chlorofluorocarbons, and ozone smog). Carpooling can help alleviate air pollution, which in turn contributes to the overall health of individuals. Air pollution can lead to various respiratory ailments, cancer, impaired central nervous functioning and cirrhosis of the liver. In addition, if individuals carpooled on a regular basis, there will be less of a need for individuals with respiratory ailments to avoid time out of doors.

Carpooling also helps the environment by reducing the total number of commuter trips. Each passenger, in addition to the driver, represent one less vehicle trip. If four people drive to work separately, those four cars, making a total of eight trips to and from work, would emit three times the amount of gas emissions into the air. The same four workers, if they carpooled, would make one trip each way, thus cutting down on the total emissions into the air. The long-term environmental benefits are significant. It is estimated that the emissions in the atmosphere today will possibly linger there for more than one hundred years. Limiting the number of emissions in the atmosphere will lessen humans' impact on global warming.

There are economic and social advantages to carpooling as well. Carpooling reduces the amount of money spent by drivers on automobile-related expenditures such as maintenance, parking, and fuel. Thus, carpooling saves consumers' money while it simultaneously creates more space in parking garages and lots. Carpooling also increases the amount of free time that riders can spend on leisure, family, and intellectual pursuits.

Free time is further enhanced by High Occupancy Vehicle (HOV) lanes, which makes time management more efficient along municipal interstates and larger highways. In addition, carpooling allows for commuters to get to know one another, encouraging social interaction. This, in turn, may lead to lowering stress when commuting to and from work.

If carpooling becomes a norm, it will help to reduce society's dependence on fossil fuels. For example, the population in the United States currently consumes over 19 million barrels of oil per day, some of which is used to power automobiles. Ten million barrels of this oil is imported. If fewer automobiles are being driven, oil consumption will decrease, resulting in a reduction in dependence on imported oil. Nevertheless, current levels of carpooling readership are relatively low. It is likely that incentives (like increased numbers of HOV lanes) and increases in gas prices will drive more commuters toward carpooling.

A major source of air pollution is the emissions from automobiles, particularly in wealthier nations.

Carrying Capacity

THE CONCEPT OF carrying capacity has a complex history; the only definition that would capture all of its meanings would be "conveyed or supported by some encompassing context, site, or resource." However, one can distinguish four major types of carrying capacity concepts since the term was coined circa 1845, and it is the variety of more specific meanings—the different Xs and Ys—and their mutual influences over time that has given the concept both its power and its flaws.

MECHANICAL CAPACITY

At its origins, carrying capacity referred to mechanical or engineered attributes of manufactured objects or systems. It arose first in the context of shipping. In 1845, a "tonnage duty" imposed by the Republic of Texas was described as applying to steamboats "according to their carrying capacity only," as distinct from the overall volume of the boats. In the late 19th century, the term was used in this sense in discussions of steam ships, Native American canoes, the British merchant fleet, and as a way of expressing the volume of the world's glaciers. Parallel applications included the carrying capacity of the electric commuter rail system in Paris, measured in people transported per hour; the capacity of lightning rods and transmission lines to carry electricity; and the capacity of irrigation ditches and pipelines to carry water.

Beginning in the 1870s, carrying capacity was applied to living organisms and natural systems, while retaining its literal sense of conveying or transporting something. In an 1873 monograph, The Topography and Geology of Santo Domingo, carrying capacity referred to how much weight the inhabitants' pack animals could haul. In the Botanical Gazette of 1887, the legs of certain bees were said to have a carrying capacity for the pollen of specific flowers. An 1888 article in *Science* referred to the carrying capacity for floodwaters of the main branch of the Atchafalaya bayou in Louisiana. The American Naturalist of 1896 used carrying capacity in relation to the cells through which water moved in cucumber plants.

LIVESTOCK AND WILDLIFE

The second type of carrying capacity concept emerged in the context of livestock in the late 1880s, when the implied subject—the animals that carried freight—became instead the things being "carried" by the land where they lived. Two articles in 1886 referred to "the stock carrying capacity" of New Zealand; in 1889, in *Science*, carrying capacity was explicitly (and without the qualifier "stock") used as a measure of rangeland productivity, in units of sheep per square mile. In essence, the meaning of "carrying" had changed from a literal to a much more figurative sense. This new concept gained momentum due to widespread and severe overgrazing in the American West at the time, and by the turn of the century it was sufficiently well established.

During the 1920s and 1930s, early wildlife managers applied this concept of carrying capacity to game animals and their habitats. Aldo Leopold encountered the term and the concept in 1914–15, when he briefly worked in the Forest Service's Office of Grazing. According to C. Meine, "the discovery would reverberate through his work for the rest of his life," beginning with the infamous collapse of the deer population on the Kaibab plateau in the mid-1920s. The episode, which recurred later in Wisconsin and elsewhere, introduced an additional variable not considered in the livestock context: predators. Leopold's pioneering 1933 textbook, *Game Management,* defined carrying capacity as "a property of a unit of range" that varied in space and time and that could be exceeded during cyclic or irruptive increases in a species's population, resulting in high mortality: "In hoofed animals there is so far no visible evidence of any density limit except the carrying capacity of the food."

NEW POSTWAR DEFINITIONS

After World War II, two additional types of carrying capacity concepts emerged concurrently, with overlapping points of origin but widely divergent audiences and applications. One retained flora and fauna as its object but transformed the epistemological basis of carrying capacity from inductive and applied to deductive and theoretical. The other shifted the object of the concept to humans and expanded its scale to continents and the entire globe, giving rise to the neo-Malthusian sense of carrying capacity that pervades general use of the term today.

In his 1953 textbook, *Fundamentals of Ecology,* Eugene P. Odum observed that populations "characteristically increase in size in a sigmoid or S-shaped fashion … regardless of whether one is dealing with fruit flies in a milk bottle or with fish in a new pond." He defined carrying capacity as the asymptote to which the sigmoid curve converged, an "upper limit" K, where "a more or less equilibrium level is reached." The apparent universality of the sigmoid curve was derived not from field measurements—which Odum conceded were "few, incomplete, and hard to come by"—but from laboratory experiments (with "fruit flies, flour beetles, or other convenient organisms") in artificially optimized environmental conditions of temperature, food, space, and so on. Such conditions were said to reveal the "intrinsic rate of natural increase" of different organisms; differential equations could then be used to infer "the environmental resistance created by the growing population itself, which brings about an increasing reduction in the potential reproduction rate as population size approaches the carrying capacity." Paradoxically, "ideal" environmental conditions allowed carrying capacity to appear as a property of organisms abstracted from any environment. Models could then be developed and tested for single or multiple species.

Odum recognized that his concept of carrying capacity could be applied to humans as well; indeed,

Conceptual Flaws of Carrying Capacity

Except in its earliest, literal sense, carrying capacity has been plagued with serious conceptual flaws due to the contrasting but frequently conflated characteristics of its various uses. Should carrying capacity be understood as a fixed quality (the tonnage of a ship) or as a dynamic one (grass in a pasture)? Is it a function of human technology and adaptation, or of natural processes? Finally, can something discerned at very small, bounded scales—in a Petri dish or a ship, a pasture or a pipeline—be accurately applied at much larger scales?

In both range and wildlife management, carrying capacity begged the question it was intended to address—that is, how many animals a given habitat could actually support. Simply using the term implied that such a number could be determined; but, as R.Y. Edwards and C.D. Fowle aksed, what if the number varied over time? Range scientists have found that many grasslands fail to exhibit relatively stable carrying capacities for livestock, especially in drier and more variable climates. In 1961, H.A. Paulsen Jr. and F.N. Ares, two prominent range scientists, concluded that "Sustained grazing capacity does not exist" on U.S. semidesert ranges in the southwest. Similar conclusions have been reached for large areas of Africa, where efforts to impose stable stocking rates have frequently backfired, both socially and ecologically.

The problem recurs in ecology more generally. Odum's generalized carrying capacity assumed an idealized growth curve and spatial homogeneity, but neither assumption stands up to empirical scrutiny. As K.S. Zimmerer noted, "the assumption of a 'continuing steady-state basis' embedded in the definition of carrying capacity is simply unwarranted." If a Petri dish can be viewed as an environment, then by analogy, so the world's ecosystems as capable of supporting a certain number of organisms—but only by assuming linearity across time and space.

Postwar carrying capacity concepts seem to have blurred into each other, the ecological providing scientific credibility and the neo-Malthusian providing political traction and hyperbole. Many prominent ecologists, such as Paul Ehrlich (1968) and Garrett Hardin (1968), have encouraged crossing back and forth between the two. It is noteworthy that when carrying capacity in its fourth sense first appeared in *Science,* in A.M. Woodbury's 1955 article, "Ecology and the Population Problem," it was placed in scare-quotes, as if the author recognized he was using the term in an unusual, perhaps inappropriate way.

the logistic equation at the basis of his model had its origins in the work of Belgian mathematician Pierre-François Verhulst (1804–49) to model human population growth. Yet the final type of carrying capacity concept differs fundamentally in scale, audience, and application. Ecologist-ornithologist William Vogt published Road to Survival in 1948, in the shadow of the horrors of World War II. Defining carrying capacity as the ratio of biotic potential to environmental resistance ("C = B: E"), Vogt conceded that "the equation finds complicated expression in terms of civilized existence." But he insisted on applying it to continental and global scales:

> The equation is, perhaps, oversimplified, but it expresses certain relationships—almost universally ignored—that every minute of every day touch the life of every man, woman and child on the face of the globe. Until an understanding of these relationships on a world scale enters into the thinking of free men everywhere, and into the thinking of rulers of men who are not free, there is no possibility of any considerable improvement of the lot of the human race. Indeed, if we continue to ignore these relationships, there is little probability that mankind can long escape the searing downpour of war's death from the skies.

It is important to recognize this as a new concept of carrying capacity, even though the idea it expressed was older than the term itself. As early as 1820, William Godwin had attempted to calculate the number of humans the world could support. In his polemical response to Malthus, *Of Population,* Godwin took China as demonstrating the maxima of possible cultivation and population density, which he then applied to the earth's habitable area, arriving at a figure of 9 billion people. Although his estimate may now appear prescient, Godwin was in fact mocking the idea of a determinate number, and neither he nor Malthus ever used the term carrying capacity.

Carson, Rachel (1907–61)

IN 1962, HOUGHTON Mifflin published Rachel Carson's *Silent Spring*. Although the book had received considerable attention prior to its publication, its actual appearance still created a sensation. The book provides a thorough, systematic, and yet passionate expose of the careless uses of chemicals by agricultural and industrial concerns, often in collusion with governmental agencies that were shortsighted in their attempts to promote increased productivity. In particular, Carson highlighted the enormous environmental hazards created by the widespread use of the pesticide DDT. Because of the book's unprecedented impact, the publication of *Silent Spring* has often been identified as the genesis of the environmental movement in the United States.

Silent Spring represented the culmination of Carson's career as a scientist and as a writer. On the basis of three previous books, Carson had earned considerable respect as a scientist and something of a literary reputation as a prose stylist. In *Silent Spring*, she supported her own observations and conclusions with references to the work of a broad spectrum of other scientists. Following its publication, many other prominent scientists came forcefully to her defense when her positions were challenged.

Nonetheless, the chemical industry marshaled its considerable resources to impugn not only Carson's thesis and supporting evidence, but also her character and motives. Carson had taken on the chemical industry at a time when it had achieved an unprecedented importance within the American economy, and the criticism was not unexpected, even though its ferocity struck her and many others as excessive. The attacks on Carson were ultimately counterproductive because they created widespread curiosity about *Silent Spring*, in which Carson's sincerity, clarity, and rationality were persuasively displayed.

Carson was born in 1907 in Springdale, Pennsylvania. Growing up among the Allegheny Mountains, she spent many solitary hours observing the natural world up close and then making precocious efforts to put her observations into words. When she enrolled in the Pennsylvania College for Women, located in Pittsburgh, she initially declared English as her major, but eventually switched to biology, graduating magna cum laude in 1929. She then completed a Master's degree in zoology at Johns Hopkins University and began completing coursework toward a doctoral degree. However, following her father's death, she assumed the responsibility for supporting her mother; about a decade later, following her sister's death, she raised her two nieces. Thus, it became financially unfeasible for her to complete a doctoral degree.

After teaching zoology for five years at the University of Maryland, Carson worked for the U.S. Bureau of Fisheries as an aquatic biologist. One of her major responsibilities involved writing feature articles on the Bureau's activities that could be disseminated to general periodicals and newspapers. Eventually, she began to supplement her income by writing, on her own time, on nature-related topics for major periodicals such as the *Atlantic Monthly* and for newspapers such as the *Baltimore Sun*. One article for the *Atlantic Monthly* prompted Simon and Schuster to offer her a contract to expand it into a book. That first book, *Under the Sea-Wind* (1941), was released shortly before the Japanese attack of Pearl Harbor and was more critically than commercially successful. In contrast, the second volume of what would become a trilogy about the sea, *The Sea Around Us* (1952), achieved great commercial and critical success, spending 86 weeks on the *New York Times* best-seller list and winning a National Book Award for nonfiction. The income from this book permitted Carson to resign from her position with the Bureau of Fisheries in order to concentrate on her writing. She completed the trilogy with *The Edge of the Sea* (1955).

In contrast to the fortuitous circumstances surrounding her contract to write *Under the Sea-Wind*, Carson had considerable difficulty in finding a publisher for *The Sea Around Us*. Therefore, when she initially conceived of the idea for *Silent Spring*, she was hardly surprised when she had difficulty finding a publisher who was interested in the project. Although Carson spent four years writing the book, its publishing gestation stretched over almost a decade. The serialization of parts of the book in the *New Yorker* did much to bring notice to the book in advance of its publication. Ironically, despite the great notoriety that the book brought her, Carson died less than two years after its publication, from breast cancer.

Carter, Jimmy Administration

JAMES EARL ("JIMMY") Carter Jr. (1924–) was the 39th president of the United States and served from 1977–81 as the leader of the Democratic Party. Walter Mondale, former U.S. Senator from Minnesota, served as his vice president. Citizens scarred by the Watergate scandal, which led to President Richard Nixon's downfall and eventual resignation, perceived Carter as exemplifying simple principles of faith and honesty. Carter claimed a desire to restore integrity and morals to the American presidency and politics in general.

In terms of environmental challenges, the Carter administration is notable in its efforts to manage the oil shortages of the early 1970s, which had contributed to persistent levels of high unemployment and inflation in the country. The oil crisis further revealed America's gross reliance on foreign oil. To address this dependence, the Carter administration planned to invest in alternative energies, together with conservation measures and an oil tax. However, this plan was stopped by the U.S. Senate. Public and political will for investment in alternative energy sources were simultaneously dampened by the core meltdown at the Three Mile Island nuclear energy plant in Pennsylvania. Nevertheless, Carter was more successful in his role in protecting 100 million acres in Alaska from land development, and establishing the Superfund to deal with environmental disasters. He also ordered the Tennessee Valley Authority to implement the 1974 Ford Foundation report to become a research-oriented society and initiate conservation techniques. An engineer himself, Carter also boldly challenged the Army Corps of Engineers, pursuing a "hit list" of high impact and expensive dam projects that he intended to derail. This last fight proved too difficult to win, but demonstrated Carter's willingness to go after even the most "sacred cows" in pursuit of environmental protection.

The later part of the Carter administration was marred by international events that overtook the domestic agenda, including the revolution in Iran that led to the captivity of American hostages in the Iranian capital of Tehran and the Soviet invasion of Afghanistan. Though he successfully negotiated arms deals with the Soviet Union, championed human rights internationally, and promoted peace in the Middle East, he lost the 1980 presidential race to Ronald Reagan, former Republican governor of California. Carter's strong record on the environment remains notable however, especially as contemporary American presidents begin to wrestle with the problem of nonrenewable energy dependence, a high-priority problem highlighted by Carter decades ago. Despite the failures of his presidency, Americans have come to admire Carter's post-presidency involvement in various public works through Habitat for Humanity and his role as a peacemaker on the international front. Carter's leadership efforts to secure peace during and after his presidency led to him receiving the Nobel Peace Prize in 2002.

Cash Crop

CASH CROPS TYPICALLY refer to food and nonfood plants whose yields are sold. Also called *export* or *commercial crops*, cash crops are intended to produce income, whereas *subsistence* crops are grown to feed one's family and/or livestock, as well as to use in barter. Cash crops are usually sold as primary commodities. Value-added processing may occur within the country of production, and/or the crops may be transported elsewhere for further processing and packaging.

Examples of cash crops include, but are by no means limited to: Bananas, cocoa, coffee, cotton, cut flowers, grains, sugarcane, tea, tobacco, and tomatoes. Cash crops can be grown in tandem with subsistence foods and one another, but more frequently they are produced in monocultures dependent on capital-intensive inputs of chemical or synthetic fertilizers, herbicides, and/or pesticides. Also, cash crop production requires water supplies (irrigation systems and/or wells), transportation, human labor, harvesting equipment, and land. Some or all of these resources might be diverted from (and thus preclude or limit) other uses. Cash crop production, therefore, has significant environmental impacts.

Cash crops now dominate the agricultural sectors of so-called underdeveloped or third world countries, and with notable social and economic effect. By the latter half of the 19th century, household- and village-level production in those regions became restructured within larger regional systems, colonial states, and world commodity markets. This forced integration of peasants and farm laborers into commodity and financial circuits controlled from overseas undermined traditional food security. In *Late Victorian Holocausts*, Mike Davis invokes a political ecology perspective to argue that it was "subsistence adversity (high taxes, chronic indebtedness, inadequate acreage, loss of subsidiary employment opportunities, enclosure of common resources, dissolution of patrimonial obligations), not entrepreneurial opportunity, that typically promoted the turn to cash crop cultivation."

Money earned from cash crop production during good export years allowed wealthier landowners to pursue crop brokerage, lending at high rates, and investing in rental properties—some of which were acquired from their less successful neighbors. Marginal subsistence producers suffered, and many were forced into circumstances that led to marked declines in their conditions of production and terms of trade. By the late 19th century, millions of agriculturists had been integrated into the world markets, where prices for their commodities were prone to fluctuations based on global supplies and imperial politicking. Further, these agriculturists were made highly vulnerable during natural disasters, such as droughts or floods. As Esther Boserup argues, the emphasis on cash crop production during the colonial era reconfigured divisions of labor among smallholders. Regardless of a society's patterns of labor in subsistence activities, cash crops and their attendant technologies tended to be introduced to men by men, restricting women's roles in this new and increasingly important agricultural activity.

The post-WWII birth and expansion of the United Nations International Monetary Fund (IMF) and World Bank provided additional channels for Western development efforts. Guided by *modernization theory*, IMF and World Bank assistance has promoted large-scale agriculture (cash crop production), industrial development, and further integration of poorer countries into global markets. Cash crop production reorients subsistence-based economies to export for foreign markets, allowing the state and its elites to acquire foreign revenue. When cash crop prices fall due to overproduction, local producers lose money—and possibly their land—while wealthier consumers get a bargain.

If producers follow the logic of economies of scale, cash crop production may then be increased to make up for the decrease in price. This may require better lands being devoted to cash crops, while staple foods are grown on lower quality lands and/or are imported. Environmental impacts of agribusinesses—and thus economies of scale related to cash crop production—include heavier demands on land that lead to deforestation to clear lands for cash crops, loss of biodiversity, decreased soil quality, erosion, increased chemical inputs, and/or pollution, among other problems.

Caspian Sea

THE CASPIAN SEA covers a vast strategic area in central Asia. It is the world's largest inland sea at around 386,400 square kilometers. An immense body of water—with many of the same properties of an ocean—it varies in salinity, climate and temperature from northern to southern latitudes. Before the breakup of the Soviet Union, the Caspian was effectively a Soviet lake, with only the southern strip of coastline controlled by Iran. After 1989 the newly formed, independent countries of Turkmenistan, Azerbaijan, and Kazakhstan all shared the Caspian, vastly complicating the indeterminate legal status of the sea. This legal problem is one of the main reasons for the increasingly alarming environmental crisis affecting the sea and the surrounding coastline. However, a long history of shortsighted exploitation of oil resources remains the main reason for a worsening ecological crisis.

Baku, the capital of Azerbaijan on the Caspian coast, began experiencing serious environmental consequences from oil development as early as 1870. More than a century of urbanization and industrialization in the Caspian zone has made the sea a dumping ground for waste. Even feeding rivers like the Volga bring in thousands of tons of petroleum and nitrate wastes from the sprawling agricultural lands of central Russia every month. Although the fall of the Soviet economy led to some decrease in pollution, new, ambitious schemes for oil production agreed between the various bordering countries threaten to severely worsen the current ecological crisis. The most famous, immediate and pressing consequence of the Caspian's developing ecological and economic calamity is the possible eradication

Caspian Sea Caviar

The sturgeons fished from the Caspian Sea have long been prized for their eggs (or "roe"), which are known as caviar from the Persian word *Khagavar* ("roe generator"). This was prized in antiquity and has long been a term synonymous in Western culture with luxurious living and opulence. Most of the fishermen were Russians or Persians—with both countries having access to the Caspian Sea.

The most popular types of sturgeon are the Beluga, the Ossetra, and the Sevruga, with the rare golden Sterlet caviar being the favorite dish of the Tsars of Russia, as well as popular with the Shahs of Persia, European royalty, and some Soviet Communist leaders. The number of sturgeon in the Caspian Sea has fallen considerably because of over-fishing, and in September 2005, the U.S. Fish and Wildlife Service banned the U.S. import of Beluga caviar from the Caspian Sea in order to try to protect the numbers of sturgeon there.

As the population of sturgeon in the Caspian Sea has fallen, sturgeon from the Black Sea are now caught in larger numbers, although the connoisseurs prefer the fish from the Caspian. In addition, fish farms have been established in France, Uruguay, and off the coast of California. The roe of the whitefish and also the North Atlantic salmon are occasionally used as substitutes when Russian or Iranian sturgeon supplies dwindle.

of the sturgeon catch, which provides almost all of the world's caviar. Pollution, pesticides, and unregulated fishing after the Soviet collapse led to an eightfold decline in the sturgeon catch from 1991–94. The Convention on International Trade in Endangered Species recommended that signatory countries refuse the import of Caspian Sturgeon. The World Wildlife Federation has suggested that the Caspian sturgeon may risk extinction if illegal poaching and consumption of caviar is not reduced.

It is not only sturgeon that may pay the price of uncontrolled petroleum development in the Caspian. Unlike the neighboring Aral—were sea levels have decreased—sea levels in the Caspian have risen dramatically, possibly as a consequence of the unbalanced climatic conditions caused by the drying of the Aral. Farms, industrial plants, and even nuclear power stations built on once-dry ground are being threatened by higher and more vigorous Caspian waves. Other biological products and resources are being sapped as land becomes saturated by oil products and the Caspian becomes more and more of a petrochemical dumping ground. Environmental groups have estimated the natural resources of the Caspian waters to be worth far more than $500 million. Oil production may reap short-term economic benefits for new and struggling post-Soviet nations; but the long-term political, social, environmental, and ultimately economic consequences of unbridled oil development will be severe.

Catalytic Converters

A CATALYTIC CONVERTER is a device that is designed to reduce dangerous emissions from combustion engines such as those used in automobiles. It works by enhancing the combustion of unburned hydrocarbons that would otherwise enter the atmosphere through the exhaust. The closed chamber of a catalytic converter is lined with a substrate of porous material through which the gas is forced to pass. This results in the chemical conversion of carbon monoxide to carbon dioxide, the reduction of nitrogen oxide to its component nitrogen and oxygen, and the conversion of the unburned hydrocarbons to water and carbon dioxide. Releasing carbon dioxide into the air is not beneficial to the environment, but is preferable to the alternative. For example, catalytic converters are credited with having reduced the numbers of accidental deaths and suicides from inhaling carbon monoxide in cars by many thousands.

Catalytic converters are customarily made of steel, but recent research has focused on the use of ceramics and alternative materials that may provide better emission control. This has had some unanticipated consequences; for example, when it was discovered that catalytic converters were found not to work in the presence of lead, which resulted in the abolition of leaded gasoline and concomitant reductions in the negative health impacts caused by the lead. Catalytic converters have been used in North America since the 1970s, and are being adopted in many countries around the world.

The Environmental Protection Agency introduced more strict emissions controls after the 1960s, and by 1975 all new vehicles were fitted with the devices. Catalytic converters may be retrofitted to older vehicles, but this kind of measure can only really be effective as part of an integrated transport and emissions strategy. Many countries have extensive public transport systems with aged or secondhand vehicles such as buses that are significant contributors to emissions.

Research concerning the genuine efficiency of catalytic converters suggests that laboratory conditions testing that approach 99 percent efficiency may dip to around 70 percent in traffic conditions. Consequently, plans to reduce emissions internationally have been undermined by the failure of technology and by the unwillingness of many governments to implement and enforce stringent, but manageable emissions controls. Catalytic converters should also be maintained and serviced properly to ensure optimum performance. This adds a cost to the policing of vehicles, especially since the testing equipment is expensive and many countries have inefficiently policed transportation systems. Nevertheless, the introduction of catalytic converters has made a significant contribution in the fight to reduce air pollution, and most new vehicles are produced with a catalytic converter. Comparatively low-cost versions have been adopted for use with two- and three-wheeled vehicles in countries such as India and China.

Cattle

CATTLE ARE DOMESTICATED bovine ruminants raised primarily for milk, meat, hides/leather, and/or labor. Cattle in many communities around the world symbolize status, as well as serve significant social and ritual functions through exchange as dowries, inheritance, and/or gifts.

The etymology of the term *cattle* underscores the claim that cattle are "wealth on the hoof" to pastoralists, agro-pastoralists, ranchers, and other enthusiasts. The Oxford English Dictionary traces "cattle" to an ancestral word, *catel*, which referred to property, wealth, and capital. Over time, the word became synonymous with moveable property or wealth. By the 16th century, English usage of *catel* privileged livestock, and the 17th century marked the beginning of the usage of *cattle* for livestock, while the Anglo-French *chattel* retained the broader meaning of property or article of property.

Applications of the term *cattle* have varied over time and place. The term *cattle* now typically refers to calves, heifers, cows, bulls, steer, and oxen, thus restricting the term to the bovine genus. But in some localities, the designation of cattle has also included sheep, goats, horses, mules, camels, swine, and other animals.

There are approximately 1.4 billion head of cattle (bovine) in the world today, all of which probably descended from the now extinct aurochs (*Bos primigenius)*. Once widespread in Europe, southern Asia and North Africa, aurochs were domesticated at least 8,500 years ago, during the Neolithic Era. They became of great economic importance to farmers, as the animals provided food for humans, directly through their milk and meat, and indirectly through their labor and fertilizing manure. Because cattle are ruminants, they can digest plant foods that humans cannot. Cattle thus transform areas that are not suitable for farming into productive lands by eating grasses and other high cellulose plants, which they then convert into protein, fat, and other nutrients. Small-scale livestock herding, as practiced by pastoralist populations, has proved well-suited to marginal lands. But, as human populations continue to escalate and the rural poor are pushed from viable resource bases, pastoralists struggle to maintain adequate herds.

Through selective breeding, humans have assisted in modifying the genetic makeup of aurochs's offspring. Today, the resultant cattle have been classified into over 270 breeds, which are typically divided into two major species: *Bos taurus* (European breeds) or *Bos indicus* (zebu breeds). These divisions are oft-contested, but breeders and the livestock industry oversee decisions about when animals constitute a distinguishable breed. Cattle do remain closely enough related to some other Bovids, such as bison and yak, that they can be interbred and produce viable offspring (e.g., Beefalo as offspring of American Bison and domestic cattle).

Despite the seemingly wide variety, certain cattle breeds dominate commercial beef and dairy production, which are in turn dominated by large corporations. As Eric Schlosser describes, the growth of fast food restaurants and franchise grocery stores has encouraged the meatpacking industry in the United States to consolidate to the point that the top four meatpacking firms account for over 80 percent of the cattle slaughtered in the United States. This has deflated prices that ranchers get for cattle and

Certain cattle breeds, including crossbreeds like these calves, dominate commercial beef and dairy production.

forced many ranchers out of the business altogether. For both beef and dairy production, many family ranches and farms have been replaced by Concentrated Animal Feeding Operations, or feedlots. Cattle are bred and fed so that their rates of maturation have increased. The spread of Bovine Spongiform Encephalopathy (mad cow disease) and the overproduction of methane have been attributed to this trend. Such trends are also occurring in many parts of the world, as demands for cattle products increase while per capita holdings decrease.

Following the logic of economies of scale, the desire to increase productivity and profitability in the beef and dairy industries has fueled certain types of biotechnology. For example, in 1993 Monsanto Corporation's bovine somatotropin (rBST), a genetically engineered bovine growth hormone, was approved by the Federal Food and Drug Administration for use in the United States to increase the production of milk in commercial dairy cows. The context for the approval of rBST and the consequences of its uses have remained highly controversial. Still, research focusing on genetic modification (GM) continues, with attempts to produce GM cash crops for cattle feed, GM cows that may present resistance to mastitis or tick-borne diseases, and more.

Center for Disease Control (CDC)

THE U.S. CENTERS for Disease Control and Prevention (CDC), located in Atlanta, Georgia, is one of the 13 major operating components of the Department of Health and Human Services (HHS), the primary U.S. government agency for protecting the health and safety of all Americans. The CDC strives to objectively measure and inform the U.S. public, Congress, partners, and stakeholders about the state of the public's health. Since it was founded in 1946 to help control malaria, the CDC has remained at the forefront of public health efforts to prevent and control infectious and chronic diseases, injuries, workplace hazards, disabilities, and environmental health threats. According to the CDC, it is globally recognized for conducting research and investigations to improve people's daily lives and respond to 21st century health emergencies such as emerging infectious diseases (such as SARS, monkeypox, and pandemic influenza); terrorism; environmental threats (such as hurricanes, wildfires, and toxic chemical spills); and lifestyle choices (such as tobacco use, poor nutrition, and lack of physical fitness).

The component of the CDC that works to prevent illness, disability, and death from interactions between people and the environment is the National Center for Environmental Health (NCEH). The NCEH is especially committed to safeguarding the health of populations that are particularly vulnerable to certain environmental hazards, such as children, the elderly, and people with disabilities. According to the NCEH, its main activities include public health surveillance, applied research, epidemiologic studies, laboratory and statistical analyses, behavioral interventions, operations and systems research, communication and education, standards, and training and technical assistance for officials of state and local health agencies in preventing and responding to public health challenges.

For the past three decades, the NCEH has provided an ongoing assessment of the U.S. population's exposure to environmental chemicals using biomonitoring. NCEH scientists have been determining which environmental chemicals enter people's bodies, how much of these chemicals are present, and how the amounts of these chemicals may be related to health. Chemicals or their metabolites were measured in the blood and urine of a random sample of National Health and Nutrition Examination Survey (NHANES) participants, aged 6–59 years.

A metabolite is a chemically altered form, as produced in the body, which reflects the level of the original chemical of concern. Participants were selected within the specified age ranges to be a representative sample of the U.S. population with respect to gender and race/ethnicity. The environmental chemicals currently being measured by NCEH reflect people's exposures to metals, tobacco smoke, polycyclic aromatic hydrocarbons (PAHs), polychlorinated dibenzo-p-dioxins and dibenzofurans, polychlorinated biphenyls (PCBs), phthalates, phytoestrogens, pesticides, herbicides, and insecticides.

One example of how NCEH's biomonitoring surveillance data serves as a powerful public health tool involves the levels of lead measured in blood before and after the United States began its phase-out of lead in gasoline in 1975. Although the human exposure data collected during the 1976–91 time-frame demonstrated a substantial decline in blood lead levels of the entire U.S. population, certain socio-demographic factors continued to be associated with higher blood lead levels, including younger age, male gender, non-Hispanic black race/ethnicity, and low income level. These data were especially critical due to the neurodevelopmental effects associated with low-level environmental exposure to lead and spurred scientists to scrutinize the environment for other sources of lead exposure.

Marielle C. Brinkman
Battelle Memorial Institute

Central African Republic

FORMERLY KNOWN AS Ubangi-Shari, the Central African Republic (CAR) won its independence from France in 1960, setting off three decades of tumult and military rule. A period of unstable civil government between 1993 and 2003 ended with a military coup and the installation of a transitional government. Barely three percent of the land area is arable, but the economy of the CAR is chiefly dependent on subsistence agriculture and forestry. The agricultural sector accounts for some 55 percent of the Gross Domestic Product (GDP), and the timber industry provides 16 percent of export earnings. Other natural resources include diamonds, uranium, timber, gold, oil, and hydropower, with diamonds furnishing 40 percent of export earnings.

Less than a third of the population lives in urban areas, and industry accounts for only one-fifth of the GDP. Unemployment rate stands at eight percent. The poor infrastructure and transportation systems make it difficult to fully exploit resources. With a per capita income of only $1,100, CAR is the 26th poorest country in the world. Vast inequality exists with the most affluent 10 percent controlling almost half of the country's resources. Despite regular grants from France and the international community, the CAR is unable to adequately meet the needs of the population. The United Nations Development Program (UNDP) Human Development Reports rank CAR 171 of 232 countries on overall quality of life issues.

LANDLOCKED AND FACING AN EPIDEMIC

True to its name, the CAR is located near the geographic center of the vast continent. Landlocked, CAR shares borders with Cameroon, Chad, the Democratic Republic of the Congo, the Republic of the Congo, and the Sudan. The flat to rolling mountainous plateau of CAR gives way to scattered hills in the northeast and southwest. Elevations range from 335 meters at the Oubangui River in the south to 1,420 meters at Mont Ngaoui in the northwest. The tropical climate produces hot, dry winters followed by mild to hot, wet summers. Floods are common throughout the country, and the north is subject to the harmattan, a seasonal hot, dry, and dusty wind that accelerates the pace of soil erosion and desertification.

The CAR population of 4,300,000 people suffers from an HIV/AIDS rate of 13.5 percent. By 2003, an estimated 23,000 deaths had occurred, and another 260,000 were living with HIV/AIDS. The people of CAR are susceptible to certain diseases due to the lack of potable water and proper sanitation. While three-fourths of urban residents have sustained access to safe drinking water, only 61 percent of rural residents do so. No more than 27 percent of urban and 12 percent of rural residents have access to improved sanitation. As a result, residents have a very high risk of contracting food and waterborne diseases, including bacterial diarrhea, hepatitis A, and typhoid fever as well as malaria, a vectorborne disease, and meningococcal meningitis, a respiratory disease. Consequently, residents experience low life expectancy (43.54 years) and growth rates (1.53 percent) and high infant mortality (85.63 deaths per 1,000 live births) and death rates (18.65 deaths per 1,000). On the average, women produce 4.41 children. The low literacy rate (51 percent), particularly for females (39.9 percent), makes it extremely difficult to disseminate information on heath and environmental issues that might bring a halt to the cycle of disease and poverty.

THREATS TO HABITAT AND ECOSYTEMS

In 2006, scientists at Yale University ranked the CAR 86 of 132 countries on environmental performance, above the comparable income and geographic groups. The poor showing was a result of the low score for the category of environmental health. Long celebrated as a major wildlife refuge, CAR is now experiencing major threats to habitats and destruction of ecosystems as a result of deforestation and poaching. Of 209 mammal species, 14 are endangered, as are three of 168 bird species.

As part of the Congo Basin, CAR is home to four floristic domains that include the Sudanopsahellan steppes, the Sudan wooded savanna, the Sudano-Guinean woodlands, and the equatorial forests. Ecologically valuable tropical timber such as Sapelli, Ayous, and Sipo are stripped from the forests as loggers select only the most valuable trees in order to defray the exorbitant costs of transporting timber. By some estimates, nearly a third of the forests have been destroyed in this fashion.

The Ministry of Environment, Waters, Forests, Hunting, and Fishing oversees the implementation and monitoring of environmental laws and regulations in the Central African Republic. The government has divided the country into two action zones. The first of these is concerned with overseeing hunting and conservation activities, while the second is made up of buffer zones that deal with agricultural and industrial activities. Protected zones within the Central African Republic have three classifications: forbidden access reserves, national parks in which no hunting is allowed, and wildlife reserves. The government has protected nearly 9 percent of CAR forests, including such areas as the Dzanga-Sangha Special Dense Forest Reserve. Working with local Non-Government Organizations, these areas generate approximately $200,000 each year from ecotourism activities.

The government of the Central African Republic participates in the following international agreements on the environment: Biodiversity, Climate Change, Desertification, Endangered Species, Ozone Layer Protection, and Tropical Timber 94. The Law of the Sea agreement has been signed but was never ratified.

Central Park (NY)

PERHAPS THE BEST-KNOWN urban park in the United States, Central Park is an 843-acre area located in the center of New York City, offering a sharp contrast to the expansive metropolitan landscape. Central Park's boundaries are marked by on the south by 59th Street (Central Park South), on the north by 110th Street (Central Park North), on the east by Fifth Avenue, and on the west by Eighth Avenue (Central Park West).

The history of Central Park is extensive. Among many lesser-known inhabitants, it was poet and newspaper editor William Cullen Bryant (1794–1878) who in 1844 called for the creation of a public park that would be open to all inhabitants, no matter their social position or ethnic origins. By 1850, most of the city's 500,000 residents lived below 38th Street, several blocks lower than the Park's current 59th street southern border. In 1853, the New York State Legislature approved a bill that designated the future location for a public park. Contrary to popular belief, Central Park was not a genuine forest preserved from urbanization: Before 1850, it combined a treeless, rocky terrain and stagnant swampland that was later to be transformed into a public park with artificial lakes.

In 1857, the commissioners of New York City had organized a public competition for architects to design the project, and received 33 anonymous entries. Finally, architects Frederick Law Olmsted (1822–1903) and Calvert Vaux (1824–95) were chosen to design the Greensward Plan in 1858. Olmsted was inspired by Birkenhead Park, near Liverpool, which had opened in 1847, as the first public park in England. Instead of a square plan as in parks in Paris or Versailles, Central Park was designed with some irregular lines that would seem more natural.

According to scholars Elizabeth Blackmar and Roy Rosenzweig, many people were first opposed to the construction of Central Park, such as the "1,600 poor residents, including Irish pig farmers and German gardeners, who lived in shanties on the site." Some fights even broke out as many farmers resisted. Nevertheless, Blackmar and Rosenzweig acknowledge that "the park first opened for public use in the winter of 1859 when thousands of New Yorkers skated on lakes constructed on the site of former swamps."

However, Central Park did not really emerge from the soil of Manhattan. According to the Central Park Conservancy website, some 500,000 cubic feet of topsoil was carted in from New Jersey, totaling more than 10 million cartloads of material by 1873. Official statistics indicate that there were more than 4 million trees, shrubs, and plants, representing more than 1,400 species, when Central Park was completed in 1878—after about twenty years of work. The Central Park Zoo was created in 1871.

Throughout the years, Central Park has encountered periods of abandon and misuse. From time to time, it was invaded by homeless people who wanted to live on its premises: thousands of victims of the 1930s' Great Depression built shacks in Central Park, which was nicknamed "Hooverville" in reference to President Herbert Hoover (1874–1964). A similar movement arrived in the 1970s, when groups of hippies spent day and night in the park. As the growing occurrence of trash, bugs, and crime became more frequent in the park, other visitors felt uncomfortable with these circumstances, proving that a park cannot be dedicated only to a single group or just for the poorest; but must remain equally accessible to the whole population. This is sharp contrast with 19th century rules, when children needed special written permission to play ball in Central Park.

From the 1960s, Central Park has been a place for demonstrations, philharmonic concerts, rock concerts, and giant gatherings like the visit of Pope John Paul II, who celebrated mass on Central Park's Great Lawn for about 125,000 people in 1995.

New sections appear from time to time in Central Park: A peace park named "Strawberry Fields" opened in 1985 as a memorial for Beatles founder John Lennon (1940–80), who was assassinated just 100 yards away from the park on Central Park West and West 72nd Streets, on December 8, 1980. The memorial's name is a tribute to a Beatles song, "Strawberry Fields Forever," composed by Lennon with Paul McCartney in 1966.

Central Park remains famous because its concept and success have inspired many other cities—like Chicago and Quebec City—to build similar large urban playgrounds since the late 19th century. Some urban parks are larger than Central Park: The Jamaica Bay Park in Queens (also in New York City) and the Fairmount Park in Philadelphia, which is about ten times the size of Central Park.

Central Planning

IN CENTRAL-PLAN ECONOMIES, major policy decisions are made in advance by the government. Most of the central plan economies were socialist or Communist countries such as the Soviet Union, China, and most of Eastern Europe. However, central plans or elements of such plans also appeared in the fascists states of Italy and Germany. The time span of central plans may vary, but three- and five-year plans were the most common in Communist economies of eastern Europe. Decisions in central planning are focused on the volume and growth of production, consumption, and construction. In almost all cases, planned economies existed for a longer or shorter period in Communist countries. Such plans are still coordinating the economies of Cuba and North Korea. Central-plan economies are usually regarded as inflexible systems. However, they gained success in the post-World War II reconstruction. Some eastern European countries, such as Hungary and German Democratic Republic, had limited economic success until the 1970s as a result of economic reforms.

Central-plan economies aim to eradicate unemployment and determine capital investment in certain branches of the economy, such as heavy industry and engineering. Consequently, consumer demand and services play a secondary role in such economic systems. In 1991's *What Happened in Eastern Europe in 1989*, Daniel Chirot described the Soviet system as the most advanced 19th-century economy in the world. While the central-plan economy develops rapidly, it can cause supply problems and lead to shortages of certain consumer goods. In extreme cases, people have had to stand in line for hours to get basic commodities such as bread, meat, and dairy products in central-plan economies. Because the black market was strongly supervised, and smuggling and illegal trade were punished, some Communist countries implemented reforms to address shortages. One of the most successful examples was 1968's Hungary. Direct plans were abandoned, and factories became partly individual market actors with the right to export and make contracts.

Economic theorists point out the frequent shortages and supply problems of central-plan economies. According to Hungarian economist János Kornai, such problems were the result of the unilateral targets of investments, heavy and chemical industry, gigantic electric dams, and large-scale mining projects. Critics of such economic systems point out that one firm was responsible for a particular field of production in central-plan economies. Therefore, only a few varieties of tractors, buses, coats, and refrigerators were available on the market. However, commodities were available on subsidized prices set by authorities and not evaluated by market forces.

The environmental aspects of central-plan production are regarded as quite negative, as they are associated with accelerated development of heavy industry, engineering, and mining. Besides numerous new factories, gigantic infrastructural projects were often carried out to improve energy production. The aims of such plans concerning industrial output might be unrealistically high, accounting for over 10 percent of the annual Gross Domestic Product. The result of such aims is the growth of emissions and different ways of environmental pollution. For example, untreated industrial sewage polluted various waterways and lakes in Communist countries. Lake Baikal in Siberia, the largest freshwater resource on the globe, has a long history of pollution and contains a number of endangered species. The Sulphur Triangle of Czechoslovakia, Poland, and the German Democratic Republic used to be one of the most polluted areas globally. There, heavy industries and mining were concentrated, and underdeveloped technology was combined with high emissions. Air, water, and soil pollution harmed the health of millions in the region.

Various infrastructural projects of planned economies were also heavily debated within and out of country borders. Giant dam projects were in favor of China and the Soviet Union, but appeared also in Eastern Europe as well. The Gabikovo-Nagymaros electric dam project has been one of the most debated large-scale projects of the former Communist countries. The project was built on river Danube between Czechoslovakia (now the Slovakia) and Hungary, and generated mass protest of over 140,000 participants in Hungary before the fall of the Communism. The highly politicized dam issue became the tool of arm-twisting of the opposition of the Communist government.

Chad

IN 1960, CHAD won its independence from France and began a 30-year period of intense civil unrest that included invasions by Libya. Even though peace was declared in 1990, periodic outbreaks of violence continued among rebels in the north. In 2005, amidst claims that Chad was sponsoring rebel fighters in Darfur in western Sudan, guerilla fighters from the Sudan joined northern Chadian guerillas in fighting Chadian government troops, attempting to unseat the controversial President Idriss Deby. Tens of thousands of people in Chad and the Sudan have been killed in the prolonged battle that has spread to other countries including Uganda. Around 250,000 black Sudanese refugees have fled to Chad, but in April 2006, the government threatened to expel them.

Less than 3 percent of the land in Chad is arable, but more than 80 percent of the labor force is engaged in subsistence agriculture and livestock production. Some 60,000 Chadian farmers have been forced to leave their homes to escape violence, diminishing the food supply that is essential to survival for poor Chadians. Oil reserves in southern Chad have been estimated at two billion barrels; and since 2000, foreign investment in the oil industry has boosted the struggling economy. Other export products consist of cotton, cattle, and gum Arabic.

Despite increasing oil revenues, Chad is still heavily dependent on foreign aid and investment capital for survival. However, in January 2006, Paul D. Wolfowitz, the president of the World Bank, suspended all loans to Chad when the government backed down on its promise that most of the revenues from the controversial Chad-Cameroon pipeline would be used for poverty reduction. With a per capita income of $1,800, Chad is ranked 185 of 232 countries in world incomes. Eighty percent of the people live on less than $1 a day in abject poverty, and 34 percent are seriously undernourished. The United Nations Development Program (UNDP) Human Development Reports rank Chad 173 of 232 countries on overall quality of life issues.

Landlocked, Chad shares borders with Cameroon, the Central African Republic, Libya, and Nigeria as well as a 1,360 kilometer border with the Sudan. The broad, arid plains of central Chad give way to desert in the north, mountains in the northwest, and lowlands in the south. Elevations range from 160 meters at Djourab Depression to 3,415 meters at Emi Koussi. Southern Chad experiences a tropical climate, but the climate of the north is desert. In addition to petroleum, Chad's natural resources include uranium, natron, kaolin, fish in Lake Chad, gold, limestone, sand and gravel, and salt. Locust plagues and droughts may occur throughout Chad, and the north experiences the harmattan, hot, dry, dusty season winds that serve to speed up the processes of soil erosion and desertification.

The inability of the Chadian government to guarantee adequate supplies of potable water and proper sanitation facilities in rural areas creates an environment in which disease and soil and water pollution flourish among the population of 9,900,000. One-fourth of Chadians lives in urban areas, where 40 percent of the residents have access to safe drinking water. In rural areas, less than a third have such access. While 30 percent of urban residents have access to improved sanitation, rural residents have no access at all. Consequently, Chadians have a very high risk of contracting food and waterborne diseases, including bacterial and protozoal diarrhea, hepatitis A, and typhoid fever, as well as vectorborne diseases such as malaria and respiratory diseases such as meningococcal meningitis. Chad suffers from an HIV/AIDS rate of 4.8 percent that has killed 18,000 people. It is estimated that 200,000 are currently living with the disease. Because Chadians are so vulnerable to disease, the country experiences low life expectancy (47.52 years) and population growth (2.93 percent) and high infant mortality (91.45 deaths per 1,000 live births) and death rates (16.38 deaths per 1,000 population). Chadian women give birth to an average of 6.7 children. The people of Chad speak three of four major African languages, and the population lacks cultural cohesion. Only 56 percent of males and 39.3 percent of females over the age of 15 can read and write either French or Arabic. These factors combine to limit the dissemination of health and environmental information.

A NASA dust storm image over Chad reflects the hot, dry, seasonal winds that speed up desertification in the north.

MISERABLE ENVIRONMENTAL RECORD

In 2006, a study by scientists at Yale University ranked Chad at the bottom of 132 countries on environmental performance with scores drastically below the comparable income and geographic groups. Particularly low scores were received in the areas of air quality and water resources, and Chad received no points at all in the category of environmental health. Just over 10 percent of Chad's land area is forested, but the government has protected only 0.1 percent of total land area. Of 134 mammal species identified in Chad, 17 are endangered, as are five of 141 bird species. About two-thirds of the land area in Chad is covered by desert, and the desert is expanding by three to five kilometers each year.

The international community is assisting the government of Chad in poverty reduction efforts. Under the guidance of the Ministry of Environment and Water and the Ministry of Land Management, Urbanism, and Habitat, environmental initiatives include the Project for Conservation and Management of Natural Resources and the UNDP-financed Integrated Plan for Water Development and Management. Such measures are designed to promote sustainable development and management. The Chadian government has ratified the following international agreements on the environment: Biodiversity, Climate Change, Desertification, Endangered Species, Ozone Layer Protection, and Wetlands. Agreements on Law of the Sea and Marine Dumping have been signed but not ratified.

Chang Jiang (Yangtze) River

AT 3,937 MILESLONG, the Chang Jiang is the third-longest river in the world and the longest river in Asia. It has its source some 16,000 feet high in the Kunlun Mountains, and flows across seven Chinese provinces (Qinghai, Yuanan, Sichuan, Hubei, Auhui, and Juangsui) before it empties into the East China Sea, just north of Shanghai. With more than 700 rivers and streams flowing into the main channel of the Chang Jiang, the river system drains more than 695,000 square miles.

It deposits about 6 billion cubic feet of silt onto its floodplain, where about half of the foodstuffs consumed by China's billion-plus people are grown, including a large percentage of the nation's rice, wheat, barley, corn, and beans. Some 350,000 million Chinese live on lands drained by the Chang Jiang River system, and there are almost 30 major cities along the river. In addition to Shanghai, the most significant of these cities are Nanjing, Hankow, and Chongqing.

The Chang Jiang is the major artery for the transportation of goods between the Chinese interior and the coast. Ocean-going vessels can navigate the Chang Jiang up to 600 miles from its mouth, and it is navigable by river steamers for another 400 miles. In addition, the Chang Jiang system is connected to the Huang He (or Yellow) River system by the Grand Canal. Because of the volume of its flow, especially during the monsoon season, the Chang Jiang has been prone to recurring, disastrous flooding. In 1911, more than 100,000 people died because of the flooding; in 1931, 145,000; in 1935, 142,000; and in 1954, 30,000. Although the loss of life from such floods has been greatly reduced in recent decades, the property loss and economic disruption has remained high. Severe flooding also occurred in 1981 and 1998.

In part to control this flooding and in part to provide hydroelectric power to fuel China's dramatic economic growth, the Chinese government has undertaken one of the greatest construction projects in history on the Chang Jiang. When it is completed in 2009, the Three Gorges Dam will be 600 feet high and 1.5 miles long. When fully operational, the hydroelectric plant at this dam will provide the equivalent of one-ninth of China's total production of electricity in 2000. The dam has had its critics. It lies along a well-known earthquake fault. Moreover, the heavy silt carried by the river may prove a chronic problem for the hydroelectric turbines and may build up behind the dam and actually exacerbate the flooding dangers. The lake that forms behind the dam will cover 80,000 acres of farmland and 140 towns and villages. In all, some 1.5 – 2 million people will be forced to relocate, along with about 1,600 industrial plants. Ecologically, the dam may greatly reduce the number of species in one of China's richest ecosystems. Of particular concern are those species found only in the river basin, most notably river dolphins, alligators, and paddlefish named for the river.

Chaos Theory

CHAOS THEORY DERIVES from physics and mathematics, and is a form of systems theory that seeks to describe highly complex and disordered systems, such as the atmosphere; although some attempts have been made to apply chaos theory to both the social and ecological sciences. The theory states that complex and seemingly chaotic systems, whose structure cannot be described by linear mathematics, are actually underwritten by orderly processes, an idea that has been termed *deterministic chaos*. The theory utilizes nonlinear mathematics to describe these systems, and attempts to understand change in terms of the values that the variables take on, in contrast to the related complexity theory, which seeks to explain change in terms of variability from outside the system in question. In rejecting linearity, both chaos and complexity theory have replaced the classical notion of linear causation with the idea of *self-organization*, in which the individual components of the system are viewed as independent agents (as opposed to independent and dependent variables) that spontaneously rearrange themselves according to their individual properties and external conditions.

VARIOUS TYPES OF ATTRACTORS

A system, according to chaos theory, can exhibit either some pattern of stability or order according to some range of values that its variables can take, or be driven into chaotic behavior based on another set of values of the variables. That the chaotic behavior arises as a function of the defining equations and the values of its variables illustrates the idea of *deterministic chaos*. The set of values for the equation that produce stable results are termed *attractors*. A perfectly stable system that never varies from its steady state would have its equation graphed out such that it would be a point (the trajectory of values never deviates the initial values); such a set of values is termed a *point attractor*. A homeostatic system, one that deviates from its original state but that is brought back to its original state, has its trajectory of values following a toroidal trajectory, forming what is known as a *toroidal* or *doughnut attractor*. In illustrating the differences in explanatory power that chaos theory offers in explaining systems behavior, what is usually depicted is the *butterfly* or *Lorenz attractor*. With this attractor, a system will follow a toroidal path for a given set of values, but small variations can cause the system to shift into an alternative toroidal trajectory. That is, the equation describes a system with two homeostatic pathways possible, with small changes at a critical moment causing them to switch between stable trajectories. The resulting graphed trajectories appear to be two adjacent and linked *toroidal attractors*, vaguely resembling the wings of a butterfly, hence the name *butterfly attractor*. Higher order attractors, with three or more stable states, are possible as well. The set of values that drive the system into chaotic behavior are termed *strange attractors*. The trajectories followed by the equation under the conditions of strange attractors often exhibit recursive self-similarity (*fractal structure*).

THE BUTTERFLY EFFECT

Both attractors and *strange attractors* illustrate another important concept in chaos theory, this being *sensitivity to initial conditions*. Very minute changes in value for the variables could cause an orderly system to switch between stable states, as in a Lorenz attractor. Alternatively, these minute changes in values could drive the system into chaotic behavior, as in strange attractors. This idea of sensitivity to initial conditions has been popularized as the *butterfly effect*, which basically states that the minute turbulence produced by a butterfly flapping its wings in one location could make the difference between pleasant weather and violent storms elsewhere on the planet. *Sensitivity to initial conditions* is a concept that chaos theory shares with complexity theory; although the two differ, in that chaos theory views this sensitivity to be endogenous to the system, whereas complexity theory tends to stress the sensitivity of its component variables to exogenous noise. Chaos theory is broadly concerned with describing closed systems, whereas complexity theory tends to view systems more openly.

Chaos theory has found only limited application to ecological systems. Robert May is generally credited with first using nonlinear equations in an ecological context in 1974. He applied these nonlinear equations in describing the dynamics of population growth, using the growth rate, carrying capacity and population as the only variables. He discovered that by varying the growth rate, a variety of responses in the population could be attained, with stable populations occurring at low rates of growth,

Damselfish Study

A study of fluctuating damselfish populations—a marine species that spawn on a monthly cycle and whose eggs hatch with the full moon—were found to fluctuate dramatically from month to month, and were not predictable in either linear or nonlinear population growth models according to standard population growth or predator-prey relationship models. Rather, researchers found that variations in exogenous factors such as winds and currents played a crucial role in the survival of damselfish hatchlings, and that when these were factored into the equations, the populations followed nonlinear dynamics. That is, the sensitivity driving chaotic fluctuations did not arise from the population variables themselves, as chaos theory would assert, but rather arose due to sensitivity to environmental noise (exogenous factors). These results are more in line with the predictions of complexity theory.

stable cycles of population levels occurring at moderate levels of growth (with periodicity of the cycles increasing as the growth rate increases), and finally with chaotic fluctuations occurring above a high threshold of the growth rate. That the equation can give various stable conditions or be driven into chaos due to sensitivity to one of its variables is consistent with chaos theory.

DETERMINISTIC CHAOS IN ECOLOGY

Subsequent research looking for deterministic chaos in ecological contexts typically focus on fluctuations in species composition, especially as situated in trophic structures. For instance, classic studies of snowshoe hare populations—which fluctuated in phase with the population of its predators, leading to the formalization of predator and prey relations—were re-examined in light of non-linear dynamics, and were found to vary according to both their food supply as well as to predator populations. Although *deterministic chaos* has been demonstrated in the laboratory setting for fluctuating populations, it has been more difficult to demonstrate in nature. This difficulty arises in no small part to a paucity of appropriate data; since a proper analysis would require monitoring the population of the species in question, its population of food species, population of predator species, and relevant environmental variables over a number of decades—and such extensive datasets are rare. Furthermore, natural systems appear to select for inhibitors; measured population growth rates are rarely high enough to initiate chaotic behavior in their descriptive equations.

The endogenous deterministic chaos predicted by chaos theory is characteristic of closed systems, and has largely only been demonstrated in laboratory settings. The climatic and atmospheric sciences have utilized chaos theory, however, since the atmosphere is largely a closed system when viewed as a whole. Although the social sciences have also begun to utilize both chaos and complexity theories, the area of human-environment interactions has largely been overlooked, but is an area that is drawing increasing attention from researchers.

Chavez, Cesar (1927–93)

A MIGRANT FARM worker in his youth, Cesar Chavez (1927–93) went on to become one of America’s most legendary labor leaders and a heroic icon for Latino/Chicano civil rights. Chavez's activism began in 1952 as an organizer for Saul Alinsky's Community Services Organization, when he became its general director in 1958. In 1962, along with Dolores Huerta, Chavez co-founded the National Farm Workers Association, which grew to become the United Farm Workers Organizing Committee, AFL-CIO four years later. In 1972, the organization was chartered as an independent affiliate of the AFL-CIO, and was renamed the United Farm Workers of America (UFW). Until his death, Chavez served as the UFW's president and was its most public representative and spokesperson.

TRANSFORMING MIGRANT LABOR

Through Chavez's work, farm workers and migrant labor were transformed during the 1960s and 70s into a powerful political force for La Causa, or The Cause, a movement for progressive social change that continues to this day. In 1965, the UFW began its successful five-year-long Great Grape Boycott against table grape purchases in order to raise awareness of poor working conditions in the vineyards. During this time, Chavez successfully allied a variety of labor unions, student groups, minority organizations, religious and governmental leaders, as well as consumers nationwide in joint protest; and Chavez undertook the first of a series of long hunger strikes that cemented him in the public's mind as a nonviolent campaigner for justice in the tradition of Dr. Martin Luther King, Jr. and Mahatma Gandhi. Inspired by Gandhi, Chavez maintained a deep spiritual concern for peace and became an ethical vegan when he realized that the principle of nonviolence mandated kindness and compassion toward all beings in a civilized society. In this respect, Chavez's influence on the UFW can still be seen today in the organization's commitment to fighting for farm animal welfare alongside its concerns for social justice and improved farm working conditions.

Under Chavez, the UFW targeted environmental racism against America's migrant farm workers. Beginning in the 1960s, Chavez introduced health and safety provisions into contract negotiations and led activist campaigns against the irresponsible use of toxic pesticides by the agricultural industry, citing the danger to farm workers who were routinely sprayed with large amounts of pesticides while working in the fields. Further, Chavez noted how large pesticide clouds entered into farm workers' communities, thereby exposing workers' families to hazardous pathogens. In his view, this constituted an intolerable systematic poisoning of people in the name of agribusiness profit and efficiency. In response, the UFW filed lawsuits on behalf of workers' right to know information relating to pesticide use, and litigation was also pressed to place bans on certain pesticides, especially DDT. For the DDT lawsuit, Chavez teamed the UFW with California Rural Legal Assistance and the Environmental Defense Fund, a major legal organization within the environmental movement. This legal action formed the basis for an eventual governmental ban on the use of DDT.

Chavez is recognized as a political leader who successfully linked labor, civil rights, and environmental issues, and contributed to the growth of the environmental justice movement, which seeks to eradicate the toxic burden that falls upon people of color in the United States.

Chemical Additives (in Foods)

VARIOUS REASONS EXIST for adding chemicals of different types to food, including the preservation of perishable items, flavor and color enhancement, and the inhibition of growth of undesirable bacteria or mold. The practice of adding chemicals to food has a long and mostly successful history; without such practices as salting and pickling, the inhabitation of many lands such as Britain, where the winter climate prevents food gathering for many months, would have been impossible. The majority of these processes relied upon natural substances and methods that are perfectly harmless and beneficial. However, particularly in the pre-modern age, chemical reactions were largely unpredictable, and harmful effects, poisoning, and illness were possible. As the number of food products have multiplied in the modern world and become subject to intensive agriculture and processing, the possible health implications of additives have also multiplied. It has become a complex and lengthy process to ensure government approval of additives, while also requiring regular monitoring of existing additives.

TESTS, LABELS, AND ADDITIVES

Testing on both laboratory animals and nonliving tissue is routinely required before such approvals are awarded. Scientists must consider not just what is a safe level of intake of the additive in a single helping, but also what may be ingested by heavy consumption over a substantial period of time. An acceptable level of noneffect (NOEL, or no-effect level) can be divided by 100 to determine a suitable daily dose. Some types of food dye have, as a result, been found to cause cancers under some conditions and have subsequently been withdrawn. Similarly, some chemical additives have been linked to conditions such as attention deficit disorder and hyperactivity in children. As standards of health care have improved, many illnesses that previously led to serious, negative health impacts have been eradicated or controlled, so the impact of what would have been considered less-important effects have become evident. At the same time, apparently new forms of allergies are becoming manifest or more obvious and, consequently, food producers are more careful in labeling and packaging their products to ensure that they comply with national and international regulations, and protect themselves from litigation.

In some cases, states have taken the decision to add chemicals to basic foodstuffs in order to promote positive health outcomes. Such cases have included the addition of vitamins, iodine to combat goiter, and fluoride to improve dental health.

However, many food additives often have little to do with health or nutrition, even though they have enabled low-fat or supposedly "healthy" products in many categories. Additional reasons include the use of coloring to disguise the unattractive results of processing. Such processes change people's expectations of food from its natural state, even though there may be perfectly valid and even health-promoting reasons for changing the food. Even when evidence of negative health effects associated with additives is unclear—as is the case with monosodium glutamate, widely used as a flavor enhancer—consumer pressure is increasing to ensure that retailers disclose the use of such additives and provide additive-free alternatives when requested. Many exotic flavorings and colorings are now sourced in tropical lands such as the Philippines, where they have come to represent important export industries and provide another reason to document and maintain the existence of often little-known flora and fauna.

Chernobyl Accident

ON APRIL 26, 1986, the worst accident in history at a nuclear power plant occurred at the Chernobyl power station near the town of Pripyat, about 70 miles north of Kiev in the Ukraine. Reactor 4 of the complex exploded, creating an inferno that spewed massive amounts of radioactive particulate matter into the atmosphere. The Soviet authorities responded by dumping boron and sand onto the inferno by helicopter. After the fire had been contained, the ruins of the reactor were encased in a thick shell of concrete. The destroyed reactor was a Soviet RBMK model, which was notorious for its design flaws. Worst of all, because the power plants with RBMK reactors were designed to permit reprocessing of fuel rods for military applications, it was not possible to provide them with the containment shells that are standard in Western plants. In addition, the staff at the Chernobyl complex was not sufficiently familiar with the intricacies of the RBMK reactors, or even with nuclear power plants. On the night of the accident, the staff attempted to power down Reactor 4 in order to conduct a safety test. However, prior to conducting the test, they disabled many safety features and proceeded despite clear indications of accelerating irregularities within the reactor, precipitating the meltdown in the core that was the source of the explosion.

Official Soviet accounts differ significantly from other sources in calculating the manifold effects of the disaster. Between 31 and 70 people died, either in the explosion or because of their exposure to massive amounts of radiation in the efforts to extinguish the fire. Some 800,000 workers, about half of them military personnel, were involved in the effort to seal the ruined reactor in concrete. Because half of these workers were from the Ukraine and the rest were from all corners of the former Soviet Union, it has been almost impossible to trace the health effects of their exposure to the Chernobyl complex. Investigators have estimated that about 15,000 of these 800,000 workers died in the decade following the disaster.

CANCER DISASTER

The population in the immediate vicinity and downwind of the plant experienced unusually high incidences of cancer. For instance, within a decade of the accident, more than 4,000 children who had lived in the vicinity of the plant were diagnosed with thyroid cancer—though the official government report on the health effects of the disaster have indicated just nine fatal cases from thyroid cancer among the affected children. It is expected that in the future, unusually high rates of other cancers, in particular leukemia, will become evident among adults in the affected region. Soon after the accident, an area 18 miles away from the Chernobyl complex was declared an exclusionary zone, off limits to all but those who continued to work at the complex, where the other three reactors continued to operate for some time after the ruined reactor had been sealed off. Because the Chernobyl complex is located only 10 miles from the border with Belarus, the most severe downwind contamination occurred there, not the Ukraine. In all, about 135,000 people were permanently relocated out of the most badly contaminated areas, while another 270,000 people have continued to live in areas with identified radiation hazards. Despite predictions of nightmarish medical consequences from this widespread exposure to high doses of radiation, the health effects have thus far been more anecdotally frightful than statistically catastrophic.

Radioactive fallout from Chernobyl was tracked across eastern Europe and Scandinavia and eventually to the eastern United States. But the damage caused by the fallout beyond Belarus and parts of western Russia was, for the most part, relatively negligible. Exceptions have included populations such as the Laplanders of northern Scandinavia, whose nutritional reliance on their reindeer herds, in which certain isotopes have become concentrated, has placed them at an increased risk. One of the most contaminated areas near the Chernobyl complex was the so-called Red Forest, where the radiation damage caused pine trees to turn red as they died. This entire forest, covering several squares miles, was buried to reduce the surface radioactivity of this "hot zone" to less dire levels. Ironically, although there has been evidence of damage at the chromosome level in the tissues of sampled wildlife, the enforcement of the exclusionary zone around the plant has amounted to the creation of a wildlife sanctuary in which the numbers of many species have dramatically increased.

Chiapas

THE STATE OF Chiapas is located in the southern part of Mexico, where it has a long coastline on the Pacific Ocean. It borders Guatemala on the east, and the Mexican states of Tabasco to the north, Veracruz to the northwest, and Oaxaca to the west. It has a land area of 28,528 square miles (73,887 square kilometers), which is smaller than South Carolina but resembles in shape. Its population in 2005 was 4,200,000, making it the seventh most populous state in Mexico. Chiapas is located in a tropical area with periods of high rainfall. In the northern area, near Teapa on the border with Tabasco, rainfall has averaged 118 inches (3,000 millimeters) per year. The area was previously dominated by rainforests; however, wide areas have been cut to make way for farming and ranching. The geography of Chiapas in the southwestern area on the Pacific Coast is a lowland area with very fertile soil. The southeastern coastal region of Soconusco is tropical and extensively farmed, with plantation crops of bananas and coffee.

With a population in 2005 of 4,200,000, Chiapas is the seventh most populous state in Mexico.

The Altos de Chiapas (Chiapas Highlands) is a high plateau in the central part of Chiapas. It contains seven parallel mountain ranges where the elevations provide a temperate climate, with frequent fogs watering cloud forests. The cloud forest Reserva de la Biosfera el Teiunfo has many horned ugans and quetzals. The rainfall decreases in Chiapas from east to west and south. However, even on the shore of the Pacific Ocean, the rainfall is abundant.

The highlands have steep mountainsides, with a rocky soil that is too thin and poor to support agriculture. The Lacandon rainforest is a jungle area with a soil that, even with modern fertilizers, would be unproductive. The several Mayan tribes have long practiced farming using slash and burn agriculture (swidden). They rotate the areas that are cleared from pristine forests or from older fields, creating a sustainable agriculture. Illegal logging, hunting, and oil exploration are threatening the area's rich biodiversity.

Notable ecological landmarks in Chiapas include the Lagunas de Montebello, located near Comitan. The Blue Waterfalls (Cascadas de Aqua Azul) are near Palenque, which is one of the most important ruins of the Mayan Indians of pre-Columbian times. Another important site in the Lacondon rain forest is Bonampak, which has the best-known Mayan murals. In 1994 an insurgency began between the Mexican government and the Zapatistas (Zapatista Army of National Liberation). The Zapatistas (EZLN) took their name from Emiliano Zapata

(1879–1919), a populous partisan who led a violent land reform movement until he was killed. The Zapatistas have established some autonomous "Zapatista municipalities" in several areas, and claim that the Mexican government neglects its people, especially Mayan Indians. The Zapatistas also point to a history of environmental exploitation and neglect in the region and include a series of sustainable agricultural and conservation issues to the planks of their governance structure in the region.

Chile

THE REPUBLIC OF Chile is a developing country in South America that has undergone many political, social, and economic transitions since becoming a democratic state in 1989. Known for its spectacular natural beauty, Chile has a varied landscape that is dotted with the Andes mountain range, the Atacama Desert, diverse forests, rich agricultural land, glaciers, and coastal environments. With a population of over 16 million inhabitants, this country has taken great strides to alleviate poverty and incorporate itself into an increasingly globalized world. A country desperate to achieve rapid economic growth and development, it initially paid little regard to the environmental consequences that would arise with such progress. This resource-rich country adopted aggressive neoliberal policies in its post-dictatorial phase, which led to impressive growth rates, macroeconomic stability, and reductions in poverty. Due to these key advancements, Chile is often praised as a model for other Latin American countries. Nevertheless, there have been troubling environmental and social repercussions as increasing pressures have been exerted on natural resources in pursuit of economic gains.

The country's forests, agricultural lands, fisheries, and minerals have been exploited to such an extent that massive degradation and ecological destruction

Valparaiso

The port of Valparaiso in Chile is located on the Pacific coast, some 71 miles northwest of Santiago, Chile's capital. Valparaiso is now an important cultural center—in 2003 it became Chile's "Cultural Capital"—and it is also a U.N.E.S.C.O. World Heritage site.

Valparaiso was a small port during the Spanish colonial period, and became the main port for the Chilean Navy after independence in 1818. It attracted many foreign ships, especially English, French, German and Italian. Soccer was first introduced to Chile by English migrants in Valparaiso. Many important political figures were born in the city, including Chilean presidents Salvador Allende and Augusto Pinochet, and Australian prime minister Chris Watson. Chilean poet and diplomat Pablo Neruda, and Nicaraguan poet Rubén Dario, both lived in Valparaiso.

Of particular interest, in terms of its layout, is that the city covers a very small flat piece of coastline, with much of the city on steep hills and cliffs. As a result, roads have sharp inclines, and advertisements for S.U.V.s in Chile frequently show them negotiating the streets of Valparaiso. Although there is a small tram service covering the immediate port area, funicular railways provide transportation, and there are countless pathways and alleyways between houses for taking shortcuts. This means that tourists, who often cannot easily negotiate the labyrinthine streets, find themselves exhausted as they make their way from cruise-ships to important tourist sites such as the house of Thomas Cochrane, founder of the Chilean Navy; the Chilean Naval Museum; and the Protestant Cemetery.

have compromised these ecosystems and biodiversity. High rates of air pollution attributed to copper mining and vehicle emissions have posed serious health threats to a large percentage of the Chilean population. Pesticide use and other waste products have put water quality at risk, and overharvesting of fish species has led to stock depletions. Native forests face heavy deforestation as well as loss of plant and animal species diversity. With these resources at risk, the poor are especially vulnerable because they largely rely on these resources to support their livelihoods. Also, most of the accumulated wealth has remained concentrated in the hands of the elite, further widening disparities and tensions between rich, poor, marginalized, and indigenous groups. The indigenous Mapuche Indians have suffered tremendous injustices, experiencing discrimination and loss of land to forestry and energy companies. They are well known for their aggressive struggle to reclaim land rights in order to preserve their culture and heritage. International attention has put these social and environmental issues in perspective.

INTERVENTION FOR THE ENVIRONMENT

After years of neglect and abuse, international pressure forced the Chilean government to acknowledge the need to mitigate detrimental practices by establishing proper environmental legislation and institutions. It was understood that the economy could not grow, let alone be sustained, if resources were in jeopardy and unsustainable practices were continued. In 1994, the General Environmental Framework Law came into place with its three sustainable development tenets revolving around environmental sustainability, poverty alleviation, and equitable growth. At the same time, the decentralized National Environmental Commission (CONAMA) was formed to take on the responsibility of coordinating government environmental policies and regulations. These efforts were crucial in creating a forum for environmental dialogue and democratic participation. The 2005 environmental performance review undertaken by the Organization for Economic Co-operation and Development (OECD) made numerous recommendations for a greener future. The more notable recommendations included strengthening international environmental cooperation and the efficient implementation of environmental policies. As Chile continues to grow in the 21st century, it must consolidate environmental policies with larger social, economic, and sectoral decisions if sustainability is to be achieved for current and future generations.

Chimpanzees

CHIMPANZEES ARE PRIMATES that belong to the anthropoid great ape family *Pongidae*, which includes gibbons, gorillas, and orangutans. Chimpanzees are in the suborder *Anthropoidea*, the order of *Primates*, and one of only two members of the genus *Pan*. As *Pan* troglodytes, Chimpanzees were until recently considered to be the sole members of the genus *Pan*. However, Bonobos, which have been variously called pygmy, dwarf, or Gracile chimpanzees, are now classified as the second species in the genus, *Pan paniscus*. Bonobos (pygmy chimpanzees) are found only on the south side of the Congo River in the Democratic Republic of the Congo. Chimpanzees are not known to swim, so rivers have acted as major barriers to their movements. Chimpanzees are found in equatorial central Africa, from Senegal to western Tanzania in tropical rain forests and savannas. There are three subspecies of the common chimpanzee (or simply chimpanzee).

The subspecies *Pan troglodytes verus* can be found from Gambia to the Niger River. The *Pan troglodytes troglodytes* subspecies live in the forest regions in central Africa. The subspecies *Pan troglodytes schweinfurthi* is found mainly in western Uganda and Tanzania. Like the other great apes, chimpanzees do not have a tail. They are strong animals with powerful arms and legs, and an arm span twice their height. They can easily grasp objects with their hands or with their feet. They range between 3.25 feet (one meter) to 5.5 feet (1.7 meters) in height. Males usually weigh 110 pounds (50 kilograms) on average, while females weigh 90 pounds (41 kilograms) on average. However, in captivity some males have attained weights of 200 pounds and females weights of 175 pounds. Chimpanzees have large ears, and arms that are longer than their legs. They can walk upright on their feet for short distances, but they usually walk on all fours. With their arms extended, their front limbs rest on the knuckles of their hands. While some chimpanzees are covered with long black hair, they are usually bald from the forehead to their crown. Some have dark faces and some have tan faces.

DIET AND COMMUNITY GROUPS

Chimpanzees eat insects, leaves, fruit, nuts, bird's eggs, fish, and occasionally small animals such as red-tailed monkeys, small bush pigs, or small antelopes. They may engage at times in organized hunts. During the day, chimpanzees move about while foraging in small bands or parties of six to a dozen members. The bands, part of a community of 25–100 members, may be all male, all mothers with infants, or mixed bands of males and females. Individuals come and go from the community. An alpha male usually rules the community, although groups of all females have been seen. Females tend to move about as individuals and eventually migrate to a separate chimpanzee community, while males usually stay in their birth community. Sexual maturity occurs around 10 or 11 years of age, with physical maturation by age 14. Mating takes place throughout the year, with a gestation period of about eight months. However, females bear only once every three or four years. The newborn chimpanzee is helpless like human babies; their mothers care for them until about five years of age.

Chimpanzees can live to be 50 years old in the wilds. However, only a few live that long. Their natural enemies are leopards, cheetahs, lions, and other chimpanzee communities. Encounters with another community may incite a deadly conflict. The greatest enemy of chimpanzees is man.

CONNECTION TO HUMANS

Using tools has been among the behaviors of chimpanzees observed in recent studies. West African chimpanzees have been reported using rocks as tools in order to crack open tough nuts. In East Africa, they have been observed using twigs as tools for feeding on termites and ants. Trees provide places of rest and sleep during afternoon naps. At night, they build nests from leaves; however, they are diurnal, and often forage at night. Chimpanzees have been known for centuries, but were only closely studied beginning in the 20th century. Researchers have found that chimpanzees and humans share a number of physical and social traits. Physically, chimpanzees and humans share almost completely (99 percent) identical polypeptides, which are proteins. The similarities between humans and chimpanzees have made them inviting subjects for medical and psychological research.

Chimpanzees are genetically the closest to humans. They have been used extensively in laboratories for medical research because they are subject to diseases similar to those of humans. These include the common cold, pneumonia, poliomyelitis, tuberculosis, influenza, and chicken pox. A disease outbreak can threaten a whole community with destruction. Ebola and other zoonotic diseases are of growing concern to researches, as increased contact with humans may endanger chimpanzees by contracting deadly diseases.

Chimpanzees are among the most intelligent of all animals. Animal psychologists have sought to use chimpanzees to study learning, communication behaviors, and intelligence. Researchers have found that chimpanzees can be taught to communicate with humans using sign language, and have had significant success in teaching chimpanzees and Bonobos sign language. Human speech is not within their natural capacities. However, both have been taught to use hundreds of symbols and hand signals.

Recent studies have revealed that chimpanzees learn from each other. Experiments that challenge them in problem solving have been used to study their intelligence. Their behaviors are mimicked and passed on to the next generation, creating a "chimp culture" in each community. These behaviors are passed down from chimpanzee to chimpanzee without any human interference or intervention. Jane van Lawick-Goodall, a famous English naturalist, conservationist, and author began patiently observing a band of chimpanzees in the Gombe Stream Game Reserve in Tanganyika (now Tanzania) in 1960. She was able to move with a band of chimpanzees, studying them ever closer as they grew more familiar with her. For months, she recorded many behaviors that other naturalists had not previously observed. When her observations and finds were published, scientific understanding of chimpanzees underwent an enormous transformation.

Among the many revolutionary discoveries Goodall made was that chimpanzees sometime eat meat and that they are not strict vegetarians as previously believed. Moreover, she noticed that they eat meat for periods, then return to a vegetarian diet for other periods. Also, they will sometimes engage in chimpanzee cannibalism, or they will eat meat when chance opportunities arise. Goodall also described the complex social order that exists within chimpanzee bands. She also described "wars" between different groups of chimpanzees. Other researchers have observed in recent years that chimpanzees engage in acts of violence against their own. Some researchers believe that these observations may offer clues to the development of warfare among humans. Goodall's findings have enabled conservationists to better protect chimpanzees, which are threatened by poachers seeking "bush meat" or babies for sale to zoos or to pet collectors. After returning to England, she championed efforts to protect chimpanzees in the wild through movies, television, books, and with political advocacy.

Chimpanzees are considered an endangered species by conservation organizations like the World Conservation Union. They were originally found in 25 countries, but are extinct in four of those and close to extinction in others. They are threatened by poaching for the bush meat trade, deforestation, and traffickers for display and medical laboratories. All three subspecies and the Bonobos are listed on the Red List of Threatened Species issued by the International Union for the Conservation of Nature and Natural Resource (IUCN) as endangered. The western chimpanzee and the Nigerian chimpanzee are the most threatened.

China

THE PEOPLE'S REPUBLIC of China has the highest population of any country in the world, with an estimated 1.311 billion people in 2006. The population of India, the second country in the world to exceed a billion people, is not far behind at 1.122 billion. The rates of natural increase for each of these Asian giants, 0.6 percent for China and 1.7 percent for India, indicates that India will surpass China in total population some time around 2040, when both countries will have over 1.45 billion inhabitants. As India continues to gain significantly in population through mid-century, China is predicted to actually decline in population between 2025 and 2050 for several reasons: 1. the continuance of its low rate of natural increase (RNI), 2. the the government's view that the birthrate is satisfactory (12 births per 1,000 people as opposed to India's 24 births per 1,000) by married women in their child-bearing years (15–49), and 3. China's continuance of its one-child-per-family policy through the next five-year plan, 2006–10.

China's experience with its one-child policy has led to some serious problems. Cultural preference is for a male child. In many instances, first-born girls have become victims of female infanticide. Despite this severe outcome, China intends to limit its population to 1.37 billion by 2010 in large part through the continuance of the one-child policy. The one-child policy has produced another inequity within China's population: By 2020 there will be approximately 40 million more men than women in the population. This imbalance has already caused many men to question whether they will have the opportunity to marry and have a family of their own.

China is the fourth-largest country, with a total area of 9.6 million square kilometers, which is slightly smaller than the United States. The country has a mid-latitude location in eastern Eurasia and an extremely diverse climatic system. The land surface is varied, with extensive mountain regimes and desert areas in the west, loess plateaus in the north, and alluvial plains in the east. Despite the size of the country, only 15 percent of the land area is suitable for agriculture. Within this sector a great variety of agricultural products are produced. Double-cropping of rice is practiced extensively in the warm and humid southeastern China. Rice gives way to wheat and other more drought-tolerant crops in the north. The arid west is dotted with oasis-type agricultural systems.

Industrial growth in China has been very rapid in the past two decades. Spectacular strides have been made in metal production, machine manufacture, energy production and use, transportation equipment, telecommunication systems, and a wide variety of consumer goods. In addition, the service sector of the Chinese economy continues to expand with employment in the industrial sector. With a total labor force nearing 800 million, China is an economic force to consider in the global arena. The agricultural sector comprises half the labor force and contributes only 13 percent of the Gross Domestic Product (GDP). The combined industry and service sectors comprise the other half of the labor force, with a collective contribution to GDP at 87 percent. The labor force in agriculture has dropped from over 70 percent in the late 1970s to its present level, and is predicted to continue this decline as more farm workers exit the rural areas and move to industrial and service sector jobs in the cities. By the year 2015, it is estimated that the percentage of the Chinese population will be evenly divided between urban and rural habitats. The significance of this shift is striking: As recently as 1975, rural residents represented approximately 84 percent of the population, while urban residents represented a mere 16 percent.

China's one-child policy has led to serious problems. Cultural preference is for a male child, spurring female infanticide.

The rural areas of the country are suffering from rapid depopulation, the abandonment or downgrading of small farms to part-time activities, and low productivity. Nonetheless, the Chinese government has provided significant financial support to the enhancement of rural education. China's nine-year compulsory education system is well established within the rural areas and literacy rates among young students have greatly improved. In addition, programs to modernize agricultural activities in rural China are expanding and thrusts are being made to improve adult education as well. The Chinese government spent nearly $12 billion on rural education in 2002, up from $5 billion in 1997. Despite these dramatic changes, the rural areas are far behind urban places in terms of economic development and social equity. The rural shortfall is related to the broader set of inconsistencies between China's phenomenal economic growth and the less than desirable increases of inequality in the social sector. The next five-year plan is taking this inequity into account. Education differences between the urban and rural areas are one of the major targets for change. China's 2000 national census showed that the countrywide illiteracy rate for those aged 15 and above was slightly over five percent. The rural areas, by contrast, registered nearly 12 percent in this category.

Imbalances between urban and rural areas exist, as well in the availability of medical and hygiene facilities. Urban places have 80 percent of these facilities available to them, while the rural areas, representing 70 percent of the population, have only 20 percent. Another area of concern to planners is China's surprisingly low per-capita income, which was reported to be $6,600 in 2005, compared to the world average of $9,190. These figures represent gross national income in purchasing price parity (GNI PPP), which refers to gross national income converted to international dollars using a purchasing price parity conversion factor. The resulting dollars indicate the amount of goods and services that cold be purchased in the U.S. market. Not only is China well below the world average in this category, it is far below Hong Kong ($34,670), Japan ($31,410), and the United States ($41,950).

Nuclear Shelters in Beijing

With the threat of nuclear war in the 1950s and 1960s, the municipal authorities in Beijing constructed nuclear shelters, otherwise known as the "underground city." The original plans were for the shelters and tunnels to protect as much as half of the population, and was initially secret, but their existence became known to outside commentators during the mid-1970s, with some foreign visitors allowed to view them from 1979–1980. Most of the tunnels are now open to the public, and tourists can buy a ticket to enter the tunnels, many of which have been refurbished. There still remain restrictions on photography in the tunnel systems.

The tunnels, which often come from corner shops, railway stations and the like, are relatively narrow but are designed for three men to walk side-by-side. It was said that the tunnels would allow most of the population of the city, walking steadily, to leave the contaminated area and get into the countryside. There are padded steel doors at intervals, and there are even ventilation shafts. Some of these still connect with hutongs (narrow alleys) and it is not uncommon for tourists visiting the shafts to hear noises and even conversations taking place in hutongs.

The larger tunnels connect with the Beijing underground and there are underground light industrial workshops, shrines, medical care facilities and sanitation. Many of the tunnels also had Communist slogans asking people to work harder and strive for a better country. The material excavated in Beijing was turned into bricks for use around the capital.

The "underground city" is believed to cover an area of 33 square miles (85 square kilometers), going out to the Western Hills, the Summer Palace and also to the International Airport. There are also another series of tunnels, which remain secret, for Communist Party officials and government bureaucrats to escape through in times of war. It has been claimed that soldiers used the tunnel during the ending of the Tiananmen Square protests in 1989.

China's rapidly expanding economic sector changed from a centrally planned system to one that is more market oriented. In the late 1970s, the country abandoned collectivized agriculture, a practice introduced early in the Maoist era and a copy of the system pioneered under the now defunct Soviet Union. In 2005, China achieved the enviable status as the second-largest economy in the world behind the United States. However, the impact of its large population growth resulted in very low per capita income. In 2005, over 150 million Chinese were subsisting below the international poverty line, which is two dollars per day. China is one of the world's leaders in energy consumption as its economy rapidly expands. Its impact on the global trade in oil is considerable. China produces over three million barrels of oil per day, but its consumption is twice that amount. The deficit is made up with imports from a variety of oil-producing regions worldwide. Natural gas and coal are extensively used in China, and the country has extensive reserves of both of these energy sources.

The completion of the Three Gorges Project along the Yangtze River stands as a symbol of the scale of Chinese development efforts. The idea of damming the Yangtze to produce hydroelectric power was first proposed during the time of Sun Yat-sen early in the 20th century. In the 1950s, following a series of floods, Mao Tse-tung ordered the country's engineers to produce feasibility studies on damming the river. The project was officially started in 1993 and is expected to be fully completed and to include a ship elevator system by 2009. The dam, which is 1.5 miles wide and 600 feet high, is by far the largest in the world and is heralded as the most gigantic engineering effort in China since the building of the Great Wall. The reservoir behind this massive structure stretches for 400 miles into the interior of China. This river system will allow ocean-going vessels access to regions rich in manufacturing activities and agriculture, and will reach the major city of Chongqing with its more than 30 million people. Hydroelectric power generation at the dam will produce over 18,000 megawatts of power, an amount sufficient to satisfy 10 percent of China's energy needs.

The dam will also be beneficial in its containment of flooding on the unpredictable and sometimes violent Yangtze River. Devastating floods along the river have claimed over one million lives in the last 100 years, and caused untold damage to communities in its path. The Three Gorges Project is economically important; however, construction of the dam was severely criticized from the beginning. Construction and the subsequent filling of the vast reservoir displaced over 700,000 people from their homes in the river valley. In addition, hundreds of small villages and towns ended up at the bottom of the reservoir, along with countless archaeological items and thousands of acres of farmland. The agricultural land lost to the project is some of the most fertile in all of China.

China's growth in energy production has led to another serious environmental issue: coal-fired plants providing desperately needed energy for urban areas and industry are spewing tons of carbon matter into the atmosphere on a daily basis. Two-thirds of the energy produced in China comes from the estimated 800 million tons of coal consumed annually. Add to this the fast-growing consumption of oil and natural gas, and it is clear that China will soon become the leading emitter of carbon into the atmosphere. Ironically, China is a member of the community of countries signing and ratifying the Kyoto Protocol aimed at limiting the global production of greenhouse gasses. China signed on even though there are no limits on the amount of pollutants it produces, because it was classified as a developing country in 1997 when the Kyoto Protocol was presented. Estimates now have China becoming the leading emitter of greenhouse gasses and surpassing the United States in that category sometime in the 21st century.

Chipko Andolan Movement

THE CHIPKO ANDOLAN Movement originated in the Indian Himalayan region of Uttarkhand, in the state of current-day Uttaranchal. The Hindi term *Chipko* means to "hug" or "cling to" and refers to peasants demonstrating against government-led logging practices by circling and embracing trees. Though the movement officially began in the villages of Mandal and Gopeshwar, it quickly spread to other mountain regions of the Indian Himalaya. The story of the Chipko Andolan Movement has inspired similar movements around the world.

Prior to the Chipko Movement, residents in the area were already skeptical of government logging practices, drawing a connection between heavy deforestation and severe erosion. Villagers around Gopeshwar were therefore accustomed to protesting the illegal commercial contracting policies of the Forest Department, advocating instead for increased employment through local contracting opportunities.

These concerns were taken up by a local nongovernmental organization, the Daushali Gram Swarajya Sangh (DGSS) or Dasholi Society for Village Self-Rule. The first Chipko Movement protest took place in early 1973, when the DGSS's request for an allotment of ash trees was turned down by the government. During the same period, and just over 10 kilometers away near Mandal, a private enterprise was granted an allotment of ash trees for the production of commercial sporting goods. Led by Chandi Prasad Bhatt, the local villagers responded to this perceived injustice by circling and embracing the trees set for commercial logging. After many days of vigilance by Chipko members, the commercial interests moved elsewhere.

In 1974, the forest department again planned another logging venture, this time not far away near the village of Reni in the Alakananda Valley. Guara Devi, the head of a village women's group, mobilized a number of locals consisting primarily of women to prevent logging operations. The loggers were eventually forced to retreat, revealing the central role of women in the overall movement. The Chipko Movement is commonly reported as singly unified; however, it has been more of a conglomeration of distinct, somewhat smaller movements.

The Reni forest protests marked a shift in Chipko movement goals from a demand for forest products to supply local industries, to a new and much broader concern over the ecological control of forest resource extraction to guarantee dependable supplies of water and fuelwood to local residents. The Chipko Movement therefore came to represent a continuation of the colonial-era defense of traditional forest rights over state encroachment. Tactically, the Chipko Movement was a postcolonial extension of the Gandhian satyagraha—a nonviolent means of confronting exploitative powers.

REESTABLISHING FOREST PRACTICES

While the Chipko Andolan Movement is notable because of its ideological and organizational influence on environmental movements around the world, it also offers a valuable point of reflection on how environmentalists retell historical narratives. Some have characterized the Chipko movement as the accomplishment of women protecting the reproductive power of forests against exploitative commercial logging practices. Others present Chipko as a movement by local peasants seeking to preserve traditional forest practices and identities. Critics suggest both these narratives rely on overly romantic tropes of Himalayan history premised on conditions of ecological and social harmony. The goal of the Chipko Movement members in the mid-1970s was to reestablish, on their own terms, a set of preestablished profitable forest practices connected to broader market and state ventures.

Chlorinated Hydrocarbons

CHLORINATED HYDROCARBONS ARE organic compounds containing carbon, hydrogen, and chlorine. They are also called chlorocarbons, chlorinated organics, chlorinated insecticides, chlorinated synthetics, and organochlorides. There are thousands of chlorinated hydrocarbon compounds. Some occur naturally, and some are toxic to humans or to the environment. Chlorinated hydrocarbons are formed by the replacement of one or more hydrogen atoms with one or more chlorine molecules. Some chlorinated hydrocarbons are part of a class of chemical compounds called alkyl halides, in which a bromine, chlorine, fluorine, or iodine atom has been substituted for a hydrogen atom. Many chlorinated hydrocarbons have industrial, agricultural, and commercial uses. The simplest chlorinated hydrocarbons are chlorinated forms of methane or ethane. Tetrachloromethane (CCl_4), commonly known as carbon tetrachloride, is a colorless, volatile, and nonflammable liquid. It is made commercially from methane (CH_4) and chlorines. It is poisonous if breathed in excessive quantities. It has been frequently used in dry cleaning, metal cleaning, and for extracting oils from seeds.

Trichloromethane (CCl_3H) is commonly known as chloroform. Used in medicine as an anesthetic, it is a sweet-smelling, colorless liquid. It use has been restricted because it is a possible carcinogen. Dichloromethane (CCl_2H_2) or methylene chloride is used in many industrial processes. These include paint stripping, paint remover manufacturing, metal cleansing and degreasing, and in the making of pharmaceuticals. Dichlorodifluoromethane (CCl_2F_2) is the most important of the Freon group of compounds. Freon was used for many years in refrigerators and air conditioners. Freon is odorless, nontoxic, nonflammable, and easily liquefied from the gaseous state. It is manufactured from carbontetrachloride and hydrofloric acid (HF). The use of Freon has been banned because when it is released it rises in the atmosphere to the stratosphere. Ultraviolet light from the sun decomposes the Freon gas, in the process freeing the two fluoride atoms. These then react with ozone molecules in the ozone layer causing increases in environmental damage, eye damage, and skin cancers.

Ethylene dichloride is the older name of 1,2-dichloroethane ($C_2H_4Cl_2$). It has also been called ethane dichloride, Dutch liquid, and Dutch oil. It is used to make vinyl chloride, which is a precursor of PVC plastics. Tetrachloroethane ($C_2H_2Cl_4$) was used for a while in large amounts as a solvent and as a metal degreaser. It was also used in pesticides and paints. It is no longer used for these purposes. Breathing tetrachloroethane is very noxious. Today it is used in the United States and in a number of other countries as a chemical intermediate in the manufacturing of other chemicals. Trichloroethylene ($Cl_2C{=}CHCl$) has been used as an industrial solvent and for extracting oils from plants. It also supplanted chloroform for a while as a general anesthetic.

PESTICIDE PRODUCTION

Many chlorine hydrocarbons have been used in the production of pesticides. Many organochlorides are powerful insecticides. These include chlordane (clorinated cyclodiene); DDT ($C1_4H_9Cl_5$); dicofol (which is made from DDT); dioxin (2,3,7,8-tetrachlorodibenzo-p-dioxin); endosulfan ($C_9H_6Cl_6O_3S$), which is also used under the names thiodan and benzoepin; heptachlor ($C_{10}H_5Cl_7$); and pentachlorophenol (C_6HCl_5O), which is a synthetic fungicide. Still in use (banned in California) is lindane (gamma-Hexachlorocyclohexane). Among other uses, lindane is a treatment for lice and scabies. The bond between chlorine and carbon atoms is strong. This means that they do not degrade rapidly and continue to persist in the environment. When released into the environment they can create a long-term pollution problem that is not rapidly weathered or biodegraded. Some of them have entered the food chain with negative consequences for many species that were not the target of pesticide spraying, and for humans.

Chlorofluorocarbons (CFCs)

CHLOROFLUOROCARBONS (CFCS OR chlorofluormethanes) are a group of chemicals containing carbon, fluorine, and chlorine atoms. They were used extensively throughout the 20th century for various applications because of their general nontoxicity and stable chemical properties. However, CFCs are also extremely potent greenhouse gases and are primarily responsible for the destruction of stratospheric ozone (O_3). As of 2003, cumulative worldwide production of CFCs was estimated at 24 million metric tons (53 billion pounds), 96 percent of which has been released into the atmosphere.

CFCs were formally introduced to the world in 1928 by Thomas Midgley Jr. and colleagues with the synthesis of dichlorodifluoromethane (now known as CFC-12, CF_2Cl_2). Midgley's work was the answer to his assignment by General Motor's Frigidaire division to develop a nontoxic, noninflammable, and noncorrosive refrigerant. To this end, CFCs proved to be an excellent, if not perfect product. In 1930, DuPont began commercial production of CFC-12 under the trade name Freon. Soon after, CFC-11 ($CFCl_3$) entered production, and together with CFC-12, formed the bulk of all CFCs ever produced. During World War II, CFCs began to be used as aerosol propellants and as key components in the production of packing, insulating, and buoyancy foams. CFCs were also used as solvents in the dry-cleaning and electronics industries. In particular, CFC-113 ($CF_2ClCFCl_2$) was used extensively for these purposes. Additional CFC varieties were produced (most notably CFC-114 and CFC-115) but accounted for only 3 percent of total CFC production.

In 1973, a study by Jim Lovelock and colleagues revealed the existence of CFCs and other halocarbons in the atmosphere over the Atlantic Ocean. The authors highlighted the practical role of these chemicals as inert tracers of atmospheric processes and described them as constituting "no conceivable hazard." The following year, Mario J. Molina and F.S. Rowland reported that the most important sink for atmospheric CFCs is likely the dissociation of chlorine atoms by ultraviolet light in the stratosphere (Molina and Rowland received the Nobel Prize for their work in 1995). They suggested that free chlorine atoms catalytically destroy ozone molecules through the following reactions:

$$Cl + O_3 \rightarrow ClO + O_2 \quad \text{and} \quad ClO + O \rightarrow Cl + O_2$$

Once stripped from a CFC molecule, a single chlorine atom can catalyze the destruction of up to 100,000 ozone molecules before it is eventually incorporated into "chlorine reservoirs" such as HCl or chlorine nitrate ($ClONO_2$).

Molina and Rowland raised significant concerns about the continuing rise of atmospheric CFCs and the importance of stratospheric ozone. In 1978, as evidence of CFCs' threat to the ozone layer strengthened, the United States banned the manufacture and sale of CFCs as aerosol propellants in spray cans (by then, the predominant use of CFCs).

By the mid-1980s, extensive research had confirmed a dramatic reduction of the ozone layer over Antarctica and attributed it to CFCs. The 1987 Montreal Protocol and subsequent amendments required industrialized nations to phase out CFC production by 1996, and by 2010 for developing nations. Although worldwide production of CFCs today is a small fraction of what it once was, the long residence times of CFCs in the atmosphere implies a slow recovery of stratospheric ozone.

While CFCs are more widely known as a threat to ozone, they also significantly contribute to the anthropogenic greenhouse effect. Over the course of 100 years, one pound of CFCs emitted to the atmosphere will reradiate as much heat as 4,600 to 14,000 pounds of carbon dioxide (CO_2). Because of this property, even the relatively small concentration of CFCs in the atmosphere (about 1 part per billion by volume) is considered to be a major contributor to global warming. Hydrofluorocarbons (HFCs) are replacing CFCs in many applications because of their benign effects on ozone. However, HFCs are also potent greenhouse gases and are recognized as such in the Kyoto Protocol.

Chlorophyll

CHLOROPHYLLS ARE A class of chemical pigments found in many types of plant life, and are necessary for the process of photosynthesis. Chlorophylls absorb light in particular parts of the electromagnetic spectrum, meaning that they have a very vivid green color, which is characteristic of their presence and encourages industrial applications as well as health promotion.

Photosynthesis is the process by which sunlight is converted into chemical energy within plant cells through organic carbon compounds. It is possible that chlorophyll or a similar substance was a vital link in the evolution of life. The 1997 Pathfinder mission to mars found some evidence that substances similar to chlorophyll might be present in Martian soil.

The five types of chlorophyll (a, b, c, d, and e) are found in the higher plants and different forms of algae; bacterio-chlorophyll is found in some types of bacteria. Chlorophylls consist of a magnesium atom surrounded by a porphyrin ring containing nitrogen and with a carbon-hydrogen chain also attached. This structure is quite similar to that of hemoglobin, which is the vital substance within blood that transports oxygen. Since chlorophyll tends to hide other colors present within plants and especially their leaves, it is when light is reduced that other colors emerge, such as during autumn, when the leaves of many deciduous trees change from green to red, yellow, or brown. The use of chlorophyll fluorescence has become a tool of considerable importance for plant physiologists and ecophysiologists, who are able to use the various techniques involved in diagnosing not just the rate of photosynthesis, but also considerable amounts of information about the health of the plant concerned and its reactions to its environment. In particular, it is useful in measuring environmentally induced stress.

Chlorophyll-bearing vegetables have been the subject of investigation in the hope that they will inhibit the growth of some cancer cells. Spinach is indicated by some research as an important dietary item that may assist with this prophylaxis.

Chromosomes

THE GENETIC INFORMATION encoded in DNA and carried in cells is normally packaged in molecules called chromosomes: long strands of DNA and associated proteins that carry many genes, regulatory elements, and nucleotide sequences. Merriam-Webster Online Dictionary defines *chromosome* as "one of the linear or sometimes circular DNA-containing bodies of viruses, prokaryotic organisms, and the cell nucleus of eukaryotic organisms that contain most or all of the genes of the individual." It is derived from two Greek words: *chroma,* meaning color, and *soma,* meaning body.

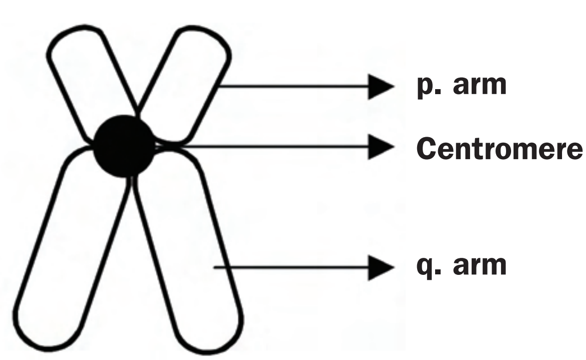
Chromosomes were first observed by a Swiss botanist, Karl Wilhelm von Nägeli, in 1842 in plant cells. Belgian scientist Edouard Van Beneden independently observed chromosomes in Ascaris worms around the same time. Walther Flemming, a German anatomist, in 1882 discovered mitosis (the process by which a cell separates its duplicated genome into two identical halves) and described the behavior of chromosomes in animals. In 1910, an American geneticist, Thomas Hunt Morgan, proved that chromosomes are the carriers of genes by studying the common fruit fly.

Chromosomes are present in every living being, whether it is bacteria, fungi, plants, insects, animals, or humans. However, each species has different number of chromosomes (see table), but normal members of a particular species all have the same number of chromosomes. The asexually reproducing species have one set of chromosomes, which is the same in all body cells. Chromosomes in bacteria are most often circular, but sometimes they are linear as well. Most sexually reproducing species contain two haploid sets of chromosomes (chromosomes are multiples of 2, and they are therefore mostly present in pairs, though there are some animal and plant species that have more than two sets of chromosomes; for example, tobacco or wheat) and are referred to as polyploid. Some wild as well as cultivated varieties of wheat have 14 (diploid) chromosomes, whereas common pasta and bread wheat are polyploid and have 28 (tetraploid) and 42 (hexaploid) chromosomes, respectively. In humans, there are 46 chromosomes that occur as 23 pairs—22 pairs of autosomes and 1 pair of sex chromosome. Each child inherits one strand from the mother and another from the father to form a pair. Aulacantha (protozoa) has largest number of chromosomes at 1,600.

Number of Chomosomes in Different Species of Plants and Animals

Species	# of chromosomes	Species	# of chromosomes
Ant	2	Fruit Fly	8
Ape	48	Guinea Pig	16
Butter-flies	3	Hare	46
Budding yeast	32	Horse	64
Cat	38	Human	46
Chicken	78	Maize	20
Cow	60	Mouse	40
Dog	78	Pig	38
Donkey	62	Rabbit	44
Dove	16	Rat	42
Earth-worm	36	Rye	14
Elephant	56	Sheep	54
Fern	1200	Snail	24

Each chromosome has two arms that differ in length and are referred to as a p (short arm) and q (long arm). The two arms are separated by a region called the *centromere* (see figure). The location of the *centromere* on each chromosome gives the chromosome its characteristic shape, and can be used to help describe the location of specific genes. Chromosomes are very small and are visible only by using an optical microscope.



The abnormalities in chromosomes can occur either by change in number, size, or structure of chromosomes. The change in chromosome structure could occur due to breakage or rearrangement—translocation, inversion, rings, or deletions—of some of the chromosome material. This leads to disorders such as Down's syndrome. During formation, an egg or sperm can sometimes have either an extra chromosome (24 chromosomes) or one less chromosome (22 chromosomes). When such an egg (or sperm) combines at conception with a normal sperm (or egg) with 23 chromosomes, the resulting embryo ends up with too few or too many chromosomes, i.e., 45 or 47 instead of the usual 46. These lead to disorders such as trisomy 21, XYY syndrome, and Klinefelter syndrome. Prenatal testing is available for the screening or diagnosis of the disorders of plants and animals.

Chronic Wasting Disease

CHRONIC WASTING DISEASE (CWD) causes nervous system degeneration in cervid animals (the deer family) in North America. CWD, like Creutzfeldt-Jakob disease (CJD) and bovine spongiform encephalopathy (so-called mad cow disease), belongs to a family of neurological diseases called *transmissible spongiform encephalopathies* (TSEs). TSEs are caused and spread by abnormal proteins called *prions* found in the central nervous system and the immune system. Prions are transmitted much like other infectious agents such as viruses and bacteria—mostly through direct contact between infected and healthy individuals, though prions may also persist in soil. Cervids that live in highly social herds and at high population densities are most likely to catch and transmit the disease. Infected animals develop lesions on the brain, lose body mass, and display behavioral abnormalities. All cases are fatal.

CWD was first observed among deer and elk in wildlife research facilities and game farms during the late 1960s, exclusively in the Rocky Mountain region. In subsequent years, cases appeared on game farms across the northern Rockies and the central plains of the United States and Canada. Wildlife pathologists discovered cases among free-ranging cervids in the Rockies in the early 1980s. By spring 2006, CWD had been detected in free-ranging cervids in 13 states and provinces, as far east as New York and as far south as New Mexico, and in captivity in several other states and provinces.

Wildlife pathologists have linked the spread of CWD with high population densities of cervids, as are found both on game farms and in regions where humans have intentionally and unintentionally created ecological conditions favorable for deer. As game farming blossomed in the 1990s, transport of infected animals between farms greatly aided the spread of CWD. CWD has killed up to 90 percent of game animals on some farms, and the United States Deparment of Agriculture has restricted the transport of animals between states. In regions such as the upper Midwest, where suburbanization and agriculture have facilitated high densities of white-tailed deer, CWD has spread rapidly among free-ranging deer. Furthermore, because of the cultural and economic importance of hunting, many residents favor a high deer population, and some tourist businesses maintain baiting stations—ideal sites for the spread of CWD. Illinois and Wisconsin have established additional hunting seasons to reduce deer populations within the area where the disease was most prevalent. Many states have enacted partial bans on deer baiting. These policies sparked controversy where hunting and game farms are economically important; some hunters and businesses dependent on hunting charge that wildlife managers exaggerate the extent of CWD. Many state wildlife management agencies also test all cervid animals killed during the regular hunting season as a surveillance measure.

CWD is most widespread in white-tailed deer, mule deer, and elk; it exists very rarely in free-ranging moose. Though bovine spongiform encephalopathy has been documented in humans as a variant of CJD, there are no known human cases of CWD. Neither have domestic livestock such as cattle contracted CWD. Many hunters, farmers, and taxidermists, however, have expressed fear that prions could spread through consumption of venison, contact between livestock and infected cervids, or handling of organs, brains, and spinal fluid.

Circle of Poison

THE "CIRCLE OF poison" (COP) describes the linkage between an American-made pesticide that is banned in the United States, but which circles back into the food supply from a pesticide used in an underdeveloped country. The circle is complete when the pesticide returns via nature or by human actions. The pesticides in the circle of poison have carcinogenic or tetragenic properties (causing birth defects). Traces of banned, American-made pesticides have been found in the Florida Keys or in other locations, including the Great Lakes. Winds and ocean currents have delivered these traces. In other cases, the pesticide circle was completed through imports of foods.

The only pesticides allowed in the United States are those that are registered for use in the United States; however, export law does not prevent unregistered pesticides from being manufactured and exported. In the 1970s and 1980s, the United States began to ban the use of pesticides that were identified as environmentally destructive or identified as carcinogens. For example, the banning of DDT in the United States did not prevent its being exported to underdeveloped countries. The 1970s also saw the beginning of increased food imports to the United States. Countries in the southern hemisphere grew increasing quantities of crops that were exported to North America and Europe. Tomatoes from Mexico, fruits from Chile, and foods from underdeveloped countries increased in the food supplies of Americans, Canadians, and Europeans.

Proven instances of the circle of poison have been rare. In one case, residues of chlordane and heptachlor, which are made only in the United States, were found on beef imported into the United States. Since 1990, the United States Department of Agriculture has generally found that pesticide residues fall within acceptable limits. In 1991, the Food and Drug Administration (FDA) examined over 10,000 samples of imported fruits and vegetables. The sampling found that in 64% of imported food, there was no traceable pesticide residue. Only four percent of the foods sampled were outside of the accepted limits. However, the FDA inspects only a small fraction of the foods imported into the United States. Most critics find the very limited inspections conducted by the FDA to be woefully inadequate.

Consumer advocacy groups have lobbied Congress for circle-of-poison legislation that would prevent the exporting of unregistered pesticides from the United States. Senator Patrick Leahy (Democrat-Vermont) and Representative Leon Panetta (Democrat-California) have repeatedly been unsuccessful in getting circle-of-poison legislation adopted. Opponents of the regulation of pesticides argue that banning them would hurt not only American manufacturers, but also people in the Third World. Pesticide use in many tropical countries has reduced malaria and allowed expanded agricultural production. Opponents believe that banning American-made unregistered pesticides will not break the circle of poison, as Third World countries will simply find new supply sources for fighting both disease-bearing insects and destructive pests. In 2006, Congress was still allowing the export of unregistered pesticides, while the number of cases of pesticide poisoning in foreign countries was increasing.

Circuses

CIRCUSES ARE COMPANIES of entertainers who perform as acrobats, clowns, and animal tamers in a circular arena. Circuses may travel or be based in permanent facilities of entertainment. Some of the early modern circuses in London and other European cities were built for this purpose. Circus Circus, a gambling casino in Las Vegas, Nevada, also exhibits the world's largest permanently housed circus; performances are given free of charge daily. Often, traveling circuses perform in a large tent designed to accommodate the circus performers and the audience.

GREATEST SHOWS ON EARTH

In the late 19th century and in much of the 20th century, the arrival of the circus was a great event. In many small towns and cities, the "advance men" would arrive days before the circus and publicize the coming spectacle. The circus performers and their circus animals would parade down a main street to generate public interest. The excitement would help to draw a fee-paying crowd to the performances in the afternoon, and for the larger show in the evening. In many rural areas, the only opportunity most people had to view lions, tigers, leopards, camels, giraffes, elephants, performing horses, and exotic snakes was when the circus came to town. Smaller circuses would often arrive in a caravan of trucks decorated with circus images of animals, clowns, and other performers. Larger circus companies, such as the Barnum and Bailey Circus, often arrived on a train designed to carry the performers, with special cars for the animals.

The ancient Roman circuses were famous long before the end of the Roman Empire. Chariot races and the exhibition of exotic animals entertained the masses. Animal exhibitions are thought to have originated in shows of animals used by Egyptians or in the ancient Middle East. The most important circuses in ancient Rome were the Circus Maxentius, the Circus Flaminius, the Circus Nenonis, and the Circus Maximus, which was located between the Palatine and Aventine Hills. Archeologists have been able to develop detailed interpretations of the Roman circus world from these ruins. Schools for training circus performers were established and operated in Roman times.

In the Middle Ages, troubadours and other wandering entertainers kept alive a sense of the ancient circus. Training animals for exhibition as trick performers was common. In modern times, the circus began to revive in the 1700s when Briton Philip Astley began to operate both traveling and permenant circuses in Britain and Europe.

Some circuses have used animals and others have not. Chinese circuses usually featured amazing acrobatic performances. In others, the clowns have drawn keen attention. In most American circuses, lion tamers (both male and female) have entered cages with performing lions, tigers, and leopards. The lion tamer's only defense is a bullwhip. Over the decades, a small number of tamers have been attacked by the cats and on some occasions killed.

Russian circuses have often featured the Eurasian brown bear (*Ursus arctos*). In Russian mythology, bears have played a special role, which has encouraged Russians to train them to dance, box, or do other tricks. Many European circuses continue to thrive despite animal rights opposition. The European Union has adopted legislation accepting the classical circus with animals. Many animal rights activists have been able to gain adoption of local ordinances that hinder the exhibition of animals in circuses. The most common allegation is the charge of cruelty to animals. For many animal rights activists, the domestication and exhibition of animals is inherently cruel and a form of speciesism. Circuses are engaged in both legal and political campaigns to defend this ancient institution.

Cities

NEARLY HALF THE world's population lives in towns and cities. Over the next quarter-century virtually all population growth will be in urban areas in less-developed countries. The environmental consequences of urban growth are considerable. Cities are prolific users of natural resources and generators of waste. They produce most of the greenhouse gases that are causing global climate change. They often also degrade local water quality, deplete aquifers, pollute the marine environment, foul the air and consume the land. Several movements are being organized today, some sponsored by the United Nations, to change city planning to address these concerns, to create "green cities."

Cities are places of concentrated human habitation. People live on almost all of the islands and continents of the world except for inhabitable places, such as Antarctica and some very small islands. In many places there are still nomads, such as the Laps and Eskimos in the Arctic, or the Bedouin in the Sahara or Arabia, or the nomads in Mongolia or India in contrast to whom are the teeming billions who live in the cities of the world.

Vast numbers of people have throughout history lived on farms and in small towns or villages; but it is in cities that most of the great achievements of human history have been accomplished, and it is in cities that ever greater numbers of human beings now live. Cities began in ancient times not long after the development of agriculture made permanent settlements possible. The first cities were in the river valleys of the Nile, Indus, Tigris, and the Yangze, among others. By modern standards these cities were usually small, although some did reach populations of over 100,000 people.

Cities have been places where humans were able to cultivate innumerable trades, crafts and practices because of the leisure that city life has afforded. Often the building of cities has meant the mining or quarrying of vast quantities of building materials. In some places these have left quarries that later filled with water or catacombs, such as those under Rome. In Rome, Paris, and other places these artificial caves have provided a place for burying the dead.

In order to build cities, supply them with goods and water, to defend them and to make them livable, architectural spaces were designed to provide water, sheltered spaces for worship, or for homes. Defenses for cities have included more than military defenses. Some cities are located in areas prone to flooding, while others experience regular threats from storms or freezing weather.

Defenses against the ravages of nature are just a part of the building concerns of city officials. In addition to aqueducts to supply water, and the establishment of marketplaces, such as the famous Agora in ancient Athens, people have found that they needed roads between cities and streets within. In the cities of world it has been necessary to provide clean sanitation facilities. In some cities, public baths have been built and used by the population. Marketplaces, water supplies, sanitation, are all necessary as are homes, open spaces and places of recreation or entertainment. In the Greek city-states an amphitheater was considered a necessity of the city. Gymnasiums were also a feature that has been adopted in modern cities.

Historically most cities have been located at ports, at river crossings, at sources of water, at crossroads or even at sacred sites. With the advent of the Industrial Revolution new industrial cities in Europe sprang up near coal supplies or on the fall lines of rivers, where water power could be used by damming local streams. With great improvements in sanitation and food production the population increased and with

Cities are prolific users of natural resources and generators of waste, producing most of the greenhouse gases that are causing global climate change. They often degrade local water quality and pollute the marine environment.

it the environmental impact of cities as they occupied ever more surrounding lands. At the same time urbanization also meant the abandonment of the countryside by increasing numbers of people.

Industrial cities at first were crowded, unsanitary and uninviting as increasing numbers of people were forced to earn a living working in factories. City planners, working with city administrators, helped to create clean, livable cities, but at times to the great disruption of large numbers of people.

In the 20th century urbanization so increased that cities became metropolises. After World War II, improved transportation allowed people to move to the suburbs in search of a taste of rural life, while remaining close to a city. As millions abandoned farms, vast rural areas returned to nature; but many rural areas have been re-occupied by suburbs, vacation homes and other luxury dwellings. The environmental impact of modern urban growth and sprawl has been increasingly destructive.

Around the world, mega-cities with populations of close to or more than 20 million people have sprung up since the end of World War II. Cities such as Mexico City, Shanghai, Tokyo, Manila, Lagos, Bombay and many others now are in this category. They present enormous challenges to city planners and administrations in the effort to create clean, safe, and wholesome living spaces that are sustainable in their environments.

Clean Air Act

THE CLEAN AIR Act is a federal environmental law in the United States that focuses on airborne pollutants known to present hazards to human health. It requires the Environmental Protection Agency (EPA) to design and enforce regulations that protect individuals from exposure to these hazardous airborne contaminants. Under the current structure of the law, the EPA sets limits on how much of an airborne pollutant can be in the air anywhere in the United States.

The Clean Air Act is actually a long series of federal laws and amendments that span a period of 50 years. The Clean Air Act of 1963 set emissions standards for stationary sources (such as factories and power plants) and encouraged the use of sulfur-removing technology and future research into the dangers of motor vehicle emissions. Eight years earlier, the Air Pollution Control Act of 1955 had been the first law regulating air pollution at the national level. It provided a relatively small appropriation ($5 million annually), but its larger significance had been to raise concerns about air pollution and to set the stage for federal regulation such as the Clean Air Act of 1963. Subsequent amendments in the 1960s strengthened and clarified the act by setting compliance deadlines, establishing detailed air quality standards, expanding local pollution control programs, and extending the act to cover mobile sources (such as automobiles).

EXPANDING REACH

The Clean Air Act of 1970 further strengthened the standards and regulations by establishing new standards for ambient air quality, setting new limits on emissions, and providing additional funding for research. Congress did amend the Clean Air Act in 1977, but in the 1970s and 1980s the EPA primarily implemented the policy outlined in the Clean Air Act of 1970 without making major changes. It was not until 1990 that the federal government again modified the Clean Air Act in any significant way. The Clean Air Act of 1990 not only strengthened existing regulations, but it also expanded the reach of the Clean Air Act to cover previously unregulated areas. It set new air quality standards and targeted motor vehicle emissions, toxic air pollutants, acid rain, smog, stratospheric ozone depletion, and interstate emissions. It also created a comprehensive pollution permit system, widely regarded as a great success for environmental economic policy.

During the 1990s, the EPA engaged in an extensive study to assess the effect of the Clean Air Act on the "public health, economy, and environment of the United States." In 1997, the EPA issued a report on the *Benefits and Costs of the Clean Air Act, 1970 to 1990*. The report found that emissions of criteria pollutants (sulfur dioxide, nitrogen oxides, carbon monoxide, particulate matter, ozone, and lead) had declined 30 to 100 percent. The report also found that these declines greatly increased intelligence quotient and reduced mortality, hypertension, and a number of other adverse health effects. They also improved visibility and avoided significant damage to agricultural crops. The report estimated a benefit-cost ratio of between 10.7 and 94.5, with a mean estimate of 42. This and other evidence indicate that the Clean Air Act has dramatically improved environmental quality and health in the United States, and that it has done so at relatively low cost.

WEAKENED STANDARDS

The most recent changes to the Clean Air Act were implemented with the Clear Skies Initiative, put forward in 2003 by the administration of President George W. Bush. This regulation weakened much of the Clean Air Act by raising emission caps, weakening regulation on older power plants, and delaying or hampering implementation of many Clean Air Act regulations. It also failed to address carbon dioxide emissions. The effects of these changes on actual enforcement or on environment quality are yet to be determined, but may very well be substantial.

Although it is a federal law, the Clean Air Act can be enforced by individual states. A state may submit a State Implementation Plan detailing how it will comply with the regulations. If the plan is approved, the state receives federal funding and takes on the responsibility for local enforcement of the Clean Air Act. Most states follow this procedure. State governments, with more detailed knowledge of their own geography, industry, and population, may be better equipped to regulate pollution efficiently and effectively within their own borders.

Clean Development Mechanism (CDM)

THE CLEAN DEVELOPMENT Mechanism (CDM), defined in Article 12 of the Kyoto Protocol, is one of three project-based flexible mechanisms authorized in the December 1997 Kyoto Protocol to the 1992 United Nations Framework Convention on Climate Change (UNFCCC). The overall aim of CDM is to provide for a more cost-effective way for industrialized countries (referred herein as Annex 1 countries) to meet their greenhouse gas (GHG) reduction targets they agreed to by ratifying the Kyoto Protocol. Article 12 of the Kyoto Protocol defines the purpose of the CDM as at least threefold: to help countries comply with their emission reduction commitments, assist developing countries in achieving sustainable development, and contribute to stabilization of greenhouse gas concentrations in the atmosphere.

In the experience so far with negotiating CDM projects, there have been issues with equity distribution of CDM resources, not unlike the equity issues that arise in other resource negotiations between developed and undeveloped countries. There has been limited involvement in the least-developed countries due to reasons such as high transaction costs of preparing a CDM project; lack of capacity to undertake a CDM project; and baseline energy scenarios that are mostly made up of biofuels such as fuelwood and other agricultural residues, which would make many projects ineligible under the CDM as compared to baseline scenarios made up of fossil fuels. A majority of CDM transactions have taken place in emerging markets such as China, India, and Brazil.

Another issue affecting equity distribution is the limitations that have been put on the land use, land-use change, and forestry (LULUCF) sector. LULUCF project activities in the CDM have been restricted to afforestation and reforestation projects only, so forest management and conservation activities are ineligible.

In the CDM context, inequities arise due to Annex 1 countries' interest in sequestering a maximum amount of carbon for the least amount of investment, and non-Annex 1 countries' vested interest in fostering sustainable development projects that not only sequester carbon, but also leave a legacy of training and long-term economic enrichment.

HOW IT WORKS

Governments and companies in Annex I countries purchase project-based greenhouse gas emission reductions in developing countries mostly to meet their obligations under the Kyoto Protocol or to trade them on the market for a potential profit. Some examples of CDM projects are renewable energy projects that include wind, solar hydro, biomass, and biofuels; methane reduction, mostly from landfill gas flaring; energy efficiency, including building efficiency; and bio-sequestration through afforestation and reforestation projects.

The money that flows to developing countries through CDM transactions is widely known as *carbon finance*. Carbon finance is basically a payment to a project entity for the emission reductions generated from that project, like a commercial transaction. The selling of emission reductions—or carbon finance—has been shown to increase the financial viability of projects by adding an additional revenue stream in hard currency, which reduces the risks of commercial lending or grant finance. Thus, carbon finance provides a means of leveraging new private and public investment into projects in developing countries that reduce greenhouse gas emissions, thereby mitigating climate change while contributing to sustainable development.

Emission reductions are calculated based on an established baseline scenario that must be explained within that project's Project Design Document (PDD), which will eventually need to be registered with the CDM Executive Board (EB), the body that regulates international project-based emissions trading under the Kyoto Protocol. The PDD, before becoming registered, must be approved by a Designated National Authority (DNA) in the project's host country and validated by an independent, third-party auditor called a *Designated Operational Entity (DOE)*. Designated Operational Entities are firms accredited by the CDM EB in order to assure that the baseline scenario is real and that the project is additional to business-as-usual practices. Once the project becomes operational, the project entity monitors the project based on a monitoring plan that is also included in the PDD. Throughout the life of the project, an accredited DOE will periodically visit; based on the monitoring plan and the data collected from the project entity, will verify that the emission reductions are actually happening and issue a report to the CDM EB stating that a certain amount of emission reductions have been generated. This will eventually lead to certification of those emission reductions and then, finally, issuance of the Certified Emission Reductions into the registries of those governments and private companies that have purchased the emission reductions from that project.

ONE CASE TO CONTEMPLATE

The world's first large-scale, forestry-based carbon offset project is the Innoprise–FACE Foundation Rainforest Rehabilitation Project (INFAPRO); its objective is to use enrichment planting and forest reclamation of indigenous tree species, fast-growing pioneers, and forest fruit trees to rehabilitate 25,000 hectares of degraded areas in Malayasia. INFAPRO is a cooperative venture between the FACE Foundation of the Netherlands—which is investing monetary resources to sequester carbon—and the Sabah Foundation, a semi-government forestry organization in the state of Sabah, Malaysia. The FACE Foundation committed a total of $15 million with expectations that the project will sequester at least 4.25 million tons of carbon.

Although there are many tangential and exacerbating issues related to the CDM, from a basic business standpoint, the system appears to be working. For example, in 2005, 374 million tCO2e (100 million tons of atmospheric CO2 equivalent), mainly of Certified Emissions Reductions (CERs), were transacted at a value of $2.7 billion with an average price climbing over $7.23. Many hope that the negative kinks in the system will be worked out over the course of time and experience; and that stakeholders on all levels will realize not only the ecological benefits of engaging in carbon trading and emissions reduction, but also the longer-term social, cultural, and biological benefits.

Clean Water Act

THE CLEAN WATER Act (CWA) began as the 1972 amendments to the Federal Water Pollution Control Act, which was passed with the goal of restoring and maintaining "the chemical, physical, and biological integrity of the Nation's waters." Specifically, the act aimed to eliminate the discharge of pollutants by 1985, provide public funding for public waste treatment works, fund the technological advances necessary to reduce discharge, and clean up polluted water resources. While much of the act concerns the establishment of funding mechanisms for water quality improvement, there are two major regulatory components. The first is the National Pollutant Discharge Elimination System (NPDES), which establishes a permit system for "point-source" discharges into water (where a point-source is a discrete conveyance such as a pipe). The second is the 404 program, which requires permits for any dredging or filling in the nation's waters, including wetlands.

HISTORY OF FUNDING

The antecedent for the funding component of the CWA is the long series of amendments to the Federal Water Pollution Control Act (FWPCA), stretching back to 1948. These acts were concerned largely with sanitation and funded sewage treatment, but had no regulatory power to compel improvements in water quality. The importance of environmental conservation was noted, but execution of the act was in the hands of the surgeon general. The antecedent for the dredge-and-fill permitting program is the Rivers and Harbors Act of 1899 (RHA), which charged the U.S. Army Corps of Engineers with protecting the integrity of navigable waterways by establishing a permit program to regulate any dredging or filling of harbors or rivers.

The RHA permit program still exists, and many projects in coastal and riverine wetlands require both a CWA and RHA permit. There was no antecedent for the NPDES permit program. The name of the act was changed to the CWA with the 1977 amendments. Other changes included the addition of exemptions for agriculture and other activities from the 404 permit program, and clarification that CWA jurisdiction covers "waters of the United States" as defined by EPA.

Because the CWA empowers the Corps to require a permit for activities that impacts waters of the United States, it potentially represents a vast expansion of federal power: Many kinds of dryland activities eventually impact water. The CWA has thus been the source of much concern from property-rights advocates, who have argued against an expansive conception of "waters," and against the Corps' power to conduct an analysis of the secondary and cumulative impacts associated with proposed dredge-and-fill projects. This struggle has resulted in legal precedents that require a "significant nexus" between the activity and the integrity of navigable water in order for CWA jurisdiction to apply. The nature of this "nexus" is not currently clear, and will be the subject of future litigation.

The Corps' long experience in water resource permitting under the RHA, as well as the political resistance to allowing a potentially powerful regulatory program to be administered entirely by the EPA, led the act's authors to have the Corps administer the permit program. The EPA was given the power to veto permits, to set the environmental criteria by which permits would be issued, and to define "waters of the United States." The Corps resisted this arrangement strenuously throughout the 1970s, arguing that it was duplicative of the RHA, adopted a definition of "waters of the United States" that excluded wetlands, and often handed out permits without reviewing project plans. The *NRDC v. Callaway* decision in 1975 forced the Corps to adopt a definition of "waters" that was expansive (and was incorporated into the 1977 CWA), and the 1984 settlement in *NWF v. Marsh* forced the Corps to adopt EPA's guidelines on the environmental criteria for permit approval.

POSITIVE RESULTS

While the wetlands permitting program has been controversial, it has resulted in a reduction in net loss of wetlands, documented in five-year reports by the U.S. Fish and Wildlife Service. In fiscal year 2005, the Corps issued permits allowing approximately 20,000 acres of wetland impact, and required approximately 57,000 acres of compensation. In contrast, the EPA administers the NPDES permit program at the federal level, but the setting of water quality standards is performed by individual states, subject to EPA approval. The slow process of setting pollutant-specific effluent standards (Total Maximum Daily Loads) that are compatible with the state-determined designated use for each individual water body is still unfolding unevenly across the country. While the zero-discharge goal has proved unrealistic, the effect of point-sources has been reduced and the effect of nonpoint source pollution (such as agricultural runoff that is not regulated by the CWA) has been thrown into sharp relief. Nonetheless, the effect of the NPDES program is visible in the dramatic recovery of Lake Erie water quality and fisheries, the improvement of previously dead rivers in the industrial northeast, and the drive to develop the technology that allows polluters to meet or exceed required effluent reductions.

Clear-Cutting

CLEAR-CUTTING IS A logging method is which whole stands of trees are non-selectively harvested over a relatively large area. The goals of the technique are to maximize economic efficiency in harvesting or create conditions to re-establish stands of trees species that require sunlight for growth, or both. As an economic efficiency measure, it allows loggers to access and remove all of the valuable older trees without having to work around protected trees and younger trees of lesser value. As an ecological management tool, it allows large contiguous areas to be opened to sunlight and regrowth.

Clear-cutting has been controversial since World War II, when it became the dominant logging method in U.S. national forests; some foresters see it as a beneficial and legitimate logging method, while some environmentalists find clear-cutting to be environmentally detrimental. Silviculturists propose clear-cutting as a necessary practice for even-aged forest regeneration: to remove trees that have been impacted by disease and/or insects; to convert land to a new tree species through planting or seeding; to provide forest habitat for species that rely upon edge and high-density, even-aged stands; and to mimic the effects of large-scale, catastrophic wildfires or hurricanes.

Conservationists, on the other hand, point to the detrimental effects of clear-cutting, since the practice can result in fragmented landscapes, landslides, increases in flammable "slash" left on forest floors, watershed degradation, habitat degradation and loss, soil erosion, soil temperature increases, aesthetic blight, species extinction, and loss of a forest's age and species diversity.

DOMINANT METHOD OF LOGGING

Clear-cutting, while financially efficient, a useful management tool, and historically a standard practice, is often applied to forests that do not benefit from the practice. During the 1970s, it is estimated that clear-cutting took place on more than 250,000 acres each year, or an acre every two minutes. On June 4, 1992, the U.S. Forest Service, in response to the public outcry against clear-cutting, announced it would reduce clear-cutting by 70 percent from 1988 levels. Yet clear-cutting remains the dominant method used for logging the U.S. national forests. Many bills have been introduced unsuccessfully in Congress to ban the use of clear-cutting in national forests.

Temperate rainforests in both the United States and Canada have experienced extensive clear-cutting, and it remains the major method used to fell forests. For instance, in the Canadian province of British Columbia, government-sanctioned clear-cutting is the dominant method of timber extraction for industrial purposes and the main cause of species endangerment for northern spotted owls; 70 percent of Vancouver Island has been clear-cut.

In underdeveloped countries, legal and illegal clear-cutting goes on unchallenged. Clear-cutting of tropical rain forests for wood exports and non-native tree plantations in Brazil, Congo, Indonesia, Malaysia, and elsewhere contributes to global warming and reduces biological diversity. According to the Rainforest Action Network, the world has already lost 80 percent of old growth forests worldwide, and less than 5 percent remain in the United States.

According to the United Nations, at least 37.5 million acres of rainforests are lost annually, an area the size of Georgia. Despite the relatively small land area they cover, rainforests are home to about half of the 5–10 million plant and animal species on the Earth.

Andrew J. Schneller
Independent Scholar

Clements, Frederic E. (1874–1945)

FREDERIC CLEMENTS WAS A founding figure in ecology, whose theory of plant succession helped consolidate the discipline in the early 20th century and continues to influence both scholarly and lay thinking about vegetation dynamics to this day.

Born in 1874 in Lincoln, Nebraska, Clements studied under Charles E. Bessey at the University of Nebraska, where he earned a bachelor's degree in 1894 and a doctorate in 1898. Surrounded by the rapid conversion of prairie to farmland, he conducted exhaustive inquiries into native grasses in the Great Plains, pioneering the use of the quadrat as a method of quantitative measurement of vegetation. His *Phytogeography of Nebraska* (1898, coauthored with Roscoe Pound), *Development and Structure of Vegetation* (1904), *Research Methods in Ecology* (1905), and *Plant Physiology and Ecology* (1907) established him as a leading figure in the nascent field of ecology, and in 1907 he accepted the post of Professor and Head of the Department of Botany at the University of Minnesota.

Clements expanded his fieldwork to the entire western United States, and in 1916 he completed his magnum opus, *Plant Succession: An Analysis of the Development of Vegetation*. The publisher, the Carnegie Institution of Washington, hired him away from Minnesota the following year and employed him until his retirement in 1941. Throughout his Carnegie career he worked summers at the Alpine Laboratory below Pike's Peak in Colorado; he spent winters at the Desert Laboratory in Tucson until 1925 and subsequently at a coastal ecology laboratory he established in Santa Barbara, California.

The central idea of Clements' theory was that units of vegetation he termed *formations* are "complex organisms" with determinate life histories. Each formation passes through a fixed sequence of "seres," or seral stages—e.g., lichens, annual grasses, perennial grasses, and trees—on the way to climax, at which point equilibrium is obtained between the vegetation, soil, and climate. Succession was the process by which formations developed through their stages. *Plant Succession* opened with the claim that this theory was "of universal application" and that it "represents the only complete and adequate view of vegetation." Four years later Clements published *Plant Indicators,* a companion volume on how to apply the theory to practical matters of agriculture and range management. Both books contained descriptions of the formations of western North America.

Upon Clements' death in 1945, A.G. Tansley wrote presciently that a theory "may be overstated, it may contain flaws which make it unacceptable in its entirety; but if it also contains, as Clements's did, a general idea of the first importance on which subsequent advance can be based, its originator's name can never be forgotten." During his lifetime, Clements's ontological claim for formations as organisms was strongly disputed, most scathingly by Henry Gleason in a 1926 journal article, "The Individualistic Concept of the Plant Association."

The field of range science, heavily indebted to succession, has struggled mightily to find an alternate theoretical paradigm; and in recent decades Clementsianism has become almost synonymous with *equilibrium ecology*, now deemed anachronistic or at least inapplicable in many contexts. Yet it seems plant ecology cannot but rely on something like successional theory to organize its myriad observations of vegetation change.

Climate

CLIMATE IS THE average of weather conditions over a period of time, usually over several years. Climate may be local, regional, or global. In contrast, weather is the condition of the air in the atmosphere of a local environment at any moment. The locality may be as small as the place where a person is standing, or it may be as large as a region affected by a giant air mass. The weather or atmospheric conditions may be hot or cold, dry or humid, rainy or dry, windy or calm, cloudy or clear in combination.

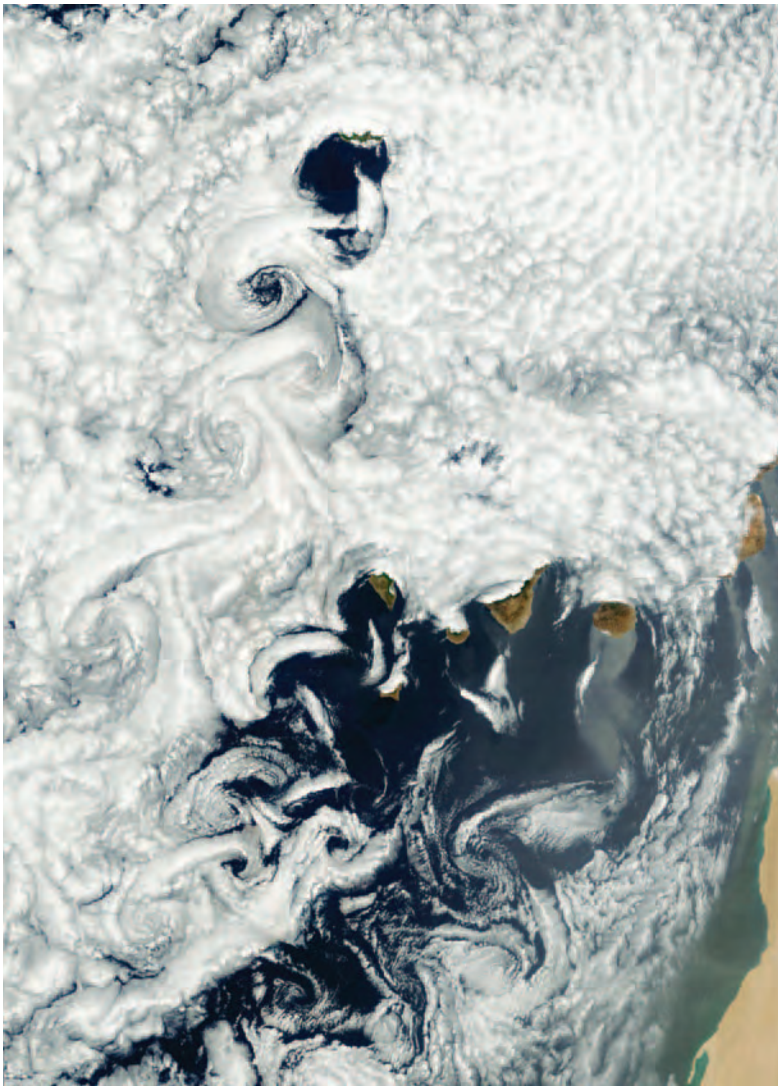
Climate is usually defined with two measures of atmospheric conditions: temperature and precipitation. Therefore, the climate of every country, land formation, region, town, continent, or even the whole planet is defined in terms of the amount of its average precipitation and its average temperature.

The characteristic atmospheric conditions of locations on the surface of the earth define its climate. A description of the long-term weather of an area (at least 30 years) defines its climate. The description should include the general pattern of weather conditions, seasons, weather extremes of storms—tornados, hurricanes, typhoons, cyclones, or blizzards—droughts, and rains over the climatic period.

Climate is affected by a number of factors. These factors include latitude; proximity to great lakes, seas, or an ocean; prevailing winds; type of vegetation; monsoon winds; mountain ranges; and the size of continents, versus an island or an island archipelago. The climate determines whether an area is a desert, forest, savannah, jungle, or tundra. Some areas have virtually the same climate year-round, such as the high mountains of Mexico and some tropical islands, both of which are near the equator. In other places, the climate varies with the season.

Temperature and precipitation varies with the season for most places on earth. It is, therefore, necessary to specify seasonal climate. For example, the winter climate of Ontario, Canada and its summer

Over the Canary Islands off the African coast, eddies create turbulent patterns called vortex streets.



climate are different: the winters are much colder than are the summers. While Ontario's daily and nighttime temperatures for every month of the year could be totaled and averaged, the results would probably not be very useful. More accurate would be averaging the temperatures for each separate season, which would give its winter climate in contrast with its summer climate. The same principle is used to describe the climate of every location on earth.

The climate in different locations is directly affected by the sunlight that reaches earth. The equator has about the same amount of sunshine year round, as it is perpendicular to the sun. The rest of the earth's surface receives varying amounts of sunlight from day to day throughout the year. This variation is a factor in the climate in different places around the world, and makes the seasons differ in their temperatures. Temperature affects winds, which bring or drive away moisture (usually from the oceans) and therefore the amount of precipitation. The variations in sunlight throughout the year make it summer in the northern hemisphere while it is winter in the southern hemisphere. Along with local conditions, sunlight variations contribute to the climate of localities and regions.

In 1900, Vladimir Koppen introduced what is now known as the Koppen Climate Classification System. It is widely used for classifying climate globally; most climate classification systems currently in use are based on it. Because climate is concerned with long-term weather patterns at the surface of the earth, Koppen organized the world's climate areas by their patterns of vegetation and soil.

CLIMATE CLASSIFICATION SYSTEM

Koppen's classification system has five major climate types that are based on the monthly and annual averages of temperature and precipitation: Moist Tropical Climates, Dry Climates, Humid Middle-Latitude Climates, Continental Climates, and Cold Climates. Moist Tropical Climates are designated with a capital *A* and have high temperatures almost every day as well as heavy rainfall. Dry Climates are designated with a capital *B* and are characterized by small amounts of rain and widely varying temperatures between night and day. This type of climate has two subtypes: semiarid (steppe) and arid (desert). The Humid Middle-Latitude Climate—designated with a capital *C*—is greatly influenced by land and water differences. The summers are warm and dry while the winters are cool and wet. Continental Climates are designated with a capital *D* and are located in the interior of large landmasses. Here, seasonal temperatures vary and precipitation is usually low. Finally, Cold Climates—designated with a capital *E*—are regions covered in permanent ice; these can be the polar regions, but may also be the tops of mountains. The Koppen system also used many sub-categories to classify variations in climate, which are designated with lowercase letters.

The major climate types around the world are polar, temperate maritime, Mediterranean, subtropical, desert with cold winter and hot summer, "Chinese," equatorial, tropical maritime, tropical, desert, temperate continentals, and polar. These climates types are so widespread, they can be referred to as climate zones.

Polar climates have long, cold winters with almost no daylight. The summers are short with very long days. They are characterized by permanent snow, ice packs, freezing temperatures, and extreme weather. The angle of the sun to the north and south poles is such that the sun's rays glance off the earth. Sunlight also has to travel through more of the atmosphere to reach the poles, which are at an angle to its rays, reducing the amount of sunlight that reaches the pole. In addition, the white ice cap reflects much of the sunlight, which adds to the lack of warmth.

Temperate maritime climates are humid year-round. The winters are not harshly cold, and the summers are warm to hot and humid. In temperate countries such as France, it is rare for the temperatures to be too hot or too cold. Moreover, the average precipitation usually varies no more than ten percent from year to year. The climate in France is complicated because it is at the junction of several climates. When the wind is from the north, the air is cool or cold and often clear, bringing a hint of polar climate. When the wind blows from the Atlantic Ocean, it brings moisture and usual rain and wind but mild temperatures. Western France has a temperate maritime climate. In general, the wind in France is westerly from the Atlantic, which gives the country a moderate and moist climate. When the wind in France is from the east, it brings a continental temperate climate. The winters in eastern France are longer and colder with more snow. In the summer, they are cooler with warm and rainy periods of thunderstorms. If the wind in France is from the south, the temperatures are usually hot and dry due to its Mediterranean climate found along its Mediterranean shores.

The Mediterranean climate, in which grapes and olives grow well, is found in Australia, California, Chile, and South Africa, as well as around the Mediterranean. The Mediterranean climate is mild and dry in summer and winter. It is wet in spring and prone to forest or brush fires in the summer. The autumn is moderate but may also be rainy. The Mediterranean climate is wet in the springtime, which causes vegetation to grow rapidly. However, the dry summer heat withers the vegetation and makes it prone to brush fires or to forest fires.

South of France and across the Mediterranean is a region of subtropical climate in North Africa. Along the Mediterranean coast, in North Africa, the Mediterranean climate soon gives way to the south to temperature increases in the subtropical climate that is usually dry.

To the south is the great Sahara Desert, which has a desert climate that is scorching hot in the day, but freezing cold at night. In winter, temperatures may be cold enough to freeze water. Cold desert climates such as that of Mongolia are cold in the winter and hot in the summer. Snow and rain occurs occasionally in winter and summer.

In contrast, across the Atlantic, the Gulf Coastal Plain of the southern United States has a moist subtropical climate that becomes more and more tropical as the equator is approached. This type of climate is sometimes referred to as a "Chinese" climate because the southeastern United States and China have mild, semi-dry winters with hot, moist summers.

The equatorial regions have in some places little change throughout the year. For example, the region of the Congo River is near the equator, where the sun shines directly overhead all year. The high moisture content and the constant temperature cause clouds year-round. However, equatorial climates have seasons that alternate between the wet season and dry season.

Tropical maritime climates are like equatorial climates because they have summer year-round. However, the rainfall pattern is different, and the trade winds moderate the temperature.

Climate varies with a number of factors besides the season or the latitude. One factor affecting climate is the elevation of an area.

MOUNTAINS AND VALLEYS

Mountain climates are not the same as the climate of a plain. In mountain zones, altitude causes a change in temperature. Climate is vertical: the higher the altitude, the thinner the air becomes. Thin air, especially thin dry air, holds less heat than warm moist air at sea level. So severe is the climate in mountain zones that nothing survives above 23,000 feet (7,000 meters). At that altitude and above, winds are usually fierce and temperatures so low that living cells are quickly frozen. Mountain zones occur all over the earth. There are mountains in the tropics—like Mount Kilimanjaro—which are near the equator, but are snow-covered on their summits all year long. The flora of mountain climates is different from those found at lower altitudes. Alpine plants have short stems that keep them hugging the ground out of the wind. Their leaves are small and waxy to prevent water loss, and they grow slowly because they grow only on warm days.

The climate of a valley below may also vary with their direction, in terms of the way in which sunlight is available or is blocked by a mountain. For example, one side of the valley may be shaded much more than the opposite side, giving the two sides of the same valley different climates. Valley climates can also be affected by winds from the ocean or by katabatic (down-slope) winds. The cooler, heavier air on top of a mountain can plunge rapidly down its slopes, bringing cold dry air to the valley below and forming frost hollows. The cold dry air of the katabatic wind can rob the plants in its path of moisture and stunt their growth. On the other hand, katabatic winds can cause fog by sending cooler air to the valley below, where the warm moist air is chilled to the dew point. In Greenland and on the Antarctic ice caps, katabatic winds have been clocked at 150 miles (240 kilometers) per hour. In temperate zones, katabatic winds can be an aid to agriculture. In Hungary and other regions where grapes are grown, katabatic winds at night can cool the grapes and promote their development. Otherwise, the nighttime heat would hinder viticulture.

Some mountain climatic zones have anabatic winds, which move up the slopes of mountains because the warm air in the valley is a sunny slope that warms quickly, sending warm air up the mountain.

Plate tectonics is one reason for global climate changes over the geological eras. These moving plates have carried the continents through different climate zones over the eons. Volcanic eruptions can also affect the weather for long periods, creating climate changes when enormous volumes of volcanic gas and ash are blown into the atmosphere, creating nuclear winters. These changes are similar to those believed to have been caused by an enormous meteorite or asteroid that hit the earth next to the Yucatan peninsula about 65 million years ago. The nuclear winter that it produced is believed to have been responsible for the extinction of the dinosaurs as well as a great number of other species.

In the last 400,000 years, it is believed that there have been five Ice Ages. Over the last 1 million years, there have been many more periods of global freezing. During Ice Ages, the earth was on average 5 degrees F (3 degrees C) cooler. This was cold enough for glaciers to form and cover half of North America. Glaciers also covered New Zealand and the Alps in Europe. Major Ice Ages include the Gunz Ice Age, 580,000 years ago; the Mindel Ice Age, 430,000 years ago; the Riss Ice Age, 240,000 years ago; and most recently, the Wurm Ice Age, which lasted 100,000 years and ended 20,000 years ago. There have also been "little ice ages." Between 1430 and 1850, the temperatures in northern Europe dropped enough to cause crop failure and starvation; the River Thames froze over every winter. However, there were also periods of sudden warming.

Interglacial periods have usually been shorter than glacial periods; the shortest lasted only 15,000 years. The present interglacial period has lasted about 9,000 years. In contrast, the shortest Ice Age lasted 60,000 years.

Long-Term Weather Cycles

The length of time of the average weather of a location, region, or of the whole earth is very important. It can last for a year, but usually the average weather is for a 30-year period. This may seem a long time in human experience, but it is an instant in geologic time. Periods of warming and cooling occur in a yet unpredictable pattern; it's very possible that the weather of a location or region experiences cycles of warming and cooling over a 30-year period. In fact, Between 1900–40, there was a warmer period with warmer winters, followed by a cooling period in North America from the early 1940s to the early 1970s. Scientists were concerned that another Ice Age was coming. However, after the mid-1970s, the climate began to warm again.

Descriptions of the climate based upon current weather records are weak. Accurate records of the weather have been kept for only about 150 years, and it is possible that weather cycles that form the climate move in 200-year cycles. Sensational journalism about the climate is usually based on inadequate averages. These overstated stories are prone to committing the fallacy of over-generalization, because they claim too much knowledge from too small of a sample. Statistical analysis of the climate is difficult simply because the data is limited.

The history of the climate of the earth begins at least three or four billion years ago, with the earth cooling enough to acquire an atmosphere. The atmosphere then was chemically quite different.

Evidence for climate changes has been found in tree rings and in the pollen record or other information found in core samples of ice drilled from glaciers such as those in Greenland. Fossil records show that there were ages in which the seas covered much more of the continents than they do today. There is evidence from fossilized pollen that some areas were warmer and others were wetter or dryer. Deposits of vast sand dunes point to areas that had a desert climate, when today the climate of that area is different. For example, fossils found in Antarctica suggest that it had a much warmer climate than its current polar climate.

The earth's climate is also affected by the long-term orbit of the sun. Revolving on its axis once a day and around the sun every 365 days (plus a bit more), the earth makes an ellipse. In addition, as the earth rotates, it is tilted from perpendicular by 23.5 degrees. The tilt is what makes the sun shine on the earth in varying ways so that it is heated unevenly, causing winds and seasons. The spinning earth on its axis in space is pointed in a particular position in the sky, a position that changes in a circular pattern. The pattern, which repeats itself every 26,000 years, is called *precession*.

A theory regarding the cause of the Ice Ages maintains that they all seem to have started and finished gradually. On the other hand, there is counter-evidence from Siberia where mammoths have been found quick-frozen while chewing flowers. This suggests that the Ice Ages started catastrophically, which may have been due to a shift in the tilt of the earth.

In addition to the earth's climate being influenced by its axial tilt, its orbit, which is affected by gravity, is a contributor. As the earth moves in 180 cycles in relation to the other planets' gravitations, influences may affect its speed enough to affect the lengths of summer and winter.

A COMPLICATED PROCESS

Climate change is a complicated process. For the climate to change, a combination of events must occur. There must be changes in the ocean temperature, the amount of clouds worldwide, the extent of polar ice, the amount of sunlight striking the earth, the position of the earth's orbit around the sun, and human activities. Human activity is the only factor that people can really control.

Clouds reflect sunlight, but they also retain heat. How much of a cooling effect by blocking sunlight and how much of a warming effect by retaining heat that clouds have is very difficult to determine. In addition, increases in moisture that the sun is evaporating over the vast oceans should lead to more clouds. However, with an increase in cloud cover, will the climate grow warmer or cooler?

Drought and winds can add dust to the atmosphere, which will block sunlight. The effect is often similar to the reflecting actions of clouds. However, if the dust includes metallic elements, it can reflect sunlight. On the other hand, it may absorb sunlight and promote climate warming. Volcanoes and great meteorites can contribute dust to the earth's atmosphere. The eruption in 1815 of the Indonesian volcano Tambora threw enough volcanic dust into the atmosphere to cause the "year without a summer" in 1816. Thousands starved because of the crop failures that were the result of very abnormal summer weather.

THE COMPONENTS OF THE ATMOSPHERE

The atmosphere is the envelope of gasses surrounding the earth. It comprises four layers: the troposphere, the stratosphere, the mesosphere, and the thermosphere. The term *atmosphere* comes from the Greek word *atomos*, meaning vapor. Atmospheric pressure is the weight of the air pressing against the earth at any given point. At sea level, the weight of the air is 14.7 pounds per square inch (1.03 kilograms per square centimeter) of surface. At places below sea level such as the surface of the Dead Sea, the atmospheric pressure is greater than one atmosphere. On mountaintops, the atmospheric pressure is less. This natural feature of the weight of the atmosphere at various places on the earth's surface is an important feature in the weather and in the climate. The gases in the atmosphere contain nitrogen (78 percent), oxygen (21 percent), argon (0.01 percent), water vapor (0.04 percent), and traces of neon, helium, krypton, and hydrogen. In addition, there are traces of ozone and carbon dioxide.

Ozone is produced in the atmosphere by lightening, and, as a greenhouse gas, is important for trapping heat in the atmosphere. If the amount of ozone in the atmosphere increases then it will have a warming effect. The ozone layer, which is very high in the atmosphere at a height of 18.5 to 31 miles (30–50 kilometers), is also important because it blocks ultraviolet light, which can cause harmful burns and eye damage and can promote skin cancer.

Carbon dioxide is a colorless, odorless gas that has an indirect effect on the weather. Small changes in the amount of ozone and carbon dioxide can have significant weather effects, mainly due to the greenhouse effect.

For human activities to affect the climate, it is likely that the changes needed would be those that affect the content of the atmosphere. However, whether human-caused changes in the atmosphere can produce predictable effects is a very hotly disputed issue. For example, chlorofluorocarbons, which were widely used in aerosol sprays and as refrigerants, have been found to be destructive of the ozone in the atmosphere. Human use of fluorocarbons appears to have damaged the ozone layer by creating a hole in the layer over the South Pole, which could have a dramatic cooling effect on the earth.

In the view of many people, the climate is in crisis. It is believed that current global warming is not completely natural, and responsibility is being assigned to human activities. The use of carbon fossil fuels since the late 1700s and the beginning of the Industrial Revolution has led to enormous quantities of wood, coal, natural gas, and petroleum being burned for heating, manufacturing, transportation, and other reasons, which has increased the amount of carbon dioxide in the atmosphere. Consequently, the increased carbon dioxide levels are believed to have caused the increase in the temperature of earth's climate—1 degree F over the last 100 years.

When fossil fuels are burned, they produce gases, the largest percentage of which are carbon dioxide. While this is a naturally occurring chemical, it is now believed to be contributing to global warming because of the greenhouse effect. Greenhouse gasses can come from sources other than just the burning of fossil fuels or wood. Methane can be produced by rice fields, garbage dumps, cattle, and pig wastes. It is 20 times stronger than carbon dioxide as a greenhouse gas.

The amounts of carbon dioxide and ozone in the atmosphere are normally relativly small. However, these gases retain energy from the sun, which keeps energy in the atmosphere. It eventually causes the surface of the earth to warm and contributes to the "greenhouse effect," which is a natural phenomenon of the earth's atmosphere. Without this effect, the biosphere of earth would not exist because the earth's climate would be too cold.

One theory of global warming argues that variations in the amounts of greenhouse gases in the atmosphere contribute to global warming and global cooling. While the burning of fossil fuels increases the amount of carbon dioxide in the atmosphere, a reverse process occurs when plants lock up carbon dioxide in plant material. If enough carbon dioxide were removed from the atmosphere, global cooling and another Ice Age could occur.

Concerns over global warming are about more than temperatures. A great number of species could become extinct. In addition, melting polar ice should cause sea levels to rise, flooding port cities, and inundating vast areas of the earth. In addition, the number and severity of tropical storms could greatly increase. Moreover, humans and livestock could undergo enormous stress from the increased heat and even starve if droughts caused crop failures.

Some scientists have predicted that global warming will increase by between 2–4 degrees F (2–5 degrees C) by 2030 unless the volume of carbon dioxide is drastically reduced. Other scientists have estimated that the amount of carbon dioxide in the atmosphere has increased 30–50 percent since 1900, and that it will continue to increase unless significant reductions are made in carbon dioxide emissions.

Deforestation is an indirect contributor to the increases in carbon dioxide in the atmosphere. Plants take up carbon dioxide for use in photosynthesis, and expel oxygen. Reductions in the number of trees globally has a deleterious effect on the atmosphere.

A region's climate is the factor that determines which plants and what animals will inhabit it. The world's biomes are a fabric woven from climate, plants, and animals. Global warming will drastically affect these biomes, destroying species and possibly causing drastic food losses and the death of billions of people. To stop the increase in carbon dioxide in the atmosphere, reductions in fossil fuel emissions, other emissions, and deforestation will be needed.

Climate Modeling

CLIMATE MODELING USES simple to highly complex mathematical formulas and computing power to simulate climate system processes. Climate-related processes often occur beyond the physical or temporal scale for laboratory experiments. Climate events such as *El Nino* occur over millions of acre-feet of water, or the retreat of entire continental ice sheets may take hundreds of years. Climate modeling simulates the behavior found in climate processes using state-of-the-art computer technology to provide timely results for analysis. The analyses of the climate model outputs use observed climate data (i.e., temperature or ice-core records) for comparison and basic knowledge of the climate system to understand the results. Climate modeling is used to understand past and current climates, or to predict future climates.

Essential components of climate modeling are *boundary conditions* (initial conditions), which are derived from observed climate data such as sea surface temperatures. Climate modeling uses *forcing* where the boundary conditions are changed (i.e., sea surface temperatures increased or mountain ranges removed) to simulate how a climate system will respond to these changes. The simulations and climate forcing use equations based on the known physical laws that drive climate. For example, increasing land-surface snow cover will increase the reflection of incoming solar radiation contributing surface cooling in the model output. A final step in climate modeling is the analysis of the climate data from the model output and a comparison of the results to a research hypothesis.

CHALLENGES TO CLIMATE MODELING

A challenge with climate modeling is that in the real world, many processes of the climate system occur on different spatial or temporal scales. For example, the uplifting of mountain ranges may occur over millions of years while land–surface heating and cooling occur over seasonal and diurnal periods. In order to deal with different spatial and temporal scales, researchers must determine what type of climate model to apply to simulate the climate processes and time period of interest. To simulate a climate process such as a monsoon, researchers may run the model for a time scale of several months or 100 years over specific geographic region. To simulate changes with significant movements of the continents, researchers may run the model to simulate for millions of years for the entire globe.

Climate modeling became a researching tool in the mid-1960s. The most simple climate models are zero-dimensional models, or *radiative equilibrium models*. These models are used to gain an idea of a planet's radiative temperature based on an assumed constant amount of incoming solar radiation and the planet's mass. For earth, these models calculate a radiative surface temperature of 255 K (0 degrees F). These models omit some of the known climate processes such as warming from greenhouse gases, hence the actual average surface temperature for earth is actually 288 K (59 degrees F).

There are two general types of one-dimensional climate models: *radiative-convective models* and *energy balance models*. The radiative-convective models were developed in the mid-1960s to analyze the thermal equilibrium of the atmosphere. These models calculate the temperature for each layer of the atmosphere based on the incoming solar radiation, surface temperatures, surface reflectivity, cloud cover, atmospheric pressure, and moisture content. Radiative-convective models are useful to our understanding of climate processes of temperature decreases with altitude or local temperature inversions. They are also useful in understanding local climate processes such as thunderstorm development. Energy balance models were developed in the late 1960s to calculate the amount of solar radiation absorbed or reflected by clouds and the earth's surface. These calculations are based on the amount of incoming solar radiation, cloud cover, and reflectivity at different latitudes. Energy balance models demonstrate how temperature decreases with increasing distance from the earth's equator.

In the early 1970s came the development of *two-dimensional climate models*. These models were a combination of radiative-convective models and energy balance models to simulate more realistic climate processes of the atmosphere. Two-dimensional climate models can represent a horizontal area representing the earth's surface or a horizontal and vertical surface representing a cross-section of the atmosphere. The two-dimensional climate models simulate climate processes of energy transport from the equator to the poles and the patterns of quasi-stationary high pressure and low pressure systems.

The climate models that aim to represent the spatial dimensions of the entire climate system are the *general circulation models* (GCMs). Boundary conditions for GCMs are set at points over a horizontal and vertical grid, representing the earth's surface and atmosphere. When simulations are run, mathematical equations relating to climate processes are solved for each point. The GCMs consider combinations of conditions related to climate such as seasonal incoming solar radiation, surface friction, cloud formation, coastlines, and mountain ranges. Although GCMs have more realistic simulations for the climate system, they do have limitations, such as the computational power for the simulation of model runs. The calculation of millions of numbers at grid points in a timely manner is a challenge for even the fastest computers. Advancements in computer technology at the world's leading atmospheric research institutions address these limitations.

The first GCMs were being developed concurrently with other early climate models of the 1960s. The early GCMs were derived from the numerical models used in the 1950s for short-term weather forecasting. A fundamental addition to GCM climate modeling was the development of *ocean GCMs* (*OGCMs*). The outputs from OGCM simulations are sea surface temperatures, sea-ice extent, and salinity, which provide boundary conditions for atmospheric GCMs. There has also been the development of atmosphere–ocean GCMs or *AOGCMs*, which combine the dynamic ocean processes (i.e., currents, temperature, and sea ice) with climate system processes to simulate climates over the globe. Because there are many other physical components and processes such as oceans that significantly affect climate, other types of models have been developed to be incorporated with GCMs. *Vegetation models* can simulate the impact a rainforest or deforestation has on local, regional, or global climates. *Ice-sheet models* can provide boundary conditions for the simulation of GCMs for glacial and inter-glacial periods for earth's climate history or future climate scenarios.

Climate, Arctic and Subarctic

THE EARTH'S ARCTIC and subarctic climates are located over the highest latitudes of the globe, typically poleward of 50 degrees latitude. Because these climates are located at high latitudes, they are mostly driven by a dramatic seasonal shift of incoming solar radiation. The summer season consists of long daylight hours, while the winter season has long nighttime hours. Locations poleward of 70 degrees have 24 hours of daylight during their respective summers and 24 hours of night during the winter.

Subarctic climates are largely continental and unique to the northern hemisphere, due to the existence of large land masses between 50–70 degrees. Most of Canada and the interior regions of Siberia have subarctic climates, which can be distinguished by the presence of extensive coniferous forests with hardy deciduous trees such as aspen and larch intermixed. A key characteristic of subarctic climates is an annual temperature range greater than any other climate zone on earth. Winters typically have minimum temperatures between –50 and –30 degrees C (–32 and –22 degrees F), while summer maximum temperatures are as warm as 15–25 degrees C (59–77 degrees F). Subarctic climates tend to be moderately dry with total annual precipitation between 30–50 centimeters (12 and 20 inches). Winter snowfall is heavy, ranging from 150–300 centimeters (59–118 inches), with higher amounts occurring over locations near coastal areas such as eastern Canada or eastern Siberia.

Ice cap climates have subfreezing temperatures year-round. Snow pack and ice are permanent features.

Polar climates occur over oceans and land masses typically poleward of 60 degrees latitude. They exist where the warmest month of the year has a mean temperature less than 10 degrees C (50 degrees F). Polar climates exist over the Arctic Ocean, Antarctica, and far northern areas of Asia and North America (including Greenland). Despite perpetual daylight hours during the summer season, the sun's low angle and significant cloudiness (60–90 percent) permits only moderate surface warming. Polar climates have two climate subtypes, tundra and ice cap.

Tundra climates are distinguished by landscapes lacking forests, but covered in flowering plants, moss, lichen, and some shrub species. An additional characteristic for tundra climates is the existence of permafrost, a permanent, impermeable layer of frozen earth below the surface. Summers are short (6–10 weeks) and are defined by daytime temperatures between 0–10 degrees C (32–50 degrees F) providing just a long enough period for snow to melt and the upper layers of soil to thaw. Winter temperatures are cold, but can vary significantly depending on the proximity to certain coasts. Tundra environments in northern Scandinavia have winter minimum temperatures between –10 and –5 degrees C (14–23 degrees F), while in northern Alaska they are between –33 and –28 degrees C (–28 and –18 degrees F). Total snowfall and annual precipitation is slightly lower in tundra climates than in subarctic climates.

Ice cap climates have persistent subfreezing temperatures year-round. Although less snowfall occurs here than in tundra or subarctic climates, snow pack and ice are permanent features of the landscape. The ice cap climates occur over the Arctic Ocean, interior portions of Greenland, and 97 percent of Antarctica. High atmospheric pressure dominates over these locations; however, the climate is made severe by year-round wind storms and surface blizzards. The Antarctic boasts the earth's coldest recorded temperature of minus 89 degrees C (minus 129 degrees F).

Climate, Arid and Semi-Arid Regions

ARID AND SEMI–ARID climates exist where more surface moisture is lost to evaporation than gained from precipitation. Arid and semi-arid climates cover 30 percent of earth's land surface, a larger land area than any other climate. These climates have low annual precipitation, abundant sunshine, and high evaporation rates. The difference between the maximum daytime and nighttime minimum temperatures is wide, ranging from 15–20 degrees C (27–36 degrees F). Low precipitation in arid and semi-arid climates is influenced by the presence of semi-permanent, subtropical high-pressure areas located across the globe around 30 degrees latitude. These high-pressure zones are large areas of descending air aloft, limiting cloud development and precipitation.

Subtropical arid climates, such as the Sonoran Desert, Rub al-Khali, Sahara, and the Australian Outback, are located at lower latitudes within subtropical high-pressure areas. These areas have very low annual precipitation between 25–150 mm (1–6 inches), and experience extremely hot summers, with temperatures commonly over 45 degrees C (113 degrees F). The world's hottest, near-surface air temperature was 57.8 degrees C (136 degrees F) recorded at El Azizia, Libya in the northern Sahara.

Mid-latitude arid climates are defined as arid regions that have more than four months with mean temperatures cooler than 10 degrees C (50 degrees F). The Gobi and the Taklimakan Deserts of central Asia and the Great Basin Desert of the United States have mid-latitude arid climates. Mountain rain shadow effects are a common influence on mid-latitude arid climates. For example, in Asia, the Himalayas block the northward flow of Indian Ocean moisture from reaching the Gobi and the Taklimakan Deserts. Summers are cooler than subtropical arid climates, and winters can be below freezing. Kashi, China, in the Taklimakan Desert, has a winter minimum temperature of minus 11 degrees C (12 degrees F) and summer maximum temperature of 33 degrees C (91 degrees F).

The world's coastal arid climates are mainly located along the west coasts of South America (Atacama Desert) and southern Africa (Namib Desert). These climates typically have mild temperatures due to the adjacent cold ocean currents. The cold ocean waters limit convection and significant precipitation. Although overcast skies and coastal fog are frequent, these climates are phenomenally dry. On average there is only 10–20 mm (0.4–0.8 inches) of total annual precipitation.

The temperatures in semi-arid climates are generally similar to those of adjacent arid climates, but annual precipitation is higher. The largest areas of subtropical semi-arid climates are found in northern Mexico, the Sahel of North Africa, the Kalahari of southern Africa, and parts of the Australian Outback. Subtropical semi-arid climates average 500 mm (20 inches) of annual precipitation, which usually occurs during pronounced wet seasons. The vegetation in subtropical semi-arid climates consist of drought tolerant grasses, shrubs, and widely dispersed trees. The mid-latitude semi-arid "steppe" climates are found over central Asia and western North America. Annual precipitation ranges from 250 to 500 mm (10 to 20 inches) and cooler temperatures reduce the amount of moisture evaporated from the surface. The mid-latitude semi-arid climates are able to support significant low-lying vegetation consisting of bunch grasses and shrubs.

Climate, Continental

CONTINENTAL CLIMATES HAVE minimal influence from marine sources due to their location in continental interiors or upwind of coastal areas. In the humid mid-latitude regions of the Northern Hemisphere, continental climates are a buffer zone separating mild, subtropical climates from the severe sub-arctic climates. Continental climates are influenced by both arctic and tropical weather systems, where severe winters and hot, humid summer days both occur. The mid-latitude jet stream frequently flows over continental climate regions and drives mid-latitude storm systems accompanied by warm fronts and cold fronts.

Continental climates are similar to sub-arctic climates in that there is wide range in the annual temperature with cold winters and warm, occasionally hot summers. What makes continental climates unique is the day-to-day variability in weather and temperature. Winters are generally cold and sometimes severe; however, dry winds from the western mountains, occasionally bring temporary mild conditions. The Chinook winds of North America descend from the Rocky Mountains during the passage of dry weather systems and these winds can increase the temperature 15–25 degrees C (27–45 degrees F) in a matter of minutes. Even with occasional mild weather, winters in continental climates are more often cold and severe, as cities such as Moscow have experienced temperatures below –40 degrees C (–40 degrees F). Summer temperatures in continental climates are generally warm and humid; however, occasional subtropical influences can create extremely hot and humid conditions lasting 1–3 weeks. Chicago, for example, has an average July maximum temperature of 29 degrees C (84 degrees F), but summer temperatures over 40 degrees C (104 degrees F) with high humidity have occurred.

Precipitation in continental climates is higher than in sub-arctic or semi-arid climates. There is typically between 500–1000 millimeters (20–40 inches) of precipitation annually, which falls as snow in the winter and as rain showers throughout the rest of the year. Continental climates usually have more precipitation during the summer, and this characteristic is most pronounced in the continental climates of east Asia. In cities such as Shenyang, China, 400 mm (16 inches) of precipitation falls in the summer and 30 millimeters (1.2 inches) falls in the winter. Precipitation is also higher in continental climates located upwind of coastal areas in places such as New York City where 1100 millimeters (43 inches) of annual precipitation falls. The precipitation in continental climates support mixed deciduous/evergreen forests or a mix forests and grasslands in the drier regions.

Continental climates are found in Eurasia and North America. These climates are generally not found in the Southern Hemisphere due to the substantially higher ocean-to-land surface ratio and a more prevalent marine influence on climates. In Eurasia, continental climates can be found from eastern Europe and southern Scandinavia eastward through Russia. There are also continental climates found in Manchuria (northeastern China), North Korea, and northern Japan. In North America, continental climates begin east of the Rocky Mountains in the United States and southern Canada and extend east through the Great Lakes Region to the Atlantic Ocean. Some of the renowned world cities such as Stockholm, Moscow, Toronto, Chicago, and New York City have continental climates.

Climate, Humid Subtropical

HUMID SUBTROPICAL CLIMATES are located in the lower mid-latitude regions of the northern and southern hemispheres. These climates typically have long humid summers and short, relatively mild winters. During the summer, humid subtropical climates are influenced by neighboring tropical zones and warm oceans. In humid subtropical climate zones, the subtropical jet stream is present in the summer, often bringing abundant moisture and thunderstorms. During the winter, humid subtropical climates are influenced by weather systems originating in tropical or continental climate zones. Occasionally, weather systems from subarctic regions can penetrate into subtropical regions, bringing severe cold lasting 2–3 days. The mid-latitude jet stream frequently moves over humid–subtropical climate regions in the winter, bringing mid-latitude storms and highly variable day-to-day weather.

Humid subtropical climates have shorter annual temperature ranges than those found in continental climates; however, these climates do have distinct seasons defined by temperature and, occasionally, precipitation. In cooler, humid subtropical locations, temperatures below freezing occur frequently in the winter, but in locations closer to the equator, temperatures below freezing may not occur every year. For example, winter nighttime and daytime temperature averages in Memphis, Tennessee are 0 and 10 degrees C (32 and 50 degrees F), respectively. In warmer humid subtropical locations such as Hong Kong, China winter nighttime and daytime temperature averages are 14 and 19 degrees C (57 and 66 degrees F), and temperatures below freezing are rare. Summer temperatures in humid subtropical climates are warm-to-hot with high humidity. Summer nighttime and daytime temperature averages in Brisbane, Australia are 22 and 29 degrees C (72 and 84 degrees F) and in Dallas, Texas, they are 23 and 36 degrees C (73 and 97 degrees F).

Precipitation in humid subtropical climates is typically high due to the proximity of warm oceans and tropical influences; however, droughts do occasionally occur. There is typically between 900–2000 millimeters (35–79 inches) of precipitation annually in humid subtropical locations. Precipitation also defines seasons in these locations, where a monsoon season is a significant climate feature. The seasonality of precipitation is present in the humid subtropical locations of south and east Asia. In New Delhi, India, October through May, on average, receives only 140 millimeters (5.5 inches) of precipitation, while June through September receives about 660 millimeters (26 inches), or 80 percent of the annual precipitation. Due to this variability of precipitation, both droughts and flooding can occur in humid subtropical climates. Coastal locations of humid subtropical climates are often impacted by tropical cyclones and hurricanes. The temperature and precipitation in humid subtropical climates support a mix of evergreen and deciduous forests or subtropical mixed forest and grassland in drier regions. Humid subtropical climates are located in the southeastern United States, southern Brazil, and northeastern Argentina. In Asia, humid subtropical climates are located in central India, southeastern China, and southern Japan. There are also locations with humid subtropical climates in eastern South Africa, and northeastern Australia. Major cities located in subtropical climates include Houston, Atlanta, Buenos Aires, Sao Paulo, Shanghai, and Tokyo.

Climate, Marine West Coast

MARINE WEST COAST climates are located in the mid-latitudes, usually on the west coast of continents along the Atlantic Ocean and Pacific Ocean. Specifically, marine west coast climates exist in Europe from northern Spain to southern Norway, including the British Isles, the west coast of North American from California to Alaska, and the southern coast of Chile in South America. Other locations include the east coast of South Africa, the southeast coast of Australia, and the islands of New Zealand and Tasmania. Major world cities located in marine west coast climates include Seattle, Vancouver, London, Paris, and Berlin.

Marine west coast climates have relatively cool, mild temperatures and receive frequent precipitation most of the year. Marine west coast climates include frequent precipitation and overcast skies, due to the proximity of these climates to the ocean and semi-permanent low-pressure areas. These low-pressure areas include the Aleutian Low of the North Pacific and the Icelandic Low of the North Atlantic. The low-pressure areas are most intense in the winter and are the origin of mid-latitude storms traveling eastward. In the Southern Hemisphere, the marine west coast climates are also located in the direct path of eastward-moving, mid-latitude storms.

A key characteristic of marine west coast climates is the moderating effect the ocean has on air temperature. Frequent cloudiness and overcast skies also moderate temperatures. In the summer, daytime maximum temperatures range from 15–25 degrees C (59–77 degrees F) and nighttime temperatures are usually 10–15 degrees C (50–59 degrees F).

Winters are mild; however, more poleward marine climates have colder winter temperatures and heavy winter snow. Depending on location, winter daytime temperatures may range from -4 to 10 degrees C (25–50 degrees F), and nighttime temperatures can range from –9 to 4 degrees C (15–40 degrees F). The warmest marine west coast climates are in South Africa and Australia, where freezing temperatures are rare. The coldest marine west coast climates are in southern Alaska and southern Norway, where winter temperatures are below freezing. In marine west coast climates, precipitation is more evenly distributed throughout the year than in neighboring Mediterranean climates. Some marine climate locations receive significantly high annual precipitation. For example, Dublin, Ireland, on average receives about 730 millimeters (29 inches) of precipitation annually, while Quillayute, Washington, receives about 2,600 millimeters (102 inches). Most marine west coast climates are wet; however, the variance in actual precipitation relates to the orographic features, which promote increased precipitation on their windward side and decreased precipitation on the leeward side.

Provided there are good, nutrient-rich soils and a sufficient growing season, many marine west coast climates are suited for agriculture. The natural vegetation biome types commonly occurring in west coast climates include deciduous, mixed, and evergreen forests. The coolest marine west coast climates such as those found in Norway and Iceland consist of subarctic-type grasses, sedges, and are treeless in some locations. The wettest marine west coast climates in the U.S., Canadian, and New Zealand west coasts have temperate rainforests with evergreen conifers and dense vegetation over the forest floor.

Climate, Mediterranean

MEDITERRANEAN CLIMATES ARE named after the type of climate along the Mediterranean coast in southern Europe, northern Africa, and the Middle East. However, Mediterranean climates also exist outside of this region in the coastal locations of southern Australia, western South Africa, coastal Chile, and California. Major world cities located in Mediterranean climates include Los Angeles, Rome, Santiago (Chile), Jerusalem, Cape Town (South Africa), and Adelaide (Australia). These climates are defined by relatively mild temperatures year-round, dry summers, and wet winters. Mediterranean climates are usually adjacent to the earth's subtropical deserts and come under the same influence of semi-permanent high pressure zones located over the Pacific, Atlantic, and Indian oceans. During the summer, the high-pressure zones that keep the earth's subtropical deserts dry also keep the locations with Mediterranean climates very sunny and dry. During the winter, the intensity of the high-pressure zones reduces, and these climates are subject to mid-latitude storms and precipitation. Mediterranean climates have cool winters, but rarely experience extreme cold or heavy snow.

Both the diurnal and the annual temperature range in Mediterranean climates decreases closer to coastal areas. This is mainly due to mild sea surface temperatures ranging from 15–25 degrees C (50–77 degrees F), which have a moderating influence on coastal land temperatures, especially in the summer. For example, in California, the coastal city of San Francisco and the inland city of Sacramento both have Mediterranean climates. The temperature during the winter for these two cities is similar; however, temperatures during the summer are much warmer inland, with daytime temperatures around 22 degrees C (72 degrees F) in San Francisco and 35 degrees C (95 degrees F) in Sacramento. The marine influence also makes coastal fog a common but short lasting occurrence in these climates. Mediterranean climates can be subject to rare but intense summer heat waves associated with winds from desert locations. These winds are called Santa Ana in southern California and Sirocco or Leveche from the Sahara.

Mediterranean climates are typically dry, but long growing seasons and winter precipitation enables the production of drought resistant crops such as grapes, dates, and olives. There is usually between 250–600 millimeters (10–24 inches) of precipitation annually in these climates with the majority of precipitation during the cooler months. In Athens, Greece approximately 370 millimeters (14.5 inches) of precipitation is received annually; however, 300 millimeters (12 inches), or 80 percent, is received from October through March. Precipitation in these climates can have significant inter-annual variability. Locations with Mediterranean climates can be subject to flooding during excessively wet winters or persistent drought, when winter precipitation is below average. The temperature and precipitation Mediterranean climates support chaparral, a vegetation biome consisting of scattered evergreen oak trees, shrubs, and grasses found in Mediterranean climates, and adapted to droughts and wildfires. Some of the most common vegetation include date palms, fan palms, eucalyptus trees, and cedar trees.

Climate, Tropical

TROPICAL CLIMATES ARE located along the earth's equatorial belt between the latitudinal belts of the Tropic of Cancer and the Tropic of Capricorn. It is over these latitudes where the solar energy from the sun enters the atmosphere more directly than in higher latitudes throughout the year. There is also less of a seasonal shift in the solar energy coming into tropical areas than seasonal shifts that occur over higher latitudes. This means throughout the year, solar energy is high, and both the ocean and land surfaces over tropical latitudes are warm year-round.

Tropical climates, especially over oceans, have the lowest annual range in temperature than any other climate on earth. It is often the case that the diurnal temperature range in tropical climates exceeds the annual temperature range, which is usually only 3–6 degrees C (5-10 degrees F). Throughout the year, nighttime temperatures are usually between 21–27 degrees C (70–80 degrees F), while daytime temperatures are 30–35 degrees C (86–95 degrees F). Temperatures below 16 degrees C (61 degrees F) or above 38 degrees C (100 degrees F) are rare. High humidity and warm nights can make some days uncomfortable, although excessively high temperatures are rare. Much cooler temperatures, however, can be found within the tropical belt at higher elevations, especially in locations such as the Andes Mountains in South America.

In most tropical locations closest to the equator, the precipitation is high and some have a monsoon climate.

Tropical climates are also the most humid climates found on earth. These climates cover the highest amount of ocean surface than any other climate, and the intense amount of solar energy over tropical oceans creates a high amount of evaporation and cloud convection. Precipitation is frequent and heavy over tropical oceans and land areas, with an annual precipitation range usually between 79–157 inches (2,000–4,000 millimeters). Generally, in most tropical locations closest to the equator, the precipitation is high each month of the year, and there is no particular dry season. The world's tropical rainforests are found in these types of climates.

In tropical climates found in slightly higher latitudes, annual precipitation is high; however, there is usually a wet season and a dry season. Some tropical locations even have a monsoon climate. Often, areas of tropical climates with wet and dry seasons are the savannah areas between wet tropical and drier subtropical locations. Locations of wet and dry season tropical climates are found in the southern Mexican pacific coast, Venezuela, Brazil, the African savannah regions, India, southeast Asia, and northern Australia. The tropical monsoon climates have the greatest wet-to-dry precipitation regime. These climates are most prevalent on the African tropical west coast and tropical southeast Asia. In some locations, precipitation during the wet season amounts to more than 197 inches (5,000 millimeters). The tropical monsoon climates occur where there are seasonal changes in the surface heating of the land and the oceans. During the season when more solar energy is directed over the oceans, dry air flows over the land toward the ocean, where convection occurs and the land areas remain dry. When the season changes and more solar energy is directed over the land surface, the winds shift and bring moisture from the ocean surface over the land, where convection and precipitation occur.

Climatology

CLIMATOLOGY IS A branch of the atmospheric sciences that focuses on long-term (monthly and longer) patterns of weather and atmospheric circulation, in contrast with meteorology, which focuses on understanding and predicting short-term weather phenomena. While climate is often described as the "average weather" of a place, it is better considered as the aggregation of all the statistical properties of the atmosphere, including averages as well as measures of the expected variability and persistence over time of atmospheric elements such as temperature, rainfall, or humidity. In other words, climate includes not just averages, but is the total picture of the behavior of the atmosphere for the globe or a region. Climatologists seek to understand the mechanisms within the earth system that produce spatial patterns in climate, as well as the causes and implications of climate variations over time scales ranging from months to millennia and longer. In recent decades, a particularly important focus within climatology has been the question of whether and how human activities have caused changes to the climate system.

The climate system refers to all of the various boundary conditions that influence global and regional climates. Examples include the brightness of the sun, the configuration of the continents and ocean basins, the tilt of the earth on its axis, the shape of the earth's orbit, and the concentration of greenhouse gases in the atmosphere. These boundary conditions change at a variety of time scales, both naturally and due to human actions, and the interaction of these factors produces complex variations in climate patterns over space and at a wide range of time scales.

Within climatology, there are many subfields, each of which approaches the study of the climate from a unique perspective. One of these fields is paleoclimatology, which attempts to reconstruct past climate patterns from the evidence of ice cores, ocean sediments, tree rings, and other types of geophysical evidence that provides a look into how global and regional climates varied over millions of years. Paleoclimatology has a great deal of applicability to the field of anthropology, as climate variations likely played a role in the cultural development and movement of our human ancestors. In addition, paleoclimatology is useful in the modeling of future climate change, as past climates provide examples of the kinds of climate patterns that are possible given particular configurations of boundary conditions.

Climatologists are also interested in identifying and explaining the spatial patterns of climates across the earth's surface. Climate classification schemes use variables like temperature and rainfall to identify particular climate types (such as tropical, arid, or polar), which can then be explained in terms of climate-controlling factors like latitude, elevation, proximity to the coast, or atmospheric circulation patterns. One of the most famous of these classification systems is the Koeppen System, which divides climates into five general categories based on temperature and moisture patterns. Climate classification provides useful descriptions of large-scale climate conditions, which is valuable in understanding spatial patterns of biomes as well as the types of human activity (such as agriculture) that are likely in particular areas.

Synoptic climatology is the study of persistent atmospheric circulation patterns and the ways in which these patterns influence regional climates. Synoptic climatologists identify patterns in the atmosphere that have a tendency to recur on a regular basis, and statistically analyze how these patterns influence regional weather. Of particular importance are *teleconnections patterns*, in which widely separated parts of the earth's surface are linked together through atmospheric circulation. For example, the El Niño—Southern Oscillation links temperature and precipitation in the United States to sea surface temperatures in the tropical Pacific Ocean.

A final major focus of climatology is the development of sophisticated computer models of the global climate. These models use current knowledge of the climate system and the physical laws controlling the movement of mass and energy through the system to produce scenarios of how the climate might respond to particular boundary conditions over decades and centuries. Introducing variations into the model, such as increasing or decreasing the concentrations of greenhouse gases, allows climatologists to understand how the climate may respond to human activities, and to therefore assess the long-term risks of such issues as global warming.

Climax Communities

A CLIMAX COMMUNITY is an idealized assemblage of plant species that represents the most advanced stage of development that can be reached for a given climate and given enough time free from disturbance. The idea was originally formalized by Frederic Clements in 1916, and went on to form the basis of the superorganic worldview of nature, community ecology, synecology, and homeostatic equilibrium models of ecosystems.

The basic premise behind the climax community is that climate is the primary determinant of vegetation communities. The community forms over long time periods, with the member species evolving in competition, and in the final climax stage, having coevolved to the point of being mutualistic. In this sense, every species in the community plays a vital role in the whole community, which acts as a single organism with constituent species comprising the organs. This analogy, whereby nature is viewed as a single living being or a fellow being to humans, is called the superorganic model. Lovelock's Gaia Hypothesis, in which the entire biosphere is viewed as a single organism, is an expression of the superorganic model. Clements's climax communities, however, included only plant species. Animals were excluded, as were their various competitive interactions. Clements, by focusing exclusively on the causal role of climate in forming climax communities, thus overlooked the importance of trophism, which includes herbivory and is now well understood to be an important factor in the formation of vegetation communities.

Clements viewed disturbance to natural ecosystems as an undesirable anomaly. Any disturbance, whether anthropogenic or natural, alters the structure and composition of a community, and hence removes it from the climax state. Clements termed such a disturbed community a *disclimax*. Any vegetation community not in its climax state would undergo a series of changes, termed *succession,* until it reached that final climax. Each stage of succession was expressed by a distinct assemblage of plant species. For example, the earliest stages of succession would exhibit a high occurrence of pioneer species (typically sun-loving, shade-intolerant species with high rates of reproduction, produce numerous propagules, disperse widely and have short life cycles). As the community approached its climax, shade-tolerant species with longer life spans characterize these assemblages. These distinct communities associated with the various successional stages were termed *seres*.

Clinton, William Administration

WILLIAM JEFFERSON CLINTON (b.1946) was the 42nd president of the United States and served from 1993–2001. Al Gore, former U.S. senator from Tennessee, served as his vice president. The leading priorities of the Clinton administration included equality for all Americans, increased safeguards of the environment, and the international spread of democracy.

The popularity of these policies with the American public, combined with strong economic times, led to Clinton's high approval ratings throughout his presidency. Despite his popularity, he experienced several setbacks during his years as president. During the 1994 mid-term elections, the Republicans gained both houses of Congress. Many believed that the Republican wins were attributed to the strong turnout of religious conservatives who opposed Clinton's policies and questioned his ethics and moral behavior. The Republican-led Congress presented legislative roadblocks for Clinton. The agenda of conservatives clashed with the more liberal-leaning policies of the Clinton administration.

As a result of this political divide, legislative battles ensued, making it difficult for Clinton to push his policies through Congress. In the greatest showdown of his presidency, the Republican-dominated Congress tried to impeach Clinton for his questionable conduct with a former White House intern and accusations of perjury; however, the impeachment atempt failed.

Clinton held the presidency during a unique time in American history. With the recent collapse of the Soviet Union and its policies, the United States found itself in a new leadership role in the post-Cold War era. Clinton seized this opportunity to forge new consensus between government, business, and society. His policies ranged from helping poor Americans to promoting greater free trade globally. Another Clinton political priority was to find a viable, nationally based health care policy, which turned out to be a failure. Despite this setback, he forged ahead with other policies.

Clinton had particular success with environmental issues. For example, he campaigned to protect the environment through the Clean Air and Clean Water Acts. The Clinton administration further set environmental policies by empowering special interest groups in their quest to achieve their goals. Supported by the strongly pro-green vice president, Al Gore, the Clinton team pursued a variety of environmental goals that often came into conflict with the interests of big business.

The explosion of the Internet and mobile communications during the Clinton presidency led to the mobilization of social and nongovernmental groups. These groups used the new technologies to organize grassroots movements to galvanize support for certain policies in a swift and efficient manner—something that had not occurred before. Environmental groups, for instance, greatly benefited from the growing technology and used it to promote their agenda in new ways. Their efforts gave prominence to such issues as recycling, oil spill prevention/clean up, and land conservation. Global warming and the release of greenhouse gases into the environment were addressed through the adoption of the Kyoto Protocol, which aimed to limit emissions on an international basis. Clinton favored the use of market-based initiatives rather than government-sponsored regulation in managing environmental change.

Cloning

ARTIFICIAL CLONING IS the process of using a single cell from an organism and its genetic information to produce an identical duplicate organism. The procedure relies on asexual reproduction, thus assuring that the new organism is genetically identical to its single "parent" cell, and not a merging of two sets of genetic information (as in sexual reproduction). While the process of cloning occurs naturally and is essential for life, for example among many plants, the concept and practice of artificial cloning has become of considerable interest and controversy as modern technology has made it possible to clone larger animals and potentially even people. The ability to clone cells of nearly all living creatures in embryo form has become a mature form of technology that may be conducted in a large number of laboratories and in vitro fertilization (IVF) clinics around the world. Frogs were cloned in the 1950s and mice in the 1980s using such techniques as transferring DNA material from the cell of one specimen into an egg cell to be born from another after the original genetic material had been removed from that egg cell.

Artificial fertilization techniques, with re-implantation of externally cultured eggs, have made this a comparatively straightforward process. However, the ability to clone cells from an adult organism is significantly more difficult because the cells have divided and differentiated into a very large variety of specialized forms and, even though genetic material such as DNA is present in those cells, it is difficult to clone the cells and cause them to grow into other forms of specialized cells. The team led by the British scientist Ian Wilmut, who cloned the sheep Dolly, achieved this, and some startling successes have subsequently been reported. However, the importance of the technology and the value of its commercial potential have persuaded a number of scientists to falsify their results. The now disgraced South Korean cloning expert Dr. Hwang Woo-Suk is perhaps the most well known of these frauds.

Human cloning has become a very controversial subject, which has been lent additional urgency by imminent improvements in technology. Proponents of cloning point out its potential value in providing replacement tissue and organs for transplants or for combating disease. The techniques also make it possible to tackle genetic diseases. However, opponents of cloning argue from a variety of religious and ethical perspectives, claiming that obtaining the material that is to be worked upon can only be achieved through methods that are immoral. This is connected with the widely held belief that it is dangerous for scientists to manipulate genetic material, because it gives humanity power over life that should only be wielded by God.

ARGUMENTS PRO AND CON

It would be possible, according to this argument, for scientists to identify sets of people who are, and are not, considered acceptable. This troubles people who believe that all life is sacrosanct, and who fear Nazi-like programs of eugenics. Following the idea that the use of genetic manipulation might be used to improve the physical condition of people able to pay for the treatments, those who could not pay would remain in an inferior physical condition. Some argue that the technology will not halt at simply replacing damaged organs or other tissue, but will also have cosmetic functions, and this is considered unacceptable. These techniques would be particularly useful in livestock industries, especially once technical difficulties have been solved.

Much of this controversy is not directly related to human cloning, but also to developments that might arise from it. There has been much debate within the United States on the use of human stem cells in research. Research concerning public perceptions of this subject suggests that a modest majority is in favor of the research, apart from the Kingdom of Saudi Arabia and the United States, where the majority is opposed to it. Some state governments find their policy toward research to be motivated in part by the possible location of large research facilities and the financial rewards that would follow successful cloning breakthroughs.

Cloud Forests

CLOUD FORESTS (ALSO known as tropical montane cloud forests) are a rare and highly threatened type of evergreen forest found in the mountains of the tropics. Their name is derived from the fact that they are frequently enveloped by clouds and mist and are persistently wet. Cloud forests are mountain rain forests. The vegetation is characterized by dense canopies, reduced tree stature, and a high proportion of biomass as epiphytes, including an abundance of ferns, mosses, and bromeliads. Cloud forests cover less than 1 percent of the earth's land area, and just 2.5 percent of all tropical forests. They are found at elevations of 2,000–3,500 meters (6,500–11,500 feet) in large inland mountain systems, and as low as 500 meters (1,600 feet) in coastal mountains and tropical islands (such as Hawaii and Fiji). Sixty percent of cloud forests are in Asia (primarily in Indonesia, Papua New Guinea, and Malaysia). Twenty-five percent are in Latin America (Mexico, Central America, and Andean South America), and 15 percent are located in Africa (notably in the uplands of the Congo and east Africa).

Despite their scarcity, cloud forests are of great ecological and economic importance. The varied topographic and climatic conditions of mountain regions provide for a multiplicity of microhabitats. Cloud forests have high rates of biodiversity (total number of species) and endemism (species found nowhere else), reflecting their immense biological wealth, and yet most species are still unknown to science. Cloud forests cover only 1 percent of Mexico, but contain 12 percent of its plant species. Andean cloud forests make up 3.2 percent of the South American land area, but harbor 65 percent of the continent's endemic mammals. There are more than 1,000 species of orchids in the cloud forests of Peru. Cloud forests provide habitat for some of the earth's rarest and most threatened species, including mountain gorillas in Africa and the *quetzal* bird of Central America.

NATURE'S WATER TOWERS

Cloud forests have an important watershed function. Because they are frequently covered in clouds, they intercept and capture water that condenses on the vegetation. This cloud stripping ability can enhance net precipitation 20–60 percent beyond normal rainfall amounts. Feeding the headwaters of streams, they provide a year-round source of unpolluted freshwater for irrigation, urban water supplies, and hydroelectric power. Because cloud forests are located on steep slopes, they also protect the soil from erosion. Cloud forests are an important source of timber and fuelwood for local peoples, as well as food in the form of fruit and game. They also contain many medicinal and ornamental plants. Cloud forests draw tourists because of their beauty, unique mountain environments, and rare birds. They may also play a role in monitoring climate change because they are very sensitive to atmospheric variation.

Ninety percent of cloud forests are gone, making those that remain among the world's most threatened ecosystems. Yet, they have received much less attention than lowland tropical rainforests. As economies grow, human migrations to frontiers increase, land values rise, and demands for marginal land intensify, people increasingly encroach on this important, fragile, and unique resource. The biggest threat is land use conversion for subsistence and commercial agriculture.

Cattle grazing in Latin America and Africa, vegetable production in parts of Asia, and drug cultivation in the Andes and in southeast Asia are problematic. Timber harvest, especially in Asia, is a grave threat. In Africa, hunting, mining, and fires are concerns. Road building is another serious threat to cloud forests because roads provide access and permit deforestation and resource extraction. Roads also contribute to habitat fragmentation, which breaks up large areas of forest into smaller, biologically less productive patches, as well as accentuating the edge effect. Forest edges are subject to drying and are vulnerable to predators and invasive species. Cloud forests increasingly exist as islands in a sea of human-impacted areas.

Immediate action is required to protect cloud forests. The Mountain Cloud Forest Initiative was launched in 1999 under the auspices of the United Nations Environment Program (UNEP). Protected areas such as national parks are the main means of conserving cloud forests. More parks, as well as better management of existing areas, are needed. Many private reserves are being created, such as Monteverde in Costa Rica. Because local people frequently live in and around cloud forests and depend on them for their livelihoods, they need to be included in the management of cloud forests. Promoting sustainable farming systems can also help. Some landowners even receive payments for so-called environmental services that cloud forests provide. Finally, ecotourism can be a benefit because people will pay to see protected forests and the wildlife they support.

Club of Rome

THE CLUB OF Rome is an international think tank that includes a collection of scientists, entrepreneurs, civil servants, and former heads of state who contribute their collective experiences to foster a better understanding of diverse issues facing the globe. The group grew out of an April 1968 meet-

Aurelio Peccei

Aurelio Peccei was born in 1908 in Turin, Italy, and graduated with a degree in economics from the University of Turin in 1930. He went to study at the University of Paris, the Sorbonne, and then started working for the car manufacturer Fiat. In 1935 he led a successful Fiat mission to China. During World War II, Peccei became a convinced anti-Fascist—he had visited the Soviet Union as a student—and worked with the Italian underground until he was arrested in 1944. Peccei was tortured and nearly executed, but survived until the end of the war.

Returning to work for Fiat as divisional manager in 1946, Peccei took over their operations in Latin America, moving to Buenos Aires, Argentina in 1953. There he established the local subsidiary Fiat-Concord, which became one of the most successful automobile firms in South America, and served as chairman of the board of directors. He then returned to Italy, worked for Italconsult in Rome from 1957, and in 1964 became the president of Olivetti. In the following year he gave a speech at a meeting for an international consortium of bankers; this caught the attention of Dean Rusk, the U.S. Secretary of State. It also came to the notice of Jerman Gvishiani, the son-in-law of the Russian leader Alexei Kosygin. Independently, they made approaches to Peccei, which were to lead to the establishment of the Club of Rome in April 1968.

Throughout the 1970s, Peccei helped organize international meetings with a North-South summit held at Salzburg, Austria, in February 1974. he was Chairman of the Economic Commission for the Atlantic Institute in Paris, France. The last meeting he organized was for Development in a World of Peace, which was held in Bogota, Colombia, in December 1983. He died four months later in Rome, Italy.

ing of a similarly diverse collection of people from across the globe convened by Dr. Aurelio Peccei, an Italian industrialist, at the Accademia dei Lincei in Rome. Initial meetings for the Club of Rome culminated in the decision to study and offer policy alternatives on a varying array of problems, including poverty, environmental degradation, demographic issues, and urban expansion, to name a few. The Club of Rome considered conventional analyses to fall short of offering more complete explanations for what it called the *world problematique* or the social, political, economic, and environmental problems plaguing the world. Instead, it sought to understand these global issues by recognizing their complexity and interdependence. It further recognized that these problems were long-standing and required solutions that were holistic in approach, global in reach, and long term.

The Club of Rome is headquartered in Hamburg, Germany, and its membership includes active, associate, honorary and institutional members. There are no more than 100 active members representing a variety of backgrounds with a recognized history of work in the international sphere. They are elected for five-year renewable terms by the Club of Rome's Executive Committee. H. R. H. Prince El Hassan bin Talal of Jordon is the Club of Rome's current (2006) president, while other well-known current active members include Fernando Cardoso, Saskia Sassen, and Wolfgang Sachs. Honorary members include eminent world leaders, including Mikhail Gorbachev, Vaclav Havel, Juan Carlos I of Spain, Wangari Maathai, and Eduard Shevardnadze, whose global reputation can help forward the club's overall mission. Additionally, the club has national associations that coordinate the implementation of its policy and provide advice to decision makers in countries across the globe.

The club holds an annual conference to help stimulate research and interaction amongst its members and generate debate around pressing global issues. It commissions reports on issues of concern, and these also offer solutions and policy alternatives. The Club of Rome is perhaps best known for *The Limits to Growth* report published in 1972, which was eventually translated into about 30 languages. Among other issues, this book considered the effect of expanding human populations on resources. *Limits to Growth* was criticized by some for raising the Malthusian specter of resource scarcities and limits to economic growth, while critically acclaimed by others who considered it to jump-start debate on resource use and environmental change. More recent reports commissioned by the Club of Rome include discussions on the future of energy resources, oceans, and poverty and underdevelopment among others. In 2001 the Club of Rome also initiated the tt30 group. This affiliated think tank includes individuals around the age of 30 who are committed to helping solve current global challenges and are interested in providing new solutions and supporting the work of the Club of Rome.

Coal

THE INDUSTRIAL REVOLUTION in 18th-century Europe and North America was propelled by a black rock called coal. Modern industrial civilization still continues to depend heavily on this rock. The word *coal* is of Anglo-Saxon origin from the word *col,* which means charcoal. Historians note that coal was already under use during the Bronze Age (around 2000 B.C.E.) in Britain. By 200 C.E., coal was being widely traded in Britain and used for fires to heat villas and military forts and also to dry grain. However, before 1000 C.E., the trade and use of coal was on a small scale. It was not until 1000 C.E. that coal began to be a prominent commodity in Britain. Initially, exposed coal seams were exploited, but by the 13th century these were exhausted, necessitating the development of underground mining from shafts.

Coal is a fossil fuel formed from prehistoric vegetation that originally accumulated in swamps and peat bogs and then consolidated between other rock strata. Silt and other sediments buried these swamps and peat bogs at great depths. This subjected the plant matter to high temperatures and pressure, which in turn transformed the vegetation into peat and then into coal. It is believed that coal formation began during the Carboniferous period about 360–290 million years ago. In Europe, Asia, and North America, the Carboniferous coal was formed from tropical swamp forests, which are sometimes called the *coal forests*. Southern hemisphere Carboniferous coal was formed from the Glossopteris flora, which grew on cold periglacial tundra when the South Pole was far inland in Gondwanaland.

Through the process of coal formation (coalification) over millions of years, various states of coal have been formed, resulting in different types of coal and coal seams that can be extracted via deep or underground mines or open pit mining. There are four main types of coal that range from high water content to high carbon content: peat (lignite or brown coal), sub-bituminous, bituminous, and anthracite. Peat and sub-bituminous coal are ranked as low coal, as they have high water content and low carbon content, while bituminous and anthracite are ranked as hard coal with a very high carbon content and therefore high energy output. The term *dirty black rock* comes from the highly ranked hard coal with a black luster, while the low-ranked coal is softer with a brown or earthy appearance.

Carbon accounts for more than 50 percent by weight and more than 70 percent by volume of coal, depending on the rank. Highly ranked coals contain 95 percent purity of carbon with less hydrogen, oxygen and nitrogen. Coal also contains incidental moisture, which is why coal is mined wet and stored wet. Low-ranked coals, such as lignite, contain considerable amount of moisture and other volatile materials known as *macerals*. These macerals are byproducts of the long process of coal formation from carbohydrate material into carbon over millions of years. Examples of macerals are vitrinite (fossil woody tissue, often charcoal from forest fires); fusinite (made from peat); exinite (fossil spore casings and plant cuticles); resinite (fossil resin and wax); and alginite (fossil algal material). Coal may also contain other mineral matter such as silicate, carbonate minerals, iron sulfide minerals, and sulfate minerals. Methane gas is also a major valuable byproduct for natural gas, but also an extremely dangerous component, as it often causes coal seam explosions in underground mines. The presence of these extraneous materials in coal seams determine the chemical composition of coal and therefore its utility for various tasks.

Large coal deposits can be found in 70 countries, such as Pakistan, where these lode car rails lead into a Quetta mine.

The different types of coal are used for various purposes. For example, lignite, the lowest rank of coal, is used largely for steam-electric power generation. Sub-bituminous coal, whose properties range from those of lignite to those of bituminous coal, are used primarily for steam-electric power generation and for other industrial purposes such as cement manufacturing. Bituminous coal, a coal that is usually black and dense with well-defined bands of bright and dull material and is highly ranked, is often used for steam-electric power generation, the manufacturing of cement, and other industrial uses. More importantly, it plays an essential role in the production of iron and steel as a metallurgical coking coal. The highest-ranked coal, anthracite, is harder, glossy, and black in character and is primarily used for residential and commercial space heating. It is preferred for domestic use due to its smokeless characteristics.

Coal is primarily used as a solid fuel for the generation of electricity and heat through combustion. To generate electricity, coal is usually pulverized and then burned in a furnace with a boiler. The furnace heat converts boiler water to steam, which is then used to spin turbines, which in turn create electricity. Coal accounts for more than 40 percent of electricity production in the world.

About 66 percent of the world's steel production is based on coal. Coke is a solid carbonaceous residue derived from low-ash, low-sulfur bituminous coal from which the volatile constituents are driven off by baking in an oven without oxygen at temperatures as high as 1,832 degrees F (1,000 degrees C) so that the fixed carbon and residual ash are fused together. To make iron and steel, the raw materials—iron ore, coke and fluxes—are fed into the top of the 2,192 degrees F (1,200 degrees C) blast furnace. The burning coke produces carbon monoxide, creating a chemical reaction that reduces iron ore to molten iron.

Coal can also be readily converted into a variety of fuels (gas and liquids), with a number of key advantages such as fuels that are sulfur-free, low in particulates, low in nitrogen oxides and low in CO_2 emissions. As the world demand for petroleum-based fuels has increased due to the escalating use of automobiles, the coal-to-liquids industry is becoming a more viable alternative. South Africa has produced commercial coal to liquids fuels since 1955. It is estimated that about 30 percent (160,000 barrels per day) of South Africa's gasoline and diesel requirements are produced from locally available coal.

The process of converting coal into liquid fuels can be done through direct or indirect liquefaction. Direct liquefaction involves dissolving the coal in a solvent at high temperature and pressure, and then further refining the liquid products to achieve high-grade fuel characteristics. Indirect liquefaction involves gasifying the coal to form a *syngas*, which is a mixture of hydrogen and carbon monoxide. The syngas is then condensed over a catalyst to produce high quality, ultra-clean products. Through these processes, various other products can be produced from coal, including ultra-clean petroleum and diesel, synthetic waxes, lubricants, and alternative liquid fuels such as methanol and dimethyl ether. Liquefaction of coal into fuel liquids has great potential for countries that heavily depend on imported oil but have large reserves of unused coal. It is one of the backstop technologies that could potentially limit the escalation of oil prices and mitigate the effects of transportation energy shortages. Projects to utilize these benefits are currently underway in import oil-dependent countries such as China, India, Australia, and the United States.

CEMENT AND OTHER INDUSTRIES

Another major use of coal is in the cement industry, in a process that requires large amounts of energy. Approximately 16 million tons of cement are used globally every year. The manufacturing of cement involves the mixing of limestone, silica, iron oxide, and alumina. This mixture is heated by coal to very high temperatures of more than 2,642 degrees F (1,450 degrees C), transforming the mixture into a pebble-like substance called *clinker*, which is then mixed with gypsum and ground to a fine powder to make cement. It is estimated that for every 900 grams of cement produced, 450 grams of coal are used. There are other byproducts that are derived from the burning of coal, such as fly ash, bottom ash, boiler slag, and flue gas desulferisation gypsum. These can be recycled as primary raw materials to replace or supplement cement in concrete.

Coal is also used in other important industries such as alumina refineries, paper manufacturers, and the chemical and pharmaceutical industries. Several chemical products can be produced from the byproducts of coal. Refined coal tar is used in the manufacture of chemicals, such as creosote oil, naphthalene, phenol, and benzene. Ammonia gas recovered from coke ovens is used to manufacture ammonia salts, nitric acid, and agricultural fertilizers. From this "dirty black stone," thousands of different products are manufactured, including soap, aspirins, solvents, dyes, plastics, and fibers such as rayon and nylon. Coal is also an essential ingredient in the production of specialist products such as activated carbon (used in filters for water and air purification and in kidney dialysis machines); carbon fiber (an extremely strong but lightweight reinforcement material used in construction, mountain bikes, and tennis rackets); and silicon metal (used to produce silicones and silanes, which are in turn used to make lubricants, water repellents, resins, cosmetics, hair shampoos, and toothpastes).

GREATEST USE: ELECTRICITY

While coal may have multiple uses, its greatest use—about 75 percent of all mined coal (about 5.8 billion tons)—may be in the generation of electricity. The United States, China, and India consume 2.8 billion tons every year (48 percent of annual global consumption). With China's growing economy, India and China alone may soon need about 3 billion tons annually. As of 2005, estimates indicated that there are more than 909 billion tons of proven coal reserves throughout the world. The largest reserves of coal are found in the United States, Russia, China, and India. It can also be found in sizable quantities in 66 other countries. Fossil fuels are finite; however, with current usage levels, the lifetime for coal could be extended 157 years and beyond through new discoveries, advances in mining techniques, and efficiency improvements.

However, there is a dark, flip side to the use of coal as a source of energy. The burning of coal produces many byproducts that are harmful to human and environmental health. The use of coal produces carbon dioxide (CO_2) and nitrogen oxides (NO_x), along with varying amounts of sulfur dioxide (SO_2). Sulfur dioxide reacts with oxygen to form sulfur trioxide (SO_3), which then reacts with water to form sulfuric acid, which falls to the ground as acid rain. Emissions from coal-fired power plants represent the largest source of carbon dioxide emissions, now known to be the primary source of global warming gases. Coal mining and abandoned mines also emit methane, another cause of global warming. Other coal waste products, including fly ash, bottom ash, boiler slag, and flue gas desulferization, contain heavy metals, including arsenic, lead, mercury, nickel, vanadium, beryllium, cadmium, barium, chromium, copper, molybdenum, zinc, selenium, and radium. These heavy metals are extremely dangerous to human, animal, and plant health when spewed into the environment. Other impurities include low levels of uranium and thorium, which could potentially lead to radioactive contamination. U.S. environmental groups claim that coal power plant emissions are responsible for tens of thousands of premature deaths annually in the United States alone. Technologies to mitigate the harmful effects of coal burning are available, but these are rarely installed in power plants as they would add to their building costs and make them less profitable.

The useful aspects of coal notwithstanding, this fascinating, simple black rock that has shaped our modern civilization now threatens it. It is undeniable that coal has transformed societies, expanded our frontiers, and sparked social movements, and continues to power electric generation. However, coal's world-changing powers have come at a tremendous price, including centuries of blackening skies and lungs, particularly the lungs of those involved in its mining. Many believe that the increasing burning of coal in power generation plants around the world is resulting in global warming and is changing the earth's climate. Scientists caution that before we plunge ourselves into reviving the coal industry as an alternative to oil from the Middle East, we need to take a step back and carefully examine the tragic legacy of coal that has claimed millions of lives and ravaged the environment. Due to the proven deleterious environmental consequences of coal, *The Economist* recently dubbed the burning of coal "Environmental Enemy No. 1."

Coastal Zone

THE COASTAL ZONE constitutes 8 percent of the global ocean surface. Most scientific definitions of coastal zones are based on coastal processes or landform. The International Geosphere–Biosphere Program defines a coastal zone as "extending from the coastal plains to the outer edge of the continental shelves, approximately matching the region that has been alternately flooded and exposed during the sea level fluctuations of the late Quaternary period." This space includes the foreshore, the beach area and natural coastal protection systems such as sand dunes and mangroves.

While the coastal zone can be divided into many types, Inman and Nordstrom devised a classification system for coasts based on plate tectonics, dividing the coastal zone into collision coasts, trailing edge coasts and marginal sea coasts. Other coastal zone types include hard rock-cliffed coasts, hard rock coastal plains, soft rock coasts, tide-dominated sediments, plains, and wave-dominated sediment.

Many natural processes influence the integrity and environment of the coastal zone. For example, the lithosphere—which incorporates plate tectonic settings, bedrock geology, coastal topography, and sediments—affect the structure and form of the coastal zone. The coastal zone is also affected by processes within the hydrosphere, which includes all marine processes such as waves, tides, ocean currents, regional currents, sea temperature and sea-level change; the atmosphere, including climate change, annual climate, precipitation, temperature, wind; and the biosphere, which includes all coastal flora and fauna.

Scientific definitions of the coastal zone are not always appropriate for the purposes of management. Definitions located within policy frameworks often differ from scientific interpretations. For example, the Commonwealth of Australia's Coastal Policy states that the "the boundaries of the coastal zone extend as far inland and as far seaward as necessary to achieve the policy objectives, with a primary focus on the land/sea interface." In Canada, the definition of the coastal zone is "the coast itself, coastal watersheds and the lower limits of large drainage basins, and the area seaward to the limit of the zone of influence of land-based activities." Coastal managers in Canada are advised that the definition should be interpreted flexibly to ensure that all activities and issues having a bearing on the planning area are addressed. The Organization for Economic Cooperation and Development argues that the definition of the coastal zone should vary depending on the nature of the problem being examined and objectives for its management.

Many nations across the world have implemented an integrated coastal area management (ICAM) process to manage the many uses and activities along and within the coastal zone. The United Nations (U.N.) Educational, Scientific and Cultural Organization (UNESCO) define ICAM as an interdisciplinary activity where natural and social scientists, coastal managers, and policy makers, focus on how to manage the diverse problems of coastal areas in the long term. The U.N. Environment Program has identified key principles for integrated coastal zone management, including: the coastal area is a unique resource system that requires special management and planning approaches; water is the major integrating force in coastal resource systems; coastal management boundaries should be issue-based and adaptive, be protected from damage from natural hazards and conservation of natural resources should be combined with integrated coastal zone management programs; that all levels of government within a country must be involved in coastal management and planning; and that conservation for sustainable use should be a major goal of coastal resources management.

Key global initiatives to achieve these management goals have included the UNESCO Coastal Regions and Small Island Platform, the Global Program of Action for the Protection of the Marine Environment from Land-Based Activities, Clearing House and the Integrated Coastal Area Management Program. At the World Summit on Sustainable Development in Johannesburg in September 2002, the Global Forum on Oceans, Coasts, and Islands was created to address global development issues.

Many countries are implementing their own coastal management strategies. In Canada—which has the world's longest coastline, where 23 percent of its population live—has implemented the Oceans Act of 1996, which included the development and implementation—with stakeholders—of plans for the integrated management of activities in or affecting estuaries, coastal and marine waters.

Cocaine

COCAINE IS A natural plant alkaloid produced by the coca plant (*Erythroxylon spp.*), a shrub native to the lower eastern Andean slopes and domesticated by Andean farmers. Benezoylmethyl ecgonine ($C_{17}H_{21}NO_4$), or cocaine, comprises .5 to 2 percent of coca leaves. While the genus *Erythroxylon* contains 17 species, only two (*E. coca* and *E. novogranatense*) produce sufficient cocaine to process into street drugs. Most coca for traditional use and the drug industry is grown in Colombia, Peru, and Bolivia.

Coca leaves have been an important part of Andean cultures for over 3,000 years. Inca state and religious rituals used coca leaves. Today, Andean people chew coca by holding a wad mixed with alkaline lime or ash in their jaw. Coca leaves are a mild stimulant and appetite suppressant. They provide critical nutrients and cure digestive and respiratory ailments. Tourists drink coca tea to combat altitude sickness. In Andean communities, sharing and chewing coca is an important social ritual. Leaves are used in religious divination and offerings to mountain spirits.

A WELCOME DRUG TURNS SOUR

German chemists first isolated and extracted cocaine in the 1850s. It soon was added to medicinal tonics, wine, and a new drink, Coca-Cola. Scientists discovered that cocaine could be a surgical anesthetic, and Sigmund Freud advocated using it to treat medical and psychological problems. Tests also proved that the drug increased endurance. By the turn of the century, the chemical company Merck was producing around three tons of cocaine annually. The U.S. and European governments urged Andean countries to increase production and exported coca to grow in Javanese plantations.

The early 1900s saw a quick shift in the United States toward condemnation and illegalization of cocaine, as doctors diagnosed numerous cocaine addictions and negative side effects. In 1914, the Harrison Narcotics Tax Act prohibited cocaine use except as an anesthetic. Under the 1970 Controlled Substances Act, cocaine became a Schedule II substance, making it illegal to sell, buy, or possess without a medical license or prescription.

Today, cocaine production, trafficking, and retail is associated with drug cartels and street gangs. Latin American coca is shipped to Colombia to extract cocaine, a multistep process that uses sodium bicarbonate, kerosene, and sulfuric acid to produce cocaine powder. Drug traffickers smuggle powder into consumer countries, where it is "cut" with fillers such as cornstarch before being sold for $50 to $150 per gram. Cocaine users snort powder, allowing mucus membranes to absorb the salt *cocaine hydrochloride*. Consumers also dissolve powder in water and inject it. Within consumer countries, cocaine powder may be processed further to produce freebase or crack, base forms of cocaine. Crack costs $5 to $20 to for a .1 to .5 gram "rock." Freebase and crack are smoked. Heat vaporizes the cocaine, which consumers inhale. Crack gets its name from the crackling sound the rock makes when heated.

COCAINE AND THE NERVOUS SYSTEM

Cocaine stimulates the central nervous system by interfering with dopamine cycling. Dopamine stimulates neurons in the brain, allowing people to experience pleasure. Normally, dopamine is active only briefly before being carried away by a dopamine transporter. Cocaine binds to dopamine transporters, so dopamine continues to stimulate neurons and drug users experience prolonged euphoria. Smoking crack produces an intense high that lasts 5 to 10 minutes. Snorting cocaine powder produces a less intense high that lasts 15 to 40 minutes. Signs of cocaine high include hyperactivity, decreased appetite, and dilated pupils.

Cocaine is a neuropsychologically rather than physiologically addictive stimulant. Its short euphoria may be followed by depression and an intense craving to experience the high anew. Persistent users build up tolerance, requiring greater doses at more frequent intervals. However, they also develop sensitivity to side effects. Excessive dosage or prolonged use can cause irritability, paranoia, and hallucinations. Cocaine can cause death by heart attack and stroke. An estimated 34.9 million Americans over the age of 12 have used cocaine at least once in their lifetime, including 2.7 million chronic users. Currently, there is no pharmacological addiction treatment. Social impacts of cocaine use include devastated families, drug trade violence, risk of disease from needle sharing, and associated theft and prostitution as users try to pay for their habit.

Cocaine production causes environmental and social problems in Andean countries, as well. Illegal coca farms have little long-term stability combined with a strong incentive for maximizing productivity. Resultant environmental impacts include forest cover loss, soil erosion, and water pollution from processing chemicals. Drug cartels in Colombia are associated with violence and political corruption.

Drug control in the United States involves border patrols, seizing cocaine stashes, and mandatory yet unequal drug sentencing. Possessing five grams of crack incurs the same five-year sentence as possessing 500 grams of cocaine powder. The justification for this policy is the greater violence associated with the crack trade. Detractors complain of racial and class discrimination, as crack use is associated with minorities and low-income neighborhoods.

In Andean countries, cocaine control has involved downing suspected drug planes, destroying processing labs, eradicating coca fields, and promoting substitute crops. These efforts are costly and may have little impact on cartel leaders. In coca eradication, crop-dusters spray herbicides over coca fields. Collateral damage includes food crops and biodiversity destruction. Crop substitution has not been successful, since producing coca earns households many times more than substitute crops such as coffee or pineapple. Moreover, many farmers produce coca under threat of violence. Controlling drug trade and cocaine addiction while maintaining Andean cultural heritage rights to traditional coca use has been difficult to accomplish.

Coffee

COFFEE, *COFFEA SP.*, is a perennial shrub that has taken on social and ecological significance for several reasons. First, coffee grows in humid, mountain cloud-forest environments of conservation importance. Coffee growing areas are found in tropical zones of over 50 countries located in five continents, generally above 1000 meters for *Arabica* varieties, less for *robusta*. The more valuable *arabica* varieties require areas of high rainfall, typically formed by orographic precipitation and occurring in mountainous zones surrounded by drier lowlands. This results in a geographic dispersion that makes coffee areas important stopovers for long-distance bird migrations and favors high rates of endemic species. Coffee agro-forests often form areas of relatively high quality ecological *matrix* that surrounds, connects, and supports conservation reserves. For these reasons, coffee-producing areas have become important to international conservation strategies.

LABOR-INTENSIVE CROP

From a social standpoint, coffee is a labor-intensive, high-value crop that provides cash income to millions of families the world over, whether as small farmers or wage laborers. Well over 6 million metric tons of coffee are produced each year—approximately one kilo for each person on earth. This remarkable social and economic reach is matched only by the violence of price fluctuations that yearly shake coffee markets and impoverish these same millions of primary product producers. Since the end of the International Coffee Agreement in 1989—a Cold War-inspired global production pact, sponsored by northern consuming countries—coffee producers have become subject to sharply lower real prices and intense price fluctuations. This long-term real price decline was accelerated by a 1990s World Bank initiative to foster *robusta* production in Vietnam, the success of which placed additional downward pressure on coffee prices. Price stagnation has fostered declines in coffee production and a population exodus from high-cost coffee-producing areas—particularly in Latin America, where production costs (outside of Brazil) are relatively high—and increases in lower-cost production areas in Africa and Asia.

From a commodity-chain standpoint, the global coffee trade links relatively poorer, rural producers in the global south with wealthier First World consumers. The coffee commodity chain is relatively simple; tracing product from fields to cafés and homes is relatively straightforward. Studies of coffee data have demonstrated ways in which primary commodity production serves to enrich every actor in the commodity chain except farmers and wage workers, furthering our understanding of how wealth accumulation and impoverishment are linked, and how this linkage figures in environmental declines. These studies show that coffee producers receive only 6 percent of the price of "cupped" coffee sold in cafés. The vast majority of the profit accrues at the upper reaches of the commodity chain, in the hands of wholesalers and retail venues. Even in terms of coffee in beans, farmers receive only 10–30 percent (the later figure if the coffee is processed on-farm) of the final sales price. Even more troubling is that as consumers have begun to pay higher prices for premium gourmet coffees (since the mid-90s), the farm share of the total price has declined.

This separation between farm prices and final prices becomes even more troubling when considering what goes into producing a top-grade coffee, which is no easy matter. First, the ripe beans need to be selectively picked, thus necessitating multiple passes through the coffee plot. Then the pulp must be delicately removed, and the beans fermented for an exact length of time. Finally the product is dried and sorted: lower quality beans, often a large percentage of the crop, must be set aside to increase the percentage of export-grade product. As the relative return to the farmer declines, her labor increases (research shows that on many family farms, women comprise the bulk of labor inputs). Total labor time per kilo comes to between 2–3 hours for poorer farmers without capital-intensive, labor-saving technology so that, after costs, farmers are likely earning under 50 cents per hour.

Commodity-chain studies also show why the World Bank-financed expansion of *robusta* coffee production in Vietnam had such a significant impact on *arabica* coffees grown in highland areas. In an effort to squeeze greater profit out of cupped coffees, cafés have learned to mix *arabica* and *ro-*

busta coffees in prepared drinks; *robusta* varieties, though lacking in flavor and aroma, provide body and have significantly more caffeine than *arabica* coffees. This provides an extra kick to coffee drinks at a lower price, thus reducing demand for—and the market price of—*arabica* varieties. The declining real price of coffee has resulted in a changing global geography of coffee production. Production in high-cost (higher wage) countries in Latin America has stagnated, and lower-wage countries in Africa and Asia (e.g., India and Ethiopia) have sharply increased production.

These three factors—conservation, economic marginalization, and clear-cut commodity flows—combine to make coffee an important commodity for contemporary grassroots initiatives (fair trade, organic, and biodiversity conservation), governmental programs (both national and international), and action-oriented research activities. Of these, the most important are alternative trade networks (ATOs) grouped under the Fairtrade Labeling Organization (FLO), and under organic and shade-grown coffee labels. The boundary between nongovernment and governmental action is often blurred, since coffee producers form an important constituency of national antipoverty and conservation programs. The aim of these ATO initiatives has been to establish a grassroots market network that guarantees coffee producers a minimum price; this price varies by continent, but has been substantially above world market prices in recent years. Fair-trade coffee, often produced under organic standards, has substantially increased the welfare of the more than half a million farmers who have become fair-trade certified since 2005, promoting both increased family incomes and strengthened local organizations that can provide access to health care, education, financial help, and other benefits.

However, the fair-trade ATO model is under stress due to four factors. First, less than 20 percent of fair-trade certified coffee is sold in fair-trade markets. The expansion of fair-trade production has outstripped demand among fair-trade consumers. This is partly due to coffee quality issues, since consumers will pay high prices for gourmet quality coffee, but primarily it reflects the power of large corporate retailers over food distribution. Second, large corporate entities such as Starbucks, Sainsbury's, Carrefour, and Utzkapeh have set up their own "responsible" and/or "sustainable" brands in competition with other fair-trade and certified-organic labels. Third, corporate entities working within FLO have offered to purchase fair-trade coffee on the condition that they receive a volume discount (e.g., Nestles); in other words, lowering the price below the present floor. Fourth, neither fair trade nor organic price premiums have increased in nearly ten years, leading to a declining participation and quality level in areas with higher production costs, such as Mexico and Central America. The percentage of final sales price received by fair-trade certified farmers—about $2 per kilo—is not much greater than that of noncertified farmers. It takes from 1.3 to over 2 kilos of farm-grade coffee to

Certified-organic and shade-grown coffee production standards provide a practical conservation regimen.

obtain 1 kilo of export-grade "prima lavado" (prime washed) coffee; thus, the fair-trade plus certified-organic price of approximately $3 per kilo is reduced to around $2.00, even before marketing costs are discounted. With high-quality roasted coffees retailing for at least four times this price, returns to farmers may hover around 30 percent range of conventionally-traded coffees. From this perspective, adoption of fair-trade coffee by mainline retailers such as Wal-Mart may be seen as much a function of low fair-trade prices as a turn toward social responsibility by retail giants.

COFFEE AND CONSERVATION

With respect to conservation, fair-trade and conservation market initiatives are interlinked—most buyers now require both fair-trade and organic certifications—such that both initiatives are at risk. To expand on the conservation strategy that underlies certified-organic and shade-grown coffees, the goal of both is to establish an organizational structure that promotes decentralized, nonterritorial conservation (conservation work undertaken outside of, and complementing, parks or reserves). Coffee biodiversity initiatives encompass areas of high conservation value. Certified-organic and shade-grown coffee production standards provide a practical regimen of conservation activities (no agrochemicals, soil and water conservation, encouragement of a biodiverse shade tree layer). These initiatives also provide an important technical extension system that includes crop inspectors and conservation workers, who oversee conservation-oriented crop practices to protect these areas, providing a high-quality environment that protects and buffers existing areas, and helps to prevent conversion of coffee farms to pastures.

The agricultural "matrix" provided by coffee farms surrounding parks and nature reserves is important for maintaining species diversity. If areas surrounding reserves become incapable of supporting movement of species to and from a particular nature reserve, then species abundance within the reserve will decline due to an inability to maintain intra-specific genetic diversity or replenish in the event of local extinction. Organic coffee, a diverse, multi-layered agro-forest cover, has been found to provide an environment, or matrix, suitable to the propagation of diverse species, such as frogs and birds, by allowing them to move freely through coffee farms from reserve to reserve. This is particularly true when coffee farms are compared against alternatives such as pastures.

Despite these conservation advantages, certified-organic coffee has, like fair-trade coffee, met with recent difficulties. The additional organic premium (currently $15 above the fair-trade price) does not cover production costs in high-cost production areas. In addition, contemporary certification schemes have become both costly and difficult to manage. The layers of inspections and technical extension (village-level and external) required to meet ISO certification standards are quite costly. Small producers, often those living in the areas of particularly high conservation value, find it necessary to join in cooperatives in order to cover certification costs. These village-level organizations reduce individual costs, but must undertake additional work and costs to cover village-level recordkeeping and technical assistance expenses. Aside from cost, these activities require skilled workers who can perform documentation and inspections activities at the village level. In the event of emigration, conservation networks dependent upon these certification schemes are easily disrupted.

Confronting poverty and encouraging conservation practices via alternative trade initiatives is at the crossroads. Given current fair-trade and certified-organic price premiums, high-cost production areas in Latin America are unable to sustain production or coffee quality levels. The cost issue is less pressing in lower-cost production areas in Asia and Africa, yet without higher prices, it will be difficult to sustain village-level conservation organizations necessary to grassroots ATOs.

Cogenerators

COGENERATORS USE WASTE heat from one activity to supply heat or energy to at least one other activity. They have the capacity to reduce the amount of energy used (especially energy derived from fossil fuels) to accomplish more work without sacrificing convenience and comfort. Cogeneration is also called combined heat and power (CHP). Cogeneration technologies were given a major boost in the United States with the passage of the Public Utilities Regulatory Policies Act of 1978, which allowed competition in the generation of electricity. Public utilities were required to purchase electricity from alternative sources, which included solar power, wind power, or cogeneration. The policy goal was to increase the amount of electricity generated in the United States, while reducing the costs along with the nation's dependence upon large coal and nuclear power plants. A further benefit was decentralization.

Hydroelectric power plants use water to generate electrical power. Thermal electrical power plants burn either a fossil fuel—natural gas, oil, or coal—or they use nuclear fuel. Whole trainloads of coal are millions of cubic feet of natural gas are burned, which heats water to very hot steam. The steam, under pressure, is used to turn the blades of a turbine fan. The fan blades drive magnets around electric wires, which generate electric current and heat. Even the most efficient of engines or production systems is unable to convert all of the fuel expended into energy. There is always some waste with the entropy described by the Second Law of Thermodynamics.

Historically, the heat was a by-product that was not used. It was dispersed with cooling towers, gas flues, or by other means. Cogeneration captures the waste heat and uses it for other purposes, greatly improving the efficiency of the whole operation. Waste heat may be used in a cogeneration system to power a second furnace that produces smaller amounts of electricity. In cold climates, the heat may be piped to heat homes, offices, and other buildings. Scandinavian and continental European countries have used cogeneration extensively because of their higher fuel costs.

Cogeneration can be used most efficiently when the secondary application is close physically to the primary use. Large operations such as hotels, universities, wastewater treatment plants, industrial plants, or other facilities that consume large quantities of fuel for lighting and heating are natural locations for cogeneration. A common example of cogeneration is the use of the automobile heater in wintertime. The heat from the engine cannot be used to power the automobile; however, it is used to heat its interior for comfort of the passengers. Futuristic visions of new cities use cogeneration extensively. Waste heat would be used not only for further energy production, but also for growing crops in the city's greenhouses.

Collective Agriculture

COLLECTIVE AGRICULTURE IS the practice of several farm households or villages working together in a food production system, often under state control. Collective agriculture is often associated with Communist economies—such as the former economies of Hungary, Czechoslovakia, and the former Soviet Union—in which collectivization was historically compulsory and imposed. The theory behind agricultural collectivization in the former Soviet Union was to replace small, unmechanized, inefficient farms with larger-scale, mechanized farms that would produce food more efficiently, and to free poor peasant workers from oppression by wealthy farmers. After the lukewarm response to voluntary participation in collectives in the late 1920s, Stalin imposed collectivization during the 1930s by seizing millions of acres of privately owned land and setting up a system of state-controlled agricultural collectives called *kolkhozes* (collective farms) and *sovkhozes* (state farms). The Soviet government controlled wages and dividends, production output, and distribution to ensure compulsory deliveries first and foremost to the state. Combined with major droughts in the early 1930s, tight government controls on production and distribution initially led to severe famine, especially in the Ukraine. Since the fall of the Soviet Union, more than half of all collective farms have been privatized and registered as companies; however, for complex political and economic reasons, many agricultural households and communities have resisted decollectivization.

Compulsory agricultural collectivization in the People's Republic of China began under Mao Zedong in 1955, in theory to free up labor and capital needed to expand the industrial sector of the communist economy. Agricultural collectives in China were broader reaching than those in the Soviet Union, as they embodied industrial and social infrastructures as well as agricultural production. Production and management inefficiencies, natural disasters, and heavy state diversion of output led to widespread crop loss and famine, and ultimately to subsequent reforms. These reforms decentralized management of the commune system, and in the late 1970s—after the death of Mao Zedong—individual households were granted more freedoms to make independent management decisions about their production decisions.

Collectivization in other countries has been voluntary and relatively successful, although not widespread. For example, in Israel collectivization has taken the form of various collective socio-agricultural economies such as the *kibbutz*, which has been the most economically important collective model in the country. In a *kibbutz*, all property except select personal items is collectively owned, planning and work are collective, living is communal, work is distributed based on ability, and goods are distributed based on need. Currently about 3 percent of Israeli citizens are members of a *kibbutz*.

Collective agriculture has not been popular in North America; however, a number of voluntary communities were established in the 19th century by both secular and religious groups including the Shakers, Mormons, Mennonites, Hutterites, and Fourierists. These communities were oriented to different degrees around shared food production, and were often broadly communal in their social, educational, and industrial infrastructures. The Hutterites have established the most successful and long-lasting collective in North America; this agricultural Christian group immigrated with Mennonite groups to South Dakota in 1874 to escape persecution in central Europe. Today, approximately 35,000 Hutterites live communally in over 430 colonies throughout North America, primarily in the Dakotas, Montana, Minnesota, Washington, and the Canadian provinces of Manitoba, Saskatchewan, and Alberta.

Colombia

WITH THE HIGHEST number of living species per area in the world, Colombia is arguably the most biodiverse country on the planet. Yet, Colombia suffers the world's longest-running civil conflict. Fueled by illicit drug production, guerilla groups, paramilitary militias and the army battle each other for control of territory. More than 100,000 civilians have been killed since 1980, and, in 2005, at least three million people were internally displaced. No part of the country is untouched by the war.

Colombia is geographically unique in the Latin America and the world. It is the only South American country with a Caribbean and Pacific coastline. The Chocó region of the Pacific northwest is the rainiest place on earth and has one of the highest rates of endemism and biodiversity on the planet. The Sierra Nevada range in the northeast is the highest coastal mountain range in the world, and the Guajira Peninsula is a unique coastal desert in the Caribbean. Three large Andean ranges traverse the Pacific side of the country and contain several exceptional tropical highland ecosystems known as *páramo*. Colombia's eastern expanse is lowland rainforest and tropical savanna, and covers 50 percent of the national territory.

Following a constitutional reform in 1991, a Ministry of the Environment was created. The Min-

Pablo Escobar

Pablo Emilio Escobar Gaviria (1949–1993) began his career as a petty thief stealing cars in Medellin, the second city of Colombia. It is also claimed that he stole and then sold gravestones from the local cemetery.

In 1971, Pablo Escobar graduated into selling cocaine. His criminal activities soon triggered him to kill a well-known dealer, Fabio Restrepo, and take over his network. By the early 1980s, Pablo Escobar was believed to control the cocaine trade selling from Colombia to the United States, Canada, and Mexico. Many of the drugs were routed through Puerto Rico, the Dominican Republic, and later the Bahamas.

To escape prosecution in Colombia, Escobar variously bribed, intimidated, and even killed law enforcement officials and judges. His Medellin Cartel then became involved in a large gangland war with the Cali Cartel. Also going into local politics, Pablo Escobar built soccer stadiums in Medellin, sponsored soccer teams and gave money to worthy causes. This made him a hero to many in Medellin, making it harder to do anything against him. At one stage, Escobar was estimated by *Forbes* magazine as being the seventh-richest man in the world.

Pablo Escobar has also been accused of involvement in the killing of three presidential candidates, and bombing Avianca Flight 203 and a security building in Bogota in 1989. Some writers also suggest that he may have been behind the killing of half the judges on the Colombian Supreme Court by left-wing guerillas.

In 1991 Escobar turned himself in to the authorities to prevent extradition to the United States. He built his own luxury prison and promised that, in return for a five-year prison sentence, he would stop selling drugs. When it appeared that Escobar was using the "prison" for further business activities, and the government planned to move him to a new location, Escobar fled into hiding but was killed in a shootout in Medellin after being cornered by the Colombian National Police.

istry oversees 46 protected areas and 33 National Parks containing one tenth of the country's total area. Meanwhile, 24 percent of Colombia's land is held as indigenous reserves, and another 5 percent is held by black communities on the Pacific slope. Concentrating in the southern Andes, the Pacific, the Amazon and the coastal deserts of the northeast, the number and size of these collective properties are unique in Latin America and hold out some promise for environmental conservation, sustainable land use, and social justice in the future.

Wartime conditions sap energy and resources, and augment environmental problems. Water pollution is particularly pronounced. The massive Magdalena River drains 18 of Colombia's 32 departments but receives 200 tons of domestic waste each day, and this does not even include chemical seepage from agricultural industries like African Palm, bananas, coffee, sugar, beef, and cut flowers. It is estimated that 50 percent of mangrove forests along the Caribbean coast and on the islands of Providencia and San Andrés have been cleared since the early 20th century. Aquaculture along the southern Pacific coast makes Colombia the 12th largest shrimp producer in the world, but threatens the very mangroves upon which the industry depends. An aggressive agricultural and cattle frontier is expanding eastward from the Andean piedmont. These environmental problems are well known to an educated and conscientious population, who find the war diverts limited resources.

Colombia is now the world's leading coca bush grower (producing 430 metric tons of cocaine in 2004), and is an important global producer of opium poppies. Drug traffickers control up to 10 percent of all agricultural lands in Colombia, a number that does not bode well for long-term sustainable land use and soil conservation. Indeed, armed conflict and areal spraying have pushed small growers up steep hillsides and into ever more remote areas, including national parks. Millions of gallons of chemicals used in eradication, coca growing, and in cocaine processing are dumped into the ecosystem each year. Drug profits also fuel money laundering schemes that expand cattle ranches and monocropping on the frontiers. Ten years ago, the Pacific slope was virtually untouched by the civil war and drug production, but now it has both problems.

Colonialism

COLONIALISM IS A system of global relationships where one nation extends its sovereignty beyond its own territorial borders, either directly controlling the population of a foreign state/location or displacing it altogether. This system of international power relations is further commonly supported by a paternalist ideology, which holds that colonized places need and benefit from colonial dominance. Though historically associated with the age of European expansion (1500–1900), colonialism persisted in a formal sense until the early 1980s, when the last states of Africa were decolonized. The legacy of colonialism is, therefore, still quite recent and arguably quite potent, and scholars continue to point to colonialism and contemporary neocolonial relationships to explain global inequalities and environmental change. Several theories of uneven development and ecological problems, therefore, involve the role of colonialism in some way.

THEORETICAL EXPLANATIONS

Modernization theory asserts that the reason some countries suffer from greater rates of poverty is that they have resisted modernizing or that their institutional and infrastructural framework is too poorly developed to lead to *take off*—a state of self-directed and sustained development. Many modernization theorists often point to colonial heritage as an important historical component for setting these conditions for poor institutional and infrastructural conditions, and favor international support and investment in modernization, mimicking the systems of the developed world. Less developed nations must then work to develop infrastructure and technologies more like the West if they wish to decrease inequalities and, by extension, reduce environmental problems. Because of their underdeveloped technology, developing countries utilize less sustainable methods of agriculture and are less likely conduct activities that prevent environmental damage. Further, modernization theorists might say that developing countries need to modernize their governmental structures in order to create and enforce more effective environmental laws.

Critics of this theory suggest that this model of modernization is in itself colonial, in that modernization essentially requires the imposition of extraterritorial controls and institutions on foreign states, typically following the same geographic patterns as historical colonialism (e.g., flowing from the United States to the Philippines or the United Kingdom to Ghana). This is accompanied by similar paternalistic attitudes, they further assert, in an ideology that holds such impositions are essential and desirable for underdeveloped nations.

By contrast, dependency theory asserts the opposite—that colonial powers exploited lesser powers, creating dependent relationships that persist to the present. World systems theory is a more elaborated analysis of the same condition, which posits that the dawn of colonialism in 1500 set into motion a change in the global network of economic relationships, establishing a persistent system of flows, extractions, and exchanges that continues into the era of globalization. According to both theories, there exist core or high-income nations, middle-income or semi-peripheral nations, and low-income or peripheral nations. European powers and the United States are core nations whose position has been maintained by a division of exchange and labor established in the colonial era, in which peripheral states became providers of raw materials and primary goods (e.g., cotton) that was exported to core states to be processed into higher-value finished goods (e.g., textiles). During the colonial era, such relationships were regulated by force. Indian textile production was disbanded under British colonial authority, for example, and cotton production emphasized. This provided both a cheap supply of cotton for British textile mills and a ready-made market for finished textiles in India. Dependency and world systems theorists maintain that these flows of labor, raw material, and finished goods remain in motion today, under their own momentum and an ideological assumption that they are either natural or inevitable.

ECOLOGICAL IMPLICATIONS

Environments were dramatically transformed by colonialism through heavy overexploitation of native resources, displacement of indigenous land covers, and by the imposition of new systems of economic and political systems that led to dramatic changes in land use. In some obvious examples, African elephants were overhunted to meet British demands for ivory, and in New Zealand, Europeans overhunted whales, then seals. In Australia, European interference with rivers stripped beaches and formed sand banks in the water. Rivers were dammed for water supply, spreading salt to land. Swamps were drained in coastal and inland river valleys, polluting streams.

European colonialists in North America cleared forests on a large scale, as they saw it as a form of improvement, clearing the land and utilizing the timber for construction and fuel. Estimates are that over 46 million hectares (450 billion square meters) of land were cleared by 1850. Similar forest clearing by European colonialists is documented in Australia, Canada, and New Zealand.

More indirectly, colonial powers typically focused on extracting a handful of export commodities for the convenience of the colonial powers' industrial production systems and global supply chains. This not only impaired the indigenous peoples' ability to grow their own food, it also had implications for the ecosystem. Perhaps the best example is in the colonization of Africa, where development of single crops for export led to over development of some areas of land and under utilization of others.

The most fertile lands in Africa—in parts of Angola, Zambia, Zimbabwe, Mozambique, Botswana, Swaziland, and South Africa—were divided up for plantation agriculture, and cash crops replaced native flora and fauna. Roads and railroads were built to transport the new cash crops for export, destroying land and displacing people. Excessive mining operations, notably for diamonds and gold in South Africa, also depleted the African environment. As the promise of riches in gold spread, more people migrated to the area, straining the environment terribly. Efforts to mine minerals for export displaced people into less-hospitable agricultural lands. For instance, approximately 55 percent of the population of Zaire is living in an area about 60 kilometers wide on each side of a railroad built for commercial and industrial purposes.

The introduction of European systems of economics and taxation led indigenous peoples to practice forms of environmental degradation once foreign to them. Historically, the peoples of South Africa generally practiced slash and burn forms of agriculture, where land was used for a particular crop for two or three years, then left fallow for 20–30 years. The time left fallow allowed the soil to become healthy with minerals once more, rather than become severely depleted and unusable. Other South Africans practiced floodplain agriculture, where crops were only planted after floodwaters subsided. Colonialism brought changing property rights and demands for cash in household economies that resulted in use of highly marginal lands and intensification of land uses without replenishment of soils, which led to severe degradation.

In western Africa, French colonial taxation policies forced peasants to devote increasingly large areas to cultivation of groundnuts, which in turn forced food production into areas that were once used for animal grazing, accelerating desertification. Further, the Senegalese took out loans to create refineries for groundnuts. Most of the profit from the exports goes toward paying off the loan instead of developing more environmentally friendly policies and practices. Cultivating and refining groundnuts has so depleted the soil that not only can farmers not make nearly enough to pay off the debts, the land is not usable for other purposes either.

Colonialism also spreads flora, fauna, animals, and insects from colonizing powers to colonized locales. In many cases, the new species of plants displaced native ones. The homogenization of the world's biology and ecology caused by colonialism has proven problematic. New insects and animals spread diseases that devastated the land as well as the populace, as evidenced in the example of colonization of the United States. In the Canary Islands, Europeans spread diseases, including dysentery and a form of pneumonia, as well as venereal diseases, that virtually eliminated the local Guanch population. Colonizers intentionally brought some animals, like horses and cattle, but others, like rats, were accidentally brought to colonized lands. Reports of European colonization in Peru describe the rapid breeding of rats, who then destroyed the crops and plants. Similar reports are documented in Buenos Aires and in Australia.

Once Europeans arrived in the Canary Islands, they introduced new plants and animals popular in Europe. Sugar crops prompted much social and ecological change. Slave labor was imported to work in fields and mills, and forests became cane fields. Trees were destroyed to create buildings for the new industry and were used for fuel to boil the fluid squeezed from the sugar cane. Deforestation created erosion.

Imported weeds took over large areas of the West Indies and Mexico, forests were destroyed for timber, and herd animals overgrazed. Bartolome de las Casas, who documented the exploits of Christopher Columbus, described large herds of cattle eating native plants to the roots, which was followed by the spread of ferns, thistles, nettles, and nightshade.

Colonizing authorities also had environmental knowledges conditioned in their home countries and inappropriate for the new contexts in which they found themselves. Unable to fully grasp the ecological dynamics in the areas they colonized, they tended to assume native practices were in need of improvement. For example, forest islands around villages in West Africa, cultivated by local practice over long periods, were incorrectly imagined by French colonial authorities to be the remnants of vast forests "destroyed" by natives. The use of fire by local people to foster pasture development and other resources was seen as environmentally irrational and destructive by colonial officials, and illegalized.

Conversely, colonial ideologies sometimes cast native people in a grossly romantic light, imagining them to be "noble savages" with no human impact on the landscape. While colonial authorities coming to the New World imagined a vast, unused "wasteland," in fact the land uses of native cultures (among many others) were historically highly intense, and had transformed much of the continent prior to the arrival of Europeans. While the view that the lands were "waste" enabled colonizers to justify their acquisition, the changes in management they brought to these lands often inadvertently disturbed already-existing systems of cultivation and management.

NEOCOLONIALISM AND ECOLOGY

Critical theorists maintain that colonial relationships persist into the present. Wealthy nations today, it is argued, often export the environmental consequences of the goods and services they consume, in the form of wastes and pollution. Dominant or core countries may have little incentive to assist colonized or peripheral countries in addressing environmental concerns, as they are benefiting from the existing arrangements and the generally lax environmental regulations in peripheral countries.

Contemporary conservation efforts in Africa, for example, have been based on preconceptions about traditional forms of African wildlife management and have prompted paternalistic efforts to create national parks with little consultation with local people. For instance, the creation of national parks in Tanzania has displaced tribes from their homelands and impoverished them. At the same time, these parks draw tremendous numbers of tourists, which often has a negative impact on the environment.

Another modern form of colonialism with environmental implications is *corporate colonialism,* in which corporations, rather than nations, reinstate historical exploitative relationships. While refining oil in Nigeria has made Royal Dutch Shell more than $30 billion, the native Ogoni people have received little financially. The impact on the environment has been extremely high, however. Shell operates in more than 100 countries, yet 40 percent of all its recorded oil spills are in Nigeria. Between 1982 and 1992, 1,626,000 gallons of oil were spilled in 27 different instances. Oil refining has destroyed trees and dried up yam and cassava crops. Spills have destroyed the land and killed fish, as well as introduced acid rain to the region.

Another "new" form of environmental colonialism is patenting of genetic materials of domesticated and wild species in the underdeveloped worlds. Today, people in South America buy seeds manufactured in the north from genetic material collected on their land in the 1970s, just as South Americans imported wool and leather made from their own animals in the 1770s. One-third of the known plant species in Brazil have been patented by transnational corporations. Labs in Europe and the United States have patented the medicinal properties of 5,000 of the 13,000 plants used in traditional indigenous medicines of Latin America and the Caribbean.

On the other hand, modernization and market enthusiasts maintain that without the flow of capital, support, and technology from the developed world to the developing world, rates of poverty and environmental degradation would be even higher than they are now. Global corporations, it is argued, can spread more advanced technology and techniques to minimize environmental disruptions. Increased incomes created by globalization can potentially be used for environmental programs. The mid-twentieth century "Green revolution," it has been maintained, provided technology that put an end to famines in places like India, which had been persistent for centuries. Debates about colonialism and the environment are as timely as ever, decades

Colonialists entering the New World perceived a vast "wasteland"; however, native land use was already intense.

after the last colonial officials packed their bags and went home.

Colorado River

THE HEADWATERS OF the Colorado River are located in Rocky Mountain National Park in north central Colorado. Its drainage area extends into seven western states: Wyoming, Utah, Colorado, Nevada, Arizona, New Mexico, and California. The river's 1,450-mile course through the arid southwest to its delta on the Gulf of California has it descending from 9,000 feet to approximately 100 feet. The river runs southwest across Colorado from its origin, continues through southwest Utah, crosses into northern Arizona through the majestic Grand Canyon, and then heads south along the border with both Nevada and California before entering Mexico between Baja California and Sonora. Seven states and part of Mexico all share in the water delivered by the Colorado River. In some years, there is barely a trickle of water as the river enters the Mexican area. In drought years, the riverbed is literally dry miles short of the delta.

In Utah the river becomes the natural sculptor of the uplifted Colorado Plateau. The unique landforms found in Arches National Park, Dead Horse Point State Park, and the Canyonlands National Park is attributed to the work of the Colorado River and its tributaries. In Colorado, the Glen Canyon Dam was constructed to provide hydroelectric power to the local area. Page, Arizona, a new town adjacent to the dam site, came into being as a result. Lake Powell, the reservoir behind the dam, began filling in 1966 and reached its maximum capacity in the mid-1980s. Since that time, due to long-term drought conditions in the Southwest, Lake Powell has receded more than 20 feet from its high point.

Just below its confluence with Nevada's Virgin River, the Hoover Dam was constructed. Behind this giant structure is Lake Mead, which supplies water to thriving metropolitan Las Vegas. Two additional dams are located along the Arizona–California border: the Palo Verde Diversion Dam and the Imperial Dam. They were built to provide irrigation water for agricultural activities in the remote stretches of desert. The Imperial Valley in southern Arizona receives its water from the All-American Canal, a channel constructed to divert Colorado River water to this exceptionally fertile but excessively dry agricultural area.

A potentially serious environmental situation involving the accumulation of radioactive mining tailings near Moab, Utah, was resolved in 2005. Uranium has been mined in the region for 40 years, and the pilings were stored a mere 800 feet from the Colorado River. Although no river pollution has been reported, there was concern over the years that the river could be degraded if seepage occurred from the accumulated pilings. In July 2005, the Department of Energy formalized a plan to transfer the uranium pilings to Crescent Junction, 20 miles northwest of its present site and safely away from any potential contamination of the Colorado River.

Allocation of Colorado River water was an early concern shared by the seven states in the region. On November 24, 1922, representatives signed the Colorado River Compact, an agreement which apportioned water between upper and lower river basin states. The upper basin included Wyoming, Colorado, Utah, and New Mexico. The lower basin states are California, Nevada, and Arizona. According to the plan, each basin was scheduled to receive 7.5 million acre-feet of water per year. The amounts of water specified implied availability during years of normal precipitation. There have been a significant number of years since inception that lower amounts of precipitation were received. In years of deficit, legal entanglements and disputes have emerged, especially among the states in the lower basin.

To simplify the allocation situation, each basin was authorized to determine the amount of water for each of its states. In the upper basin, a contract signed in 1948 assigned each state with the following percentage allocation: Colorado: 52, Utah: 23, Wyoming: 14, and New Mexico: 11. Development in the upper basin has proceeded at a much slower rate than in the three states to the south. Consequently, none of the upper basin states have used their full allocation of Colorado River water. At the end of the allocation chain is California, the state using the greatest amount of water from the Colorado River. California's population is expected to increase significantly over the next two to three decades virtually assuring greater draw on the limited water delivered by the Colorado River.

Columbian Exchange

THE COLUMBIAN EXCHANGE is the transfer—both intentional and unintentional—of biological material across the Atlantic. It began with the first voyage of Christopher Columbus from Europe to the Americas in 1492. This voyage initiated a process that continues to this day, linking the ecosystems of the Americas with those of the rest of the world.

The term *Columbian exchange* was coined by the historian Alfred W. Crosby in his 1972 book, *The Columbian Exchange: Biological and Cultural Consequences of 1492*, which advanced Crosby's claim that "the most important changes brought on by the Columbian voyages were biological in nature."

Some species, such as domesticated plants and animals, were intentionally introduced with dramatic consequences. For example, sugar, which was domesticated in Asia, transformed the ecosystems of the West Indies and Brazil and motivated the forced migration of millions of enslaved Africans to labor on the plantations. Farther north, and a little later, the introduction of cotton, also domesticated in Asia, would have similar impacts. European farmers brought their cereal crops with them as they emigrated to the Americas: wheat, barley, oats, and rye. They also brought vegetables and fruit such as onions, cabbages, peaches, and pears. Africans carried domesticated varieties of African rice, as well as the knowledge to cultivate it in a new environment. Later, Asian varieties of rice would also be grown in the Americas with African labor and expertise. In addition, sorghum, millet, and yams, all eastern hemisphere domesticates, were transferred to the Americas. As human populations increased in the Americas over the next several centuries, the cultivation of these crops encouraged the transformation of the landscape through deforestation, draining of wetlands, and reduction of biotic diversity.

The plants that were carried eastward—from the Americas to Europe, Africa, and Asia—had equally significant effects. Maize, domesticated in Central America, was growing in Africa by the early 1500s. Manioc and peanuts would also prove to be important food crops in Africa. Potatoes replaced a variety of cereal grains and vegetables in the fields of Europe after they were introduced from the Americas. Like maize, potatoes offered a high caloric return and therefore could support a larger population on the same acreage planted to European crops; potatoes and maize helped to fuel a population surge that would ultimately lead to Europe's industrial revolution. Vegetables and fruit that made the voyage from the Americas included tomatoes, squash, pumpkin, avocado, and pineapple.

Native Americans had domesticated relatively few animals (dogs, llamas, fowl, and guinea pigs) in comparison to Asians, Europeans, and Africans. However, the introduction of new domesticates such as horses, cattle, pigs, sheep, and goats reshaped American cultures and landscapes. Domesticated animals had been important sources of food and labor in the eastern hemisphere, and would serve similar purposes in the western hemisphere. Horses played significant roles in the conquest of the Americas by Spanish conquistadors, but when they arrived on the North American Great Plains and the South American pampas, horses revolutionized the traditional subsistence patterns and cultural forms of indigenous groups. Likewise, the introduction of sheep impacted native groups such as the Navajo. Introduced animals affected the American landscape even more dramatically than introduced crops, at least in the first centuries after introduction. The native ecosystems of Hispaniola, for example, were severely damaged by cattle, horses, and pigs brought to the island by Europeans.

MAJOR DEMOGRAPHIC SHIFT

The Columbian exchange also comprised the largest demographic shifts in world history. European slavers forced the migration of some 10 million Africans to the Americas. The vast majority of these slaves were captured in West Africa, between the Senegal River just south of the Sahara Desert and Angola on the central African west coast. On average, 10 to 20 percent of the slaves that boarded ships in Africa died before they reached the Americas. By 1650 Africans made up over half of the settlers in the Americas, and up to the time of the American Revolution, six of every seven people who journeyed across the Atlantic were Africans. Approximately 80 percent of the Africans were carried to the Caribbean islands and Brazil.

The unintentional introductions to the western hemisphere were in some cases a nuisance and in others a devastating force. Weeds invaded native ecosystems, often abetted by the ecological disturbances created by livestock. Small mammals, most notably rats, accompanied the earliest European immigrants. However, the truly devastating introductions were too small to see: the microbes that caused diseases in humans. It is difficult to accurately determine the population declines of Native Americans after 1492 due to disease. Recent estimates suggest precontact populations between 43 million and 100 million. One estimate places the population in the Americas in 1492 at 54 million with about 50 million of these south of the present-day United States. This population was reduced by an estimated 76 percent between 1492 and 1650. Other scholars have estimated significantly higher mortality rates. Much of this population loss was due to infectious diseases such as influenza, measles, smallpox, bubonic plague, chicken pox, diphtheria, cholera, whooping cough, and scarlet fever. The worst of the epidemics occurred in the first century after contact. The first large-scale epidemic, primarily smallpox, broke out in the Americas in 1519 on the island of Santo Domingo, where it decimated the population of the Arawaks, the first natives that Columbus had encountered three decades earlier. From Santo Domingo the epidemic made its way to Mexico, where it paved the way for the conquest of the Aztecs by Cortez. Several factors explain the susceptibility of Native Americans to the diseases of the eastern hemisphere. Eastern hemisphere diseases were left behind as the earliest Americans crossed the Bering land bridge and moved southward and eastward through the Americas. Equally important, because indigenous Americans domesticated relatively few animals, the Americas did not develop the many infectious human diseases that originated in animal populations. These two factors left Native Americans defenseless, leading to what demographers refer to as "virgin soil epidemics."

Command and Control Regulation

COMMAND AND CONTROL regulations of the environment use standards set by a regulator. The standards are set in order to regulate the environment or ecology in such a way that its natural integrity is maintained at an acceptable level. The standards are mandated at some level and are enforced in law. The focus of the mandated standard is to outlaw excessive amounts of pollution. The mandated standard makes what might be otherwise an allowable overage of pollution an illegal act. The goal is to establish a legal principle to which the potential polluter must adhere and which the government can enforce. The results will be an efficient level of pollution control.

Command and control regulations are a form of public policy that uses laws, measurements, rules, standards, and sanctions to enforce compliance with the policy of a clean environment. The command and control regulations require polluters to meet specific emission reduction targets or face fines. They may also have to install expensive equipment, which will be used to reduce their offending pollution.

Standards may be ambient, emission, or technology. Ambient standards regulate the amount of pollution present in the ambient environment. For example, oil seeps naturally from the ground into water sources, a cause of natural pollution. To measure what is naturally in the environment and compare them to human activities enables an ambient standard to be established.

The standards are set by making numerous daily observations over several seasons. If the observations reveal that a human polluting source is a contributing factor, then the goal will be to locate its source in order to eliminate it legally. The Clean Air Act set federal standards for ambient air quality for a region as well as localities, because pollution is can spread over wide areas. Ambient standards can be used to mandate regional compliance through a regional compliance plan.

Emission standards regulate the level of emissions that the government will allow in order to prevent pollution. Emission standards may regulate the number of particles of SO_2 emissions permitted per hour by a coal-fired electricity plant, or the levels of biochemical oxygen demand that can be allowed in wastewater.

Ambient standards and emission standards may not always be in a harmonious relationship. This is because emissions may exceed limits normally allowed because weather conditions create runoff or storm damage that interferes with the normal level of emissions. Electrical demand may have to be elevated during severe winter weather, which may mean a temporary increase in polluting emissions.

Technology standards are mandated to allow polluters freedom to choose the technology to eliminate pollution. Technology standards permit the use of the "best practicable technology" for an industry or for a industrial practice.

Some critics of environmental regulation believe that command and control regulation of the environment has failed. For them, it has fallen into disrepute because it is obsolete and did not fulfill its purpose due to inefficiency. Another criticism is that it interferes with the fundamental rights of people to the free and fair enjoyment of their property. In addition, it is not clear that human behaviors have been modified in any significant or fundamental way through command and control regulations.

Some critics advocate a system of incentives. Instead of the dictatorial command and control system, market-oriented critics promote economic means for reducing pollution. In meeting ambient standards, some have proposed using a system of credits that can be purchased. Pollution is allowed and not eliminated, while economic benefits go to those able to gain them while externalizing the pollution costs to others. In response, supporters of command and control regulations point to the enormous progress in cleaning up the environment. The American government and others around the world have made significant investments in time and money. These have created a system in which pollution has been reduced and has allowed many streams, rivers, and other natural environments to return to a closer proximity to their original natural state.

Commerce Clause

ACCORDING TO ARTICLE 1, Section 8, Clause 3, the Commerce Clause of the U.S. Constitution, "The Congress shall have power… To regulate commerce with foreign nations, and among the several states, and with the Indian tribes." There are essentially three different interpretations of this clause. First, there are those who claim that the clause gives Congress and the federal government the unique right to regulate all commerce. Another interpretation suggests that the clause also gives states the power to regulate commerce, a power that is only preempted in cases where state regulations contradict or preempt federal power. The third interpretation of this clause suggests that states and the federal government have different, sovereign zones of regulation. The federal government cannot violate the state zone or vice versa. The current interpretation of the Supreme Court evolved from a complicated combination of these different views argued in several cases. This interpretation basically limits the ability of states to regulate commerce in particular ways even as states and the U.S. Congress can regulate commerce in different zones concurrently.

For several key environmental laws, the Commerce Clause has been interpreted to extend federal authority over what might otherwise be separate state jurisdictions. Most prominently, the 1972 Clean Water Act is understood to be constitutionally sound insofar as the federal authority extends to waterways and wetlands via the clause. Recent petitions have been made to curtail the successes of the Clean Water Act by asserting that federal authority only extends to literally "navigable" waters (those suitable for use by commercial vessels) and only those wetlands and streams directly adjacent to waterways.

This clause has had a major impact on the ability of the federal government to enforce in-state environmental policy, leaving the states with the power to regulate beyond minimum federal standards. In some cases, however, the Supreme Court's interpretation of the Commerce Clause has limited the ability of individual states to enforce environmental policy if this policy has an adverse consequence for interstate commerce. In *Philadelphia vs. New Jersey* (1976), the Supreme Court ruled against a New Jersey law prohibiting the importation of garbage into the state. The Court saw this as a discriminatory ban against commerce from another state. In *Hughes vs. Oklahoma*, 1979, the Court also struck down an Oklahoma law intended to preserve and protect fish by prohibiting the export of minnows across the state. The Court rejected the idea that states can own wildlife, making it not officially an article of commerce. In *Maine v. Taylor*, 1986, however, the Court ruled that Maine had the right to prevent the import of certain baitfish to prevent the introduction of parasites because no alternative to discrimination against other state commerce existed. Thus, in most cases, the demands of commerce were preserved over the environmental policies. As the law presently stands, states have the power to regulate and preserve their environmental resources; but they cannot do so at the expense of interstate commerce, unless there is no other alternative.

Commodification

COMMODIFICATION IS A widely if often somewhat loosely used term, usually with some sort of critical or pejorative connotation. But what does the term actually mean, what processes does it refer to, and what might rigorous perspectives on commodification have to offer to the study of environmental politics and environmental change?

At the most basic level, a commodity may be defined as that which is produced for sale. This is less an evaluation of the actual material character of production and more a recognition of the sociological significance of intent, with production for use being distinguished fundamentally from production driven by desire for exchange, and for profit. This distinction—one made by Aristotle, Marx, and Polanyi, among others—recognizes that there is something quite different about producing (e.g., fishing) for subsistence needs as opposed to producing for exchange and the generation of surplus. There is also something different about consumption mediated by market relations, particularly when production and consumption networks spread across vast expanses of space, as is characteristic of the contemporary global economy. If we accept that production primarily for sale is the defining feature of a commodity, then commodification refers to the uneven, dynamic, and *always* incomplete tendency toward circulating certain types of "things" as commodities, but it also refers more generally to the proliferation of more and more commodities, as production for use displaces production for exchange.

That said, production for exchange is not unique to capitalism. But the sheer proliferation of commodities, and the extent to which seemingly everything and anything can be produced as a commodity for exchange, is a defining feature of capitalist political economy, and particularly, of its expansionary tendencies. This expansion has been fruitfully discussed as having two interlinked facets, the first "deepening," the other "stretching." Deepening refers to the tendency of more and more "things" to be commodified— produced primarily for exchange. Stretching refers to the expansion of commodity markets, and thus the expanding scope of exchange dominated production, displacing production for use. Examples of deepening might include farmers increasingly buying commercial, synthetic fertilizers as opposed to using on-farm organic wastes, while stretching would include the ongoing international expansion of commercial markets for such fertilizers via the Green Revolution and liberalized trading regimes. And indeed, these selfsame tendencies toward the commodification of on-farm inputs have been theorized as a key facet of the development of capitalist agriculture more generally. Important links connect stretching and deepening with the commodification of labor power. This is because production for exchange, particularly on an expanding scale, gives rise to the purchase of labor power as a commodity (or at least based on the pretence that it is a commodity like any other) via payment of wages. Price-based competition fueled by expanding, wage-labor based production can push out petty commodity producers, and production based on other systems of social organization, such as mixed production for subsistence and barter exchange on a limited scale. This dynamic of competition has the effect of both deepening and stretching commodification. In addition, however, commodification of labor power is central because the increasing dependence of workers on wages used goes hand-in-glove with the production of more and more "things" as commodities for sale (food, clothing, shelter, etc.).

COMMODIFICATION AND ENVIRONMENT

There are important connections between commodification and environmental studies. For one, commodification is no stranger to resource and environmentally intensive production, so that the provision of biophysical resources as commodities (e.g., coal, oil, timber) underpins the material and energetic basis of capitalist economic production, often attended by serious and geographically uneven environmental impacts. Oil, for instance, is arguably the world's most important single commodity and is among the world's most heavily traded commodities, and oil companies were among the first modern, transnational firms.

But this points to a fundamental tension between commodification and the biophysical world. On what basis is it possible to say that production is primarily, if not exclusively, for sale (exchange) when all production, including the reproduction of labor power, depends on ecological production of various kinds? This is one of the reasons that nature as a category has been termed a fictitious commodity—it only *appears* to be produced by capitalist firms and allocated by markets. Nature is sustained and reproduced by ecological circuits not wholly subsumable to social coordination. Moreover, biophysical nature is also subject to contending social demands that compete with market pressures. As Polanyi noted, the allocation of land (nature) cannot be wholly subordinated to the market because this would result in society tearing itself apart.

Despite this, neoliberal efforts to deepen and stretch capitalist markets via the privatization and commodification of more and more discrete environmental resources and services make commodification an immediate concern in environmental studie. Examples include privatization and sale of fishing rights, private for profit water utility service provisioning, and waste disposal services. Significantly, this can include not only the commodification of material nature, but also commodification of representations and images of nature (such aspastoral images used to sell ski vacations). In fact, entire "political ecological imaginaries" circulate along with material commodities as a kind of surrogate for direct knowledge of production conditions, in the context of spatially stretched relations between producers and consumers. This semiotic commodification shapes and fuels desire for commodities in markets, and acts as a crucial link between producers and consumers. But it is also a potential source of leverage in progressive struggles to achieve social and environmental justice in commodity production by means of labels and branding. Whether robust social and environmental justice can actually survive commodification, with all that entails, is an open question indeed.

Commodification, via the expansion of production for exchange as opposed to production for use, arguably deepens an instrumental, utilitarian disposition toward biophysical nature that many identify as a cultural origin of modern environmental problems. Moreover, precisely because of the fictitious character of nature as commodity, there are particular problems and contradictions associated with making discrete elements of the biophysical world ciculate as such. How, for instance, is continuous ecological variation discursively rendered into the sort of acceptable, discrete gradations that market differentiation requires, such as discrete grades of wheat or lumber? What "work" is required to equilibrate and sunder discrete biophysical entities and processes to allow them to be exchanged as commodities? And since prior ecological (not to mention social) production sustains all formally capitalist, economic commodity production, commodification is necessarily and always uneven and incomplete, begging the question as to how commodification proceeds and how it articulates with wider networks of socio-ecological production and regulation.

Commodity

THE COMMODITY IS intimately located at the interface of economy, society, and the environment. Referred to as "the DNA of capitalism" and the heart of contemporary market economies, the commodity appears as such a simple and obvious thing. We buy things to fill a perceived or required need. When one gets down to it, though, commodities are fascinatingly complex and multifaceted. They are vessels for a multitudinous array of social, political, economic, geographical, and environmental relationships. Think of just some of what went into bringing you that cup of coffee that started your day: the intensive labor of a small farm family in Mexico (or Ethiopia, Vietnam, Indonesia) or that of a plantation worker in Brazil (or Guatemala, Kenya, Columbia); the pesticides used; the processing/pulping plant with concrete drying slabs and bean-grading equipment; the containerized coffee sacks driven, shipped, and driven again to a massive roasting facility; and the store clerk who placed the carefully grown, harvested, sorted, roasted, and shipped coffee beans wrapped in a vacuum-sealed one-pound foil bag on the supermarket shelf.

And, yet, when we hold up a cup of coffee, a frozen chicken, new shoes, an mp3 player, a banana, or indeed any commodity—we are unable to "see" those relations behind these objects. This is what Karl Marx called the *fetishism* of commodities. An incredibly complex concept at the best of times, commodity fetishism can be understood as the ability of the commodity to hide the relations—social or otherwise—of its production. Commodities appear as if they are independent and naturalized forms apart from the people and environments that produced them. This leads to confusion and a concealing of these relations between people and ecologies, which are replaced and reconstituted as reified relations with commodities. As the geographer Michael Watts puts it, this obfuscation "…is central to the alienation [of both producers and consumers] rooted in a world in which everything is for sale, and everything is a thing." Further, looking back at the cup of coffee, the concern is for how this obfuscation works to veil the exploitation of small-scale, marginalized farmers and plantation workers as well as the ecological destruction caused by, among other things, chemical-intensive coffee production. Considered this way, drinking our morning java is an act of connection that brings us into relationships with literally hundreds of thousand of people; global economic, political, and trading institutions; and local, regional, and—to an extent—global ecological systems.

The concern is for how commodity obfuscation may veil the exploitation of small-scale plantation workers.

Commodities contain and express three forms of value. First, they have a *use value* in that they satisfy a human want and can be "used" for something. Coffee's historic use value has been to not only wake us up in the morning but make us more productive as laborers. Second, commodities have an *exchange value,* meaning they have the ability to be exchanged for other commodities. A bag of coffee might be exchanged for a hammer, four banana bunches, or a ready-to-eat chicken. Rather than this bartering of commodities, these days economies are organized into thoroughly monetized commodity systems. Watts describes this *commodity circulation* as the "process by which a commodity is exchanged for money, which in turn permits the purchase of another, different commodity." And, importantly, value is not imputed into commodities through price, but through the amount of labor expended to produce them.

The third form of value is loosely known as *sign value* and involves the *semiotics* of commodities: the social construction of value through branding; aesthetics; and an association with quality, status, and/or taste. This often translates into greater monetary price for particular branded commodities such as a Starbuck's latte or a bag of fairly-traded, shade-grown, organic coffee. Yet, this might not always be the case: Relatively low-cost McDonald's food sold outside the United States is a consumable proxy for "American culture" or "modernity."

Commodification is the process whereby something becomes a commodity. There are two essential *moments of commodification*: the material manipulation and transformation of "nature" into a priceable and sellable form; and the semiotic production of commodities through the use of meaningful symbols, logos, brands, language, and images that surround us in contemporary society. Still, commodification is often incomplete or partial. Many peasants produce much of their own food or other consumable goods, yet also sell commodities like livestock or cultural products to enable the purchase of cooking utensils or their children's schooling.

Additionally, there are what Karl Polanyi calls *fictitious commodities*. These "special" commodities—labor, land/nature, and money—are treated as commodities and enter markets but are not intentionally produced in commodity-like form. Thus, labor can be sold as units of money per hour, but people are not produced as commodities as such. The exception—and a nefarious one at that—is of course slavery.

Commoditization is the process of the spread of commodification to all parts of society and life. Jürgen Habermas called this the "colonization of the lifeworld" through the deepening and broadening of the commodity form. Commoditization is a defining feature of post-modern society as literally everything is now for sale, from genetic material, bodies (i.e., babies and women) and body parts, clean air, knowledge and ideas, to whole ecosystems.

Commodificiation and commoditization are complicit in and influenced by processes of globalization. We can see this most vigorously in the spread of American products in the iconic forms of Coke, the Big Mac, and Mickey Mouse. Some argue this contributes to the *homogenization* of global culture through the marginalization of local difference. George Ritzer characterizes this as the "globalization of nothing" in the vacuous commoditization and consumption of signs through global brands. Others, like the anthropologist Daniel Miller, argue that cultures make these products "theirs," localizing global brands culturally and economically. His work speaks to how, in a local context, Coke has come to express *differentiation* as the "sweet black drink" from Trinidad.

Commodities have *biographies*. They are "born," create and follow chains and circuits across places and people, are marketed, consumed, used, and discarded. Commodity biographies tell stories—from the rich and vibrant to the plain and mundane—of the trials, tribulations, and travels of goods in market economies. Commodities also have varied and moveable *social lives* as they slip in and out of various meanings, forms, uses, and trajectories over time and space. The most obvious example might be the cans and bottles set on the curb to be recycled by the local municipality, sold to a manufacturer, and transformed into a new product. Yet, those commodities (and their changing values) become part of "second-hand commodity cultures" such as goods sold at a charity shop or a garage sale, or items "re-gifted" to friends and family. Many go through an established circuit: they are first created as a product, invested with a value; then used as a "useful" object; then used up or not used at all, becoming "valueless" (a

Radical Concepts

There are other, more "radical" ways to address the nexus of overconsumption, commodification, and the environment. These confrontations often involve the active resistance to globalized commodification and privatization, or at least a slowing down and directional shifting of their processes. Several phenomena are important here: the movement for indigenous and local people's rights in both the global north and south around the concept of community-controlled (and often noncommodified, noncommodifiable) resources and landscapes; a "re-embedding" of commodity production and consumption in natural processes and local communities in the markets for organic, fair trade, and artisanal foods; the growth of Local Exchange Trading Systems (LETS), where communities develop their own local currencies for goods and services to promote community economic development and social networks; and the "subvert" movement led by Adbusters which turns commodity semiotics against itself by humorously "culturejamming" the meanings and messages of advertisements into those of hard-hitting "truths" about a product.

jacket that doesn't fit any more); and finally, given to a charity shop where they are "re-valued" and sold as second-hand goods. The success of eBay is a billion-dollar testament to the circulating social life of commodities and the re-valuation of goods.

In modern societies, unregulated commodification and commoditization are a large part of the environmental problem. We can see this most clearly in crude extraction industries, such as agriculture, forestry, and mining, but also in commodity manufacturing. Access to extractive and other resources fuels conflicts and warfare the world over. Further, it is the complex interweaving of both the aforementioned commodity moments and the creation of desire which puts considerable pressure on environmental resources. For example, marketing of grossly oversized SUVs for the urban "jungle" fosters demand for gas-guzzling behemoths, promotes overconsumption, further resource extraction, and a dose of pollution.

Deeper commodification has been posited as the solution to environmental problems. This is exemplified through "cap and trade" pollution control, whereby both pollution (and by proxy, clean air) are turned into purchasable commodities; the commodification of nature in the outright purchase of landscapes and rainforest reserves by environmental groups (e.g., the Nature Conservancy and Conservation International); and the commodification of ecosystem services in carbon trading program with the purchase of "carbon sinks" (such as forests and grasslands) in the global south by carbon dioxide-emitting corporations located in industrialized countries.

Commodity Chains

A COMMODITY CHAIN is the connected path across which raw materials travel to become processed into finished goods, and eventually consumed. For example, coffee may move along a commodity chain from the site in Columbia, where it is grown by a peasant producer, through a buyer in Argentina, to a processing plant in Jacksonville, Florida, to a big box store in Des Moines, Iowa, where a consumer buys it and drinks it in Cedar Rapids. At each point along the chain, the coffee is physically transformed and value is added to the product. With each successive sale, an increasing profit is made; processors generally earn more than growers, retailers more than processors.

Commodity chains encapsulate systems of social and spatial relationships connecting production and consumption. They are comprised of linear "links" representing discrete, but interrelated, activities involved in the design, production, and marketing of a product. Commodity chains emphasize relationships between commodity processes, societal practices and the institutions and environments in which commodities and their meanings are produced and circulate. Two intellectual traditions have dominated: global commodity chains perspectives and systems of provision approaches.

GLOBAL COMMODITY CHAINS

The global commodity chain literature draws on the world systems theory. Much of the early global commodity chain literature analyzed agricultural and industrial commodities, depicting how commodities were produced in peripheral regions of the world for consumption by a core of countries. This literature has highlighted the organization of chains—and the power of institutional agents such as manufacturers, buyers, and distributors—to influence and maintain flows of materials, peoples and knowledge.

An important aspect of the global commodity chain literature has been the concept of governance, with chains characterized as buyer- or producer-driven, depending on the type of firm that coordinates and/or controls relations along the chain. The growth of producer- (or supplier-) driven chains is linked to the emergence of a Fordist regime of capital accumulation post World War II, facilitated by the provision of export processing zones and the import substitution policies of both developed and developing nations. Producer chains are typified by vertically integrated transnational corporations that are capital- and/or technology-intensive (such as automobiles, aircraft, and computer firms). In contrast—in buyer-driven chains—retailers, marketing and branded manufacturers govern supply, and/or production of commodities, often through decentralized production networks. Buyer-driven chains have been associated with labor-intensive and consumer goods industries such as apparel, footwear, toys, and consumer electronics. Their rapid growth since the 1960s is a part of a general transformation from "manufacturer shift" to "consumer pull" assisted by a shift in the industrial strategies of developing countries from import substitution to export-oriented growth, and encouraged by neoliberal government policies and International Monetary Fund and World Bank policies. Buyer-driven chains have attracted much controversy because industrial production has frequently occurred in areas of low-cost labor, with minimal environmental standards or working conditions, and poorly unionized workers. In buyer chains, control of flows of information, skills, products, logistics, marketing, and design and branding remains in the core countries.

While the global commodity chain literature has emphasized the political economy of production and consumption links, research on food and agricultural commodity systems, the French *Filière* tradition, and "systems of provision" examines the transformations (and trajectories) of the commodities themselves and the systems, social relations, and sites that shape their flows. These approaches accommodate material and symbolic constructions of commodities, highlighting how chains for different commodities are constituted and expressed very differently, a consequence of the composition of the "systems" of production, circulation distribution, and consumption in which they are located.

The distinction between the global commodity chain and systems of provision approaches has become increasingly blurred. Both are useful for understanding how commodities connect people and places at a range of scales and for examining the political, social, and environmental expressions of chain formation in contemporary and historical contexts. Many social and environmental justice movements and organizations draw on the chain metaphor to emphasize connections between producers and consumers, and their practices to evoke consumer activism and to change government policy, and/or corporate practices. A politics of connection is also evident in the establishment of fair-trade commodity chains, and in the sale of commodities which make "ethical" or environmentally sustainable forms of production explicit.

Examinations of chains have been used to establish positions on academic and popular debates about globalization, sustainability, free trade, and the power of transnational corporations. There has also been controversy over the environmental expression of commodity chains. For example, in agro-food commodity chains, European consumers can contribute to land degradation in the form of over-cropping in Africa, and consumer preference for fast food and can be linked to air and water pollution through intensive agriculture. Following a commodity chain beyond purchase also discloses environmental consequences—the disposal of inorganic waste, for example, poses a significant environmental challenge.

The increasing complexity of a globalizing world has challenged the commodity chain as a model for understanding connections between production, consumption and place. Commodity chains have also been criticized for positioning consumption as a consequence of production, yet they remain a powerful metaphor for academic and populist understandings of production and consumption linkages, and the social and environmental contexts in which these occur.

Common Law

COMMON LAW IS the judge-made law developed in England after the Norman Conquest. The judges rode in circuits to different locations where court would be held. After about 1080, they began to decide cases between the people—none of whom were English, but were rather Celtic remnants, Saxons, Angles, Danes, Norsemen, Britons, and others who would eventually meld together to become English.

Between 1100 and 1300, the traveling judges developed the law common to all of England. In London, where they would return after they had finished riding their circuits to hear cases, they had their permanent residences and would meet in inns. From these meetings were established permanent legal institutions that have continued until the present as the Inns of Court.

The decisions of the judges that developed the common law and its principles were made well before the establishment of English Parliament as a legislature, which would make statutory laws. The key feature of the English and eventually Anglo-Saxon common law system is that it is judge-made law. Over what is usually a long series of cases, the judges develop the law on many issues.

The common law, as it developed in England, was stable because the common law developed the principle of "like cases should be tried alike"; it therefore followed precedents set in previous cases, which is called the rule of *stare decisis* (Latin for "let the decision stand"). The common law was not very flexible—in order to bring a case for damages, actual harm had to occur. However, a tort suit for recovery from a harmful action is meaningless if the harm is irreparable. If an orchard of 50-year-old walnut trees was cut down, there is no remedy to replace them. In order to prevent irreparable harms and injustices that could occur under the common law, another form of judge-made law also arose, called *equity law*.

The common law was exported to English colonies, including the United States. After the American Revolutionary War, common law and equity law were incorporated into the American legal system as a part of the Constitution of the United States.

In the United States, England, and other English-speaking countries where the common law was received, great areas of life are still regulated by the common law. In contrast, on the European Continent and in many other countries, the civil law system has been adopted. This system uses a code of general rules that have been formulated by jurists and other specialists in the law. The Civil Code of France, which began as the Code Napoleon, is an example. It has its roots in the ancient Roman Law and its legal institutions. The legislatures of the countries that adopt civil law codes assign to judges the responsibility to apply the rules of the code to the facts of a case. A similar function is also found in common law countries, when judges apply statutory law. However, in the United States, the existence of judicial review as a legal doctrine means that all statutory and administrative rules and regulations are ultimately reviewed by judges in cases as if these were also facts in a case, rather than the controlling legal rules.

There has been a radical change in the American legal scene since the advent of the Environmental Movement and a series of environmental crises after the 1960s. Historically, the common law protected the environment in a variety of ways. One of these was through bringing a suit to abate a nuisance. Nuisance actions can include not only an injunction to prevent (equity) the nuisance, they can also include the use of damages for restitution.

Another form of common law action was the use of trespass law. The ownership of property creates rights; the common law holds property in high regard. To invade it by some form of trespass, including the passing of airborne, waterborne, or land pollution, means that a defendant's actions can be held liable for damages to the quality of the environment.

Riparian rights are another area of law that was protected by the common law. Water in a stream or lake beside a piece of property was under the common law, not the property of a landowner. Riparian rights allowed water users to sue if the quality of the water was damaged.

ENVIRONMENTAL REGULATORY STATE

In the United States, an environmental regulatory state has developed. Rather than the interested parties and the judges creating cases, which economists believe is a more efficient way to regulate problems, enormous regulatory bodies have been created by Congress and all the 50 state legislatures. The assumption was that the common law system was inadequate to deal with environmental problems.

One particular case, the Love Canal case, has become important in the history of environmental regulation. The chemical company, Occidental Petroleum, was forced by eminent domain actions by the local school board to sell land where it had stored chemical wastes. It was not really the chemical company that created the environmental disaster that followed; it was by a governmental agency that acted unwisely. The terrible birth defects and health problems that followed occurred despite the very stern warning of Occidental Petroleum Company. However, Love Canal became a rallying cry for statutory and administrative regulations.

Many lawyers and political observers believe that the adoption of a bureaucratic regulatory mechanism for environmental supervisions will in the long run produce more problems than if the common law system had been allowed to take its course. The political realities are that legislation is subject to politically shifting tides of opinion where it is not in a system of judge made rules that are insulated from political fashions.

Civil law systems emphasizes social stability, but from a governmental perspective. The common law instead focuses on the rights of individuals. When the rights of individuals are in conflict with asserted claims of societal rights, there may be a serious loss of personal liberty.

Common Property Theory

COMMON PROPERTY THEORY addresses the use and abuse of resources often held in common, such as pastures, forests, fisheries, groundwater, and even the global atmosphere. Common property theory has evolved from a concern with the Tragedy of the Commons, through a series of detailed studies documenting successful traditional systems for managing common property resources, and into a sophisticated body of theory addressing the conditions under which people are able to forge sets of rules and practices that coordinate the use and conservation of common resources.

According to the Tragedy of the Commons approach, a resource owned in common will almost certainly be abused. In a common property pasture, for example, individuals gain all the benefit from putting more sheep on the pasture; all the milk, meat, and wool belongs to the individual. However, each sheep added to the pasture subtracts from the total grass available. These actions of individual shepherds would inevitably lead to overstocking and grass depletion.

TRAGEDY OF THE COMMONS

The concept of "free-riding" is central to the Tragedy of the Commons formulation. "Free-riders" are resource users who shirk the work and responsibilities of contributing to resource management. For example, free-riders can eschew such work of investing in an irrigation system, but still enjoy the benefits of water delivery. When a person cannot be excluded from benefits that others provide, there is little motivation to contribute to joint efforts. If everybody decides to free-ride, however, there are no benefits from sound resource management. The free-riding problem makes voluntary contributions to a public good (such as common property maintenance) illogical; solutions require outside coercion. According to this early formulation of common property theory, only privatization or state control could resolve this dilemma. Either the resource must be allocated to individual owners who will suffer their own consequences if they overstock, or else the state must impose rules to restrain the effects of individual rationality.

One way to summarize the Tragedy of the Commons view is the adage that "everybody's property is nobody's property." For many, this formulation remains the Commons problem, in spite of a great deal of work documenting successful common property management regimes. Such ideas continue to have great cultural resonance in Western thinking. On the one hand, private property evokes the "invisible hand" of the market that guides individually selfish actions toward the greatest social good. On the other, lack of private property leads to brutish chaos and disorder.

Current common property theorists identify several conceptual errors in the Tragedy of the Commons formulation. Common property is not everybody's property. Instead, common property is one of several different ways to organize ownership of common pool resources—a class of resources for which it is difficult to exclude people and for which use involves the ability of subtraction. A fishery is a clear example of a common pool resource; it is difficult to keep fishers out, and when a fisher makes a catch, it is no longer available for other fishers.

There are four basic property regimes for such resources. Under open access, there is no exclusion and no rules governing individual use. Under private property, the resource is parceled out to individuals. Under state property, the state retains ownership and regulates the resources. Under communal property, which is often referred to as "common property," an identifiable community of resource users is able to exclude other users and subject the resource to customs and rules. It is a misunderstanding to conflate "the commons" or "common property" with open access. Tragedy of the Commons only portrays a very small subset of common pool resource ownership arrangements.

Common property theory addresses the use and abuse of resources often held in common, such as forests.

COMMON PROPERTY IN THE PAST

Over the years, the Tragedy of the Commons perspective has spawned a heated counter-response, especially from anthropologists, geographers, and other researchers familiar with the numerous small-scale, often non-Western societies that have successfully developed social practices to manage common pool resources. Ethnographies provide details on the diverse societies in the past and present that have independently come up with communal arrangements to manage common-pool resources. Many of these communal property systems have persisted for long periods, because they build on knowledge of the resource and cultural norms that have evolved and been tested over time. From medieval common grazing lands to wild beaver populations in subarctic Canada, different societies have frequently been able to work out rules for the orderly use of common pool resources of interest to them.

The rules for orderly use in different societies are often stunningly complex and intricately embedded in cultural systems. Researchers note, for example, that rural tenure systems in developing countries are typically quite different from the notion of exclusive private property in land, which has evolved over several centuries in the West. In contemporary rural societies, for example, there may be coincident rights to fruits from a tree, the firewood it produces, and the land it grows on. Rights holders are similarly complex. They include villages, kinship groups, households, men, women, government-sanctioned cooperatives, and national forest departments. Taboos, religion, and local views of morality often underline tenure systems. Local structures of authority—such as chiefs, temples, and village councils—play important roles in maintaining these rights and arbitrating disputes. A moral economy is often involved in maintaining these common systems.

Unfortunately, these complex resource-management systems are often susceptible to breaking down following clumsy interventions from the state, commercialization, land degradation, population pressures, encroachment, and the expropriation of common resources by outsiders or a few members of the community. In forests, for example, an anticommons attitude often resulted in nationalization or privatization via concessions. These policies sweep away established local systems of resource control, converting communal management regimes into open-access situations where the state has nominal authority, but no real power. The "real tragedy of the commons," according to some common property theorists, is the destruction of common pool resource management systems and subsequent environmental degradation following the intrusion of modernizing states and modern economic relationships.

Currently, debates about common property go beyond the Tragedy appraoches. Analysts now develop theories of common pool resource management that attempt to explain whether, and under what circumstances, common pool resource users can individually organize and achieve sound management of their fishery, forest, global atmosphere, or other common pool resource.

One group of common property theorists does not challenge the basic notion of a dilemma between individual and collective rationality; rather, it identifies the difference between open access and a common property regime, where internally-enforced rules, or social institutions, harness individual rationality to the collective good.

This school argues that free-riding is not always the dominant rational strategy. With adequate institutions, understood as rules that coordinate social relationships, cooperation becomes a rational strategy. For contemporary commons researchers, the question is under what circumstances are communal management arrangements appropriate, and can the state, the market and civil organizations together promote efficient, fair, and conservative use of common pool resource management?

Institutional Choice is one of the most influential and theoretically powerful attempts to address this question. The approach holds that people have the ability to craft the institutions (understood mainly as rules) that govern their use of a resource held in common. Institutional Choice addresses two basic issues. The search for design principles identifies and catalogues the features and rules shared by successful commons management systems. Institutional Choice also assesses the conditions under which groups of people are likely to develop successful common pool management systems. Institutional Choice rests on a notion of rational individuals making cost–benefit analyses of whether or not to invest in processes of institutional change.

SEVEN KEY DESIGN PRINCIPLES

Through fieldwork and a careful comparison of a large number of case studies of different types of long-enduring communal management regimes, common property theorists have identified about seven key design principles.

First, successful common pool management systems have *clearly defined boundaries* of the resource and its users. Second, there is a *proportional equivalence* between benefits and costs, such that rights of usage are balanced with obligations to invest labor, materials, and/or money into the management system.

Third, there are *collective-choice arrangements,* in which most resource users are included in the group and able to modify the rules. Fourth, there are *monitors*, sometimes the resource users themselves, who actively audit both physical conditions and user behavior, and who are at least partially accountable to the users.

Fifth, there are enforcement mechanisms with *graduated sanctions*. Violators of resource use rules are punished in accord with the seriousness and context of the offense. Sixth, *conflict-resolution mechanisms* are available so resource users and their officials can resolve conflicts amongst themselves. Seventh, the state grants resource users some *minimal recognition of rights to organize*. The state does not challenge locally devised institutions, and it recognizes users' long-term tenure rights to the resource. For resources that are part of larger systems—such as mountain pastures and large-scale irrigation systems—commons management systems are often "nested enterprises" with resource use, monitoring, enforcement, and conflict resolution organized in multiple layers of "nested organizations."

The Institutional Choice approach to common property theory also assesses the conditions under which groups of people are likely to develop successful, common-pool management regimes. According to this approach, rational actors choose to invest in rule changes based on an analysis of benefits and costs. A framework for analyzing institutional change summarizes these variables in a number of factors favoring collective action. First, users of a commonly held resource agree that lack of change will harm them; they know they have a resource-use problem. Second, the resource users care about the continuation of benefits from the common property resource. Third, they face relatively low information, transformation, and enforcement costs. Fourth, they share norms of reciprocity and trust. This includes a capacity to communicate and make binding agreements, the ability to arrange for monitoring and enforcement provisions, shared norms of guilt, concepts of self-worth, social censure, and patterns of reciprocity. Fifth, the group of resource users is well-defined.

Other things being equal, it may be more difficult to organize with a large, dispersed, and ethnically heterogeneous group than with a smaller, ethnically homogenous group living in a single settlement. While heterogeneity was originally viewed to inhibit collective organization, subsequent refinements to theory recognized that internal difference might foster cooperation via trade benefits. Other analysts stressed the importance of communication, preferably face-to-face, as a catalyst for collective decisions on rules of common-pool resource management.

CRITICS OF INSTITUTIONAL CHOICE

Several criticisms of Institutional Choice have arisen. Because Institutional Choice emphasizes the role of local communities in resource management, and often obscures the role of states, influential market structures, and other powerful actors operating at multiple scales, some point out that common property management regimes evolve or erode amongst resource-use influences and power relations embedded in local, regional, national, and international scales. For some common property theorists, these are much more important than the local-scale situational factors fostering collective action or the types of rules associated with successful commons management. Common property theorists call for increased attention to the relationship between common property management regimes and outside structures, such as market structure, the multiple implications of commodification, state programs, and even international trade agreements and regulations.

A cultural critique rejects the idea that rational choice can successfully explain the commons. For these common property theorists, institutions of common pool resource management, the community, the individual person, and culture are all interpenetrated items composing a realm of meaning and identity. Commons users are not only embedded in specific historical sets of political and economic structures, but also in cultural systems of meanings, symbols, and values. For this approach, the commons is culture, so rational choice only makes sense within a specific cultural context, and is often constrained by deeply rooted moral economies.

Common property theory is also challenged by the global scale of common pool resource management issues. Questions remain, for example, about the extent to which the design principles and situational variables central to common pool management regimes at the local scale will transfer to the realm of international cooperation and other large-scale, common pool resources.

Finally, common property theorists also struggle to factor in the inherent uncertainty and instability of environmental systems. It is difficult to separate environmental flux from the role of social institutions and human activities when analyzing common pool resource management successes and failures.

Despite these continuing disagreements and uncertainties, common property theorists agree that common pool resources are not always destined for a tragedy of over exploitation. They agree that the commons can be successfully managed by a wide variety of ownership arrangements.

Commoner, Barry (1917–)

BARRY COMMONER IS renowned as one of the early founders of the environmental movement. He was educated at Columbia and Harvard Universities. He became a cellular biologist and was working at Washington University in the 1950s when his attention was drawn to the effects of nuclear fallout resulting from the testing of nuclear devices in the Nevada desert. His investigations led him to challenge government insistence that there were no health implications of the tests, and also challenge of data being classified. He helped establish the St. Louis Committee for Nuclear Information in the bid to pierce this secrecy. His careful observations were able to demonstrate the negative effect of fallout on children, and his work was instrumental in the creation of the Limited Test Ban Treaty of 1963, which was signed by the United States, Soviet Union, and the UK, and outlawed testing of nuclear devices underwater, in outer space and, most importantly, within the atmosphere.

Commoner argues in *Making Peace with the Planet* that managing the pollutants and by-products that result from the modern industrial and consumer-based society is not practical given the environmental damage it causes. Instead, it is necessary to reorganize the whole of society on lines that are more environmentally sustainable. This caused him to help establish the Citizen's Party (1979–84), which proposed a manifesto of quite radical environmental initiatives born out of frustration with the policies of existing parties. At the 1980 presidential election, Commoner ran with La Donna Harris and received nearly 250,000 votes. Subsequently, Commoner has been involved with education and the furthering of science as well as promoting his ideas for the reorganization of the industrial systems of the developed world. He has become associated with the thesis that environmental degradation results from industrial development rather than from population pressure, as argued for by Julian Simon. Consequently, he does not argue that the number of people should be controlled or that management of industrial functions, if properly effected, can be sustainable.

In 2006, he taught at Queens College in New York City, where he moved after his unsuccessful presidential bid. He has been recognized by various eminent authorities and by his home city of St. Louis. His work has extended across a range of scientific investigations, in addition to the well-known environmental issues for which he has come to be much celebrated. This has also included research into ozone layer depletion and the practicalities of redistributing wealth and income on a global basis.

Communications, Interspecies

INTERSPECIES COMMUNICATIONS IS a phenomenon and an area of study. The systematic study of communications within and between species is an emerging discipline that seeks to find ways to develop human communications with other species and to identify and understand communications between different species. Communications, the sending of messages that have intelligent or rational meanings that can be comprehended, takes places when feelings or thoughts are shared between one life form and another. Intraspecies communications occurs between members of the same species. Interspecies communications occurs between members of different species. From the most ancient times, people have observed species communicating among themselves. Fish, reptiles, birds, and mammals communicate in forms of intraspecies communications.

Beginning in prehistoric times, humans began to domesticate wild dogs, donkeys, hawks, hunting cats, camels, and cows. Simple observation of domesticated animals demonstrates that humans communicate with a large range of different species. Humans have trained dogs, birds, horses, camels, and donkeys as working livestock. When humans use trained dogs to guard and herd sheep, the dog uses signals to move sheep in a desired direction. Much of this communication is reflexive or instinctual. Dogs, horses, and elephants have also been trained for war, which seems to excite the aggressive nature in these animals and also communicate fear or aggressiveness. Since the end of World War II, extended studies have been made of dolphins and some of the great apes. These studies have attempted to teach animals language that can be understood by humans. The U.S. Navy has trained dolphins to locate explosive sea mines and scout for enemy vessels, especially submarines.

RATIONAL COMMUNICATION

Recent studies with dolphins and primates such as Bonobos and chimpanzees have sought to demonstrate that they can learn words and communicate rationally with humans. Since the 1960s, a number of ape-language projects were established to study the possibility of developing communications between apes and humans. One ape sign language center was the Yerkes Regional Primate Research Center of Emory University in Atlanta, Georgia. Bonobos (*Pan paniscus*), the most rare of the great ape species, are found in the Republic of Congo. They are very matriarchal and about the size of chimpanzees. Kanzi, a Bonobo studied at Emory University, learned to communicate with humans using a keyboard with 120 symbols. He was such a quick learner that he apprehended the meaning of words and symbols without any instructions, or with little training. His active vocabulary increased to over 200 words and to 500 words for his receptive vocabulary. Psychological studies of the ways children acquire language skills, developing rapidly in the 1970s, were helpful in teaching Kanzi. In return, Kanzi was a contributor to an emerging theory that children could be taught to sign as communication long before they learn to speak.

Some researchers have engaged in studies of communications with whales using music. Others have sought to develop communications with cetaceans using echolocation clicks, songs, and whistles. Communication by humans with other species that is an exchange of rational thoughts requires humans to function on the behavioral time of the species. Children often tell adults that they can communicate with animals, but have been told that it's "just their imagination." Research efforts have noted that some imagination is required for humans to be empathetic with an animal communications subject, especially when the communication is nonverbal and nonbehavioral telepathic. The Samantha Khury Institute of Interspecies Communications in Sweden specializes in this from of communication.

Interspecies communications studies of the variety of ways that animals communicate between themselves have been conducted in increasing number in recent decades. Researchers all over the world have advanced understanding of the vocabulary and syntax of animal species languages. The rapid development of computer devices that can be used for interspecies communications holds great promise for future breakthroughs of communications by humans with other species. These devices could possibly enable not only speech recognition, but also smell, behavioral, or animal sentience to be transformed in a hand-held black-box by a system of artificial intelligence that delivers intelligible communications.

Communism

AS AN ECONOMIC concept, Communism represents the establishment of communes, where large numbers of people work for the collective good. For many people during the 19th century, an agricultural cooperative was seen as a good idea in theory. However, many of these cooperatives failed. Robert Owen's establishment of New Harmony in Indiana in 1825 was one of the best-known of these cooperative ventures, but it failed. There was then the influence of Charles Fourier, who promoted the concept of communes. Both Brook Farm and Fruitlands, run by the Transcendentalists during the 1840s, failed within a few years of their formation. A large number of similar cooperatives in Latin America during the middle of the 19th century also failed.

The *Communist Manifesto* of 1848 by Karl Marx advocated the idea that Communism would be the last stage of Socialism, at which time goods would be so abundant that they could be distributed on the basis of need rather than endeavor. It was in support of this idea that the Bolshevik wing of the Russian Social-Democratic Workers's Party, which came to power during the Russian Revolution of 1917, changed its name to the All-Russian Communist Party in 1918. Soon afterwards many of its allied parties in other countries also changed their name to Communist Party, although a few continued to operate under other names, but stated that their doctrines were "Communist."

SOVIET UNION: THE UKRAINE

Communism in practice was very different to Communism as a theoretical construct. In the Soviet Union, the first task for the new government was to try to repair the damage during World War I and the Russian Civil War. Economically the country was in poor shape, and the industrial base, which was weak at the start of the Russian Revolution in 1917, was in tatters by the end of the wars. This led to what became known as War Communism, which lasted from June 1918 until March 1921, and the introduction of policies such as the expropriation of private business and also the nationalization of all industries, along with the forced requisition of surplus grain and other foods from peasant farmers. These measures damaged both agricultural and industrial production, reducing the incentives for people to grow surplus grain, and it also encouraged secret hoarding by many peasants. The result was that by 1921, industrial production had fallen to 20 percent of the level in 1913, with wages falling by one-third.

The resulting public discontent led to demonstrations and strikes, which were part of the cause of the Kronshtadt Rebellion of March 1921. This led to the Communists delaying their plans to introduce a socialist economic system by decree, and the introduction of their New Economic Policy. The Communists, therefore, had to embark on a massive campaign of industrialization. Vast factory complexes were built, the mining sector was expanded, and the plan was to build an economy based on coal, iron ore, and steel.

The workers who had supported the Communists coming to power in the Soviet Union also had to be housed after the Russian Civil War. The devastation that had taken place in the countryside had resulted in an influx of many people into the cities. To deal with the housing shortage quickly, many drab apartment buildings were erected on the outskirts of many of the main cities throughout the Soviet Union. This was combined with an upgrading of public transport to bring these people from satellite suburbs into work at factories and in cities. There was also the building of resorts along the Black Sea and other warmer regions.

In 1932 and 1933, millions of Ukrainian peasants starved when vast grain reserves were requisitioned by the government to feed the people in the cities. In spite of a drought and reduced harvest yields, the government under Stalin advocated farm collectivization for economic reasons, or as many suggest, to stifle any resistance to collectivization and eliminate nationalist sentiments.

The German invasion of the Soviet Union in June 1941 destroyed vast tracts of western Russia, and then in the guerilla wars that followed. Once again, the Soviet Union had to devote much of its resources to providing housing for the people rendered homeless after the war, with many drab office blocks and apartment buildings being erected in many of these cities such as Minsk, Smolensk, and Kiev. After World War II, the Soviet Union embarked on a nuclear power and nuclear weapons program. Two underground nuclear test sites were established—at Novaya Zemlya Island in the Arctic Circle, and at Semipalatinsk in Kazakhstan.

SOVIET UNION: ASIA AND MONGOLIA

With the introduction of Communism into Central Asia, large cities were built either for administrative or military reasons, as well as close to sites of mining or industrial ventures. Soviet urban planners laid out enormous city complexes such as Alma-Ata (founded in 1854 as the small garrison town of Verny). The Soviet Union also used Kazakhstan and other parts of central Asia for military installations and parts of their space program. Many towns and cities, such as Chkalovsk in Tajikistan, were closed to foreigners. The development of new farmland was introduced with the Virgin Lands program. Massive infrastructure projects saw the construction of large dams and power plants such as those on the Dneiper River. Nuclear power also initially seemed to provide much cheap electricity, but the Chernobyl accident in 1986 created massive awareness of widespread pollution, not just in the nuclear field, but also industrial pollution and the prevalence of chemical waste, especially in some parts of central Asia.

Communism in Mongolia also led to many changes in the country. Initially after the death of Lenin in 1924, Stalin was content to allow Mongolia some level of independence—the proclamation of the Mongolian People's Republic took place in 1924, making Mongolia the first Communist nation outside the Soviet Union.The moves introduced by Sükhbaatar, the leader of the Mongolian People's Party, were initially moderate; but in 1920 Choibalsan became the minister of foreign affairs, and started to dominate the economic life of the country. Land was seized from landlords and handed over to peasants or turned into cooperatives. It has been estimated that 27,000 people (including 17,000 monks)—up to 3 percent of the population at the time—were killed. Gradually the moves became more extreme, with harsh punishments for any form of dissent. As with the Soviet Union, large numbers of office blocks and drab apartment buildings were erected in Ulan Bator and in newly created cities throughout the country. Although infrastructure was good during much of the Communist period, it was costly, and as soon as Communism ended, massive social problems arose with much of the population unprepared to adapt to free market policies.

CHINA, NORTH KOREA, VIETNAM, CUBA

The Communist victory in China in 1949 resulted in the whole of China being put under central planning for the first time. Initially, the changes were minor and administrative in many areas, with so much of the population at peace in the country since the warlord period of the 1920s, the civil war, the war with Japan and the final stage of the civil war from 1945 until 1949. China's industry was badly damaged in the fighting, as well as substantial amount of the country's infrastructure—roads, railways, hospitals, and schools. This meant that the new government had to divert many resources to these projects, as well as to sending soldiers to Korea from 1950 to 1954, and giving support to other friendly governments such as North Vietnam.

After land reform, the breakup of the big estates, and destruction of the landlord class, the next program embarked by the Chinese Communist leader Mao Zedong was to see through his plans for the industrialization of the country. The Great Leap Forward campaign of 1958–60, urging for the creation of a large steel industry, failed because it relied too heavily on small producers rather than major factory projects. This policy was gradually reversed, but the economic advancement of the country was dramatically affected with the Great Proletarian Cultural Revolution that started in 1966. It put ideology ahead of economic progress and led to major economic, cultural, and social problems, which were to plague China for many years. With the rise of Deng Xiao-ping, the Communist Party's role remained unchallenged, but a capitalist economy was introduced.

Although there were environmental advances made in China during this period, there was little protection of wildlife. However, the panda bear became heavily identified with the country, and panda bears were given to zoos around the world as a gesture of goodwill and friendship.

Other Communist countries around the world experienced varying levels of success with their economic policies. In North Korea, collectivization started soon after the Communists came to power in 1945. Korea had long been isolated from the rest of the world, and after the Korean War of 1950–54, the Communist leader Kim Il Sung isolated his country even further by introducing his Communist concept of Juche, by which the North Korean economy was able to become wholly independent. Their industrial wealth was largely responsible for this, but North Korea has always suffered from its lack of agricultural land. When the harvests failed in the late 1990s, mass starvation followed.

North Vietnam and Cuba, also Communist countries, tried to engage with the rest of the world after Ho Chi Minh and Fidel Castro, respectively, came to power. However, they quickly became identified too strongly with Communist China and the Soviet Union; Vietnam eventually broke with the Chinese and allied with the Soviet Union.

Eastern Europe

Much of eastern Europe—Albania, Bulgaria, East Germany, Hungary, Poland, Romania, and Yugoslavia—had similar experiences of Communism as the Soviet Union, with the first Communist rulers having to embark on massive urban development projects to house those made homeless during World War II. They faced an unprecedented move from the countryside to the cities and towns, and the necessity of providing employment. Much of this came from a boost to the agricultural sector and, at the same time, a large industrialization program around projects such as the Gdansk shipyards in Poland. There were also continuous problems with eastern Europe—the Hungarian Revolt of 1956, the rift with Enver Hoxha's Albania, the ending of the Prague Spring of 1968, the split with Tito's Yugoslavia, problems with Nikolai Ceausescu in Romania, and finally the emergence of the Solidarity Trade Union Movement in Poland. Whatever the political disagreements, with the exception of the split with Albania, economic policies in many of these countries remained stable. This resulted in an improvement in the standard of living of many people, although at the same time vast waste of economic resources. Environmentally, large tracts of eastern Europe were polluted.

DISASTEROUS CONSEQUENCES

The most extreme form of Communism was in Cambodia, where the Khmer Rouge under Pol Pot launched their hardline Maoist policies of collectivization within hours of coming to power. They evacuated the cities and towns, and tried to recreate an agricultural society. It was a disaster, with up to a million people killed by the regime or dead from disease, malnutrition, or overwork. It ended in December 1978 when Communist Vietnam invaded and established its client regime, the People's Republic of Kampuchea, with a civil war fought from 1979–91. There have also been Communist governments in Africa: Angola, Mozambique and Guinea-Bissau. All three had been former Portuguese possessions, with the first two enduring long wars against pro-Western guerilla movements backed by South Africa and the United States.

The environmental policies of Communist countries have varied considerably, with many facing severe shortages of resources because of wars. Underdevelopment and restrictions on movement, as well as on private land development, have helped some natural resources survive. However, many other areas have become badly polluted because of economic mismanagement and the lack of concern of some officials for the natural environment. While wildlife diversity and national parks were created in some countries, flora, fauna, and the environment have suffered badly in other areas.

Community Forestry

COMMUNITY FORESTRY IS an approach to forest conservation and management in which forest inhabitants participate in management activities and ideally enjoy the economic and livelihood benefits. Community forestry contrasts with exclusionary models of forestry, including logging concessions to large firms and national parks that prohibit most human uses.

Community forestry appeared in the context of three broad social trends. First, there was the late 20th-century context of political change, including the widespread replacement of authoritarian regimes with democracies throughout the world and the rise of neoliberal development policies that encouraged states to decentralize, deregulate, privatize, and generally withdraw from many traditional management activities. Second, the analysis of conservation and forestry projects repeatedly identified social conflicts between managers and forest residents that often jeopardized conservation goals. Third, there were increasingly influential social movements of indigenous people and other traditional forest inhabitants demanding greater autonomy and self-determination. Within this context, states have increasingly recognized the legitimacy of forest residents' land claims, and in some cases, implement forest regulatory structures that permit forest inhabitants to participate in forest management. In other cases, states maintain forest ownership but grant concessions to communities, or create joint management arrangements between forest departments and local groups. In addition, many communities still occupy and manage forests without official state sanction, but they risk suddenly finding their forests scheduled for logging or exclusionary preservation.

Community forestry also varies greatly in the rights of communities to benefit from forests. In many countries, timber is one of the few forest values recognized by existing markets, but it is rare for states to recognize full community rights to its commercial use. Where economic benefits are denied, community forestry is little more than a way for states to dump environmental management responsibilities on communities while granting the rights to economic benefits to forest departments, or other privileged, noncommunity actors.

MULTIPLE APPROACHES

There are multiple approaches to community forestry in different countries. Mexico exemplifies an approach in which the state recognizes village members as collective owners of specific areas of forest where they have the main responsibility for forest management. Villagers often establish forest management enterprises that engage in logging and forest management. Except for normal taxes, the state makes no claim to community revenues from the sale of forest products. In Guatemala, most forests remain state property; but in some cases, the state grants concessions to communities as a strategy to protect forests from illegal logging or clearing for agriculture. The Guatemalan community concessions do not concede ownership rights, but they do include the rights to harvest timber, take nontimber forest products, and even to continue farming on previously cleared agricultural lands surrounding villages. India's most widespread approach to community forestry is called Joint Forest Management.

This approach does not transfer ownership of forests; instead, beneficiaries are organized into village committees and given recognition of rights to collect minor forest products. They are also entitled to a portion of the proceeds from the sale of forest products, including trees. The proportion of the harvest that goes to the community varies from 100 percent in a few states to only 20 percent in others.

In the United States, 56 percent of forests are private, 38 percent are on government lands, and 6 percent are owned by indigenous peoples. Logging in these forests is increasingly embroiled in paralyzing conflict about endangered species, unsustainable timber yields, and industrial restructuring. Community-based collaborative partnerships are increasingly important in U.S. natural resource management, as groups of people work together to define and address common resource management issues that affect specific places but cut across government regulatory agencies. A few U.S. national forests have entered into isolated collaborative efforts with local communities. Stressing the idea that healthy forest ecosystems depend on healthy human communities, regional movements of community forest activists advocate wider legal and political openings for increased local stewardship over forests, despite opposition from some environmental organizations.

Community forestry remains controversial. Some conservationists prefer preservationist approaches, usually with a stronger role for the state in forest management and protection. Others criticize the romantic way in which community forestry policies sometimes overlook social difference, social conflicts, and injustice within communities. Despite these criticisms, it is often successful in improving both rural development and forest conservation outcomes.

Community Gardens

URBAN COMMUNITY GARDENS are cool green oases in city environments that are often overwhelming in their density and complexity. Beyond their role as refuge, however, community gardens have provided the basis for a number of novel sociocultural experiments. Neighborhood residents grow vegetables to supplement their grocery budgets, giving them greater control over their own food and nutrition. Children have an opportunity to learn about gardening, plants and insects, and the ecology of their own neighborhoods. Artists stage music, theater, and other performances in gardens for audiences who otherwise might not have access to cultural resources. With the advent of development and the struggle to defend green space, the community gardens have also become the locus of grassroots political organizing.

HISTORY OF COMMUNITY GARDENS

Urban agriculture has a lengthy history in the United States. The Work Projects Administration (1935–43) sponsored relief gardens in vacant lots and city parks during the Depression, and many urbanites grew Victory Gardens on city land during World War II. Historical accounts of community gardening, however, usually begin with the 1970s. American cities like New York, Detroit, and Boston were experiencing severe fiscal crises, city services were unavailable or very low quality in many neighborhoods, and properties were abandoned or burned down by absentee landlords. The vacant lots, plagued by illegal dumping, vermin, and crime, were a disaster for property values and neighborhoods' quality of life.

The community gardens were born out of citizen direct action in response to this urban devastation. Gardeners cut locks on fences, hauled away tons of trash and rubble, and on occasion drove away drug dealers by force. In place of these unwanted land uses, gardeners created a wide variety of public green spaces. Many of the community gardens reflected the ethnic character of their neighborhoods and gardeners. For example, Puerto Rican gardeners throughout New York recreated the Puerto Rican countryside with *casita* gardens.

Poster for the U.S. Department of Agriculture promoting World War II victory gardens and vegetable growing.

In many cases, land for community gardens was provided as a sort of city service, akin to the Victory Gardens of the World War II era or the allotment gardens in the United Kingdom. For example, New York City's Operation Green Thumb helped gardeners secure free temporary leases to their lots. In such cases, the leasing process was often a bureaucratic challenge, requiring the gardens to establish a board of directors and regular meetings. Many of the garden groups lacked the experience or resources to pursue this route, so many of them persisted in a semi-legal status, facilitated by benign neglect from authorities.

On the other hand, many gardeners were essentially squatters, occupying city-owned or vacant lots without any sort of official sanction. As urban real estate values climbed through the 1980s, gardens increasingly came under pressure from development. Community garden activists responded in a variety of fashions, from fund drives to direct action. The New York garden conflicts became famously bitter; Mayor Guiliani told garden supporters, "This is a free-market system. Welcome to the era after communism." Meanwhile, garden supporters compared the mayor to Hitler. Many of these conflicts over community gardens remain unresolved, even when a number of specific settlements have been reached and the political context of community gardening continues to evolve.

Community-Based Conservation

COMMUNITY-BASED CONSERVATION IS commonly seen as having two central objectives: to enhance conservation of wildlife, biodiversity, and/or the environment; and to provide economic, social, cultural, and political benefits to local people. These objectives are connected; when communities benefit from conservation, they will be more likely to support it. Community-based conservation is also a process achieved by a variety of mechanisms, including devolution of control over resources from states to communities, development of community institutions to manage those resources, meaningful participation of communities in decision making about conservation, and legalization of property rights. Central to the community-based conservation concept is the assumption that people living closest to and depending on a resource will be most affected by its depletion, and thus have high stakes in its sustainable management.

The predecessors of community-based conservation include the concept of buffer zones, introduced by UNESCO in 1979, and Integrated Conservation and Development Projects, popularized in the late 1980s and early 90s. Both have been criticized for their failure to adequately involve local people in planning. In theory, community-based conservation is different than its predecessors, because it places the community's involvement at the center of conservation, rather than the mechanism (such as a park or project) for achieving it. Thus, participation is critical to the community-based conservation concept, and takes place ideally at all stages, from planning to implementation, management, and monitoring.

RESPONSE TO "FENCES AND FINES"

Community-based conservation and its predecessors arose in response to critiques of the traditional parks and protected areas, or "fences and fines" approach to conservation. This approach relies on excluding people from protected areas, eliminating consumption of resources within those areas, minimizing the impacts of preferred forms of use (leisure, recreation, and scientific research), and enforcing rules by the state. Critiques of this traditional approach address pragmatic, philosophical, and justice concerns. Pragmatically, the amount of land that can ultimately be protected and the costs and effectiveness of protection efforts have been questioned. Without local support, the biological goals of conservation can be undermined through encroachment and illegal harvesting activities, and efforts to enforce exclusion can consume disproportionate amounts of conservation funds. Philosophically, parks and protected areas historically were linked to North American romanticism and European utilitarianism, both of which emphasize the separateness of humans from nature. This vision of separateness has routinely conflicted with local visions of human–environment relations in many developing countries and can undermine local cultural and social norms, and traditional knowledge. From a justice standpoint, parks and protected areas impact most on local human populations living near them by restricting access to resources and associated livelihood activities. Thus, parks can exacerbate inequities between rural people living next to them and those who gain through visiting parks or receiving wider environmental benefits of protection. Thus, community-based conservation operates on a principle that local residents with legitimate claims to land or resources must be allowed to participate in their management and conservation.

The rise of community-based conservation also reflects more general trends, including the global spread of democracy, interest in social justice, and indigenous rights movements as well as the overall emphasis on sustainable development. With conservation and development defined as "opposite sides of the same coin," conservation organizations began to acknowledge the development needs of local people, and community-based conservation was envisioned as the way to meet these needs. The concept was so widely promoted in the 1990s that it became almost impossible to talk about conservation without referencing the community's involvement. Community-based conservation was in danger of becoming little more than a conservation catchphrase, appealing as it did to a wide array of conservation and development policymakers and practitioners.

Community-based conservation has experienced mixed success in practice, encountering several major obstacles. First, its implementers have failed to operationalize community participation in project identification, design, and management. Participation is, rather, often seen as a means to get people to support predetermined conservation programs. Second, community-based conservation projects have often been undertaken without an adequate understanding of local social and economic contexts and by environmental nongovernment organizations with limited experience in community development. A common recommendation for community-based wildlife conservation projects, for example, is the uncritical promotion of ecotourism, an activity that often relies on the continued existence of parks and protected areas. Third, *community* is a problematic term, too often treated as self-evident or generic. Communities are assumed to be homogenous entities, acting collectively to achieve common environmental goals. Little consideration is given to individuals within communities and the motives they might have to work against conservation programs. Fourth, the preoccupation with community has often meant that the ways in which communities are embedded in (and constrained by) larger economic and political systems have been overlooked. Finally, community-based conservation projects have focused too much on economic incentives and have often failed to enable genuine empowerment and social justice.

Proponents argue that critiques of community-based conservation arise from failure to properly implement it, rather than from any fundamental flaw with the concept itself. In contrast, a "resurgent protectionist" argument that calls for a return to people-free parks and protected areas is increasingly evident. Driven by some prominent conservation biologists, the argument cites the failure of community-based conservation to adequately protect biodiversity. What is not clear is how such a return will be done without also returning to original critiques of the protectionist paradigm. While community-based conservation may be flawed, it arose in response to real problems with parks and protected areas and it should not be deserted lightly.

Commuting

COMMUTING IS THE movement of people and vehicles between the place of work and the place of residence. Two peak traffic hours, at 7-8:00 a.m. and 5-6:00 p.m., correspond to the critical times of traveling to work and school in the early morning, and going back home in the evening.

The U.S. Census Bureau estimated the average travel time to work was 24.3 minutes in 2003. There are not significant differences between big cities—New York, NY, is 38.3 minutes; Chicago, IL, is 33.2; Los Angeles, CA, is 29.0; Miami, FL, is 29.0—but variation is remarkable compared to the cities in the last positions—Wichita, KS, is 16.3 minutes; Corpus Christi, TX, is 16.1. American workers of 16 years and over spend more than 100 hours commuting to work each year. However, averages hide important differences between automobile commuters and bus and train commuters, because mass transit requires extra time for transfers or the search for stops in poorly serviced areas.

Various commuting types depend on the directions of movement. *In-commuting* is a process of movement from suburbs to the central city in the early hours—completed with a reverse commuting in the late evening. *Lateral commuting* occurs where there are mixed land uses—particularly within residential areas or suburbs—where job opportunities emerge with service demands. Because residential areas are mostly located outside the city center, *in-commuting* prevails. This category of commuting, however, corresponds to an urban structure where the city core holds a central business district which excludes residential areas, and that is not the case of old cities with historical districts or high urban density areas.

This massive movement has a direct negative effect on mobility, engendering congestion and compromising urban sustainability. Once carrying capacity of roadways is exceeded, average speed diminishes and traffic congestion leads to supplementary public demands for increasing capacity with improved infrastructures. New capacity eases movement and favors further urban sprawl, increasing the total number of trips and the length of the movements, so new congestion emerges. The effects on the environment are higher levels of air and noise pollution, a reduction of green lands for building roads, and a greater dependence on fossil fuels. Strategies such as carpooling help to reduce the emissions per person, but usually require dedicated HOV (high occupancy vehicle) lanes, usually shared with buses.

Commuting has two basic accessibility requirements: a wide, complex, and interconnected road network for automobiles and buses, complete with an effective and multiple transit system—including light and heavy train, metro, bus, or ferryboat. However, mass transit has certain dysfunctions. Infrequent services are in low density areas, while others are overcrowded; or cities are almost totally car-dependent because the public transportation system has been scaled down.

Commuter buses and trains offer services with higher frequency at specific hours, fixed routes, and frequent stops and changeovers, and they serve metropolitan areas as an extension of the core city. *Intermodality* facilitates passengers' access in an integrated manner to multiple systems, responding to the complex urban structure or to local environment. Also, park and ride terminals—located in main train stations—allow commuters to leave their private vehicle and transfer to public transportation.

Both commuting time and trip length have slightly increased as congestion becomes more intense. The adaptive response is housing and job suburbanization and the relocation to less congested areas in searching for affordable housing. Concurrently, companies change their facilities, offices and factories from city center to the periphery—approaching the workers—and shopping malls move to reach consumers. This response strengthens lateral commuting and reduces inward and outward commuting. In the same way, more compact, dense, vertical cities with mixed land uses contribute to reduce travel times and facilitate walking or cycle commuting, notably reducing congestion. This happens in some European and Asian cities, where almost 30 percent of commuting falls in this category.

Once carrying capacity of roadways is exceeded, average speed diminishes and traffic congestion results.

Commuting garners not only environmental, economic, or urban planning costs, but also social costs. Families have to pay for high transportation costs, which are progressively increased with rising gasoline prices. This, in turn, induces changes in transportation patterns, favoring a greater use of public transportation. People usually overestimate the benefits of the transaction—better house, salary or school, lower rent—and tend to underestimate the losses—social connections, free time, and stress—resulting in dissatisfaction. Some low and moderate income households can only find affordable housing far from their jobs, or dual-income households fail to live near both jobs, leading to the growing phenomenon of extreme commuting. The percentage of extreme commuters, those who travel 90 or more minutes and even up to 3 hours one way, has increased from 1.6 percent in 1990 to 2.8 percent in 2000.

Complexity Theory

"COMPLEXITY" IS A multifaceted term. Scientists, managers, and the public may mean quite different things by the term, since they each have distinct personal experiences that influence ideas and processes. Complexity science and related theories derive from natural science disciplines such as physics and chemistry. There is a widely recognized fact that the practice of managing human-environment interactions is complex. Complexity science and theories have become increasingly influential in environmental management in the last decade or so, following in the footsteps of broader systems and ecosystem concepts that became influential in the 1960s and 1970s.

The earlier incorporation of systems and ecosystem approaches into environmental planning and management brought home the connected and hierarchical nature of human–environment systems: connections between ecosystems, economies and societies, and between levels of ecological or government systems, for example. It also underscored basic thermodynamic implications: every activity uses or transforms energy and matter and produces waste, which in turn must go somewhere, being transformed again and again but never actually going away.

COMPLEX AND DYNAMIC INTERACTION

As environmental research continued, most famously into forest-insect pest dynamics, fisheries management and weather and climate forecasting, it became clear that ecosystems and human–environment systems were much more complex and dynamic than assumed. This made them difficult or impossible to predict, and even harder to manage for specific, maximum, sustainable yields and similar optimum goals. Change is increasingly recognized as normal and common, and predictability as rare—whether we are looking at animal populations, weather changes, or the desired and undesired effects of new products or management approaches.

What is meant by complexity? To begin with, complexity may encompass many parts, but that in itself is complicated. And if there are many parts involved, then statistics and probability come into play and yield a form of predictability. Complexity in an environmental management context means more than a few (but not astronomically large) numbers of parts—what Gerald Weinberg called *middle number systems*. Complexity also entails extensive connectedness of a system.

These are connections between social, economic, and ecological structures and processes; between individuals and organizations; and across scales from the local to the global. Complexity approaches recognize that systems are not static or unchanging, or even necessarily stable. In fact, they may change in major, qualitative, and sudden ways, and exhibit patterns of change over time that are themselves very complicated or even complex; this is not the simple straight lines or even gradual oscillations on a traditional x-y graph that we base our thinking. Patterns of change may seem completely random, or "chaotic," never repeating or showing any noticeable pattern at all.

The key natural science complexity theories that underlie these insights include chaos theory, self-organization, fractals, and others such as catastrophe theory that go back to the 1960s. All of these derive from looking at the structure and behavior of physical and chemical systems in space and time, and later from applications to biological, ecological, economic, and social systems with varied degrees of success and rigor.

The roots of chaos theory go back to the 19th-century physics and dynamics work of Henri Poincaré, which was first credited to Edward Lorenz's work in forecasting weather and atmospheric dynamics. He found that small errors in describing an atmospheric system's initial state rapidly amplified to large errors in a prediction of its future state. This has been called *sensitive dependence on initial conditions*. It is a result of nonlinear dynamics in the system, positive feedbacks, and other interactions that greatly amplify small differences as the system evolves in time. Self-organization ideas derive from work in complex chemical reactions that self-catalyze, and exhibit spatial and temporal patterns; or from the dynamics of lasers. Such systems dissipate energy and resources in maintaining their internal dynamics (like living organisms) through complex internal structure and connections. They go through periods of stability followed by instability in which their internal condition fluctuates, but ultimately "self-organizes" through internal nonlinear dynamics and amplification into a particular future state—which may well be a sudden, major transformation. Fractals are a form of complexity found in spatial, physical objectives—most famously in coastlines that get longer the finer the measuring stick you use, and which, like snowflakes, show similar patterns as different scales of resolution. The various complexity theories are connected at fairly deep, mathematical, and theoretical levels. For example, complex systems may exhibit complex, but not random patterns in time. These are called *attractors,* and mathematically, some are fractal in structure.

All of these theories are difficult to apply to human-environment systems in a quantitative way—it's a challenge even in purely biophysical contexts such as ecological or atmospheric systems. So they have primarily had influence by analogy and metaphor, as inspirations for newer, more systems-oriented frameworks for analyzing and describing human–environment systems. They have been a strong influence in ecosystem approaches and ecosystem management. Adaptive management, which seeks to adapt to uncertainty by treating management as an experiment and designing and implementing management to ensure ongoing learning, was an early response.

C. S. Holling and his colleagues have extended adaptive management into panarchy theory, which sees adaptive cycles of stability, disturbance, release, and reorganization in many human–environment systems. Fikret Berkes and colleagues write about resilience and social-ecological systems and their connectedness, changeability, and integral social, cultural, and institutional elements. Others have developed an Adaptive Methodology for Ecosystem System Sustainability and Health (AMESH) that draws deeply on complex systems ideas as well as the linked ideas of post-normal science.

Overall, the implications of complexity for human–environment systems include greater prominence for disturbance and change; greater recognition of how human intervention can alter natural processes that can have unintended consequences; greater recognition of the potential for sudden change in natural and human systems; and greater efforts to adapt to uncertainty through approaches such as adaptive management, adaptive governance, or precautionary management. An understanding of system dynamics is improved through nuanced notions of stability, including resilience and resistance, as well as more knowledge of the potentially complex, yet nonrandom patterns of system behavior. Researchers and managers are also increasingly driven to new approaches in science and human–environment systems intervention, driven by the complexities and uncertainties of the systems. While the implications of complexity for environmental planning and management are just beginning to be filtered, there are strong hints of the new understanding to be gained and the new approaches that are needed. These will extend traditional, single discipline-based prediction, master planning, and control to multi- and trans-disciplinary, participatory, and action-oriented development of many smaller, and adaptable plans that seek to influence—rather than control—complex human-environment systems.

Composting

Composting is a natural process that farmers and gardeners have practiced since time immemorial.

COMPOSTING IS A natural process of decomposition of organic matter (once living materials—including plant remains, plant leaves, and fruit and vegetable peels) into a dark earthy substance that can be used as an enriching garden soil or as a natural fertilizer for plants. Composting is a controlled aerobic process carried out by successive microbial populations combining mesophilic and thermophilic activities, leading to production of carbon dioxide, water, minerals, and stabilized organic matter. Composting is a natural process that has always occurred in forests, when the leaves from trees and plants fall on the forest floor and mix with the earth through a process of decay and decomposition. The living roots reclaim the nutrients from these decomposed leaves and finish the process of natural recycling. Farmers and gardeners have practiced composting since time immemorial. "Night soil," vegetable matter, animal manure, and household garbage are placed in piles or in a pit and allowed to decompose until ready to be used as fertilizer.

COMPOSTING NATIONS

The main development of composting has been in India, China, southeast Asia, and east and south Africa, but in recent years there has also been much interest in mechanizing the process of composting in developed nations for treatment of waste. The potential benefits of using earthworms in composting has led to a "sub-variety" of composting, referred to as *vermin-composting*. This is especially recommended for composting for households. Compost plants can be classified into two broad categories—*windrow* and *in-vessel*. Windrow systems involve the use of long heaps of material (windrows) that can be either static, or periodically turned. In the static type, the aeration is accomplished without disturbing the windrow and can be of two types: passive aeration and forced-air aeration. Turned-windrow aeration involves the breaking down and rebuilding of a windrow. In-vessel composting is done inside reactors to accelerate the composting process through maintaining optimum conditions for microbial activity and to minimize or eliminate adverse impacts upon the ambient environment.

There are many important factors to consider when composting. Carbon and nitrogen are the two most important elements in the process. Carbon is an energy source for the microorganisms, and nitrogen is important for microbial population growth. The bacteria need this carbon and nitrogen from a balance of green (such as kitchen waste) and brown (such as leaves) sources. With favorable conditions, bacteria can multiply every five or six minutes. Oxygen and temperatures are important factors. They fluctuate because of the microbial activity, which consumes oxygen and generates heat. Aerating the compost will re-supply oxygen and carry away excess heat. This allows for what is known as *aerobic* composting. Another important consideration for decomposition is moisture. However, a balance must be maintained. If the pile is too wet, the oxygen supply will lessen; if there is too little water, it will result in *anaerobic,* or without oxygen, decomposition. This can cause odors and other by-products.

Composting presents both benefits and undesirable environmental impacts. Benefits of composting for soils and plants include improvements to soil structure by adding organic matter. In sandy soil, the compost will hold moisture and help prevent the soil from degrading. Compost particles bind with clay particulates that will improve soil structure in a heavy clay type soil by allowing surface water movement through the larger aggregates. Compost can help the soil retain water and resist surface erosion and crusting. The addition of compost to the soil can also improve soil aeration. Compost helps the soil by supplying it with necessary nutrients such as phosphorus, calcium, nitrogen, and trace elements. Some chemical fertilizers release nutrients and mineral elements at such a fast rate that it is not possible for plants to benefit from it. Use of compost provides a slower, more sustained release of nitrogen and phosphorus, which conserves them for plants throughout the growing season.

On the other hand, there are several potential environmental impacts. One of the main problems with composting is the offensive odor from anaerobic composting. The offensive smell does not become a health hazard up to a certain level (there is no standard for this intensity level), but the main sufferers are the residents near the composting sites. Air emissions are also generated during waste collection and transport, as well as carbon dioxide from the process of composting.

When the composting turns anaerobic, methane gas is also produced. Microbes are also transported out of the pile by dust. Runoff is a problem mainly during rainy seasons. Waste in compost can attract rodents and flies. It is also a breeding ground for mosquitoes, which spread some illnesses. Finally, when compost is applied to soil, it decomposes and sometimes releases some unwanted and potentially hazardous elements like cadmium, chromium, lead, mercury, nickel, and zinc.

Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA)

THE COMPREHENSIVE Environmental Response, Compensation, and Liability Act (CERCLA) was enacted in 1980 in the wake of growing public concern over the health risks associated with abandoned hazardous waste sites. Years ago, there was less understanding of the potential environmental, health, and safety threats posed by hazardous wastes that had been buried, abandoned, or disposed of in landfills. In the 1970s, the national media brought public attention to the plight of several residential communities impacted by abandoned wastes sites and there were calls for government action to address the problem.

LOVE CANAL AND OTHER HAZARDS

The most famous abandoned waste site was known as Love Canal. In the 1940s, the Hooker Chemical Company had disposed of more than 20 tons of hazardous waste in a former canal located near Buffalo, New York. Later, the land was sold to the city, and homes and schools were built over the former disposal site. In the 1970s, residents of the area began experiencing severe health problems that were attributed to this past waste disposal. Studies conducted by the New York Department of health confirmed the health dangers posed by the chemicals, and residents attempted to gain compensation for their losses.

At another site in Kentucky, over 4,000 leaking drums were found to be contaminating soil, groundwater, and surface water and impacting the health of nearby residences. This site became known as the Valley of the Drums.

Love Canal and the Valley of the Drums highlighted the problem of abandoned hazardous waste sites, but they were merely indicative of a larger and more pervasive problem. A survey of contaminated sites conducted in 1979 by the Environmental Protection Agency (EPA) identified 250 hazardous waste sites considered to pose "significant threats of damages" to human health. Many of these sites were characterized as *orphan* sites, meaning that the party responsible for cleaning up the contamination could not be identified.

CERCLA was enacted to identify the worst sites, finance the cleanup of existing contaminated property, and deter generators from improperly disposing of hazardous wastes in the future. It provided for the remediation of soil and groundwater at contaminated sites, and held owners or operators of a property financially responsible for cleanup, regardless of whether the contamination occurred prior to CERCLA's enactment or even whether they contributed to the contamination.

SUPERFUND

Congress charged the EPA with establishing a National Priorities List (NPL) that identified the sites that posed the greatest threat to public health and for establishing the criteria for cleaning up and closing hazardous waste sites. The initial government cleanup was financed through the Superfund, a trust fund established through taxes on petroleum products and chemical feedstocks. The government could then seek reimbursement from "responsible parties" who owned the site or contributed to contamination at the site. Subsequently, CERCLA is often called Superfund.

CERCLA imposed liability for cleanup without regard to fault or negligence. Several parties could be found liable: current owners or operators, past owners or operators, those responsible for transportation or disposal of hazardous substances, and those who arranged for its transportation. Even lenders could be held liable for waste cleanup if it was determined that the lender had the "capacity to influence" the waste management practices of the operators. The liability provisions were intended to provide a strong incentive for generators, transporters, and others to manage waste in a responsible manner. In some cases, a purchaser is allowed to claim that it had no way of knowing that hazardous waste was on the property. In such cases, the purchaser can avoid liability by invoking what has come to be known as the "innocent landowner" defense.

Prior to 1980, Congress had attempted to address the problem of improperly disposed hazardous waste through the Resource Conservation and Recovery Act (RCRA) and indeed, many of CERCLA's opponents argued that no additional legislation was necessary. However, while they are both designed to protect human health and the environment from the dangers of hazardous waste, RCRA is primarily concerned with managing hazardous waste and cleaning up active hazardous waste sites, while CERCLA is primarily concerned with addressing inactive or abandoned sites.

CRITICISM AND CONTROVERY

CERCLA and its Superfund provisions have been controversial since their inception. The Government Accounting Office (GAO), the Rand Institute, and others have criticized Superfund for the slow pace and high cost of cleanups. A 2000 GAO study, for instance, found that it could cost between $25 and $140 million to clean up a single Superfund site, with the average cleanup taking 10 years. Superfund has been assailed by its detractors as being a "Superfailure" and a "hazardous waste of taxpayer money" for spending too much money on attorneys and not enough money on actual site clean-ups.

Advocates for Superfund contend that Superfund must be evaluated within the context of CERCLA's dual goals of cleaning up contaminated sites and serving as a deterrent to improper waste disposal. Supporters argue that Congress initially underestimated the scope and magnitude of the problem and did not take into account the length of time it would take to implement a cleanup from beginning to end. Furthermore, they argue that avoiding high cleanup costs is an incentive for generators, transporters, and disposal facilities to manage wastes properly.

Despite criticisms of inefficiency, Superfund was reauthorized in 1986 when Congress passed the Superfund Amendments and Reauthorization Act (SARA). SARA increased the Superfund trust fund to $8.5 billion, to be financed through chemical taxes, general revenue, and costs recovered from responsible parties. It also set strict cleanup goals, established provisions for cleaning up leaking underground storage tank sites, and added "right-to-know" provisions requiring industries to provide the public with information on chemicals stored on site and released to the environment.

Another criticism of CERCLA was that its strict liability provisions deterred new businesses from using or developing so-called *brownfields* sites, which are sites that have had a history of environmental contamination. Often these sites are located in urban areas, and critics argue that fear of being held liable for the cleanup of brownfields sites has caused businesses to seek out *greenfields*, or previously undeveloped sites, in the suburbs. In response, the EPA introduced its Brownfields program in 1995. The program provides loans and other incentives to the private sector for the purpose of cleaning up and redeveloping contaminated sites.

THE FUTURE OF CERCLA

The Superfund is now funded primarily through the Treasury Department rather than through taxes on chemicals. In November 2003 a special advisory council recommended that the CERCLA program focus on improving the efficiency and effectiveness of the program while also acknowledging the program's success in cleaning up 900 NPL sites since its inception. Although CERCLA and Superfund have been characterized by controversy since the legislation was first enacted, it appears that they will remain fixtures of U.S. environmental policy for years to come.

Conflict

THE DEFINITION OF the term *conflict* is not so straightforward. C*onflict* can be defind as an open clash between two opposing groups (or individuals) or as a hostile meeting of opposing military forces in the course of war. The term *conflict*, as has been used in political science, sociology, anthropology, and psychology, refers to tension, which may explode into full-fledged violence, hostility, and insecurity. Conflict among humans is nothing new; it has always existed from antiquity to the present in one form or another.

In the context of society and environment, it is believed that dwindling natural resources have fueled conflict between members of different groups throughout the world. Many see environmental disruption in its all manifestations—global warming, soil depletion, desertification, water and air pollution, etc.—as a possible cause of future conflict. The most often quoted theorist on the relationship between population and resources is Thomas Malthus who first wrote his *Essay on the Principle of Population* in 1798. Malthus argued that in nature, plants and animals produce far more offspring than can survive, and that man, too, is capable of overproducing if left unchecked. His conclusion was that unless family size for the poor was regulated, man would experience misery, vice (conflict), and famine, which would put population growth in check. His propositions that poverty and famine were natural outcomes of population growth and food supply have been heavily criticized in the scholarly community. Nevertheless, his ideas continue to be influential as far as the link between population, resources, and conflict is concerned. Ideas of influential scholars such as Charles Darwin, Karl Marx, and modern day neo-Malthusians such as Paul R. Ehrlich, author of *The Population Bomb*, have their foundation in the Malthus principle of population growth.

POLITICAL CHANGE AND VIOLENCE

In recent decades there has been a spurt of models advanced by neo-Malthusian scholars, in which they attempt to link population and economics to a third variable, political change, and political violence, and to show how the variables interact. The

1994 work of Robert Kaplan, the 1994 and 1999 works of Thomas Homer-Dixon, and the 2002 work of Michael Dobkowski and Isidor Wallimann are recent examples that attempt to link population variables to conflict for resources. In these works, the argument is that natural resources help fuel conflict, either by attracting predatory groups seeking to control them or by financing wars that were initially caused by other factors. The ongoing conflicts in Sierra Leone, Angola, Democratic Republic of the Congo, Sudan, and Rwanda are explained in these terms. Conflicts have also flared in areas where the benefits of mining and logging projects accrue to a small group of elites, while the social and environmental burdens are borne by local communities. Excellent examples of such conflict include oil in Columbia and the Niger Delta in Nigeria, and timber and natural gas in Indonesia.

VIOLENCE AND DESTRUCTION

When conflict escalates into violence, many lives are lost and the environment and natural resources also suffer in various ways. As Michael Renner points out in his 2002 article, "The Anatomy of Resource Wars," governments, rebels, and warlords have made billions of dollars by selling conflict commodities and have used the money to arm themselves and line their own pockets. The cost of these conflicts in human toll has been unprecedented with more than five million people killed during the 1990s, and as many as 20 million driven from their homes. There has also been considerable environmental destruction in conflict hot spots. Mozambique and Angola are two examples of the worst affected countries in the world due to conflict during the period 1970–2000. The effects of this conflict are still being felt long after the guns have gone silent. Angola and Mozambique are the most landmine-afflicted countries in Africa, with land mines laid over decades by the Portuguese, South African, Cuban, Angolan, and Mozambican government forces, and the rebel groups of UNITA in Angola and RENAMO in Mozambique. In both countries, millions died and millions were displaced as refugees in surrounding countries during the course of the conflict.

Angola and Mozambique are also excellent examples of how land mines were deployed to degrade the environment, making them an environmental and health problem. Most of the land mines in Angola were laid on paths used by civilians to go to fields, schools, markets, and medical centers. The second major area of landmine injuries is along roadsides where land mines target people who leave the road to take a shortcut or to rest. Built-up areas have not been spared, and the spate of landmine casualties has resulted in the desertion of villages. Land mines were also planted on riverbanks, especially around bridges and along or on railroad tracks, to disable trains and target people who use the tracks or embankments as footpaths. To kill elephants for ivory, poachers—many of them belonging to the fighting factions—often laid antitank mines on elephant paths. The whole business of laying mines in Angola and Mozambique has affected not only the fighting factions, but also the civilians, particularly children and women. Land mines affect a large portion of the population, with 80,000 amputees in Angola alone and an ever-expanding number of victims under the age of 15.

Warfare exacts a toll on natural ecosystems and resources as well as on human populations. Environmental damage associated with conflict, including disruption of agriculture and infrastructure, is a cost of war that may hinder a nation's ability to recover after hostilities have ceased, as illustrated amply by the cases of Angola and Mozambique. Since the end of World War II in the 1940s, there have been numerous conflicts throughout the world, particularly in the developing world. There is general agreement that there is a great need to understand why violence occurs and how future conflicts could be prevented. It should be understood that the root causes of conflicts are complex and cannot be reduced to Malthusian principles alone; there is the interplay between political, economic, and historical factors, which ultimately result in civil war and the failure of states as illustrated in the conflicts in Somalia, Sierra Leone, Cote D'Ivoire, Rwanda, Democratic Republic of the Congo, and elsewhere in the world.

It is important to note that the debate about the extent to which abundant or scarce natural resources contribute to fueling conflict is ongoing and quite intense. It is a fact that throughout history, countries have fought over resources. In various parts of the world, conflicts have erupted over fishing rights, oil, diamonds, and access to water and other resources. In the case of water, many major rivers cross international boundaries, making water a precious commodity in semi-arid environments such as the Sudan and Egypt through which the Nile River passes. Overuse of the Nile waters in source areas such as Ethiopia, Uganda, and the Sudan, may jeopardize Egypt's water needs, which might result in interstate warfare. Generally, the common denominator of resource conflicts has been the presence of greedy elites monopolizing the resources or one ethnic group or nationality taking more than its fair share of a commodity that transcends international boundaries. Experts agree that equitable access to natural resources essential for life, stable political institutions, and peaceful international agreements are crucial for a secure future.

Congo

AFTER ACHIEVING INDEPENDENCE in 1960, the French region of Middle Congo became the Republic of the Congo. In 1990, the country discarded 25 years of Marxism in favor of democracy. Seven years later, a Marxist-led rebellion overturned the democratic government, setting off a period of civil unrest that ended only in 2003 when a tenuous peace was declared. International groups have continued to pressure the government over human rights violations. Once a major exporter of oil, Congolese reserves have declined. Other natural resources include timber, potash, lead, zinc, uranium, copper, phosphates, gold, magnesium, natural gas, and hydropower.

With a per capita income of only $700, the Congo is the eighth poorest country in the world. Around 37 percent of the people are severely undernourished. Less than one percent of the land is arable, and agriculture provides for only 6.7 percent of the Gross Domestic Product (GDP). While industry accounts for 62.4 percent GDP, Congolese industries vary from village handicrafts to sophisticated oil companies. The government sector is overstaffed, draining revenue away from essential services. Since the 1980s, petroleum reserves have steadily declined, and oil earnings have been used to pay off huge government loans. The government turned to the World Bank and the International Monetary Fund for help and applied for debt relief under the Heavily Indebted Poor Countries initiative. In March 2006, the World Bank approved a $2.9 billion debt relief package contingent on the eradication of corruption in state-run oil companies.

In addition to a 169-kilometer stretch bordering the South Atlantic Ocean, the Congo is bordered by Angola, Cameroon, the Central African Republic, the Democratic Republic of the Congo, and Gabon. The terrain of the Congo is generally flat with a coastal plain and a central plateau that give way to southern and northern basins. The highest point in the country is only 903 meters at Mount Berongou. The climate is tropical. The rainy season from March to June is followed by a five-month dry season. Temperatures and humidity are consistently high and are known to be particularly enervating in the section that strides the Equator. Flooding is common during the rainy season.

Like many of the poorest African nations, the Congo produces a social and physical environment conducive to disease. The population of 3,700,000 suffers from an HIV/AIDS rate of 4.9 percent. Some 90,000 Congolese have contracted HIV/AIDS, which has killed 9,700 people since 2003. The people of the Congo also have a very high risk of contracting food and waterborne diseases, because only 46 percent overall and 17 percent of rural residents have sustained access to safe drinking water, and only 9 percent overall and 2 percent of rural residents have access to improved sanitation. Common diseases include those borne by food and water such as bacterial diarrhea, hepatitis A, and typhoid fever and malaria, a vectorborne disease. High incidences of disease have led to low life expectancy (52.8 years) and growth rates (2.6 percent) and high infant mortality (85.29 deaths per 1,000 live births) and death rates (12.93 percent per 1,000 population).

On the average, Congolese women give birth to 6.07 children. The United Nations Development Program (UNDP) Human Development Reports rank the Congo 142 of 232 countries on overall quality of life issues. Approximately 70 percent of Congolese live in either Brazzaville or Poine-Noire or along the rail line that connects the two cities. In these areas, the Congo is experiencing air pollution from vehicle emissions. Between 1980 and 2002, carbon dioxide emissions tripled. Water is polluted from the dumping of raw sewage. Deforestation has occurred as trees are cut or burned for agricultural use and as an energy sources. The government has protected 6.5 percent of land area covering around 1.5 million hectares. Of 450 mammal species identified in the Congo, 40 are endangered, as are 28 of 345 bird species. In 2006, scientists at Yale University ranked the Congo 112 of 132 countries on environmental performance, roughly in line with the comparable income and geographic groups. The overall score was reduced by the poor showing in environmental health.

In 1991, the Congo passed the Law of the Environment, creating the Ministry of Environment and instituting the National Environmental Action Plan. Major projects targeted rural development and conservation of natural resources. The government established protected areas that included the closed forest of Nouabale-Ndoki, the community reserve at Lake Tele, a sanctuary of savannah and gallery forest at Lefini-South, and the reinforced mixed gallery forest of the Condouati Reserve.

The Republic of the Congo participates in the following international agreements on the environment: Biodiversity, Climate Change, Desertification, Endangered Species, Ozone Layer Protection, Tropical Timber 83, Tropical Timber 94, and Wetlands. The Law of the Sea agreement has been signed but was never ratified.

Congo River and Basin

THE CONGO RIVER is the second largest river in Africa (after the Nile) with a length of 2,718 miles. It has greatest flow of any river in the continent and second only to the Amazon worldwide. The river drains more than 1.3 million square miles, making its watershed, the Congo Basin, once again second only to that of the Amazon. Due to the fact that part of the Congo River flows above the Equator and the rest below it, it has a year-round flow and no dry season. In its final descent from Malebo Pool in the Democratic Republic of Congo into the Atlantic Ocean, the river falls more than 1,000 feet in merely 200 miles. Because of its perennial flow and topography, Congo River alone accounts for about one-sixth of the world's hydroelectric potential. Recently, the South African state-owned power enterprise, Eskon, has announced plans to build the largest power-generating dam in the world on the Congo. Once completed, it would produce twice as much energy as the Three Gorges Dam in China. A major transportation route, the Congo River houses several towns and cities along its banks. These include the capital of Democratic Republic of Congo, Kinshasa, and Brazzaville, the capital of the Republic of Congo.

Several, mostly small chieftaincies have historically existed along the Congo, their livelihood predicated upon fishing. In 1485, a Portuguese explorer first came across the mouth of the Congo River, and thereafter several expeditions tried to approach its source. Each of these attempts, however, was futile because of the strong flow of the Congo and the presence of more than 30 imposing cataracts in the first 200 miles. It was only in 1885 that the British-American explorer Henry Morgan Stanley managed to navigate the entire length of the Congo. He did it, however, from the opposite direction. Stanley's group started in Zanzibar on the eastern coast of Africa and decided to follow the route of the Congo River, first believing that it was the Nile. A few years later, Stanley was contracted by King Leopold II of Belgium to further explore the river and set up trading and military stations along it. This sowed the seeds for full-blown colonialism in Congo; carried out at first personally by Leopold, and after his death in 1909 by the Belgian state.

Political dynamics have been central to the environmental history of the Congo River and basin. The river is perfectly navigable after Malebo Pool, and portage railways were built by forced labor in the 1890s to bypass the cataracts. This set the base for massive exploitation of resources such as ivory, rubber, copper, and gold in the interior of Congo during the colonial period. Large-scale deforestation for timber and rubber plantations was routine during the Belgian colonial occupation of the Congo in the first half of the 20th century. The legacy of plunder has been continued by postcolonial rulers of Congo. Mobuto Sese Seko, the president of Congo for 32 years, amassed great personal riches from the Congo's vast resources. After a coup that ended Mobuto's tyrannical rule in 1997, however, Congo spiraled into civil war that cost millions of lives.

The Congo River flows through the second largest rainforest in the world. It has received some attention with regards to the political ecology of climate change, but not nearly as much as the Amazon basin. Both state-led and unregulated logging and incessant mining in the region—often to finance warring militias—pose a threat to the forests and to biodiversity in the region. If unchecked, this will not only deplete a significant carbon sink, it will prove to be devastating for millions of people whose livelihoods depend on the rainforest.

Congo, Democratic Republic

AFTER OBTAINING INDEPENDENCE in 1960, the Belgian Congo experienced a period of political and social instability that set the stage for the frequently brutal 32-year tenure of Colonel Joseph Mobutu, who changed the name of the country to Zaire. An influx of refugees from Rwanda and Burundi helped to topple Mobutu in 1997 and led to the establishment of the country as the Democratic Republic of the Congo (DROC) under Laurent Kabila. The ensuing battle for power led to interference from Rwanda, Uganda, Zimbabwe, Angola, Namibia, Chad, and the Sudan before peace was

Brazza

Pierre-Paul-François-Camille Savorgnan de Brazza, who was born near Rome in 1852, was an Italian who became a French citizen in 1874. After a short time in the French Navy, he became involved in exploring the Congo, establishing what became the French (Middle) Congo (present-day Republic of the Congo), and also founding the capital, Brazzaville.

The French-American explorer, Paul du Chaillu, had started the French colonial interest in Gabon during the 1850s, and the land on the left bank of the River Congo was taken over by the Belgians with the help of the Welsh-American journalist and adventurer Henry Morton Stanley. Brazza, finding himself in Equatorial Africa from October 1875 until November 1878, decided to try to secure the right bank of the Congo for the French.

Brazza explored the Ogooué (Ogowe) River and basin from the Atlantic coast of Gabon to the interior, managing to find his way to the source of the river, and also finding a tributary of the Congo River, the Alima River. As a result the French asked him to navigate the Ogooué River again in 1880. On this occasion, near Stanley Pool (modern-day Malebo), he signed treaties with the local tribal chiefs to establish a French protectorate over the region. In 1891 this became the French Congo.

After spending some time in Gabon, Brazza returned to France in June 1882 and was able to see the French government ratify the treaty. In 1884 he returned to the Congo, founding the city of Brazzaville, and then was governor of the colony from 1886 until 1897. He was then recalled to France, and French companies started vying for concessions in the Congo. Brazza was sent in 1905 to investigate accusations that funds were being misappropriated, and died at Dakar, Senegal, on his return voyage to France.

declared in July 1991. By that time, 2.33 million Congolese has been displaced internally and another 412,000 had fled the country. Estimates place the total death count at 3.3 million people, with most dying from starvation and disease. Despite ongoing conflict in some areas, Joseph Kabila managed to effectuate a semblance of national unity after his father was assassinated in 2001.

With a per capita income of only $800, the DROC is the eleventh poorest country in the world. Over seventy percent of the population is severely undernourished. The ongoing political strife and government corruption have produced a weak infrastructure that has made in impossible for the government to realize full economic potential from the wealth of natural resources that include cobalt, copper, niobium, tantalum, petroleum, industrial and gem diamonds, gold, silver, zinc, manganese, tin, uranium, coal, hydropower, and timber.

Less than three percent of the land area of DROC is arable, but agriculture accounts for more than half the Gross Domestic Product (GDP). Industry, on the other hand, produces only 11 percent of GDP. DROC has a distinct geography. In addition to straddling the equator, the country possesses a narrow strip of land that controls access to the lower Congo River and provides a 37-mile coast along the South Atlantic Ocean. Dense tropical rain forest spans the central river basin and the eastern highlands, covering almost one million square miles and comprising 47 percent of total African tropical forests. DROC shares land borders with Angola, Burundi, the Central African Republic, the Republic of the Congo, Rwanda, the Sudan, Tanzania, Uganda, and Zambia. The low-lying plateau with its thick rainforest gives way to mountains in the east. Elevations range from sea level in the extreme west to 5,100 meters at Pic Marguerite on Mount Stanley in the northeast.

The tropical climate is generally hot and humid in the equatorial river basin. The southern highlands experience cool, dry weather, unlike the eastern highlands, where it is cooler and wetter. South of the Equator, the wet season (November to March) is followed by a six-month dry season. Elsewhere, a short dry season (December to February) is preceded by the wet season (April to October). Periodic droughts occur in the south. During the wet season, the Congo River is prone to flooding. The Great Rift Valley of the east is home to a number of active volcanoes.

The population of 62,600,000 is constantly threatened by poverty and disease. DROC has an HIV/AIDS rate of 4.2 percent. It is estimated that since 2003, the disease has killed 100,000 people, and 1.1 million others are living with it. Less than half the total population has sustained access to safe drinking water (29 percent in rural areas). Only 23 percent of rural residents have access to improved sanitation as compared to 29 percent of urban residents. Consequently, the Congolese have a very high risk of contracting food and waterborne diseases that include bacterial and protozoal diarrhea, hepatitis A, and typhoid fever as well as schistosomiasis, a disease caused by contact with infected water. Ricks of vectorborne diseases that include malaria, the plague, and African sleeping sickness (trypanosomiasis) are high in some areas.

DISEASE AND LAND DEGRDATION

Because of high incidence of disease, the Congolese experience low life expectancy (51.46 years) and growth rates (3.07 percent) and high infant mortality (88.62 deaths per 1,000 live births) and death rates (13.27 per 1,000 population). Congolese women give birth to an average of 6.7 children. Low literacy rates (76.2 percent for males and 55.1 percent for females), a school attendance rate of only 30 percent for all levels, and a highly rural population (68.2) combine with ethnic and religious differences to make the dissemination of health and environmental information difficult. DROC has a major problem with poaching that threatens to destroy the wildlife population. Extensive deforestation has occurred as refugees have cut down trees to use for cooking and fuel. Tree loss and flooding have accelerated the processes of soil erosion and degradation. Irresponsible mining activities employed in the process of extracting diamonds and gold have resulted in extensive environmental damage in DROC, including the practice of allowing miners to take over national parks. Apes have become extinct because they are hunted for bush meat.

In 2006, scientists at Yale University ranked DROC 119 of 132 countries on environmental performance, in line with the relevant income group but below the relevant geographic group. The lowest scores were received in the categories of environmental health and biodiversity and habitat. Five percent of the land area of DROC is protected. Some 11,000 species of plants, 450 mammals, 1,150 birds, 300 reptiles, and 200 amphibians have been identified in the rain forest. Of 200 endemic mammal species, 15 are endangered, as are three of 130 endemic bird species.

The Minister of Environment, who is charged with enforcing and monitoring environmental laws, has begun working with local communities to better protect the fragile environment. In April 2006, the government ceded control of the Tayna Nature Reserve and the Kisimba-Ikobo Nature Reserve so that endangered Grauer gorillas, eastern chimpanzees, forest elephants, and okapi would be protected. The government plans to increase the number of protected areas to 15 percent. DROC is one of the countries included in the Congo Basin Forest Partnership established by the United States and South Africa in partnership with 27 public and private groups to alleviate poverty and promote sustainable development and conservation of natural resources and wildlife in the area.

DROC participates in the following international agreements on the environment: Biodiversity, Climate Change, Desertification, Endangered Species, Hazardous Wastes, Law of the Sea, Marine Dumping, Ozone Layer Protection, Tropical Timber 83, Tropical Timber 94, and Wetlands. The agreement on Environmental Modification has been signed but not ratified.

Coniferous Forest

CONIFEROUS FOREST IS dominated by conifers—evergreen, cone-bearing, needle-leaved trees such as spruce (*Picea*), fir (*Abies*), hemlock (*Tsuga*), or pine (*Pinus*). Larch (*Larix*), a deciduous conifer that drops its leaves in winter, may be common in some coniferous forests, especially in more northern latitudes. Conifers are the signature tree species of coniferous forests, but some broad-leaved deciduous tree species, such as birch (*Betula*) and aspen (*Populus*), are minor components of coniferous forests.

Coniferous forests are largely confined to the Northern Hemisphere and consist of several types. The world's largest expanse of coniferous forest is the boreal forest or taiga, covering over 18 million square kilometers. Taiga occurs as a broad circumpolar belt located between 50 degree and 70 degree north latitude, including parts of North America, Europe, and Asia. Montane coniferous forest occurs at higher elevations and covers over 3 million square kilometers in temperate North America, Europe, and Asia. Wet coastal coniferous forest—temperate rain forest—occurs in a narrow strip of northwestern North America from Alaska to northern California and in Japan. Local coniferous forest types such as the pitch pine (*Pinus rigida*) coastal plain forests are also recognized in the northeastern United States, among others. Many coniferous forests in warmer climates are successional, such as the extensive pine forests of the southeastern United States. In the absence of human or natural disturbance—especially fire—successional coniferous forests are replaced in time by deciduous forests.

Climate plays a key role in determining the distribution, composition, and productivity of coniferous forests. The taiga climate is the most extreme, with a growing season of 50–100 days, and winter temperatures that often drop below –30 degrees C. The annual precipitation is low, ranging from 40–50 centimeters, and falling mainly in summer when temperatures range from 12 degrees C to 15 degrees C. The climate of the montane coniferous forest is generally milder and wetter than that of the taiga, but topography, elevation, and aspect create a diversity of climatic conditions. In the European Alps, annual precipitation varies between 80–260 centimeters, winter temperatures range between 0 degrees C and 5 degrees C, and summer temperatures average 10 degrees C to 18 degrees C.

In the North American Rockies, annual precipitation varies from 40–120 centimeters, with winter and summer temperatures ranging from –5 degrees C to –10 degrees C and 15 degrees C to 20 degrees C, respectively, depending on latitude. North America's wet coastal coniferous forests have the mildest climate with a frost-free period that can exceed 240 days and winter temperatures that rarely surpass –5 degrees C. Annual precipitation ranges from 40–200 centimeters and is often embellished by sea fog. North America's wet coastal coniferous forest is the most productive on the continent, harboring species like coast redwood (*Sequoia sempervirens*) that may grow 100 meters tall and reach 2,000 years in age.

Humans have exploited coniferous forests for food, timber, fuel, and fiber for millennia. Today, many coniferous forests are intensely managed for timber and pulpwood, like the pine forests of the southeastern United States. Other coniferous forests, like the taiga of Russia and Canada—which contain 50 percent of the world's old-growth forests—are under increasing human pressure for harvest and oil development. The peat soils of the taiga are an important global carbon sink and heavy development may influence global warming rates.

Conservation

CONSERVATION IS THE protection of certain features from modification and use. The evolution of conservation ideas, coupled with the creation of particular models of natural resource management, are rooted in key historical events, ethics, political philosophies, and understandings about the relationships between humans and the environment. These ideas also differ culturally, as many countries have pursued their own conservation strategies that fit with local understandings of the environment. Interest in conservation in the United States expanded at the end of the 19th century as the result of economic, demographic and environmental factors. Prior to this time, industrial and urban expansion on the continent superseded a national concern for conserving the American landscape. Environmental historian Roderick Nash argues that Americans were primarily afraid of the wilderness landscape and were intent on modifying it for their comfort and use.

The early settlers cast the environment in superstitious tones that presented it as a threat to their existence, consisting of evil elements and spirits. These ideas were supported by the need for raw materials to support the Industrial Revolution, which made the clearing of the environment part of the national mission. These pressures began to be challenged as people became increasingly aware of the value of the American landscape. Historian Frederick Jackson Turner published an influential essay in 1893, which asserted that the American frontier, the iconic representation of American character and lifestyle, had disappeared. The U.S. census at that time marked the official end of the frontier with the closure of the American West. The westward expansion that accompanied Manifest Destiny and the Homestead Act had effectively transformed the region while laying the foundation for a growing conservation ethic.

Conservation principles and ideas have been heavily influenced by a number of American writers in the 19th century. Primarily located in the urban Northeast, a number of authors helped instill a sense of beauty for the natural world. One such group was the Transcendentalists, who broke from the principles of the Enlightenment in asserting that truths could be discovered not through science, but in vision and emotion. Transcendentalists argued that wilderness was critical to experience and that the natural world represented and reflected spiritual truth and moral law. Key among them was Henry David Thoreau, who in his classic book *Walden* detailed his time spent in nature near his Concord, Massachusetts home. In a classic lecture before the Concord Lyceum, Thoreau argued that the preservation of the world could be found through experiencing nature.

AN EMERGING STEWARDSHIP

The Transcendentalists were not the only group arguing for a changing relationship between humans and the environment. In his book *Man and Nature*, George Perkins Marsh asserted that the destruction of the natural world represented a threat to the survival of human civilization. In suggesting that ancient civilizations declined because of their abuse of the environment, Marsh helped develop an emerging stewardship for the natural world. Another influential writer and activist was John Muir, who spent much of his adult life in the wilds of the Sierra Nevada Mountains of California. Muir became a nationally recognized figure, and worked in concert and in opposition with key actors to help establish Yosemite National Park and other protected areas. One of Muir's key legacies is his advocacy for preservationism as a guiding conservation philosophy. Preservationists argue that the natural world should be left to its own devices. This belief contrasted with utilitarianism, which asserts that the utilization of the environment is acceptable and necessary. One key utilitarian advocate, Gifford Pinchot, became the first chief of the Forest Service and argued that conservation was best realized through the use of natural resources and development. In one of the central rifts of the early conservation movement, Muir and Pinchot fought over the damming of the Tuolumne River in the Hetch Hetchy Valley of Yosemite National Park. The decision to build the dam within the national park represented an early victory for utilitarian conservation.

CONSERVATION MODELS

One of the central conservation models has been the national park, which has its origins in the United States in the 19th century. Writers and activists were successful in pushing forward the idea of a national park to protect natural landscapes and wildlife from intrusion. Also important were various industries, including tourism and railroad, that were looking for opportunities to expand into the American West. Several expeditions were funded by financiers to help develop interest in the western landscape. The Washburn–Doane Expedition of 1870 is regularly cited as a catalyst for the creation of Yellowstone National Park, but the expedition's influence was only part of a convergence of factors for the creation of Yellowstone National Park in 1872, which was the first protected area of its kind. Yellowstone was a bit of an oddity; it did not prompt the immediate expansion of the national park system and was intended to benefit the expanding tourism industry into the Western United States. The Yellowstone bill specifically identified the geysers, hot springs, and other geological features to be the most critical for protection. Wildlife species were not given the same consideration, and early park management was intent upon removing various predators that were believed to threaten the bison and other wildlife the tourists wanted to see. It would not be until the 20th century that wildlife and fire management strategies would be changed within the national park system.

An expanding urban population in the Northeast fueled an increasing desire to experience nature. This resulted in a growing tendency to associate wilderness with the frontier and pioneer past. Wilderness was believed to be responsible for many unique and desirable national characteristics and acquired importance as a source of virility, toughness, and savagery. Natural landscapes were increasingly invested with aesthetic and ethical values, and as such, they become valuable for contemplation and recreation. National figures such as Theodore Roosevelt, Gifford Pinchot, and John Muir helped push for expanded conservation in the United States through the Forest Service and Antiquities Act. The National Park Service (NPS) was established in 1916 in an effort to connect the various national parks under one department. The NPS began working to expand the number of national parks while meeting the needs of a growing number of tourists.

DRAMATIC EXPANSION

Conservation expanded dramatically in the United States in the latter half of the 20th century. The environmental and health effects of continued industrialization and development prompted the passage of various pieces of legislation. In the classic book *Silent Spring*, Rachel Carson warned of the health impacts of chemicals upon ecological systems. Her dire warnings prompted the banning of DDT as a pesticide following World War II and helped the recovery of bird species, like the bald eagle, whose population numbers were in decline. In *A Sand County Almanac*, Aldo Leopold used ecological principles to argue that a land ethic was needed to change the relationship between humans and the environment. Various pieces of environmental legislation were signed into law that helped make the environment more central to national policy. The Clean Water Act, Safe Drinking Water Act, Clean Air Act, and Endangered Species Act (ESA) were all critical pieces of legislation. The ESA established a list of endangered species that are managed by the U.S. Fish and Wildlife Service. The 1964 Wilderness Act established a national network of wilderness areas managed by the Forest Service, National Park Service, Bureau of Land Management, and Fish and Wildlife Service. There are now many different conservation types in the United States, including national parks, state parks, national monuments, wildlife refuges, sanctuaries, national and state forests, and tribal lands. Their management is entrusted to local, state, and federal agencies.

SUSTAINABLE DEVELOPMENT

Conservation principles have expanded globally through sustainable development, which attempts to merge economic development with environmental sustainability. The origins of sustainable development can be traced to the 1970s as the result of a number of events and conferences. The United Nations (U.N.) Conference on the Human Environment held in 1972 in Stockholm, Sweden, was the first major summit on environment and development. Attendees from 113 nations agreed to a number of principles, including the idea that economic growth and environmental sustainability could coexist. The Stockholm Conference was followed by the World Conservation Strategy (WCS) of 1980, which attempted to integrate development goals with conservation planning. The WCS helped merge conservation of the environment with mainstream development processes. A major event in the establishment of sustainable development was the World Commission on Environment and Development (WCED) *Our Common Future* Report of 1987, which defined sustainable development as "[meeting] the needs of the present without compromising the ability of future generations to meet their own needs." Among its many goals was the conservation of the natural resource base and the merging of environment and economics in decision making. Sustainable development has played a key role in the expansion of conservation throughout the developing world. Conservation areas were linked with sustainable development principles and premised as key areas of protection for threatened flora and fauna species. Their creation was considered all the more important, considering the rates of deforestation and habitat destruction occurring around the world.

The concept of the national park did not exist solely within the United States and Europe. Throughout Africa, colonists created conservation areas to provide natural experiences in wild Africa. The interplay between human and nonhuman species in these constructed geographical spaces was designed to allow wildlife to be observed unfettered by human interference. In the post-colonial era, African countries found that national parks,

Social Movements

Conservation in the 20th century of the United States increasingly involved protests and social movements. Various environmental organizations, including Earth First!, Sierra Club, Greenpeace, Nature Conservancy, and the World Wildlife Fund increased in influence. The year 1970 marked the first Earth Day, a national gathering to focus on environmental concerns. Since then, Earth Day has become an annual international gathering. Other events reflected an increase in public concern for environmental issues. The debate over water management and large dam construction, begun between John Muir and Gifford Pinchot, would become central to the American conservation movement in the 20th century. The successful construction of the Hoover Dam kicked off a wave of dam building in the western United States. Utilitarian and preservationist perspectives clashed again as various actors cited the Glen Canyon Dam, which was completed in 1966, as either a technical miracle or an ecological disaster. Attempts by the Bureau of Reclamation to establish additional dams on the Colorado River, including one in the Grand Canyon, were heavily resisted by environmental groups and the public. Activists like David Brower of the Sierra Club helped push preservationist views in suggesting that large infrastructure projects had their limits.

Concerns for specific environmental issues, including biodiversity, desertification, deforestation, and human population growth, increased in intensity in the 1970s. This was particularly the result of several alarmist studies. Paul Ehrlich and others argued that global population was expanding beyond the capacity of the natural world to sustain it. In *The Population Bomb,* Ehrlich argued that human population growth would result in the deaths of hundreds of millions of people. This text was mirrored by other studies, including the Club of Rome report in 1972, which used computer modeling to assert that major changes in geopolitical relations would be needed to stem an environmental catastrophe and population collapse. The energy crisis that accompanied the embargo from the Organization of the Petroleum Exporting Countries (OPEC) was an additional reminder that critical resources were not limitless.

and other types of conservation areas, presented a significant source of revenue. Tourism became a contributing factor to conservation and these areas presented a source of economic growth for national governments.

These trends have expanded the presence of national parks and protected areas around the world. Between 1900–49, less than 600 protected areas were established worldwide. Between 1950–90, however, this figure grew to nearly 3,000, of which 1,300 were established just in the 1970s with the majority located in the developing world. The World Conservation Union (IUCN) has categorized protected areas into eight separate management domains: scientific reserve/strict nature reserve; national park; national monument/national landmark; managed nature reserve/wildlife sanctuary; protected landscape; resource reserve; natural biotic area/anthropological reserve; and multiple-use management area/managed resource. At the end of the 20th century, more than 25,000 protected areas existed worldwide and approximately 5 percent of the land surface of the planet had been set aside as protected areas with a variety of management goals and structures. More recently, the 2003 U.N. List of Protected Areas identified more than 100,000 protected areas that constituted roughly 11.5 percent of the land surface of the planet.

The drive to protect biodiversity and habitat often comes at the expense of human populations that live adjacent to national parks and protected areas. Concerns for the impacts of national park planning upon local populations have expanded interest in community conservation strategies that attempt to integrate local livelihood needs and concerns with the broader conservation mandate. Community

A German Shorthaired Pointer explores the Great Dismal Swamp National Wildlife Refuge in Suffolk Virginia, which is protected by a Conservation Easement. There are now many different types of conservation areas in the United States.

conservation is a broad category that includes community-based conservation, community wildlife management, collaborative management, community-based natural resource management, and integrated conservation and development programs (ICDPs). There are examples of these approaches all over the world, such as the extractive reserves in Brazil and the Communal Areas Management Programme for Indigenous Resources (CAMPFIRE) program in Zimbabwe. CAMPFIRE was created in 1989 to allow private property holders to claim ownership of the wildlife on their land with the goal of providing incentives to protect environmental resources. CAMPFIRE was designed by the government's Department of National Parks and Wildlife Management (DNPWM) to decentralize management authority and decision-making of common property resources (CPRs) to the local communities that incur the costs of management. Since its beginnings, the CAMPFIRE approach has been applied to the management of other CPRs, including grazing, forest resources, and fisheries. Other community conservation initiatives, like extractive reserves in the Brazilian Amazon, have increased in popularity as a means of reconciling the competing demands of human development and conservation.

Another strategy for combining conservation with development is ecotourism. Tourists continue to visit international destinations for their diverse ecological features. Often labeled ecotourism, this trend represents a promising opportunity to generate revenue for conservation while providing incentives for developing countries to protect their environments from development. The International Ecotourism Society defines ecotourism as "responsible travel to natural areas that conserves the environment and improves the well-being of local people." This involves the following principles: minimized impact, development of environmental and cultural awareness, generation of financial benefits for conservation, and the support of human rights and democratic movements. A number of countries, including Costa Rica, Belize, and South Africa, have been aggressive in promoting their national parks and assorted conservation areas to generate financial revenue through ecotourism.

Various environmental challenges confront conservation ethics and the global community. Biological diversity is threatened with the continued deforestation of various habitats around the world. Global warming remains one of the most significant challenges that will require shifts in energy consumption, infrastructure, and planning. Underpinning these issues are continued debates about the appropriate relationships between humans and the environment. It remains hotly debated as to whether conservation should be guided by a preservationist or a utilitarian perspective.

Conservation Biology

CONSERVATION BIOLOGY IS a scientific field that studies the processes and patterns that maintain or alter biological diversity, and engages with applied research and policy in order to further biodiversity conservation. In order to achieve its positive and normative goals, conservation biology draws upon several subfields of ecology as well as the social sciences and philosophy to understand the human and ethical dimensions of ecological change and inform appropriate policy responses. Ecological subfields that contribute to basic and applied research in conservation biology include genetics, population and community ecology, as well as ecosystem and landscape ecology. Several social science disciplines—including economics, geography, anthropology, political science and sociology—have contributed theoretical and methodological tools.

The long history of human-induced transformations of the earth dates back at least to the dawn of plant domestication approximately 10,000 years ago; the conversion of natural ecosystems having accelerated in the past three centuries. Recent human-induced transformations of the environment, however, are widely perceived to be unprecedented in scope, rate and magnitude, and a significant driving force of global environmental change. Human population growth, along with political-institutional, socioeconomic, technological, and cultural factors are the primary anthropogenic drivers of ecological change, and have led to biodiversity loss and species extinctions in several locales. Global-scale declines in biological diversity during recent history gained widespread scientific recognition by the 1970s; this led to the emergence of a multi-disciplinary conservation biology in the 1980s. Conservation biology as a field is a targeted response to this biodiversity loss, and blends traditional disciplinary research with applied scientific fields such as forestry and natural resource management. Michael Soulé, the co-founder of the Society for Conservation Biology, referred to the immediacy of conservation needs when he referred to conservation biology as a *crisis discipline*, one that forces conservation scientists to balance scientific knowledge with policy advice, often despite prevailing uncertainty.

The field's philosophical roots reach back several centuries. Biological diversity and nature in general has been valued based on its intrinsic worth as well as for utilitarian purposes, such as sustained flow of goods and services for the benefits of human societies. In the United States, one philosophical approach to conservation focused on a spiritual–aesthetic appreciation for nature and its intrinsic value, and may be traced to the ecocentric Romantic–Transcendental ethic as reflected in the writing and legacy of such figures as Ralph Waldo Emerson, Henry David Thoreau, and John Muir in the mid-1800s. The utilitarian perspective, espoused on the other hand by John Stuart Mill, Gifford Pinchot, and others, was rooted in an anthropocentric view of nature's worth, and espoused the conservation of natural resources to ensure "the greatest good of the greatest number for the longest time." Aldo Leopold's Evolutionary–Ecological Land Ethic combined the tradition of the utilitarian resource conservationists with developments in the scientific disciplines of ecology and evolution, conceptualizing nature as a system of interacting parts, and laying the foundation for present-day conservation biology.

Meffe and Caroll (1994) propose three "guiding principles" for conservation biology: a focus on evolutionary change to better understand the dynamics of biodiversity through a historical perspective; a focus on the changing, stochastic, uncertain and non-equilibrium nature of ecosystems, which has increasingly replaced previous closed-system, equilibrium conceptualizations of most ecosystems; and a focus on human agency, in both its positive and negative aspects, for a better understanding and pragmatic approach to biodiversity conservation. These principles remain relevant for various scientific and applied/policy concerns within the discipline, including the design of nature reserves, restoration ecology and the management of endangered species.

SPECIES DIVERSITY

Species diversity has been the target of most conservation efforts for the longest time, and of significant biodiversity legislation, such as the Convention on International Trade in Endangered Species (CITES) and the U.S. Endangered Species Act (ESA). The identification of global "hotspots" of biodiversity, mostly located in tropical systems, also focuses on areas with very high levels of species diversity and endemism, as well as the threat of habitat loss. Rare, long-lived, and keystone species may often be particularly vulnerable to extinction. However, deciding what constitutes a species is no simple task, and different conceptualizations of species (e.g., biological, cladistic, evolutionary, ecological, and others) pose scientific challenges to their definition and therefore conservation. Most legislation is based on the biological species concept. Species richness can be divided into three major components: the number of species present in a small homogenous habitat; changing species composition across a range of habitats (e.g., along an environmental gradient), and diversity across larger spatial scales, such as landscape gradients.

Although species afford a useful framework for conservation and provide publicly and legally identifiable entities that may be valued, tracked, and managed, a species-only approach to conservation fails to address several fundamental threats to ecosystems and habitats. Structural, compositional and functional aspects of biodiversity are now commonly conceptualized at a number of critical hierarchical scales, including genes, species, populations, communities, ecosystems, and landscapes, that include both spatial and temporal variability and change.

SUSTAINABLE DEVELOPMENT

Conservation biologists now combine basic and applied scientific research with resource monitoring, spatial analysis and decision support systems such as satellite image processing and geographic information systems to track changes in ecosystems and habitat. In addition, the field has increasingly opened up to the concept of sustainable development, acknowledging the interdependence of human development needs and environmental conservation. The United Nations Man and the Biosphere Program was among the first attempts to explicitly move from earlier preservationist approaches to a more pragmatic and socially aware conservationist approach by adopting the goal of ecologically sustainable economic development for Biosphere Reserve Conservation.

Participatory conservation–development is another relatively recent trend in conservation biology, wherein local communities are identified as critical stakeholders in the conservation process, and their participation is sought in research, planning, monitoring, and educational activities. In reality, however, the integration of conservation with development in protected areas can be difficult. Conservation/development policies in many protected reserves may fail to protect biodiversity, or have socially detrimental impacts such as wildlife–livestock conflicts, social displacement, armed conflicts, and strengthened authoritarian regimes. Effective conservation policy requires an approach that combines basic ecological/biodiversity research and effective monitoring/modeling tools with social science research and policy analysis that highlights the complex and dynamic interactions among communities; prevailing land tenure, property regimes, policy and market institutions, and local ecological systems.

Conservation Easements

A CONSERVATION EASEMENT is a negotiated contract between a landowner and either a nonprofit organization or a government entity. In exchange for giving up some portion of a property’s development rights, the value of the property is lessened and the landowner receives an economic benefit. This benefit results usually in lower property taxes, often in a reduction of estate taxes, and if donated, may also qualify for an income tax benefit. Because conservation easements have been viewed as providing a flexible and nonregulatory mechanism for achieving conservation goals, they have increasingly become a major tool used by land trusts and governments to protect land.

As legal agreements, conservation easements derive from the "bundle of rights" property concept that allows a portion of rights to be separated from the whole and held by another entity. Unlike other easement types, which permit the holder to do something, conservation easements allow the holder to prevent particular uses or types of uses. As a result, the separated rights are "retired" and become encumbrances on the property deed that travel with the land and bind future property owners. Easements may be written for a specified period of time, but are typically written to last "in perpetuity." The specifics of each conservation easement and the piece of land to which it pertains are generally determined on a case-by-case basis through negotiations between the landowner and the organization. Land trusts tend to tailor conservation easements to individual landowner needs, while government agencies have tended to use a "one-size fits all" approach.

EMERGENCE OF EASEMENTS

In the United States, conservation easements emerged as a market- and incentives-based alternative to the use of regulatory tools, such as outright acquisition through the use of eminent domain or zoning-related land-use restrictions. First used in Boston, Massachusetts, in the 1880s as part of Frederick Law Olmsted's park design, they were also important to the creation of a number of scenic parkways. However, it is their use by nongovernmental organizations, such as land trusts, to meet diverse conservation goals that has been most celebrated. Over the past century, conservation easements have become one of the most widely used tools to protect land that is valued for its ecological significance, including the presence of wetlands, or as wildlife or endangered species habitat; aesthetic importance or scenic beauty; for agricultural or forestry production; beaches and other recreational features; or historical significance.

The use of conservation easements, both inside and outside the United States, is growing. Between the late 1950s, when this conservation tool first became more widely known, and 2003, there were approximately 17,800 conservation easements covering a total of approximately 7 million acres in the United States. Much of this activity occurred after 1998. Likewise, conservation easements have been used elsewhere, including in Canada, Costa Rica, and Mexico. They are also being advocated as a possible solution to conservation issues in South America and beyond.

There have been a number of concerns about the growing use of conservation easements, which have potentially important implications for their future use. First, it is unclear how well existing conservation easements contribute to emerging conservation goals, particularly the creation of integrated networks of protected areas that are seen as essential to biodiversity conservation and habitat protection. In particular, this concern about efficacy derives from the application of ecological principles to easement design. On one hand, this concern centers on the technical adequacy of the management requirements for individual properties and whether these sufficiently address issues of ecological change. On the other hand, conservation scientists question the extent to which the pattern of specific parcels is sufficient to conserve an area's biodiversity or natural resources. Taken together, these concerns signal the potential need for greater government involvement in ecological conservation. Second, conservation easements have been lauded as voluntary and nongovernmental conservation interventions, but several challenges to this view are emerging. Because they rely heavily on the economic incentives created by tax relief, they are in fact expenditures of public funds. In some cases, government agencies may even provide funds directly to private groups that negotiate conservation easements. In both cases, questions have been raised about the appropriateness of spending public funds on these activities. Third, questions about who benefits from conservation easements and issues of equity are being raised. U.S. tax rules have tended to limit the economic benefits associated with easements in ways that disproportionately benefit higher income landowners. This issue led to congressional hearings on the practice in 2005.

Conservation Reserve Program

THE CONSERVATION RESERVE Program (CRP), run through the office of the U.S. Department of Agriculture's Farm Service Agency, was first established in the Farm Security Act of 1985. This voluntary program aims to promote sustained land and soil conservation efforts by private agricultural land holders by retiring highly erodible or environmentally sensitive farmland from active crop production for a period of 10–15 years. In exchange, landowners are provided annual rents. By retiring land from active crop cultivation, the program's objectives are to help stem the rate of soil loss and erosion, reduce nutrient runoff, leaching, and sedimentation into streams and rivers, improve water quality, and enhance wildlife habitat conditions by planting more appropriate grasses, trees or cover crops. As of 2005, nearly 424,000 farmers across the United States, along with approximately 35 million acres were participating in this program.

Landowners may sign up for CRP during specified time windows, and to be eligible for enrollment, must have owned or operated the land parcel for at least a year prior to signing up for the program. Additionally, the land must have been planted with an agricultural commodity at least four out of the previous six years. Federal aid through the program compensates landowners with annual rental payments for land under long-term conservation contracts. Rental payments are calculated based on local soil productivity and market conditions. Furthermore, a 50 percent cost-share program helps landowners who wish to plant approved cover such as grasses, trees or other alternatives on their land to improve soil, water, and habitat conditions. Several federal, state and local agencies, including the Natural Resources Conservation Service, the U.S. Department of Agriculture's Extension Service, and state forestry agencies provide technical support for the program, while the Farm Service Agency is responsible for overall administration.

More recently, the Conservation Reserve Enhancement Program (CREP), an offshoot of CRP implemented with the 1996 Federal Agriculture Improvement and Reform Act, has bolstered federal, state, and local stakeholder partnerships in targeting agriculture related conservation efforts. While similar to CRP in many ways, CREP differs in that it is limited to specific geographic areas with high-priority environmental concerns, requires measurable environmental outcomes and must involve cost-share between federal and state funds.

There has been some concern about the economic implications of CRP on local communities. Farmland retired from production will have an impact on the demand for agricultural and allied services, including those providing farm inputs and related agricultural processing services. Likewise, there is the possibility for declines in local agricultural labor markets as well. Initial studies suggest that CRP's economic impacts vary geographically; and while in many cases the economic impact might be minimal, smaller rural counties that serve as agricultural service hubs might face more acute conditions. All the same, advocates of CRP have argued that the long-term environmental benefits of this program would positively influence long-term economic security. The most recent Farm Security and Rural Investment Act of 2002, which extends funding for agricultural and rural development programs through 2007, reaffirmed CRP funding and its objectives.

Consultative Group for International Agricultural Research (CGIAR)

THE CONSULTATIVE GROUP for International Agricultural Research (CGIAR) is a network of research laboratories and largely public-sector organizations that was formed in 1971, at a time when it was feared that massive famine was likely throughout the developing world. The CGIAR focused on the productivity of agriculture, and success in this area helped prevent at least some of the projected famines. The roots of the network were nurtured by the co-operation between the U.S. government, the Rockefeller Foundation, and the Mexican government in the 1940s to identify methods of increasing agricultural production. A team of scientists led by Norman Borlaug, who won the 1970 Nobel Peace Prize, managed to develop semi-dwarf varieties of wheat that tripled yields of this cereal and helped make Mexico self-sufficient in food production. The CGIAR was created to extend this successful research to other parts of Latin America, Nigeria, and the Philippines.

Research centers were established in Colombia, Nigeria, and the Philippines in the late 1960s. To create the CGIAR on a firm basis, a series of consultative meetings was scheduled with key future partners in the World Bank, British and American governments, the United Nations (U.N.), and the Rockefeller and Ford Foundations. World Bank President Robert McNamara pushed through an agreement in which his institution would take a leading role in promoting the Green Revolution. His success led to a significant increase in the scope and size of World Bank activities, with several thousands of scientists trained at its newly opening facilities and the new varieties of wheat being planted around many parts of the developing world. The CGIAR has subsequently gone on to achieve many successful improvements in global agriculture. The original objectives adopted by the CGIAR were to examine the needs of developing countries for specialized efforts in agriculture; harmonize international, regional, and national efforts to finance and undertake agricultural research; provide finance for high priority agricultural research activities; and to undertake continuing review of priorities. A Technical Advisory Committee was also established to provide an independent source of advice about technical and scientific issues to guide board members.

Fifteen separate research institutes are currently members of the network: the Africa Rice Center in Benin; the Centro Internacional de Agricultura Tropical in Colombia; the Center for International Forestry Research in Indonesia; the Centro Internacional de Mejoramiento de Maiz y Trigo in Mexico; the Centro Internacional de la Papa in Peru; the International Center for Agricultural Research in the Dry Areas in Syria; the International Crops Research Institute for the Semi-Arid Tropics in India; the International Food Policy Research Institute in the United States; the International Institute of Tropical Agriculture in Nigeria; the International Livestock Research Institute in Kenya; the International Plant Genetic Resources Institute in Italy; the International Rice Research Institute in the Philippines; the International Water Management Institute in Sri Lanka; the World Agroforestry Center in Kenya; and the WorldFish Center in Malaysia.

This network is governed by a series of institutions and councils led customarily by an executive from the World Bank. Disharmony has broken out from time to time concerning the proper future directions of the CGIAR and the research on which it focuses. The early successes achieved by the CGIAR in improving agricultural production in a range of different crops and animal livestock have meant that its scientists have been able to consider a broader range of research topics. However, it has been argued by some that the CGIAR's choice of such activities has been inappropriate in some cases in that they do not reflect the core competencies and competitive advantage that the network has to offer; further, more attention should be paid to private sector research and the growing importance of intellectual property rights (IPR) in the research process. These issues are reflective of a larger controversy about IPR that divides the developing world from the developed world. The latter, so it is claimed, is using IPR to obtain inequitably higher levels of control and influence over agricultural production in the former. By awarding IPR production to private sector products and then aggressively marketing them to developing world farmers, it is feared that the international community will be able to control those farmers and lock them into purchasing comparatively high-cost products from companies in developed countries.

Consumers, Ecological

THE TERM *ECOLOGICAL CONSUMERS* refers to species that cannot produce their own food, and so get energy and nutrients by eating other organisms. Properly termed *heterotrophs*, they are distinguished from *autotrophs*, or producers, that produce their own food via photosynthesis (plants and cyanobacteria) and chemosynthesis (carried out by bacteria near deep ocean hydrothermal vents). Consumers occupy the highest levels of the trophic hierarchy, a system of classification in which species are grouped according to their position in food chains and webs. Other levels of the trophic hierarchy involve the conversion of energy (solar and heat), gases and inorganic gases into biotic carbohydrates and proteins (via producers), and back into the abiotic components (via decomposers, such as fungi), whereas consumers strictly cycle biotic compounds and energy.

Consumers are further subclassified according to the nature of predator–prey interactions. Primary consumers engage in herbivory (considered to be a form of predation). Secondary consumers prey directly upon primary consumers, and include carnivores and insectivores. Tertiary consumers include top carnivores and omnivores, and include all of those species that prey upon multiple trophic levels. For example, bears are tertiary consumers, as are humans, because they eat fruits (producers), herbivores (primary consumers) and secondary consumers (such as salmon). Consumers play an important ecological role in maintaining biodiversity in that they keep the populations of prey species in check, and cycle nutrients and energy through the ecosystem.

Between each trophic level, some energy is lost to heat. Due to these inefficiencies, the biomass of each successive trophic level decreases. A given mass of vegetation in an ecosystem will support a smaller mass of herbivores, which in turn support successively smaller mass of secondary and tertiary consumers. The reduced mass of consumers across each of the levels typically translates into decreased populations of respective species. A given landscape will typically support a higher number of primary consumers than secondary consumers, with tertiary consumers being fewest in number. A general rule of thumb cites a 90 percent loss of energy across each trophic level, but this figure varies greatly between differing species and systems when analyzed empirically.

Large populations of tertiary consumers thus need a larger productive base to support them. Similarly, human societies have differing levels of impact on the landscape based on consumption habits and affluence. For example, ecologists often compare the number of people a certain amount of land can support through grain production, if those people consume the grain directly or if the grain is first fed to cattle, and the cattle subsequently eaten by people. Due to the inefficiencies across multiple trophic linkages, the land supports a smaller human population through beef consumption than if people consumed the grain themselves; that society requires substantially more land and has a higher ecological impact.

Alternatively, pastoral nomadic societies survive in semi-arid grasslands precisely because of these same inefficiencies across multiple trophic levels. Despite being unable to directly digest grass, people are able to survive in these inhospitable climates by keeping livestock that digest the grass, then consuming the livestock's productivity. Similarly, range-fed beef is considered by many to be a more ecologically sound choice than grain-fed beef.

Consumers, Economic

THE ORIGIN OF understanding of consumers and consumption derives from the microeconomic frameworks first constructed in the 19th century. This economic viewpoint depends on the concepts of utility and rational thought. It is assumed that the consumer has a finite stock of money that can be spent on a variety of different commodities or products. Since it is possible for individual consumers accurately to place a specific amount of happiness (or utility) on the possession of a unit of each available product—and the value of that utility declines if the consumer already has bought some unit of that item—then the consumer will make rational decisions in order to maximize the amount of utility that can be obtained. This model remains influential, although it has undergone a number of refinements over the years.

First, the concept of rationality was challenged on the basis that it demanded high levels of information and that it was clear that this did not reflect reality. In fact, sellers generally know far more about the utility offered by goods than buyers do, and it is difficult to place an accurate value on gaining information. As a result, rationality has been replaced by the concept of *bounded rationality,* which implies that consumers will accept that seeking to obtain full information about products would be an inefficient process.

A second area of improvement to the understanding of consumers and their behavior was provided by Maslow's Hierarchy of Needs, which represented a slightly more sophisticated understanding of how consumers choose their products. According to Maslow, consumers will first of all look for the deepest psychological needs (safety, health, food) and, once these needs have been satisfied, the next level represents well-being such as family life, comfort, and purpose. Higher levels of need add self-realization or status. This model of consumer behavior has proved to be quite robust. Intensive research into the psychology and nature of consumers in various sets of circumstances has added to Maslow's Hierarchy of Needs, which has shown that people can behave differently in the presence of various sets of situational or environmental factors. This understanding has led to a huge increase in the sophistication and efficiency of the retail and service sectors.

The term *consumer* refers to a person who uses up or destroys some kind of resource. This was not previously considered problematic in an age in which the ability of humanity to dominate nature appeared to be both inevitable and a suitable solution to the growing level of demand within economies. However, as the pressure on the environment continues to increase and the strain becomes evident in terms of environmental degradation, global warming, and the limited levels of fresh water, the need to reform the understanding of the consumer has become more urgent. It is no longer possible to consider as acceptable the individual as a consumer who will participate in the Tragedy of the Commons. Instead, people and institutions are often reinvented as caretakers or husbands of resources, ensuring their sustainable use and development. This has led to conflict with commercial interests who profit by exploiting unsustainable resources and who believe that continued economic growth without constraints is a genuine possibility.

Consumption

CONSUMPTION CAN BE understood as the complex sphere of social relations and discourses that center on the sale, purchase, and use of commodities by individuals and households. Consumption, as more than an act of purchase, considers the range of practices and discourses through which people make and give meaning to goods and services, including choice and selection, rituals of use, resale, and disposal. While consumption implies the using up of things, it also involves the production of meaning, experiences, knowledges, or objects. Central to the notion of consumption is the commodity—a good, service, idea, or even person, which takes its form as an object of consumption and exchange. In capitalist societies, commodities exchanged through an economic system assume a use value (the capacity to satisfy a want or need) and an exchange value (the ability to command other commodities in exchange). However, because commodities both convey and create meaning, their consumption is equally about symbolic value. The meaning ascribed to commodities is also a significant part of the material culture of societies and their environments. Like commodities themselves, consumption practices and their meanings occupy different social and spatial "moments" as they are transformed over time and distances. This means that consumption, and its expression in different environments, can only be understood within specific contexts in which discourses and practices of politics, economics, citizenship, gender, race, age, and religion are involved.

Although societies are characterized by an abundance or paucity of commodities, consumption matters as part of individual wants, needs, and desires. Consumption has been an intrinsic part of social relations since humans first created, used and exchanged objects, but the emergence of "modern" consumption is said to have it's origins in 17th- and 18th-century Europe in societal changes that accompanied the Industrial Revolution. The development of new technologies, factory-produced commodities, the separation of production from consumption sites, and the emergence of new socialites and consumer practices around consumption evolved during this time.

However, it was during the 19th and earlier part of the 20th centuries that the sphere of consumption expanded rapidly, facilitated by the global extension of the capitalist mode of production, new technologies, burgeoning advertising and marketing industries, and wider availability of industrially produced commodities. In the 20th century, *commodification* (the process where more and more aspects of social life become subject to exchange in the marketplace) has been accompanied by social change directed toward consumerism. Consumerism entails the everyday lives of individuals becoming enmeshed in commodity acquisition.

CONTEMPORARY CHANGES

Over the second half of the 20th century, the sphere of consumption has become more complex, deepening and broadening to encompass new spaces, practices and relationships. More and more consumption is occurring in dematerialized spaces, via information and communications technologies, including the Internet. There are numerous consumption sites such as e-shopping, trading, and gaming. Internet auction site eBay, for example, set up in the United States in 1995, now provides a medium of consumption for tens of millions of registered users globally.

While themed shopping malls, fast-food restaurants, chain stores and commodified leisure activities are most often cited as evidence of the growing visibility of consumption in contemporary landscapes, they continue to evolve alongside other forms of consumption, many of which may be more mundane (outdoor/indoor markets, grocery stores, auctions, and secondhand commodity exchange) but none the less important. Consumers frequently service more of their own needs through consumption than previously (for example, automated tellers, via self-service retail outlets, and vending machines).

Consumption activities have also become subject to de-differentiation, where previously discrete consumer activities such as shopping and banking, medical services, travel, theme parks, and shopping malls now merge. The term *McDonaldization* has been coined to examine how this trend has become increasingly instrumental and rationalized due to predictability, control, efficiency, and quantification. Themes and visual activity in such spaces (such as video, live entertainment, and leisure activities) provide a means of re-enchanting such spaces and promoting both excitement and a point of difference for consumers.

EXTENSION INTO SOCIAL CONTEXTS

The significance of consumption in contemporary societies extends well beyond the individual consumer and their use of commodities. While consumption is commonly equated with "shopping" practices connected with identity, such a view is limited; as the sphere can involve a whole range of commodity practices involving goods and services connected with such things as daily needs, leisure, sport and recreation, tourism, housing, and education. The extension of the commodity form to more and more aspects of social life connects consumption with other social, political, and cultural formations. Marketers, advertisers, and designers of goods and services help reflect and create consumer taste, while simultaneously establishing particular modes, and norms of consuming. Spaces of consumption may also shape consumer identities and practices through surveillance and the regulation and representation of appropriate ways of consuming. Privately-owned shopping malls, for example, frequently masquerade as "public spaces," yet are often policed and controlled.

Consumption has a role in the constitution of a diverse range of social groups and institutions from the "family" to the "state." States, and other institutions in turn, also have a role in promoting or prohibiting forms of consumption (for example, encouraging patterns of consumption centered on particular constructions of gender, domesticity, and family), and in the making of consumer "citizens"—for example, patients and students constructed as consumers of medical and educational services respectively.

The increased significance of consumption discourses, practices and spaces in contemporary societies has been associated with the theorized emergence of a post-modern condition from the 1970s. As part of this condition, consumption is assumed to have a greater economic and political significance, having an important role in the formation of human desires. Commodities and their meanings provide individuals with a repertoire of identity choices. Consumption plays a role in the formation of lifestyle or consumer cultures, built around such things as fashion, food, leisure activities, and music; it also provides a social identity for movements built around ethical responses to consumption (such as Green consumerism, slow food movements, charitable organizations, and recycling groups).

However, a post-modern view of consumption as "identity shopping" centered on hedonistic, materialistic, and individualist consumerism is problematic. This concept tends to neglect the mundane and social reasons why people consume, ignoring that commodities also exist through noncommodified moments (as in gift-giving) and that some forms of consumption (such as the state providing housing, education, or health) do not center on the commercial purchase of goods.

There is considerable debate over the significance of consumption in identity formation and whether processes of consumption are actually new or simply an extension of much older relationships and practices. The rapid opening up of previously Communist-run European countries to commodification and new practices of consumption, for example, has not replicated the experiences of the new emerging capitalist economics in the 18th and 19th centuries.

Extension of capitalist relations of consumption and production in Russia, for example, have occurred unevenly—with access to many of the new forms of consumption and commodities concentrated in larger cities and accompanied initially by increases in inflation, crime, poverty, and social division. Rapid increases in car ownership have produced undesirable environmental effects, particularly in cities, exacerbating traffic congestion and contributing significantly to air pollution.

GLOBALIZATION AND CONSUMPTION

Contemporary change in consumption has been linked to processes of globalization, which result in increasing homogeneity and social and spatial convergence—for example, the serial repetition of consumer spaces such as shopping malls, theme parks, and fast food outlets, and global availability of brand-name commodities. Western ways of consuming and rising consumerism are assumed to erase social difference and diversity, subsuming local cultures, practices, and environments under processes variously described as *Americanization*, *Coca-colonization,* and *McDonaldization*. While globalization has exposed more people to a wider range of commodities and to different ways of consuming, the notion of global homogenization is partial, relying as it does on people and places as passive recipients of cultural change emanating from "outside" and failing to acknowledge the extent to which globalization is also a material practice, and one that also produces new kinds of difference in society and environment. Globalization may heighten inequalities in access to goods and services. It can also have a role in distancing people from the effects of their actions, spatially separating consumption and production processes, and removing their immediate social and environmental consequences from households and shifting the environmental costs of consuming to other institutions or places.

Consumption involves a whole range of commodity practices connected with such things as daily needs.

While globalization has meant many people have had greater exposure to a wider range of commodities and their meanings, the geography of consumption is uneven and contradictory. The Worldwatch Institute reports 60 percent of private consumption occurs in the 12 percent of the world population that lives in North America and western Europe, while the one-third living in south Asia and sub-Saharan Africa only accounts for 3.2 percent. Inequalities in access to resources, wealth, and ability to purchase cannot only be mapped between countries but within borders of nation-states as well. While consumption provides a medium for identity construction and choice, it can also operate as a source of social exclusion. In the United States, changes in desires and the expectation of a "good life," changing concepts of needs and wants, and a desire to "upscale" has been labelled *Affluenza*, yet the percentage of families going hungry or homeless continues to rise. Commentators argue rising consumer aspirations and purchases have both undesirable social effects (sweatshops, social polarization, debt, and poverty) and environmental consequences (landfills, resource depletion, pollution, and a decline in biodiversity from land development).

CONSUMPTION AND ENVIRONMENT

Though consumption is conceptualized as the selection, purchase and use of commodities by "final" consumers (individuals and households), debates about the environmental effects of consumption often include consumption by the public sector and the use of resource and material inputs by companies. The state may be a direct consumer of resources, but it may also naturalize particular forms and patterns of consumption (for example, through promulgating notions of consumer sovereignty, facilitating private home-ownership, or through differential taxing of goods and services). Similarly, firms consume resources, goods, and services as part of commodity production. The concept of an "ecological footprint" has been promoted as a means of measuring the consumptive capacity of populations. This involves calculating the amount of productive land and sea resources consumed by humans on different parts of the planet, and has been used to encourage reflection on consumption patterns as well as to speculate on future resource depletion.

SUSTAINABLE CONSUMPTION

While households and individuals are not the largest contributors to environmental degradation, consumer practices and preferences can be linked via commodity chains (particularly buyer-driven forms) to production processes and their environmental challenges. Individual and household consumption is nevertheless still significant, having steadily increased over the last two decades. Global expenditure by households on goods and services was more than $20 trillion in 2000, increasing fourfold since 1960. Harmful environmental affects result from the use of vehicles, food consumption, cleaning products, home heating and air conditions, and waste disposal practices. Increasing numbers of goods are used and discarded (including packaging), with the amount of municipal waste in Organization for Economic Cooperation and Development (OCED) countries expected to grow by 43 percent from 1995 to 2020. A consequence of the purchase of computer and electronic commodities, for example, is their discards often end up as stockpiles of toxic e-waste, a proportion of which is exported to countries with less stringent occupational and environmental regulations. While local people's economic livelihoods have become established around the reprocessing and sorting of computer, television, and mobile phone components, workers are frequently unprotected from the damaging effects of lead, cadmium, toner, mercury, barium, and beryllium common in high-tech waste; and these toxic elements may contaminate both ground and water supplies.

There is a diverse range of factors and institutions that both promote and constrain consumption practices. These include price, availability, policy and regulatory frameworks, media discourse, belief systems, processes of identity formation, lifestyle, purchasing patterns, gender, family and household structures, socio-economic status, education, technology, and infrastructure. Consumption is also influenced by moral dispositions, which can inform particular politics and agendas for change. Visible representations of "the hungry" in the media, for instance, may conjure polarized metaphors of under-consumption by the poor, or overconsumption by rich. Moral imaginings of consumption as greed and materialism, or more positive constructions of consumption in terms of caring, social justice, and ethical obligation, can both be used to promote politics of action designed to alleviate poverty and encourage sustainable resource use. While consumption is not intrinsically negative, it is important to recognize that individual consumption choices that may be morally good for some (such as purchasing a larger vehicle to transport more people at once, land clearance for self-provision of food) may be destructive for others (resulting in more pollutants, use of fossil fuels, deforestation, and greenhouse gas). Most of the negative consequences of consumption tend to occur at the regional or national level, so ascertaining how individual consumption choices leads to particular environmental consequences is not straightforward.

Altered moral dispositions about consumption influence how the negative environmental effects of consumption might be addressed. Viewing consumption solely as a matter of individual choice, for example, would suggest an appropriate action to reduce environmental effects would be to change the conditions in which people make consumption decisions via such measures as education, fuel taxes, or more public transportation. When consumption is understood as a social phenomenon, change might involve addressing particular social relations and norms such as the link between consumption of electronic commodities and marketing focused on disposability and fashion.

The recognition that sustainable consumption is a necessary component of sustainable development emerged from the United Nations Conference on Environment and Development and the publication of Agenda 21. Sustainable consumption does not necessarily mean the reduction of consumption, but involves changing patterns of consuming goods and services so as to minimize the use of natural resources, toxic material, and emissions of waste and pollutants. Individual governments have facilitated sustainable consumption through their legislation and policy, as well as international treaties such as the Kyoto Protocol and the Basal Convention on Hazardous Wastes. Nongovernmental organizations have also had a significant role in promoting more sustainable patterns of consumption, including the United Nations Environment Program and its Commission on Sustainable Development, and the Environment Directorate of the Organization for Economic Co-operation and Development. Yet institutional action and reform is only part of reducing environmental impacts of consumption. Questions about the sustainability of consumption cannot be separated from politics and economics, nor from how consumption is practiced, experienced, understood, and manifested by individuals in particular social and environmental contexts.

Continental Shelf

THE CONTINENTAL SHELF is the submerged outer edge of a continent. The shelf begins at the shoreline's low tide mark and slants gently beneath the ocean. At the outer edge of the shelf, a continental slope breaks downward to the great ocean depths. The maximum width and the depth of the shelf vary. The depth is generally less than 330 feet (100 meters) to 660 feet (200 meters) deep. The width varies from less than one mile (1.6 kilometers) to several hundred miles.

A continent's position relative to tectonic plate boundaries influences the width and depth of its shelf. A continent has a narrow shelf where it sits on the leading edge of a plate that collides with an oceanic plate. Jolting earthquakes and erupting volcanoes accompany the convergence. The crunch also causes downward movement (subduction) of the oceanic plate and creates a deep oceanic trench. The shelf is narrow because the collision causes the edge of the continent to rise and the continental slope to plunge sharply into the deep trench. River-borne sediments do not ordinarily accumulate in thick layers on the narrow shelf; they quickly slough off into oceanic trench. The trailing edge of the same continent is too distant to experience earthquakes and volcanic activity. As a result, its continental shelf slopes gently beneath the sea, where it accumulates thick layers of sediments carried to the ocean by eroding streams and glaciers.

The North American continent is a good example of a continent with both types of continental shelves. The west coast has a narrow continental shelf due to ongoing or relatively recent tectonic plate convergence. Conversely, North America's east coast is thousands of miles from the violent edges of conflicting tectonic plates, so its continental shelf sinks gently beneath the sea, and in some areas, it extends hundreds of miles offshore.

Sedimentary rocks of some continental shelves contain biogenous components (parts of dead plants and animals) that form hydrocarbon compounds, such as oil and natural gas. These fuels are the most valuable geological resources of the continental shelf. The offshore dredging of loose aggregates (gravel and sand) and the extracting of salt from evaporation ponds generate incomes locally. Additionally, coastal winds cause phosphorus and nitrogen-based nutrients to upwell from the shelf floor. As a result, some of the best commercial fisheries in the world occur in zones of coastal upwelling. Herring, sardines, and anchovies are the main commercial fish harvested from these areas. Oysters, clams, scallops, and mussels are the main shellfish varieties. Seaweed, which is an important food item in Asia and an additive in other foods, is the most important commercial plant harvested on continental shelves.

The management of resources of the continental shelf is vital to the security of national economies and to the global economy. Thus, most nations are signatories to the 1982 United Nations Convention of the Law of the Sea (or Law of the Sea Treaty). This treaty allows coastal nations to extend their control of the ocean's resources from their coastlines to 200 nautical miles (370 kilometers) and to as far as 350 nautical miles (649 kilometers), if the shelf extends beyond 200 nautical miles.

Continents

CONTINENTS ARE THE large dry landmasses of the earth. They are areas of continental crust atop subterranean areas of the lithosphere. The continental crust is thicker, but less dense than the oceanic crust, and is floating on the molten mantle. While the continents hold deposits of heavy materials such as iron or gold, they are mostly felsic materials that are lighter rocks composed mostly of silicate minerals, sodium, potassium, and aluminum. Each continent is connected to the oceanic crust or the sea floor that adjoins it. Continental margins are the sides of the continents. They are composed of the continental shelf, the continental shelf break, the continental slope, and the continental rise. The bottoms of the continental margins exist in the ocean basins as zones that are directly adjacent to a continent. They include the belt of continental crust and lithosphere that is in contact with the oceanic crust and its associated lithosphere. This is an area that often has an active plate boundary. Continental shelves are areas covered by relatively shallow seawater. Barrier islands are areas of sand built up on the continental shelf such as the barrier islands off of the coasts of Georgia or Texas.

The continental shelves surrounding the continents usually reach a maximum depth of 600 feet (200 meters). They extend from a few miles to several hundred miles from shore. At the outer limits of the continental shelf, there is a drop off called the continental shelf break. The transition from the gently sloping continental shelf to the deep ocean basin is called the continental slope. The continental shelf break marks the beginning of the continental slope, and occurs at an average depth of 430 feet (130 meters). The dropoff moves rapidly down thousands of feet to the boundary between the continental crust and the oceanic crust. Here, the ocean depth increases rapidly, reaching several thousand meters within a few kilometers. The continental rise is the gently sloping seafloor lying at the foot of the continental slope and leading gradually into the abyssal plain of the deep ocean floor. At the base of the continental slope is the boundary between the continental crust and the oceanic crust. Sediments washing over the edge of the slope or scraping off of a subducting plate form the slope. Generally, continental slopes located at active margins, for example the Chile Trench, are steeper than those located at passive margins like those in the Drake Passage.

PLATE TECTONICS

Continental shelf wedges are thick bodies of sediment formed by deposition on a subsiding passive continental margin in shallow waters of the continental shelf. Continental accretion is the increase in volume of the area of the continental crust due to the formation of granitic and andesitic rocks. These formations occur within mobile belts. They are also formed by collisions between continents that causes plate subduction and orogeny. The continents are all oceanic islands and include Africa, Asia and Europe, North and South America, Australia, and Antarctica. Asia and Europe are part of the same landmass, in which Europe is a branchy peninsula extending from Asia. Some islands such as Ireland, Britain, Greenland, Sicily, Sumatra, Java, New Guinea, and Tasmania are *continental islands,* areas of land that rise up from the continental shelf. Continental drift is an older hypothesis introduced by Alfred Wegener and others in the early 1900s. The hypothesis asserted that several hundred million years ago there was a single continent that Wegner called Pangaea ("universal mother earth"). It began to break up in the Mesozoic Era, and the pieces drifted apart to the present positions of the continents.

The current theory of plate tectonics is similar to continental drift, but not exactly the same. The continents have been compared to ships of rock that are "drifting" on plates of rock riding over the earth's molten core. The splitting of continents happens along rift fault lines. Continental ruptures occur when there is a doming up of the continental lithosphere and its crust to create a continental rift or rift valley. One of the most dramatic examples is the Great Rift Valley that begins in eastern Africa and runs through the Dead Sea Valley to Turkey. Continental rifts can also create continental rift islandssuch as the micro-continental islands of Madagascar, some of the Seychelles, and the Kerguelen Islands. Continents have varied features, which are mostly variations of plains or mountains. In addition, there are inland seas such as the Caspian, Aral, or the Great Lakes that are virtually freshwater seas. The vast areas of the continents allow for the formation of continental air masses, which can be polar, dry, or wet. These continental air masses may be dry if coming from the interior of a continent. Others may be moist equatorial air masses.

Continental divides are mountain areas on continents from which water flows to one ocean rather than to another. In the eastern United States, the continental divide separates waters that flow eastward to the Atlantic Ocean from water that flows west and then south to the Gulf of Mexico through the Mississippi River Valley. There are similar divides on other continents for waters flowing into the Pacific, Indian, or Arctic Oceans. Continental glaciers occur in high mountain areas where the temperature remains cold even in the summer. During ice ages, continental glaciers spread from a base location to cover enormous areas of continents. Continental shields are areas of continental crust, such as the Canadian Shield (Laurentian Plateau). It is a vast area of rock of igneous and metamorphic rock, most of it Precambrian or Archaean-age. In the case of the Canadian Shield, the rock was elevated above the sea and has never been covered with sedimentary deposits. Rock in the shield was exposed by the actions of continental glaciers, enormous ice sheets that covered much of the northern hemisphere in the most recent Ice Ages.

Continent collisions happen when plate tectonics brings continents into headlong contact. The ocean between them shrinks, causing a continential suture, a continental suture is a long, narrow zone of crust deformation. The Himalayan Mountains and the European Alps are being pushed ever higher by under-thrusting and intense folding as India drives into the Asian continent or as the African continent moves toward Europe. Continents are sometimes subdivided by geographers into subcontinents, such as the Indian subcontinent. Because the continents are isolated from one another, different fauna and flora have developed on each continent.

In recent years, there has been a general rethinking of the categorical status of continents. Geographer Martin Lewis and historian Kären Wigen have argued, for example, that for the most part, our distinction of continents (Asia from Europe as a most egregious example) has been historically conditioned by social and cultural preconceptions, rather than tectonic or biogeographical considerations. Insofar as Europe, Asia, and Africa are part of one land mass, and South and North America are contiguous, the insistence of historians, geographers and others to distinguish them must be seen as part of larger historical habits including Orientalism (imposing essential definitions of East and West) and colonialism. Continents in most respects better reflect historical worldview than distinct metageographic realities.

Contingent Valuation

CONTINGENT VALUATION (CV) is a method used to estimate an economic value for goods and services that aren't typically bought and sold in the market. Most commonly, CV has been used to estimate values for environmental goods and services, such as endangered species, improved air and water quality, open space provision, wilderness areas, outdoor recreation opportunities, and other types of environmental amenities. To a lesser extent, CV has been applied to estimate values for cultural heritage, health care, and public education. During the last 25 years, CV has been used by many agencies with environmental responsibilities, including state and federal agencies in the United States and over 50 foreign governments and international organizations. The majority of the studies have been conducted to facilitate policy analyses, though more prominent applications have included natural resource damage assessment cases such as the Exxon Valdez oil spill.

The primary goal of the CV method is to create a hypothetical market for a good or service and elicit, via a survey, people's economic value for that good or service. In the survey, different states of the world are described to a respondent, and they are then asked about their preferences for one or more of the states described. As a simple example, a survey might describe a treatment to improve air quality, and then ask respondents how much they would be willing to pay for this air quality improvement. If respondents are truthful, their answers reflect their economic value for the described change. This value is often referred to as *willingness-to-pay,* or WTP. Conversely, the survey may ask respondents how much monetary compensation they would require in order to accept a decrease in air quality. This measure is referred to as *willingness-to-accept,* or WTA. Though asking respondents open-ended questions about their WTP or WTA is a straightforward approach, it is not the approach favored by most survey researchers working in the CV field. More often, respondents are given a choice question to elicit their preference for the good. Generally, in CV studies the choice question asks respondents to either (a) say yes or no to paying a specified dollar amount for a proposed change, (b) vote for or against a referendum that would bring about the proposed change at some additional cost to the respondent, or (c) support or not support a program that would bring about the proposed change at some additional cost to the respondent.

The CV method has been in use for over 20 years, and more than 2,000 papers have been written on the topic, though not without debate. Much of the criticism stems from the hypothetical nature of the survey and the potential bias this may induce. Some evidence has shown that what respondents state they are willing to pay in a CV survey may be considerably larger than what they actually pay, while other studies have shown that values produced from CV studies compare favorably with actual donations. Debate has also ensued as to whether respondents get moral satisfaction from paying for an environmental good, independent of the characteristics of the good itself, a concept referred to as a *warm-glow effect*. Other criticism focuses on strategic behavior on the part of the respondent by either yea-saying (saying yes in order to please the interviewer), or nay-saying (saying no even though the respondent has a positive value for the good in question).

The controversy surrounding CV use has led to a more thorough understanding of both the limitations and the appropriate uses of the method. In 1993, a panel of experts sponsored by the National Oceanic and Atmospheric Administration and chaired by Nobel Prize winners Kenneth Arrow and Robert Solow convened to review the CV method. The panel determined a set of guidelines to help ensure the reliability of CV surveys, and ultimately concluded that, when guidelines are followed, CV studies can produce reliable estimates of economic value.

Convention on Biological Diversity (CBD)

THE CONVENTION ON Biological Diversity (CBD) is an international treaty signed by a coalition of 153 countries at the 1992 United Nations Conference on Environment and Development (UNCED). The convention became officially recognized in December 1993 and has 188 members. The United States is the only country that has signed but not yet ratified the CBD. Based on the principle of sustainable development, the main goals include "the conservation of biodiversity, the sustainable use of its components, and the fair and equitable sharing of the benefits arising from the utilization of genetic resources." Member countries, adopting a precautionary principle approach, are legally required to create plans for identifying and protecting biodiversity, restoring degraded areas, and preventing possible impacts of the introduction of nonnative species and genetically modified organisms into the environment. The convention also recognizes the importance of public participation and protecting the rights of traditionally marginalized communities most directly affected by environmental threats. To do this, it sets a framework utilizing both economic criteria (based on the market value of environmental resources) and noneconomic factors, such as cultural significance, to determine the value of biodiversity as well as the risks and benefits of economic growth.

The governing body of the CBD is the Conference of Parties (COP). Made up of representatives from all member countries, the COP is responsible for identifying priorities, proposing plans of action, reviewing national proposals, and coordinating with international institutions. It also has the authority to create advisory panels like the Subsidiary Body on Scientific, Technical and Technological Advice (SBSTTA), a group assisting with and assessing the convention's implementation. As of 2006, the COP had eight regular meetings with focuses ranging from protecting marine, forest, and agricultural diversity to examining technological cooperation and intellectual property rights. In 2002, the COP adopted a strategic plan for meeting the three goals of the convention, aiming to achieve a broad reduction in the rate of biodiversity loss by 2010.

In addition, the COP called an extraordinary meeting in 2000 to introduce a supplementary agreement to the CBD, the Cartagena Protocol on Biosafety, which came into force September 2003. By April 2006, 132 countries had ratified the protocol that established rules on the transboundary movement, handling, and use of genetically modified organisms (GMOs). Expressing the mandate of the CBD, member countries are encouraged to adopt a precautionary principle approach in assessing the potential environmental, human health, and socioeconomic risks of GMOs. There have been a number of measures taken to facilitate national capacity building, including financial support and the establishment of the Biosafety Clearing-House, an online database for international information exchange.

CONFLICTS AND OBSTACLES

Nevertheless, there are numerous obstacles to the implementation of the CBD and the Cartagena Protocol. Primarily, efforts at strengthening national mechanisms for biodiversity protection have come into conflict with the World Trade Organization (WTO) over the regulation of biotechnology. The WTO, adopting U.S. regulatory views on the safety of genetically modified products, has focused on opening international markets and protecting intellectual property rights for biotech corporations. In contrast, the Cartagena Protocol establishes a framework for countries to adopt stricter scientific criteria for determining acceptable risk, allowing the refusal of genetically modified products until their safety can be proven. In this sense, the protocol acts as a counterweight to the WTO by augmenting the bargaining power of developing countries. This conflict is evident in a recent $38.4 million biosafety project carried out in 123 countries to fulfill the requirements of the Cartagena Protocol. Sponsored by the United Nations Environmental Program (UNEP) and the Global Environmental Facility (GEF), the goals are to create national legislative and decision-making systems for biotechnology regulation.

In Guatemala, public consultations opened a space for struggle over possible environmental, human health, and socioeconomic risks and benefits of agricultural biotechnology. Although not resolving intense national disagreement, Guatemala was one of the first countries to complete the project, resulting in a protocol that could form the basis for future legislation. In October 2005, though, the U.S. Department of Agriculture (USDA) Foreign Agricultural Service began a technical review process, revising the proposed UNEP-GEF legislation to reflect U.S. regulations and excluding civil society groups. While the USDA argues that the national proposal exaggerates the potential risks of the technology and would hinder free trade, Guatemala's program representatives believe the protocol was based on sound scientific evaluation and negotiation between different civil society groups and that the suggested revisions threaten national sovereignty.

These problems also illustrate conflict within the CBD itself that arose during its negotiation from 1989–92 between southern and northern countries. During this time, debates over the control of genetic resources led to ambiguously worded articles recognizing both the sovereignty of southern countries and local communities in decision making and the authority of international trade norms. Although the environmental movement has been influential in shaping the implementation of the CBD since then, conflicts in its creation further reflect internal tensions over contrasting views of development and conservation. On one hand, the CBD adopts the tenets of green environmentalism, which critics assert reduces biodiversity to a commodity traded on the world market. In the case of biotechnology, the CBD has helped codify the rights of transnational corporations to reap the profits of biodiversity, while local communities see little benefit. On the other hand, it has created spaces for southern states and social movements to negotiate alternative views on the cultural and socioeconomic value of nature and the potential risks of current economic growth strategies to biodiversity.

Convention on International Trade in Species of Wild Flora and Fauna (CITES)

ILLEGAL TRADE IN endangered wildlife and flora is having a significant negative impact on the world's biodiversity. To try and reduce this impact, the World Conservation Union signed the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES). After ten years of negotiations, the text of CITES was finally agreed at a meeting of representatives of 80 countries in Washington D.C., on March 3, 1973. It entered into force on July 1, 1975. Today, CITES has been endorsed by over 166 countries. The aim is to "protect endangered species…from overexploitation by regulating or prohibiting their international trade." This is done by subjecting selected species to certain controls and regulations, including a ban on the trading of live animals or body parts.

Appendix I of CITES bans the commercial trade of over 800 endangered species. Among the 167 Members Species, those usually threatened with extinction include the slipper orchids, leatherback turtles, cuscuses, and gorillas.

Appendix II permits trade in approximately 32,500 listed species, but requires an export permit verifying the species were legally obtained, and the contents are not detrimental to the survival of the species. While not threatened with extinction, these species nonetheless face real challenges to their survival if unregulated trade continues. Appendix III permits trade but requires exporters to declare that their shipments were acquired legally.

The trade of species listed in CITES Appendices II and III (1995–99), included over 1.5 million live birds, almost 300 tons of caviar, 1 million pieces of coral and 21,000 hunting trophies.

Since its inception, the CITES Secretariat has forged strategic alliances with other parties. For example, there is the Memorandum of Understanding between the CITES Secretariat and the Secretariat of the Convention on the Conservation of Migratory Species of Wild Animals. TRAFFIC is a wildlife trade monitoring network that assists in the implementation of CITES.

Wildlife trade is an inherently political issue, and is worth billions of dollars each year. Consequently, CITES often attracts contention, especially in light of the complex social and economic consequences that arise from the imposition of regulations on the trade of certain species. For example, following the slaughter of an estimated 700,000 elephants in 10 years (for ivory products), there was a 50 percent drop in their population numbers. CITES placed an international ban on the trade in ivory and other elephant products in September 1989. While the CITES ban on trade in elephant ivory is credited with helping elephant species recover and decreasing poaching, the remaining stockpiles (prior to the 1989 ban) offered economic opportunities to nation states that the ban prevented from exploiting. This factor, combined with rising elephant numbers, led CITES to relax its ban on the sale of ivory tusks in 2002. This has caused dismay in conservation circles, as there has since been an upsurge in illegal trafficking of elephant ivory.

Critics of CITES argue that trade is an ineffective tool for species conservation, there are no mechanisms to account for the volume of illegal trade that still occurs, nor any mechanisms to protect species that are not listed in any of its Appendices.

Nonetheless, CITES provides some protection to over 30,000 species of flora and fauna and continues to play a central role in ensuring that international cooperation is achieved to protect certain species from overexploitation and ultimately extinction.

Most of the world's coral reefs, while useful to humans in many ways, are in trouble mainly due to human impacts.

Coral Reefs

CORAL REEFS ARE massive and complex structures made of limestone that is deposited by living sea organisms. The reefs are mainly composed of the skeletons of tiny, fragile animals called coral. Although there are hundreds of different species of corals, they are generally classified as either "hard coral" or "soft coral." Hard corals grow in colonies. Their skeletons are made out of calcium carbonate, which hardens and eventually becomes rock (i.e., coral reefs). Soft corals are nonreef building corals often resembling plants or trees.

Coral reefs are found in over 100 countries and cover an estimated total area of 109,700 square miles (284,300 square kilometers) worldwide. Most reefs are located in oceans between the Tropics of Cancer and Capricorn, but they are also found farther from the equator in places where warm currents flow out of the tropics (such as Florida and southern Japan). Corals prefer clear and shallow waters where sunlight filters through to their symbiotic algae. Other factors affecting their growth are salinity, turbulence, and the availability of food.

Coral reefs are one of the most spectacular, complex, highly productive, fragile, and biologically diverse ecosystems on the earth. They cover less than 1 percent of the ocean floor but support around 25 percent of all marine life, including over 4,000 species of fish, 700 species of coral, and thousands of other plants and animals. The reefs are useful to humans in several ways. The rich biological diversity of reefs is a natural treasure and a key part of the natural heritage of the world. The interlinked network of species supported by coral reefs has long been a significant source of food for millions of people living in tropical coastal areas and islands. Unique chemical compounds found in coral reef organisms have been used to produce several important drugs including AZT, a treatment for people with HIV infections. Coral reefs form natural breakwaters protecting the fertile coastal lands and human settlements of many island and continental nations from the pounding of ocean waves. The beauty of the coral reefs has long been a source of wonder to people. Many countries with coral reefs generate significant portions of their income through tourism. The reefs are also directly linked with traditional spiritual and cultural values of many people who live in reef areas.

Most of the world's coral reefs are in trouble due mainly to direct human impacts, such as overfishing or destructive fishing, mining of coral and dredging of sand and gravel for construction and industrial use, soil erosion and use of pesticides for agriculture on lands draining into coastal coral reefs, intensive and ill-considered coastal development activities with hotels and infrastructure, discharge of sewage, collection of specimens by and for visitors, and international trade in ornamental corals and shells. It is estimated that around 20 percent of the reefs have been effectively destroyed beyond likelihood of recovery; 24 percent are under imminent risk of collapse; and a further 26 percent are under a longer-term threat. Long-term changes in the oceans and atmosphere, natural stresses of highly variable seasons, severe storms, earthquakes, volcanic eruptions, and increased incidence of coral diseases are other reported factors behind the reefs' destruction. Many coral reefs (approximately 40 percent) that were seriously damaged in the 1998 El Niño/La Niña global coral bleaching event are either recovering well or have recovered, especially well-managed and remote reefs. Scientists, however, fear that this recovery could be reversed if the predicted increases in ocean temperatures occur as a result of increasing global climate change.

Scarcity of resources, poor awareness, poor enforcement, inadequate political will to tackle difficult environmental problems, and lack of coordination among countries that have reefs are some of the major barriers in effective conservation of coral reefs. Many coral reef countries lack trained personnel, equipment, and financial resources to effectively conserve coral reefs, establish marine protected areas, and enforce regulations. This lack of resources is often exacerbated by a poor awareness of the problems facing coral reefs and their significance in local economies and related ecosystems.

Most of the human activities causing loss or degradation of coral reefs are believed to be the result of ignorance rather than deliberate actions. A crucial approach toward conserving the coral reefs and improving their management, therefore, is to spread awareness among government and business officials as well as the general population of the importance of coral reefs and related ecosystems and to encourage communities, companies, and governments to take steps to protect them. Community leaders and decision makers should become familiar with the issues of coral reefs, marine environments, and resource protection so that these can be reflected in planning and policy. In particular, the issue of incorporating the full environmental and waste management costs of programs and developments should be recognized and addressed early in the policy planning process.

There have been some new initiatives toward the conservation of coral reefs in recent years. The World Summit on Sustainable Development (2002) called for a major international effort to reduce losses in biodiversity, including the biodiversity on coral reefs. Some international nongovernmental organizations (NGOs) are responding to this call by combining their expertise and resources to establish networks of marine protected areas and improve management capacity, particularly in high biodiversity regions of southeast Asia and western Pacific. Some of these NGOs have developed rapid assessment methods to select sites for urgent protection and also designed tools to assist resource managers protect reefs from global change stresses.

Costa Rica

COSTA RICA IS home to approximately four million people and covers 19,344 square miles (50,100 square kilometers). Its geographical smallness belies immense physical diversity; Pacific and Atlantic oceanic influences combine with three mountain ranges to support a wide variety of plant and animal life. Within the Costa Rican parks system, an estimated 500,000 to one million species of flora and fauna are protected, and Costa Rica is ranked as one of the most biologically diverse countries in the world.

Costa Rica is often seen as an anomaly in Central America. Politically, it has a long history of democracy and has enjoyed peace in a region plagued by civil wars, most recently in the 1980s and early 1990s. Following one short civil war in 1948, Costa Rica's army was disbanded. Socially, Costa Rica has experimented with a welfare state. A social security system, labor code, and universal health care and education were all implemented in the 1940s. Economic restructuring in the 1990s and 2000s has entailed cuts to many social programs and resulted in some social unrest. In spite of these cuts, in 2003 Costa Rica ranked 47th on the United Nations human development index, highest in Central America and outranked only by three countries in all of Latin America and the Caribbean.

ECONOMICS AND ENVIRONMENT

Economically, Costa Rica has facilitated economic growth via an export-oriented economy, centered traditionally on coffee and bananas, but dominated by tourism since the early 1990s. While Costa Rica experienced a debt crisis in the early 1980s, it recovered relatively quickly compared to other countries in the region. Low prices for coffee and bananas have continued to hurt the agricultural sector, but this has been offset to some extent by continued growth in tourism and recent and rapid growth in electronics manufacturing. Nevertheless, the government grapples with internal and external deficits and internal debt.

Environmentally, Costa Rica has cultivated a "green" image and it is recognized as a leader in the region for its extensive environmental laws. Twenty-eight environmental laws were passed between 1965–85, predating much of the international attention given to the environment in the late 1980s and early 1990s. More recent laws include the 1995 Organic Law of the Environment and the 1998 Biodiversity Law. While such laws undoubtedly contribute to Costa Rica's green image, the centerpiece is its extensive system of parks and protected areas. Costa Rica protects 23.4 percent of its land in 158 protected areas recognized under the various categories used by the World Conservation Union (IUCN); this is in great contrast to the 8.3 percent of land protected in Central America and the Caribbean and the 10.8 percent protected globally.

CRITICAL PARK SYSTEM

The parks system is critical to the country's tourism industry. Costa Rica began investing in tourism in the 1950s, when it established the Costa Rican Tourism Institute, declared tourism an industry, and offered incentives for investors. Since then, tourism to Costa Rica has grown consistently. The boom in tourism began in 1986 and international tourist arrivals grew at an average of 14 percent per year until 1994, with peak growth of 27 percent in 1992. In 1999, tourist arrivals surpassed one million for the first time, and growth has continued at an impressive rate (17 percent in 2004).

Political, social, and economic stability have played a role in the development of tourism, as all are attractive to tourist and investors alike. While these factors may have influenced growth rates initially, the global rise in popularity of ecotourism has undoubtedly played a major role since the late 1980s. Costa Rica has been described as *the* ecotourist destination and as ecotourism's "poster child." In the region, perhaps only Belize equals it as a perceived ecotourism hot spot.

The Costa Rican parks system is also used for bioprospecting. The Costa Rican National Institute of Biodiversity was formed in 1989 to manage emerging bioprospecting activities. One of the most publicized deals was made with U.S.-based pharmaceutical firm Merck and Co. in a series of three contracts from 1991–99. With these and other bioprospecting deals, a portion of research budgets and Costa Rica's share of any royalties are directed to the national parks system. As with tourism, Costa Rica's parks system combined with its political, social, and economic history to attract bioprospecting deals. For example, Merck acknowledges that, in choosing a partner for biodiversity prospecting, socioeconomic features of Costa Rica were as important in the choice as was the level of biodiversity and the parks system.

While central to both tourism and bioprospecting, Costa Rica's parks system is not without problems. Environmentally, Costa Rica's national parks system is juxtaposed with degradation outside of its boundaries, particularly through high levels of deforestation, one of the highest levels in the region. Deforestation has meant that Costa Rica's protected areas often exist as isolated "islands." A 1991 restructuring of the protected areas system by joining smaller separate areas together into larger Regional Conservation Units may have partly redressed the "island" problem. Some environmental problems have been caused by ecotourism itself; the parks system is generally recognized as overtaxed by high levels of tourist visitation, especially at some sites, and as understaffed and underfunded overall. Attempts by the national park agency to increase revenues derived from tourism (e.g., by raising entrance fees) have been resisted by the tourism industry, and the park system continues to rely partially on funding from a variety of external donors, including conservation organizations and bilateral and multilateral assistance agencies.

Socially, local support for protected areas has often been lacking. Resistance has been encountered throughout the park system's history, from the establishment of the first national park in 1971. Four factors are generally identified as contributing to social tensions. First, protected areas have often been created without prior consultation with local people, who lose access to resources through parks creation. Second, compensation for lost land has often been inadequate, delayed, or nonexistent. Third, due to high population growth rates, high population density, and increased levels of private landownership, landless peasants have increasingly been forced to encroach on protected areas. Finally, restrictions on resource use in reserves work against

Impressive National Parks

The Central American country of Costa Rica has a Pacific Ocean and Caribbean Sea coastline, and has twelve distinct ecological zones. As a result, it has a wide diversity of plant and animal life, with an impressive conservation record and a large number of national parks. In recent years there have been a large number of tourists visiting the country.

Costa Rica established its national parks from the 1960s, and there are now about 35 in the country, covering 13 percent of the land area. They are maintained by the Servicio de Parques Nacionales in San José, the capital. Along with buffer zones and forest reserves, which are not fully protected, the total area regulated comes to 27 percent of the country.

The most well-known national park in the country is probably Santa Rosa, in the northwest of Costa Rica, along the west coast. It has tropical dry forest, abundant wildlife, and good beaches. It also allows campers.

Another popular national park is the Parque Nacional Volcán Irazú located around the Irazú Volcano. It last had a minor eruption in 1963, when over an inch of volcanic dust was dumped on San José. The Parque Nacional Volcán Poás which is also located around a volcano. It emitted some volcanic ash in 1989 and again in 1995, but has been quiet since. Because the parkland in both parks are largely on volcanic soil, the flora is particularly good, and there are many twisted trees in the latter, much photographed by tourists. The Parque Nacional Rincón de la Vieja has an active volcano in it, with nearly 300 different species of birds recorded in the park.

Other national parks in Costa Rica include the Parque Nacional Palo Verde, which is a major bird sanctuary; the Parque Nacional Tortugero on the Caribbean coast, where many green turtles breed; the Parque Nacional Cahuita, which has a small coastal rain forest and a coral reef; and the Parque Nacional Chirripó, which has the highest mountain in the country.

small farmers, while major logging and hydroelectric schemes continue. Rather than attempt to overcome these limitations, the government appears to rely on nonenforcement to avoid or reduce tensions with local communities, and this, combined with financial constraints, means that some protected areas exist only on paper.

Both ecotourism and bioprospecting have the potential to increase local support for parks and protected areas, through providing employment and income opportunities. However, many government policies have promoted large-scale, foreign-owned tourism development, and there is evidence of high levels of leakage and low levels of local ownership at many ecotourism sites. Bioprospecting deals in Costa Rica and elsewhere have been critiqued as inequitable, with the majority of benefits accruing to pharmaceutical companies. Local employment (in positions as "parataxonimists") is fairly minimal (only 30 people in the early 1990s), and there is the additional complication of how local knowledge is treated and valued; while parataxonimists are paid wages for their services, intellectual property rights to resultant products are ceded to pharmaceutical companies. Thus, as of yet, neither tourism nor bioprospecting appears to have met their full potential vis-à-vis benefiting local communities.

Cost-Benefit Analysis (CBA)

COST-BENEFIT ANALYSIS (CBA) is an economic technique for assessing the efficiency of a given project, whether it is a policy, construction, or other activity. The general CBA methodology involves identifying all costs of implementing the project and all benefits that will arise from the project and making a comparison. CBA is widely used by business and government to assess whether or not a project should be undertaken or to select the best choice or priority ranking among a group of options.

The initial step involves identifying a baseline from which to measure costs and benefits. The baseline might be the conditions if no project is undertaken or the conditions if the best project assessed-to-date is undertaken. Next, the affected parties and region of concern must be identified. These are the stakeholders that will bear the costs and/or experience the benefits of the project. A time frame over which costs and benefits accrue is necessary to identify the full stream of costs and benefits into the future. Future costs and benefits are not equivalent in value to present costs and benefits, necessitating choice of a discount rate for calculating the present value of future costs and benefits. The U.S. Office of Management and Budget sets a discount rate of 5 percent for federal projects, but some argue that the discount rate should be lower than this for resources that are not easily replaced such as natural resources. High discount rates can make the value of resources in the future low, raising equity issues with future generations.

Once all necessary information has been gathered, each category of costs and benefits should be summed following proper discounting. If the net benefits of the next best option are known, they should be included as a cost, the opportunity cost of the project. Opportunity costs can also be considered the net benefits of how funds would be spent if the project is not undertaken. The present value of all costs should be subtracted from the present value of all benefits, giving the net present value of the project. If the result is positive, the project is economically efficient. For easier assessment across projects, a benefit-to-cost ratio can be calculated. A related technique, cost-effectiveness analysis, involves comparing costs across options for a given quantity of benefits. Cost-effectiveness analysis is used particularly when benefits are difficult to quantify but have been deemed desirable and justify costs.

GROWING USE

CBA has grown in application since the 1930s when it was introduced by the U.S. federal government for assessing proposed flood control and water projects. A wide range of state and federal legislation requires that projects meet CBA efficiency tests, including the Toxic Substances Control Act and the Federal Insecticide, Fungicide, and Rodenticide Act. The U.S. executive branch has issued orders that federal agencies must conduct cost-benefit analyses of rules to be issued, although the particular implementation of this order is controlled by the current president. Additionally, though, several pieces of federal legislation regarding environmental policy explicitly disallow the use of CBA, such as sections of the Clean Water Act, the Clean Air Act, the Endangered Species Act, and the Resource Conservation and Recovery Act. This is typically because the costs of inaction are deemed unacceptable.

While CBA is a straightforward and typical initial step in economic assessment, critiques exist. Certain shortcomings of the technique demand additional consideration or analysis, particularly when assessing environmental and social factors. The full range and extent of consequences of a project with environmental impacts are not easy to predict. Environmental and human health benefits are typically difficult and controversial to quantify in monetary terms. It is often hard to determine the full range and extent of environmental and social impacts. Furthermore, most environmental and social costs and benefits do not have readily accepted values. Therefore there is a tendency to underestimate, including only the readily identifiable values, and values employed are more difficult to justify and verify than those with documented market-determined values.

A variety of techniques have been developed by economists to determine values of environmental impacts. These include stated preference techniques such as conjoint analysis and contingent valuation that directly ask individuals questions designed to elicit preferences and willingness to pay for benefits. Travel cost and hedonic pricing techniques use revealed preferences via market expenditures to determine the values that individuals hold for various environmental amenities. Examples for estimating a park's value would include respectively determining the amount spent to visit the park and real estate price differences.

Environmental and social impacts also face problems of short planning horizons and future value discounting. When benefits are likely to accrue to future generations, such as under projects to slow climate change, discounting might lead to large future benefits assessed as low values at the present. Also, when projects permanently remove an environmental amenity, such as dams and downstream river recreation, the long-term future stream of costs to society carry little weight.

The distribution of costs and benefits and associated equity considerations do not garner explicit measurement in CBA. Therefore, costs might largely fall on one segment of the population, while benefits accrue to another. One project might provide a high net financial benefit, while a separate project provides less overall benefit but a much larger swath of society experiences some benefit. Various theories on taxation on market forces might dictate allocating all benefits to a certain segment of the population for financial return purposes. The same benefit allocated to different individuals might have different total welfare benefits. For example, based on marginal analysis and diminishing returns, one might expect that someone who already has a large amount of a given resource will not benefit as much from an additional unit of that resource as would someone who has very little of it.

Cotton

COTTON REFERS TO a plant and also to the fibers from the plant. Cotton plants are shrubs in the genus Gossypium, characterized by seed capsules ("bolls"); in some species the seeds are attached to cellulose fibers. The fibers, which may have evolved to help disperse the seeds by attracting nest-building birds, attracted early human interest because they are flat, convoluted and so spinnable into thread. This property led to a remarkable history which included pivotal roles in ancient trade, the Industrial Revolution, New World slavery, the pesticide revolution, the spread of genetically-modified crops into developing countries, and world trade disputes. Cotton is the world's most widely used natural fiber, with a popularity that cuts across class, culture, and geography. However, its history has a dark side, and the political economy and ecology of cotton today are problematic.

Four Gossypium species were domesticated in prehistory. The diploid New World species G. *barbadense* and G. *hirsutum* were being used for textiles by 3600 B.C. (Barbadense in Chile, Hirsutum in Mexico). Sea Island cotton is a famous variety of G. *barbedense*, noted for a long staple (fiber length) that binds into thread especially well. Cultivation of G. *barbadense* is mostly restricted to lowland areas. G. *hirsutum* is more amenable to widespread production; hirsutum fibers are somewhat shorter (although still longer than Old World cottons). The Old World gave us the tetraploid species G. *herbaceum* and G. *arboreum* (tree cotton), both of which may have originated in Africa. Both were in use in the Indus Valley by around 2000 B.C. New World hirsutum varieties have mostly replaced local arboreum and herbaceum in cotton production in the Old World, largely due to colonial agricultural programs.

India dominated the global market for cotton products for over one thousand years; Greek and Roman ships sailed under sails of Indian cotton. Early writers, including Herodotus, described the wondrous wool-bearing tree of India, leading Europeans to depict the plant as a chimera with actual sheep growing on it. Once oceanic trade routes connected Europe to the East Indies in early 1500s, commerce in cotton textiles greatly increased. India continued to dominate this trade, providing high-quality calicoes and muslins were that highly desired in Europe.

Cotton was instrumental in the Industrial Revolution. By the end of the 18th century, England—which previously had engaged only in small-scale, cottage-based textile production—had assumed dominance of cotton weaving. This was the combined result of key inventions, the emergence of

Cotton has been interwoven with more important and troubling threads of history than perhaps any other plant.

capitalists, and state policy. Key inventions from the 1770s–1870s included the spinning jenny (which boosted thread weaving), the water frame (which wound the thread onto rollers), the "mule" (which allowed these functions to be powered by steam engine), and the power loom. These inventions facilitated the development of textile factories, organized by early capitalist entrepeneurs. The state provided protection by banning the East India Company from importing calicoes. England's demand for cotton to feed its textile industry stimulated production of hirsutum cotton in the U.S. south, especially after the 1793 appearance of Whitney's gin, which allowed rapid separation of fiber from seed. Cotton became a key driver of U.S. economic expansion, accounting for half of exports by the mid-1800s. These events also led to a sharp rise in demand for slave labor in the southern states, raising the cost of slaves and stimulating slave trading after the 1807 ban on this activity.

The ecological problem in cotton cultivation is predation by a wide range of insect pests, including weevils and bollworms that devour bolls, and "sucking insects" that feed on sap. Cotton absorbs more insecticide than any other single crop, and in some areas it uses as much as all other crops combined. Cotton is the ultimate "pesticide treadmill" crop; its pests often develop resistance to insecticides and force development and use of new pesticides. In India, with the largest area in cotton cultivation, this crop accounts for five percent of farmland but absorbs over 40 percent of pesticide. Pesticide resistance is a severe problem that continues to play a role in suicides by bankrupt Indian cotton cultivators.

These problems of the cotton pesticide treadmill have created a niche for crop genetic modification, a major early accomplishment of which was the insertion of an insecticide-producing gene into cotton (and several other crops). "Bt cotton" (named for the bacterium *Bacillus thuringiensis* in which the gene originated) was widely adopted in the United States in the late 1990s, and by the early 2000s it was leading the march of genetically modified crops into developing countries, especially China and India.

Cotton has also been at the center of global trade disputes. During an era of trade liberalization and reduction of agricultural subsidies in some countries, the United States has continued lavish cotton subsidies, leading U.S. farmers to expand production despite low global prices. It has been pointed out that U.S. cotton subsidies were literally (if indirectly) killing farmers in Africa and elsewhere, and this situation has galvanized opposition among developing countries. In 2004 the World Trade Organization ruled the U.S. subsidy illegal (in a challenge filed by Brazil), but by two years after the ruling, little had changed.

In a major public relations campaign, advertisements sang that cotton was "the fabric of our lives." This is perhaps truer than most people realize, as this plant and fiber has been interwoven with more diverse, important, and troubling threads of our history than perhaps any other plant.

Cradle-to-Grave Regulation of Hazardous Waste

THE TERM *CRADLE-TO-GRAVE* refers to an environmental policy of managing hazardous industrial wastes from their point of generation (cradle) to their final disposal location (grave). The cradle-to-grave provisions for managing hazardous waste are found in Subtitle C of the Resource Conservation and Recovery Act (RCRA), which regulates the generation, transportation, storage, treatment, and disposal of hazardous wastes. RCRA, enacted in 1976, was a departure from earlier legislation such as the Clean Water Act and Clean Air Act, which primarily regulated pollutants at the "end-of-pipe."

All companies, big and small, generate wastes, ranging from everyday items such as fluorescent lights and batteries to industrial wastes such as paints, plating solutions, and pesticides. In the United States, it was once legal to dispose of hazardous wastes in unlined landfills or dumps, where they often contaminated lakes, streams, and underground aquifers.

RCRA, an extension of the Solid Waste Disposal Act of 1965, was enacted in response to increasing concerns over the health dangers posed by the disposal of industrial wastes. Its waste management provisions were a departure from other environmental legislation. Its goals are threefold: to make sure that wastes are handled in a manner that protects human health and the environment; to reduce the generation of hazardous waste; and to encourage recycling and conservation of natural resources. RCRA is especially concerned with mitigating the impacts of waste disposal in landfills or dumps, where wastes can seep into groundwater and contaminate drinking water supplies.

There are six basic elements of hazardous waste management under RCRA: (1) generators must identify the types of wastes produced; (2) wastes must be managed safely on site; (3) wastes must be tracked using a manifest system to ensure that wastes reach their final destination; (4) all hazardous waste treatment, storage, and disposal facilities (TSDF) must be permitted to ensure their safe operation; (5) TSDFs must follow U.S. Environmental Protection Agency (EPA) guidelines for acceptable disposal and treatment options; and (6) generators, transporters, and TSDFs are subject to government enforcement action if regulations are not followed.

A generator must first determine if it has generated a s*olid waste,* defined in part as "any garbage, refuge, sludge … or discarded material" whether or not the waste is in a solid, liquid, or gaseous form. The generator must then determine if it has generated a "hazardous waste."

A solid waste may be determined to be hazardous if it either exhibits one of four hazardous characteristics (ignitibility, corrosivity, reactivity, or toxicity), or it is on one of four lists of waste. The lists of wastes are referenced as the F-list (nonspecific source wastes), the K-list (specific source wastes), the P-list, and the U-list (wastes from discarded chemicals). Common F-listed wastes are degreasers or cleaning solvents. An example of a K-listed waste is waste from pesticide manufacturing. P- and U-listed wastes are virgin products that have been discarded because they can no longer be used for their intended purpose.

Wastes must be transported using a hazardous waste manifest, which notes the name of the generator, the type of waste generated, the name of the transporter, and the name of the disposal facility. The manifests must be signed at each stage.

To encourage recycling, there are reduced recordkeeping and management requirements for some wastes such as used oil and scrap metal. In addition, large quantity generators of hazardous waste must certify that they have a plan in place to reduce hazardous waste generation.

Congress expanded RCRA in 1984 with the Hazardous and Solid Waste Amendments (HSWA). These amendments placed restrictions on the kinds of wastes that could be put in a landfill, specified permitting deadlines for TSDFs, and expanded RCRA's scope to include small waste generators. It also placed restrictions on the export of hazardous waste, to discourage generators from avoiding stringent U.S. waste disposal requirements.

Congress allows individual states to manage their own hazardous waste program. However, the state's program must be at least as stringent as the federal program. California and Minnesota are two examples of states that have more stringent waste disposal requirements than the federal government.

Critical Environmental Theory

CRITICAL ENVIRONMENTAL THEORY broadly refers to critical theories of society that attempt to illuminate the relationship between advanced industrial power and the domination of nature in connection with ideological issues of race, class, gender, and species. With the rise of modern environmentalism as a powerful social movement, critical environmental theories have also begun to chart the modes and meanings of resistance posed by environmental groups in an attempt to better understand the environmental movement's evolution, its successes, and failures. Additionally, since the early 1990s, ecocriticism and green studies have increasingly gained currency within the humanities, producing a large body of work by transdisciplinary scholars who seek to interrogate the politics of representation as regards the relationship between culture and nature and human and nonhuman species.

Ecocriticism is more narrowly associated with related disciplinary developments in the field of literary studies. However, the Association for the Study of Literature and the Environment, which is the primary organization for the development of ecocriticism, is composed of a wide range of praxis-based alliances between academic literary critics, activists, environmental educators, and artists concerned with natural themes. In this way, the academic movement for ecocriticism emulates other politicized scholarly movements such as Marxism, feminism, and critical race studies that have attempted to utilize institutional and noninstitutional positions to respond to perceived social crises by furthering debate, articulating new values, and organizing political collectives. Thus, ecocritics hope to promote awareness of ongoing environmental crises in academia, as well as to ultimately generate wider environmental literacy and social transformation in order to foster a more sustainable world characterized by ecological well-being. There are two distinct traditions of critical environmental theory, based in social theory and literary hermeneutics respectively, though there is ultimately significant overlap.

Critical environmental theory that aims at the emancipatory critique of societal domination of nature has its roots in the social scientific tradition of critical theory begun by the Frankfurt School. As part of their radical critique of Enlightenment ideology, capitalism, and the industrial production of mass culture during the 20th century, Frankfurt School theorists such as Herbert Marcuse, Max Horkheimer, and Theodor Adorno made important conceptual contributions that helped found the basis for critical environmental theory's contemporary approach and goals. Drawing in part upon Marx's critical social theory, which made its own nascent gestures toward environmental critique, these theorists analyzed how a dialectical relationship existed between the societal domination of external nature (the environment) and societal domination of internal nature (the psyche). In this way, they theorized that the growth of consumer capitalism was symptomatic of the oppression of peoples and environmental destruction.

EXPOSING THE POLITICAL MACHINE

Unlike Marx, however, the Frankfurt School theorists maintained less optimism for the prospect that social progress could be achieved through rationally planned economic and technological growth. Drawing upon Max Weber's ideas, which linked the establishment of modern society to the normalization of instrumental rationality and the naturalization of bureaucracy and hierarchy, Frankfurt School theorists also developed a critical environmental theory that attempted to expose the ideological workings of the political machine imposed by the ruling class.

Marcuse perhaps went furthest in this respect by claiming that modern industrialism produced nothing less than a one-dimensional technological society characterized by its need for total administration, further arguing that a hallmark of this form of society is its general desire to interpret life instrumentally as a natural resource form of commodity. In opposition, he offered theories advocating the free play of biological and psychological instincts as part of a historical struggle for the liberation of individuals' subjectivity, including the future realization of the subjectivity of nature itself. In this way, Marcuse anticipated environmentalists' critique of anthropocentrism, as well as the movement for animal rights.

These theories influenced radical environmental theorists and leftist activists during the 1950s, 1960s, and 1970s, and have helped to articulate a vision for militant environmental practices. While not a member of the Frankfurt School proper, Murray Bookchin, the founder of the important critical environmental theory known as Social Ecology, branched from the ideas of Marcuse, Horkheimer, and Adorno to craft a rigorous form of anarchist ecological politics. In his monumental book *The Ecology of Freedom*, Bookchin retained the Frankfurt School's emphasis upon the relationship between human oppression and environmental crisis, as well as the centrality of domination and hierarchy as political concepts, but refuted the idea that these concepts could be applied to nature directly. Rather, in Bookchin's social ecological turn, environmental crises arise out the social malformations that are produced through institutionalized human domination of other humans.

Therefore, in his view, the only way to arrive at a more sustainable and humane society for nonhuman animals is through the dismantling of current social forms and norms in order to engage the organic reconstruction of egalitarian, spontaneous, and mutualistic communities. While social ecology remains well regarded within some environmental circles, largely through the ongoing work of the Institute for Social Ecology in Plainfield, Vermont, the competing popularity of environmental theory known as Deep Ecology—which Bookchin declared to be a dangerously noncritical (and even "eco-fascistic") theory in a series of diatribes during the 1980s—has greatly reduced the role critical social ecological theory plays amongst environmental activists at present. On the other hand, there is renewed academic interest in the environmental potentials of Frankfurt School lineage critical theory, including work by or about Jurgen Habermas, William Leiss, Timothy Luke, Douglas Kellner, and Steven Best.

Another major branch of critical environmental theory has emerged among literary critics, where scholars use the term *ecocriticism* to define a recent transdisciplinary field that studies the relationship between literature, aesthetics, and the physical environment. While various historical figures have been hailed as forerunners of the ecocriticism movement, the 20th-century literary critic Kenneth Burke is arguably the first to have rigorously theorized ecocritical methods in books such as *Attitudes Towards History* and *Permanence and Change*.

Alternatively, many ecocritical texts point to Joseph W. Meeker as the field's progenitor. In his 1972 book *The Comedy of Survival*, Meeker theorized the study of *literary ecology,* which he defined as the analysis of the biological relationships and themes of literary works, and the attempt to discover the ecological role played by literature in the evolution of the human species. Meeker's views on the science of ecology and evolutionary theory are now best considered as dated, however, and his reputation has been diminished overall. Still other ecocritics trace the founding of their project to William Rueckert, who is considered to have first coined the term *ecocriticsm* in his 1978 essay "Literature and Ecology: An Experiment in Ecocriticism." In Rueckert's view, ecocriticism should methodologically utilize the concepts and findings of scientific ecology in order to interpret literature. Yet, exactly how natural science is to be properly used to study cultural texts has proven extremely difficult to determine. As a result, literary critics, even those with an interest in environmental themes, were not quick to adopt Rueckert's terminology, as they feared that ecocriticism implied an expertise in ecological science that most English scholars lacked.

STUDIES IN ECOCRITICISM

In 1992, the Association for the Study of Literature and the Environment (ASLE) was formed, and a year later the Association launched the publication of *ISLE: Interdisciplinary Studies in Literature and the Environment*, which along with its younger British counterpart, *Green Letters*, has become a preeminent ecocritical journal. While ecocriticism must still be considered a marginal academic movement overall, since the last decade ASLE significantly expanded its membership to include affiliated chapters in the United States, Canada, the United Kingdom, India, Japan, Korea, and Germany. Additionally, it has held a number of major international conferences on the topic of ecocriticism, and is now discussed seriously in universities of every continent.

Initially, ecocriticism's major agenda was to reaffirm the genre of nature writing and to identify important works that were primarily environmentally oriented. An emphasis was also placed on outdoors experiences in order to move ecocriticism outside of the academy, connect theory with practice, and link culture with nature. In his 1995 book *The Environmental Imagination*, Buell crucially outlined a methodological ecocriticism, in which he signaled four ways that literature could be categorized as environmental in an ecocritical sense: the nonhuman environment serves as a textual presence and not just a setting or frame for the plot; the interests of human characters are not the sole legitimate interests of the story; an ethical orientation exists in the narrative in which there is demonstrated a human accountability to the environment; and there is an implicit or explicit depiction of the environment as nonstatic, evolutionary, or otherwise engaged with some form of historical process.

Along with these criteria, many ecocritics called attention to work that either influenced the mainstream environmental movement that had emerged in society since the 1960s, or could be linked in some fashion to that movement itself. In this way, many anthologies of primary literature, critical essays, and other related theoretical works were released in an attempt to map the emerging field and legitimate its venture. Thus, alliances were made with other scholars who theorized diverse fields like ecofeminism, ecotheology, environmental history, deep ecology, and other modes of environmental philosophy and environmental education. Yet, on the whole, ecocriticism's early stress was on highlighting its prophets and practitioners, most often in the context of the literary traditions of American and British Romanticism, as well as other recent American nature writing exemplified by authors such as Gary Snyder, Terry Tempest Williams, Annie Dillard, Edward Abbey, and Wallace Stegner.

Unfortunately, the unintended consequence of ecocriticism's self-linkage to the ideals and rhetoric espoused by mainstream environmentalism—particularly in its long-standing American celebration of pristine "wilderness" places—was that the field lacked social diversity and often took a surprisingly uncritical stance toward its own ostensible subject-matter, instead favoring praise narratives that celebrated the aesthetic experience of being outdoors in nature. By 1999, a crisis began to erupt and as had happened in other social movements such as environmentalism and feminism themselves, a second wave of ecocritics began to emerge who criticized the movement as overly white and privileged. While it remains unclear as to what the end result of this recent criticism will be, it has generated significant controversy and heightened attention to acknowledged problems. Thus, ecocriticism has increasingly moved to include previously unattended topics such as urban environments, environmental racism, social justice literature, post-colonialism, anti-imperialism and globalization, and comparative international ecocritical studies.

REFORMATION OF ECOCRITICISM

As ecocritics have been challenged about their right to speak for and provide definitive representations of the environment, wilderness, and nonhuman animals, there has been a greater opportunity for cross-cultural knowledge about how different peoples relate to and understand nature. On the other hand, the critique of the social construction of nature has led some ecocritics toward more reactionary positions. Hence, a major ideologue for the movement, Leo Marx, has derided ecocriticism for its disavowal of anthropocentrism as the main reason for environmental conservation and for its adoption instead of an ecocentrism that attaches intrinsic value to nonhuman beings. Still others, such as John Elder, have strategically moved away from more radical ethical positions to advocate ecocriticism that advocates for a more moderate view of human stewardship over the earth. This shift can also be seen in the work of Glen Love, who rejects a strong anti-anthropocentrism in favor of complex analyses of what it means to be human in the world. For Love, this means bringing ecocriticism full circle and attempting to base it once again in the scientific knowledge of biology and ecology, which he believes can provide the universal foundation to escape the relativistic perils of postmodern social constructionism, as well as forms of hubristic anthropocentrism in which the human is divorced from the natural order.

Ecocriticism is ultimately concerned with revealing the roots of global environmental crises and with reconstructing a more just and sustainable world in which culture and nature work harmoniously.

Changes in the field, then, must be understood as responding not just to the discipline's inner dynamics, but also to the needs of present environmentalist politics. Therefore, ecocritics' desire to adopt a scientifically based ecological literacy and ideology of stewardship perhaps reflects a larger turn in the environmental community away from the deep ecological theories and practices that were dominant during much of the 1980s and 1990s.

Croatia

HISTORICALLY PART OF the Austro-Hungarian Empire, the Croat people joined the Serbs in creating the eastern European nation of Yugoslavia in the post–World War I period. At the end of World War II, Yugoslavia became a Communist state, but ethnic and religious differences continued to haunt the federation. After the dissolution of Yugoslavia, the Croats battled for complete independence from the Serbs. Although Croatia declared independence in 1991, the country did not achieve complete sovereignty until 1998 when the United Nations (U.N.) stepped in to mediate the conflict. Geographically, Croatia is a land of alternating plains and low mountains. The mainland section of the Adriatic coastland stretches for 1,102 miles (1,777 kilometers). Another 2,516 miles (4,058 kilometers) of the coast surrounds the Croatian islands. With its Mediterranean climate, the coastal area experiences mild winters and dry summers. The continental climate in the rest of Croatia results in hot summers and cold winters. Destructive earthquakes are a threat.

Within the Federation of Yugoslavia, Croatia was outranked only by Slovenia as a major industrial power. The breakup of the federation and the ensuing civil strife put Croatia in the position of having to struggle to regain its economic health. After centuries of exploitation, the wealth of natural resources—including oil, small amounts of coal, bauxite, low-grade iron ore, calcium, gypsum, natural asphalt, silica, mica, clays, salt, and hydropower—is helping Croatia to reach economic stabilization in the twenty-first century. Tourism, banking, and public investments have provided additional assets in economic progress. Even with a per capita income of $11,600, 11 percent of the 4,500,000 population of Croatia live below the poverty line. Unemployment remains high at approximately 19 percent. On general quality-of-life issues, the U.N. Development Program (UNDP) Development Reports rank Croatia 45th among the nations of the world.

Environmentally, Croatia suffers from air pollution caused by numerous metallurgical plants, and coastal areas are heavily polluted by industrial and domestic waste. Croatia's infrastructure is still recovering from the long years of war, and significant resources are directed toward the removal of land mines that serve as a constant reminder of the recent strife.

Croatia's forests are at risk from acid rain, and nine of the 76 mammals endemic to Croatia are threatened with extinction, as are four of the 224 bird species endemic to the area. Before the 1970s, Croatia's forests were being steadily depleted. Subsequently, Croatia passed the Forest Act and incorporated components of the Helsinki Convention of Forests into Croatian law. All wood cutting in the forests requires a special permit, and loggers must leave at least two old or dried trees per 2.47 acres (one hectare) to promote biological diversity.

As in most industrialized nations, the percent of the Croatian workforce involved in agriculture is low at 2.7 percent. Most of the farming in Croatia takes place in the east and was traditionally under the control of large, socially owned agribusinesses. Environmentally unsound agricultural management led to the excessive use of chemicals and severe land degradation. However, considerable ecological progress is now underway in Croatia. With 7.5 percent of its land protected, Croatia is above the average for Europe and Central Asia. Approximately 95 percent of the forests now demonstrate a natural composition, and the extensive grasslands are relatively free of fertilizers and chemicals.

The Croatian Parliament adopted the Declaration of Environmental Protection in 1992, aimed at correcting harmful practices of the past and moving Croatia in a more environmentally responsible direction. As a result, the Croatian government began passing a body of legislation designed to protect the environment. For example, in 1994, the Nature Protection Act and the Environmental Protection Act established guidelines for reducing environmental threats and established goals for promoting natural resources and sustainable development. In that same year, the Agricultural Land Act attempted to check the use of harmful substances in agriculture while promoting improved land management. The following year, the Air Protection Act identified measures for air quality and improvement. Other laws established guidelines for water management, regulated hunting and breeding of wildlife, and promoted the protection of marine life.

The Croatian government currently participates in a trilateral agreement with Italy and Slovenia to protect the environment of the Adriatic Sea and coastal areas. Croatia is also a party to the World Bank Mediterranean Action Plan in which a number of southeastern European nations have joined together to reduce pollution from land sources and improve water quality for the region. Croatia is involved in the Adriatic-Ionian Initiative, which works to promote environmentally responsible development in the area. On a broader scale, the Croatian government has committed itself to environmental responsibility by participating in the following international agreements: Air Pollution, Air Pollution–Sulfur 94, Biodiversity, Climate Change, Desertification, Endangered Species, Hazardous Wastes, Law of the Sea, Marine Dumping, Ozone Layer Protection, Ship Pollution, and Wetlands. Croatia has signed but not ratified the Air Pollution–Persistent Organic Pollutants agreement and the Kyoto Protocol.

Cronon, William (1954–)

WILLIAM CRONON IS one of the most distinguished and influential contemporary environmental historians, receiving numerous honors for both his research and teaching. He is currently the Vilas Research Chair and the Frederick Jackson Turner Professor of History, Geography, and Environmental Studies at the University of Wisconsin-Madison.

Born September 11, 1954, in New Haven, Connecticut, William Cronon received his B.A. (1976) from the University of Wisconsin, Madison. He holds an M.A. (1979), M.Phil. (1980), and Ph.D. (1990) from Yale, and a D.Phil. (1981) from Oxford University. Cronon's earliest book, *Changes in the Land: Indians, Colonists and the Ecology of New England* (1984) documented the differences in ecological practices between Native Americans and European settlers. Contrary to common perceptions at the time, he argued that the introduction of European farming techniques impoverished the land through the cutting of forests, stripping of topsoil, and changes to waterways. In addition, Old World animals took more than they returned to the land. This analysis is counterposed to Native American practices.

Nature's Metropolis: Chicago and the Great West (1991) examined the economic and ecological relationships between Chicago and the region from Wisconsin to the Pacific, arguing that Chicago's location made it an ideal gateway city between the West and the industrial and financial centers of New York and the east coast. He focuses primarily on three commodities—grain, lumber, and meat—and documents Chicago's role in the ecological degradation of the western frontier. He also links the decline in Chicago's processing industries to the pushing back of the frontier. In 1992, he co-edited *Under an Open Sky: Rethinking America's Western Past*, a collection of essays on the prospects of western and frontier history in American historiography. In *Uncommon Ground: Rethinking the Human Place in Nature* (1995), a collection edited and introduced by Cronon, his approach shifted from an economic history of people/nature interactions to a cultural and symbolic history of people's perceptions of the environment. He specifically critiques the concept of "wilderness," showing why it was important in forging the identity of the western frontier, and also how and why this concept changed through history. The concept of wilderness was constructed as an "other" to civilization and a realm of pure nature, fueled by a romantic quest to escape the confines of industrial capitalism. Cronon documented its symbolic place in North American history, but also pointed out its ironies and its misleading role in framing contemporary environmental practices. One its most ironic implications was the fact that national and state parks, viewed by urbanites as sites of sublime wilderness experience, were constructed through expelling Native Americans from those areas, often violently. The collection has therefore been influential for anthropologists studying conservation issues, especially from a historical perspective.

Most recently, Cronon's research has centered on a history of Portage, Wisconsin, exploring how people's senses of place is shaped by their narratives about their homes, lives, and the landscapes they inhabit. In the process, he has written a number of articles on the role of oral history in understanding peoples's senses of place and space. He is also finishing a book titled *Saving Nature in Time: The Past and the Future of Environmentalism* on the changing relationships between environmental history and environmental movements, and what the two might learn from each other.

Crop Plants

CROP PLANTS ARE vegetables that are grown primarily for food or fodder. They include species of the *Liliopsida* (monocot) family such as maize, rice, garlic, and onions, and the *Magnoliopsida* (dicot) family, such as lettuces, beans, cabbages, and potatoes. Crop plants provide a large proportion of the nutrition required by humans and animals. New varieties have been introduced into large-scale production in recent decades, as the products of countries once considered remote now earn international recognition. Crop growing has become a large, resource-intensive industry in developed and

When large fruit plantations are created, they have often been worked by groups of transient migrant workers.

developing countries, with extensive use of chemical pesticides and similar products aimed at destroying agricultural pests. Some farms have become organic, which prohibits the use of pesticides. In less developed countries, farmers tend to use whatever technology and local knowledge is available to boost productivity.

Growing crops successfully requires different configurations of inputs and labor, including plowing, fertilizing materials, irrigation, and the need to leave soil fallow at intervals. The invention of the plow and its powering by animals considerably assisted in the growth of crop planting. Rotating crops has helped to mitigate the problems of poisoning or depleting the soil, and the need to let it lie fallow. Selection of hardy specimens has helped crops become more productive and useful. The provision of irrigation has assisted in promoting wet rice paddy farming and, with fish introduced into the ditches, provides an additional source of protein. In regions with favorable climates, two or more growing seasons for crop plants are possible. For nomadic people, swidden (slash-and-burn) farming may be used to clear comparatively fertile ground that is then used until its value decreases. Despite all of the accumulated knowledge and technology used to assist in growing crop plants, sudden climatic changes or infestation by pests can dramatically reduce harvests or even eradicate them entirely.

Industrialization of agriculture has inspired the creation of single-crop or cash crop farming. Such farming renders the farmer vulnerable to changes in the terms of trade and the vagaries of international marketing and business. In traditional forms of agriculture, farmers will grow a staple crop (such as rice or wheat) and will grow various others to provide nutritional and culinary variety. Excess of the staple crop is sold to a merchant, who then typically markets it in urban areas.

When single crops are grown, the farmer's livelihood becomes subject to the risks facing that crop and market variations in demand and price. It also tends to place extra pressure on the fertility of the soil. Since farmers rarely have the capacity to do more than grow their crops, intermediaries often capture the additional added value available from prepared foods using those crops as inputs, leaving the farmers comparatively poor.

Large-scale crop growth has significantly changed the landscape of much of the settled land of the plant. Croplands are increasingly regularized and homogenized to facilitate the movement of machinery and the application of technological solutions. When large fruit plantations are created, they have often been worked by groups of transient migrant workers; sugar cane plantations of the Caribbean, for example, provided an economic imperative for the movement of slaves from Africa to the Americas. Grown crops become part of national and regional cultures, especially when they are used in localized signature dishes, which can be highly culturally specific. The thought of corn or wheat or rice farmers can have a powerful hold on the imagination, impeding rational discussion, causing difficulty when organizing multilateral trade agreements on agricultural products.

Crossbreeding

CROSSBREEDING IS THE process of mating two strains of a particular plant or animal species to produce offspring that display desirable characteristics. This process remains popular within agriculture in particular, because of the phenomenon of heterosis (also known as hybrid vigor), which dictates that the hybrid offspring tend to perform better than their parents. However, mating the hybrid offspring as a new generation is generally less successful, and there is a need to retain the purity of the family line of the original parents for subsequent crossbreeding. Successful heterosis requires a suitable level of complementarity between the specimens. While most large cities of the world contain populations of crossbred dogs, which show the vigorous fertility of so many crossbreeding encounters, there are nevertheless limits to the ability of creatures to mate with each other and produce viable offspring. Further, the desirable characteristics identified by breeders may also be accompanied by less desirable characteristics which may not be immediately evident.

While crossbreeding is most commonly associated with agriculture and agronomy, it is used intensivly in animal performance industries, such as racehorse management and pet modeling. There is also an undercurrent of supposedly scientific research and ideology purporting to demonstrate the superiority of some groups of people over others and advocating the maintenance of the "purity" of human races.

In recent years, the issue of crossbreeding has received increased attention as part of the larger effort to modify the genetic material of plants or animals in desirable ways. This has enabled some hybrid plants to obtain the ability to fix nitrogen, for example. The intensive methods used in modern agriculture, combined with programs of crossbreeding and genetic manipulation, has led to significant levels of consumer unrest in some societies. Although crossbreeding and its related techniques can be used to improve the quality of products, marketing pressures often instead produce entirely homogeneous and tasteless items that are visually appealing but nutritionally inferior. The relative superiority of genetic manipulation in place of crossbreeding means that the latter has been largely supplanted in most parts of the world. However, it remains popular in industries in which individual animals or plants are of considerable economic value, for example among beef cows.

Croton River Aqueduct

THE CROTON RIVER Aqueduct was built in 1837–41 under the supervision of Chief Engineer John B. Jervis and is one of the oldest dams of the modern United States. It is 38 miles long and located in the southeastern part of the state of New York. It is part of a system of waterworks that is used to transport water to New York City. This includes tunnels, one of which passes beneath the Harlem River; Highbridge, which is a Roman style aqueduct; and the New Croton Aqueduct, which was built 1885–91. The aqueduct was hailed as a huge engineering success of its day, and three former and current presidents of the United States attended its opening, when the 50-foot-high fountain in City Hall Park was turned on in October of 1842. The reservoir that received the water had a capacity of 180 million gallons.

As the city has grown, the intensity of demand for water has grown at an enormous and unpredictable rate. Future planning for water demand and maintenance of the existing system are important and complex issues. In its early years, New York was built mostly from wooden houses, which were vulnerable to the rapid spread of fire. Available water sources included wells and cisterns, which may have been suitable for domestic use, but were inadequate to fight fire.

The growth of industry also added to the demand for water, and pollution became a significant problem. Cholera and yellow fever threatened the people of New York. The Croton River Aqueduct helped to solve these problems until it became superseded and, in 1940, the Commissioner for Parks and Recreation ordered it to be drained and filled. The New Croton Dam continues to supply up to 10 percent of the city's need for water.

The pressure to maintain water quality and regularity of supply has become even more intense as the result of demand for housing and development within the Croton watershed area. The land is available at comparatively cheap rates and is all the more attractive for the pressure on permits elsewhere in the vicinity. Local public and private sector groups have consulted to plan for future development. Water management requires representatives from areas under numerous jurisdictions and technical experts from a variety of disciplines. Consequently, competing interests seek to exploit and protect a scarce resource.

Cryptosporidium

CRYPTOSPORIDIUM IS THE genus of parasitic protozoans that cause cryptosporidiosis, a diarrheal disease of humans found worldwide and transmitted locally through contaminated drinking water. Outbreaks occur frequently in dairy farming regions because young cows readily transmit the disease via feces. The organism was discovered in 1907, but it is considered an emerging infectious disease because physicians first observed its role in human illness during the 1970s. Cases of diarrhea are now frequently attributed to this parasite, and the infection is endemic in many developing countries. *Cryptosporidium* may infect large portions of local populations and may be severe, persistent, or fatal among those with compromised immune systems such as AIDS patients. In the 1980s, increasing rates of cryptosporidiosis were associated with the spread of HIV. Even those with healthy immune systems experience acute symptoms, including abdominal cramps and frequent, watery diarrhea as well as fever and nausea for one to two weeks.

CRYPTOSPORIDIUM CARRIERS

A wide variety of livestock and vertebrate wildlife species carry *Cryptosporidium*, and their feces are the primary source of the parasite in water supplies. The oocyst stage of the *Cryptosporidium* life cycle is the agent of transmission; its hardy shell allows it to survive for long periods and under a variety of conditions outside the body of the host. The practice of permitting cattle near streams is most commonly blamed for the deposition of *Cryptosporidium* oocysts in water. Livestock exclusion, and particularly exclusion of young cows, from stream areas may help keep oocysts out of drinking water and therefore prevent outbreaks; however, oocysts may travel through groundwater or soil as well. Feral pigs and free-ranging deer also carry the parasite and shed oocysts in their feces, and so may be important contributors to contamination in areas where their populations are high. *Cryptosporidium* has been found even in protected watersheds far from human habitation and agricultural activities.

Cryptosporidium oocysts may persist even in treated water; they survive outside the body of host organisms and are resistant to chemical disinfection methods such as chlorination. Filtration is the only means of removing oocysts from water, but it is not absolutely reliable. Outbreaks have occurred where filtration systems were in compliance with federal water safety standards, and one study has suggested that up to 97 percent of surface waters in the United States contain *Cryptosporidium*.

HISTORICAL OUTBREAK

The most notable outbreak of cryptosporidiosis occurred in Milwaukee, Wisconsin, in April 1993. Public health investigators believe that spring runoff carried *Cryptosporidium* oocysts from nearby abattoirs and cattle grazing establishments into Milwaukee's rivers and hence to Lake Michigan, the source of the drinking water supply. Over 400,000 individuals contracted the disease, and several patients with immune deficiencies continued to suffer symptoms over a year after the initial exposure. Though filtration plants were operating within legal standards, changes in turbidity should have alerted managers to the need for corrective measures. The outbreak cost the city several million dollars, strapped local health facilities, and left key public service agencies understaffed. Since the 1980s, the U.S. Congress has amended the Safe Drinking Water Act to mandate additional checks against *Cryptosporidium* contamination. Water treatment facilities must now test more frequently for water turbidity, but this is not a failsafe against outbreaks.

Cuba

UNDER REPRESSIVE COLONIAL Spanish control, the slave population of Cuba fueled the coffee and sugar plantations of the colonial period, creating massive human and environmental damage. Spanish hegemony ended during the Spanish American War (1898), leaving the United States in effective indirect control of the island nation, which lived under a series of dictators until the revolution in 1959. Under Fidel Castro during the period since, the economy of the island came to depend on support from the Soviet Union, whose collapse led to the subsequent withdrawal of several billions of dollars in annual subsidies from the Cuban treasury. The following recession in the early 1990s was exacerbated by an ongoing economic embargo by the United States.

The developmental situation of Cuba is complex. While Cuba has a per capita income of only $3,300, resulting in an income ranking of 157th among 232 counties, its health and human development conditions are relatively high by global standards and extremely high compared to other Caribbean nations. The United Nations Development Program (UNDP) Human Development Reports rank Cuba 52nd of 232 countries on overall quality-of-life issues, and access to health and education is higher than anywhere else in the region.

Located 93 miles (150 kilometers) south of Key West, Florida, Cuba is bordered by the Caribbean Sea and the North Atlantic Ocean, resulting in a coastline 2,316 miles (3,735 kilometers) long. The Guantanamo Bay Naval Base, covering an 18-mile (29-kilometer) area, is located at the southeastern section of the island. While it is geographically part of Cuba, it is leased by the United States. Cuba has limited access to freshwater sources. The tropical climate is moderated by trade winds. The dry season, which lasts from November to April, is followed by a six-month rainy season.

The terrain of Cuba is generally flat with rolling plains except in the mountainous southeast. Droughts are frequent in Cuba, and the island experiences hurricanes on an average of one every two years. Generally occurring from August to November, many hurricanes leave massive environmental damage behind. Cuba's rich natural resources include cobalt, nickel, iron ore, chromium, copper, salt, timber, silica, and petroleum. Over a third of the land is arable, and 21.2 percent of the workforce is engaged in agriculture.

The major environmental issues in Cuba are air, water, and soil pollution, deforestation, and the loss of biodiversity. Extensive soil degradation is partially the result of both past and present irresponsible waste control practices of the sugar industry. The poor air quality is largely a byproduct of liquid industrial waste such as torula yeast, which is toxic. When such contamination reaches streams, it is transported out to sea.

POLLUTION AND OTHER PROBLEMS

Agriculture and other industries also contribute to pollution on the island. The cement industry emits dust and smoke; chemical and metallurgical industries produce acid steams, smoke, and soot; and mining companies release dust into the air and byproducts into the water. Consequently, Cuba's bays are polluted, and beaches and coastal areas have eroded. Salinization also causes major difficulties in low-lying coastal areas.

In 2006, a Yale University study ranked Cuba 41st of 132 countries on environmental performance, well above its income group and slightly above its geographic group. The lowest ranks were assigned in the fields of air quality and sustainable energy. Over three-fourths of the Cuban people live in urban areas, and the country generates 0.1 percent of the world's carbon dioxide emissions despite the fact that there are only 16 passenger cars per 1,000 people on the island. The state protects 69.1 percent of Cuban land. Of 31 endemic animal species, 11 are endangered, and 18 of 86 endemic bird species are in the same precarious situation.

RESPONSIBILTY FOR THE ENVIRONMENT

In 1976, the Cuban constitution assigned the responsibility for the environment to both the state and the population. Since that time, specific environmental efforts have included the establishment of the National Commission for Environmental Protection and the Rational Use of Natural Resources (1977), the creation of similar agencies in provinces and municipalities in 1980, the Environmental Protection and Rational Use of Natural Resources Act (1981), and the National Protection System (1990). An extensive system of national parks and protected areas was created to promote biological diversity. In 1993, Cuba's National Program on Environment and Development established 214 objectives and 816 actions designed to protect the environment and promote rational use of natural resources. The following year, the Ministry of Science, Technology, and the Environment was created to implement environmental policy. Laws were revised again in 1997. Unfortunately, enforcement is difficult, and the protective institution is considered ineffectual by many environmentalists.

Cuba has expressed commitment to the global environment by participating in the following international agreements: Antarctic Treaty, Biodiversity, Climate Change, Kyoto Protocol, Desertification, Endangered Species, Environmental Modification, Hazardous Wastes, Law of the Sea, Marine Dumping, Ozone Layer Protection, Ship Pollution, and Wetlands. The government has signed but not ratified the Marine Life Conservation agreement.

Cultural Ecology

CULTURAL ECOLOGY IS the study of how or cultural groups interact with their biophysical environment. With deep roots in the disciplines of geography and anthropology, cultural ecology is an interdisciplinary approach to understanding the origins and development of human–environmental relations in places where people depend on their immediate environment for sustenance and symbolic meaning. The cultural ecology approach argues that human–environmental relations are tied dynamically to demography, technology, food production, and social organization.

Cultural ecology is closely associated with the work of Julian Steward. When Steward first coined the phrase in 1955, he sought to understand "the effect of environment upon culture," but later clarified his ideas by saying that cultural ecology "is the study of the processes by which a society adapts to its environment." By stressing human–environmental interaction, Steward pursued a compromise between environmental determinism (which he felt over-emphasized the role of the environment in shaping culture) and possibilism (which he felt neglected ecology).

Stewart argued that cultural ecology provided a methodology to study adaptive processes: how certain cultural traits—what he called the *cultural core*—related to specific (or what he called *relevant*) features of the natural environment. By examining cultural traits most closely tied to subsistence activities and economic arrangements, and by scrutinizing how they interacted with the relevant environment, Steward was able to show why hunters, pastoralists, or farmers in dissimilar environments and in distinct historical periods shared or did not share cultural traits. Although the scope and intent of cultural ecology has changed, Stewart's emphasis on adaptive process remains central to the cultural ecology approach.

Scientific revolutions in quantitative and biological sciences pushed cultural ecology in new directions during the 1960s. In his seminal 1968 book *Pigs for the Ancestors*, anthropologist Roy Rappaport used a cultural ecology approach (also known as ecological anthropology) to study the Maring peoples of Papua New Guinea. By examining human behavior and its functional relationship with the environment, Rappaport showed that belief systems and their associated rituals served as self-regulating mechanisms that kept people below the carrying capacity of their habitat—that is, in balance with their ecosystem. Rappaport's innovation was to regard the Maring as "a population in the ecological sense" and, thus, amenable to study as part of an ecosystem like any other social mammal. Contemporaneous cybernetic models involving systems, information networks, feedback loops, homeostasis, and perturbation combined with biological analogies such as trophic exchanges, stress, and niche to examine the role of culture in maintaining social harmony in bounded natural ecosystems.

This approach helped solidify the notion of culture as learned behavior transmitted through practice. Work by Rappaport, Marvin Harris, and others at what became known as the Columbia School suggested that many aspects of culture—such as specific religious beliefs that were assumed to be historically contingent—had deeper functional and environmental origins because they kept social groups in balance with one another and their ecosystem. Regardless of its limitations, Rappaport's brand of cultural ecology had a large impact on the study of human–environmental relations.

CRITICISM

By the 1970s, Rappaport's "neofunctional" view of cultural ecology faced severe criticism from all sides. Because neofunctionalists focused on relatively isolated groups already deemed to be adapted, it was difficult to understand the adaptive process itself; behaviors were simply judged to be adaptive since the people studied were considered to be isolated and self-regulating. The argument became circular and teleological. How could we study maladaptive groups, or come to know maladaptive processes? How did people reach their self-regulating condition? Did it make sense to assume people were bounded spatially or isolated culturally and economically? What about differences within the groups? As scholarly concerns shifted to nonisolated groups, Third World development, and peasant studies during the era of the Vietnam War, the cultural ecology approach became less appealing.

Yet even during this period, geographers such as Harold Brookfield, Piers Blaikie, and Karl Butzer—as well as anthropologists such as John Bennett, Robert McNetting, Emilio Moran, and many others—kept cultural ecology significant because they sought to explain social and environmental change and the relationship between the two. In the work of these scholars, small and isolated groups were avoided. Instead, they examined larger and more complex societies undergoing demographic, environmental, or social change. Concerns shifted from seeing culture as a regulating black box to a dynamic social and individual force that made decisions by weighing and rejecting alternatives.

Behavior was not viewed as strictly functional, but the outcome of a social process that engaged a larger political economy. Scholarly research concentrated on how people responded to change, how they adjusted their behaviors, how they intensified land and resource use, and adopted or rejected new technologies. Scholars found that an "adaptive dynamic" existed between people, their cultural beliefs, social values, knowledge, forms of social organization, economic opportunities, population growth, and environmental change (which they themselves were partly responsible for). Understanding how people made adjustments in their environmental practices to remain socially viable became the challenge for cultural ecologists.

Over the last decade, cultural ecology has broadened to examine more complex aspects of society–nature relations. Greater attention to the geographic notion of scale—particularly how local adaptive processes are mediated by regional and global political economies—became an important topic of research. The biophysical environment also received greater attention by cultural ecologists and is viewed as increasingly complex, nonlinear, and less predicable. Many cultural ecologists today deconstruct notions of culture by examining environmental discourse and the origins, circulation, and deployment of local knowledge. Cultural ecologists commonly investigate livelihoods as they relate to peoples' access to natural resources. They seek to understand the role of customary rights of access to resource commons in traditional resource management, and how state-centered policies affect this relationship. Cultural ecologists no longer consider social groups as homogenous units devoid of class, racial, ethnic or gender differences. Gendered knowledge and differential access to and control over resources, for example, have become important focuses within cultural and related political ecology approaches to society-environment relations. Contemporary cultural ecology also brings its core foci to study biodiversity, environmental knowledge, and conservation policy to enhance innovative forms of nature conservation that promote social justice.

Culture

OF ALL OF the words in the English language, *culture* and *nature* are two of the most complicated and multi-faceted, making any discussion of "culture" in the context of environment–society relations fraught with complexity. The Latin word *cultura*, from which "culture" is derived, had the primary meaning of cultivation or husbandry, the process of tending natural growth, especially crops or animals. The concept was eventually extended to the process of human development, and "culture" was often used in the 18th century as a synonym for "civilization." In the late 17th century, Matthew Arnold introduced the notion of culture as *high* *culture,* that which is beautiful, sublime, and perfect, the best of what has been thought and said. In this view, culture is embodied by extraordinary works of literature, painting, music, and philosophy. More recently, social scientists have argued by contrast that "culture is ordinary," and that popular or mass culture is also worthy of study.

In 1952, anthropologists Alfred Kroeber and Clyde Kluckhohn catalogued 164 definitions of culture. One common definition is culture as a distinctive, "total way of life" including meanings, values, norms, and ideas embodied in institutions, social relations, belief systems, customs, and material artifacts. Clifford Geertz argued that culture should be understood as "webs of meaning" coded in symbolic forms, such as artifacts and rituals, which can be interpreted like a text. Culture in this view is concerned with the production and exchange of meanings between members of a group. Culture is also often thought of as a way of organizing society through a system of signs or signification, and a set of stories that a society tells itself about itself. It is learned rather than biological or innate, but is often learned unconsciously, passed through generations by instruction, example, and imitation. Culture shapes awareness, perception, and the way an individual makes sense of the world, and thus is also intimately linked to knowledge and representation.

WHAT IS CULTURE?

Many "common sense" ideas about culture have been critiqued and refined in recent years. For example, some social scientists have recently stressed that culture should not be thought of as an object, and that meanings can be challenged and can change. Culture is shared, but also contested, and some members of a society almost always have more power or ability to shape meanings than others. Moreover, culture is differentiated; members of a society of different genders, status, occupation, and age have particular roles and types of knowledge. Different cultures, or subcultures, can exist within a larger society; these boundaries are not fixed.

Culture is neither just a set of material objects that characterize a particular group (sometimes referred to as material culture), or just a bunch of abstract ideas and symbols, but also includes the relationship between the two. Some sociological views have suggested that culture is distinct from behavior, but others have insisted on the centrality of *cultural practice*. In this view, meanings are important and powerful because they organize and regulate social practices. A few critics have gone so far as to argue that "there is no such thing as culture," by which they mean that "culture" is not an adequate final explanation for actions or behaviors, but instead is something that itself needs to be explained. A less extreme version of this approach is to emphasize *cultural mobilization* or *cultural politics*, that is, to ask how the idea or category of "culture" gets deployed, and what gets accomplished by invoking "culture."

As might be expected given the complexity of the term "culture," many different approaches can be taken to the relationship between culture and the environment.

EARLY CULTURAL ECOLOGY

In its early formulations, cultural ecology, with its focus on humans as part of their surrounding ecosystems, tended to examine small tribes in isolation from the rest of the world. Cultural ecologists explored how their cultures—including traditions, rituals, and religions—were adapted to the environment and functioned to keep them in balance, or equilibrium, with their surroundings. For example, Roy Rappaport argued that the ritual cycles of pig sacrifice and warfare of the Tsembaga Maring of New Guinea functioned to prevent environmental degradation, even though the Maring themselves were not aware of that function. This type of approach was eventually criticized for focusing only on small, rural groups of people; for ignoring the fact that even these groups have been influenced by larger histories and processes of colonialism, state policies, and regional and national markets; and for its assumptions, which have been challenged by new developments in ecology, that ecosystems are always in equilibrium.

Despite these criticisms, this early work contained valuable insights whose influence can be seen in a number of themes in contemporary studies of culture–environment relations. Key among these is the recognition that members of different cultures perceive, experience, know, and manage their external environments in different ways. What looks "degraded" and barren to one group of people might look vibrant and alive to another. For example, researchers have shown that Chinese state officials in Inner Mongolia see shifting sand dunes as "wasteland," whereas local Mongolian herders value the same sand dunes for environmental, practical, and aesthetic reasons. Han Chinese see crop cultivation on the pastures as "opening up the wasteland," while Mongolians call the same process "shattering the land."

A related finding from culture–environment research is that many practices that have looked irrational, backward or destructive to Western observers actually turn out to be quite suitable for the contexts in which they are practiced. One extensively studied example is shifting cultivation—or "swidden" agriculture—a practice in which farmers grow crops for several years and then move on to new fields, leaving fields fallow for up to several decades as forest cover and soils reestablish to become suitable for crops again. Until recently, shifting cultivation was looked down on as "primitive" (as reflected in its other name, "slash and burn agriculture"), and blamed for being unsustainable and for destroying forests. However, detailed research has shown that shifting cultivation has had a long, successful, and sustainable history in many places. It also maintains a remarkable degree of agrodiversity. One study found that the managed forests around "swidden" fields on the island of Borneo contain up to 800 edible plants and are home to more than 100 species of edible ground fauna and several hundred species of birds. Although shifting cultivation can lead to soil erosion under some circumstances, modern "scientific" agriculture—with its much simpler biological structure, much smaller number of species, and use of industrially produced fertilizers and pesticides—has in many ways much more environmentally harmful effects.

A related finding is that a great deal of knowledge is embedded in the management of fields as well as surrounding second-growth forests in shifting cultivation. More generally, different cultures have different specialized systems of knowledge about various aspects of the surrounding environment. This is reflected in language. One well-known example is that most English speakers distinguish cold weather precipitation simply as "snow" or "sleet," whereas avid skiers make finer distinctions between different types of snow. The Inuit of the Artic circle have many more terms that make even finer and more complex distinctions, reflecting how their culture conceptually classifies, perceives, experiences, and knows the world.

ETHNOBOTANY

Ethnobotany is also concerned with the conceptual classification schemes of different cultures, in particular with systems of naming and use of plants for food, clothing, shelter, ritual, and medicine. In many parts of the world, average people can name and know how to use far more species of plants than can the average American, suggesting a different day-to-day relationship with the natural world. The Chácabo Indians of the Amazon, for instance, have 305 uses for the 360 species of vascular plants in the forest surrounding their village. Ethnobotanists have found that specialized healers or shamans among some cultural groups encode extensive, specialized knowledge of the properties of many plants in a language of myth, dream, and magic. More than half of all modern medicines are either derived or modeled on compounds from wild species, and today pharmaceutical companies are actively prospecting for plants that could be used to produce medicines. This has produced a new respect for the extent of the cultural knowledge of groups of people formerly thought of as "primitive," but it has also created new problems and disputes about intellectual property and adequate compensation.

What happens when culture is analyzed not just as a transparent fact, but also as an idea that can be mobilized for various purposes? In thinking about their own culture's relationship with the environment, writers in the West have often used other cultures as a foil. This has generally taken one of two forms. First, some have argued that Western culture—or civilization—is superior to others because it is more modern and scientific, and that it has been uniquely able to develop the scientific knowledge and techniques needed to protect the environment. This view, which still persists today, is often at the basis of policies that take control of environmental management out of the hands of local people in the developing world. On the flip side, other writers have blamed Western civilization for an underlying alienation of humans from nature, which is seen as being at the root of environmental ills today.

INDIGENOUS KNOWLEGE

This search for alternatives has also often turned to indigenous peoples, who are sometimes portrayed as ecologically noble. Groups such as the Kayapo of the Amazon are represented as living in a harmonious and nonexploitative relationship with the natural world. Their attitudes toward nature are seen as holistic and organic rather than mechanistic and individualistic. It is important to distinguish between two views about traditional—or native—cultures and the environment. One is the recognition that different cultures have specific beliefs and practices that grow out of particular relationships with the natural world, which are often environmentally benign. The second is a "noble savage" view that members of these cultures are automatically programmed to do only that which is ecologically wise.

This latter, romantic view has a number of problems. First, it is easy to find empirical evidence of environmentally destructive practices caused by groups of people portrayed as ecologically wise. Second, these representations can have the effect of denying that these people have their own unique history. When certain cultures are portrayed as being so "close to nature" that they get collapsed into nature itself, the people of those cultures are denied full humanity. Third, claims about indigenous or traditional ecological knowledge are often anachronistic. For example, Tibetan exiles frequently claim that, guided by their Buddhist beliefs, Tibetans have always been aware of ecological interdependence and the need to safeguard the environment. However, the concepts of "ecology" and "environment" are actually thoroughly modern and rather recent. While sets of cultural practices may have had the effect of what we would today call environmental protection, attributing these to the modern notion of "ecology" is to impose a concept on practices driven by other cultural beliefs and values. Nevertheless, many marginalized groups of people today find it very useful to invoke ideas about the inherent ecological friendliness of their cultural beliefs and practices. In many cases, this helps them to negotiate politically both for respect and for their right to continue living in their traditional territories.

What we call the environment, or nature, can only be known through cultural frameworks, or "cultures of nature." This is true not just of indigenous peoples living in remote forests, but also of wealthy, urban citizens of industrialized countries such as the United States. For example, the American view of nature is often thought of as "wilderness areas" being untouched by human modification, despite the fact that the movement to set aside wilderness areas only came after the removal of Native Americans

SUV Irony

Sport Utility Vehicle (SUV) advertising shows that some members of a society (in this case, corporations) have a disproportionate ability to shape cultural meanings, including cultures of nature. SUVs are often associated with safety, security, freedom, and individuality. But print and television advertisements also depict SUVs off-roading in storms through vast, uninhabited territories, scaling impossible mountaintops, and conquering all challenges posed by nature. Brand names such as "Explorer," "Mountaineer," and "Pathfinder" make the vehicles attractive in their ability to bring the driver closer to a particular conceptualization of "nature" (a wild place without people), while overcoming environmental obstacles that might lie in the way. These advertisements work in part by appealing to already-existing American cultural notions of nature, which call for an escape from the city into wilderness, as a place for solitude, truth, and self-discovery. Ironically, the SUV comes to embody a certain culturally-constructed idea of a desirable relationship with nature, while obscuring its own actual environmental effects. However, like all cultural ideas and practices, these meanings are subject to challenge and change; they are not fixed forever.

to reservations. This ideology can be traced back in part to the way that European colonists saw the land they encountered as "natural" in the sense of being untouched by human influence. They failed to see that the landscapes had actually been thoroughly shaped by Native American cultural practices. These included the annual burning of extensive sections of forest, which made the forest open and park-like, and helped attract and increase the population of game animals including elk, deer, turkey, and quail. The ideology of wilderness obscures not only Native American cultural transformations of the landscape, but also the history of violence through which they were removed. It also helps to produce a binary view of wilderness, land that is "worth saving," vs. land that is already spoiled by human modification and thus beyond redemption. This has contributed to the American environmental movement's strong focus on some issues, while ignoring others.

CULTURE SHAPES THE ENVIRONMENT

Finally, culture shapes the environment in many ways, even in realms which aren't immediately connected to "nature." A good example is American automobile culture. U.S. automobile use has a tremendous environmental impact. Among other things, the burning of gasoline produces pollutants that react in sunlight to form tropospheric ozone and smog, which are harmful to human health. Transportation accounts for roughly one-third of all carbon dioxide emissions, contributing significantly to a rise in global average surface temperatures, which are projected to cause significant sea level rise, increased intensity of severe weather events, disruption of water supplies, spreading of malaria, and the loss of species. Rapid expansion of roads fragments ecosystems and causes loss of habitat, thus contributing to the loss of biodiversity. Despite these well-known environmental effects of driving cars, American driving habits are remarkably resistant to change.

This is due in part to the cultural meanings that Americans associate with cars, none of which have to do with environmental degradation. For one, driving is understood as a source of freedom: the freedom of movement, the pull of the open road, and the expectation of new experiences are all central to the imagination of America in movies, literature, and advertising. These images manage to prevail over other possible meanings of the car, such as the division of home from workplace, lengthy commutes, congestion, and environmental impacts. Cars have also become a way for people to express themselves as individuals and to announce their status, particular lifestyle, and socioeconomic class. In the United States, cars are also associated with rites of passage and coming of age.

Car culture is not limited to the car itself, but also includes the way the system of highways, parking lots, and layout of the suburbs has been historically structured around the automobile. This in turn was shaped by specific economic and political forces, such as various subsidies that made the cost of driving an individual car less than taking public transportation. As soon as American society started to be "locked in," there were huge returns for producing and selling cars and for their infrastructure, products, and services. This led to a change in the way Americans think about and use space and time, how they socialize, and how and where we live. It makes possible the separation of business and industrial districts, and of retail outlets from city centers.

Culture—both our own and others—is intricately connected to the environment. Cross-cultural examinations are useful in showing that there is usually more than one meaning, explanation, set of values, and way of managing or relating to the natural world. Using the same analytical tools on ourselves shows that what is familiar is not necessarily universally accepted. Indeed, many of the environmental ideas and practices that we take for granted as natural are actually culturally specific.

Currents, Ocean

OCEAN CURRENTS ARE horizontal layers of seawater that move. There are three types of currents: coastal, surface layer, and deepwater. Coastal currents occur immediately adjacent to the shore. Wave action, gravity, and hydrostatic pressure generate such currents. Longshore currents, the ebb and flow of tidal currents, and dangerous rip current are common examples of coastal currents. Freshwater inflow from rivers, friction with the seafloor, and irregular coastlines add to their variability. Surface layer currents and deepwater currents occur farther offshore.

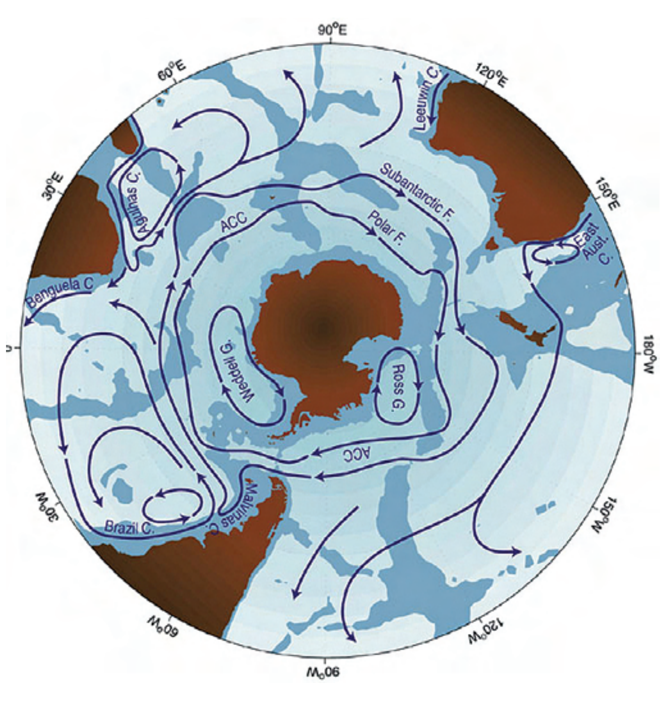
The sinking of cold, salty water in polar regions creates deepwater currents. These currents bring oxygen to marine life at great depths. The sinking of surface water and the upwelling of deepwater makes up a "conveyor belt" that includes both surface layer and deepwater currents. The belt slowly exchanges water between ocean basins. Climate experts believe that fits and starts in this conveyor belt may explain climate shifts over intervals of 1,000 years or more. Upwelling and downwelling also alter nutrient levels of the water that affect marine ecosystems and fishing patterns.

Surface layer currents are the most understood of the three currents. Persistent winds drive them. When winds blow across the ocean surface, friction transfers energy from the wind to the water. The transfer depends on the velocity of the wind, surface tension of the water, and roughness of the surface. Friction transfers kinetic energy into the water, and also transfers kinetic energy downward in progressively lesser amounts, so that wind-driven currents are usually restricted to the upper 1,300 feet (390 meters) of the oceans and generally to even shallower depths. The speed of the resulting current is about 3 to 4 percent of the wind speed.

The largest surface layer currents form gyres in subtropical latitudes. Gyres are large water circulation systems that flow around the peripheries of the oceans in the subtropical latitudes. The currents flow clockwise in the northern hemisphere and counterclockwise in the southern hemisphere. The trade winds and the westerlies create the gyres. Besides these winds, the Coriolis effect, configuration of landmasses, and higher sea levels near the centers of the gyres affect the flow of the currents. Separate subtropical gyres are present north and south of the equator in each ocean except in the Indian Ocean, which has only a southern gyre. Each gyre has an equatorial current, which absorbs energy from the tropical sun and flows parallel to the equator, a warm western current that delivers the tropical heat to polar latitudes, and a cold eastern current that returns to the equator.

The fastest and deepest currents are the warm western currents. There are five such currents: the

Strong winds drive the the world's largest current, the Antarctic Circumpolar, from west to east around Antarctica.



Gulf Stream (in the North Atlantic), the Japan or Kuroshio Current (in the North Pacific), the Brazil Current (in the South Atlantic), the Agulhas Current (in the Indian Ocean), and the East Australian Current (in the South Pacific). There are also five cold eastern currents: the Canary Current (in the North Atlantic), the Benguela Current (in the South Atlantic), the California Current (in the North Pacific), the West Australian Current (in the Indian Ocean), and the Peru or Humboldt Current (in the South Pacific). The world's largest current is the Antarctic Circumpolar Current. This eastward flowing cold current encircles the Antarctica, but contributes cold water to the southern gyres.

Surface layer currents have much the same effect on climate in their areas as do the winds that generate them. For instance, warm ocean currents warm nearby air and tend to add water vapor to the air through evaporation. Thus, coastal areas next to warm currents tend to have humid climates. Conversely, cold ocean currents add little moisture to the nearby air. When the cool, dry air travels over a continent, it results in very little precipitation on the coast. Fog may form over both types of currents, but is more frequent over cold currents due to the chilling effect they have on the overlying air. The circulating gyres moderate global temperatures. As a result, equatorial areas are cooler and higher latitudes are warmer than they might be otherwise. An example is the mild temperatures imparted to northwestern Europe and Scandinavia by the North Atlantic drift, a branch of the warm Gulf Stream. The temperatures of these regions are much warmer than the same latitudes in Canada.

Cuyahoga River

THE CUYAHOGA RIVER runs north for 100 miles in northeastern Ohio before emptying into Lake Erie. The river flows through areas of heavy industry and high population densities, especially in its last 40 miles. The negative effects of industrial wastes spilled into the river have been devastating. The river surface was literally set aflame in 1936 when sparks from a blow torch set fire to oils and material on the surface. Although the incident was widely noted at the time, remedial action to any significant degree was negligible. In 1952, boats on the river and an office building were also set aflame. Further destruction occurred in the 1960s as the river continued to serve as a refuse dump for industrial wastes, flammable oils and other liquids, and sewage overflow. Pollutants from the Cuyahoga and other rivers feeding into Lake Erie were largely responsible for that Great Lake during that time to be declared dead.

In 1969, another fire on the Cuyahoga was noted nationally. This time, a groundswell of public outrage against environmental degradation resulted in a host of legislative actions aimed at reversing the destructive trends. One of the major pieces of legislation to be enacted was the Clean Water Act, which grew out of the 1977 amendment to the Federal Water Pollution Control Act of 1972. The Clear Water Act set the goals for regulating the discharge of all forms of pollutants into the rivers and lakes in the United States. In addition, the act authorized the Environmental Protection Agency to set wastewater standards for industry and municipalities. The Clean Water Act set in motion the mechanisms for the creation of other laws aimed at stopping environmental degradation. Of greatest pertinence to the Cuyahoga River was the enactment of the Great Lakes Water Quality Agreement of 1972 and its renewal in 1978, which brought together the governments of the United States and Canada to work together to reduce the deposits of pollutants into the Great Lakes. The general aim of the agreement is to commit each country to restore and maintain the chemical, physical, and biological integrity of the Great Lakes Basin Ecosystem. At the time of its enactment, many in the scientific community had grave doubts in particular about the prospects for

Lake Erie, which for years had lost virtually all of its fish and plant species to the ravages of pollution. Fortunately, the lake did make a remarkable turnaround and is now considered to be in a generally healthy state.

The improved health of Lake Erie and the other Great Lakes could not have been accomplished without considerable remediation in the condition of the rivers that feed into them. In 1988, the lower 45-mile course of the Cuyahoga River was designated as one of 43 Areas of Concern around the Great Lakes. With this designation, the Cuyahoga is covered by a Remedial Action Plan (RAP) created to guide local officials in implementing effective anti-pollution measures. The RAP aims at restoring and protecting 14 specific beneficial uses for the river, uses that had been lost due to damage by pollution. The uses include a number of particular points regarding fish and animal life, restrictions on dredging, control of algae, improvement of drinking water sources, safety of public beaches, and improvements in the conditions of both industry and agriculture along the course of the river.

Cyprus

IN 1960, THE island of Cyprus obtained independence from Britain after years of organized resistance. Three years later, ethnic tensions between the Greek Cypriot majority and the Turkish Cypriot minority led to violence in Nicosia, the capital city. United Nations peacekeepers were deployed in 1964, but sporadic violence continued. After intervening to put down a Greek-led revolt a decade later, the Turks gained control of a third of the land area of the island, proclaiming it the Turkish Republic of Northern Cyprus. However, other nations have refused to recognize Turkey's claim to this area. An attempt by the United Nations to resolve differences failed in 2004, and the island of 780,000 people continues to operate under divided loyalties.

Cyprus operates dual economies. With a per capita income of $21,600, the Republic of Cyprus is considered the 48th richest nation in the world. On the other hand, northern Cyprus is classified as the 109th richest with a per capita income of only $7,135. That income is heavily dependent on remittances from Turkey. In the Republic of Cyprus, the service sector accounts for more than three-fourths of the Gross Domestic Product, with tourism and financial services dominating the economy. Agriculture plays a more important role in northern Cyprus, employing 14.5 percent of the workforce as compared to 6 percent in the Republic of Cyprus. Likewise, unemployment is higher in the north (15.6 percent versus 3.8 percent), as is inflation (19.1 percent versus 2.5 percent). All Cypriots have access to safe drinking water and improved sanitation. The United Nations Development Program (UNDP) Human Development Reports rank Cyprus 29th in the world in overall quality-of-life issues.

Bordered by the Mediterranean Sea, Cyprus has a coastline of 402 miles (648 kilometers). Northern and southern Cyprus is generally mountainous with plains in the central area and along the southern coast. The temperate and Mediterranean climates produce hot, dry summers and cool winters. Cyprus experiences droughts and moderate earthquake activity. Natural resources include copper, pyrites, asbestos, gypsum, timber, salt, marble, and clay earth pigment. Less than 8 percent of the land area is arable.

In the absence of natural reservoir catchments and prolonged dry periods, the entire island suffers from a lack of fresh water sources. Because sea water has intruded into the largest aquifer, increased salinization has become a problem in the north. Sewage and industrial wastes have polluted the water, and coastal areas are experiencing degradation. Irresponsible urbanization has led to a loss of biodiversity. In 2006, a study by scientists at Yale University ranked Cyprus 29th in the world in environmental performance, well above the relevant income group but slightly below the relevant geographic group. The lowest score was received in the category of air quality. Nearly 70 percent of the population live in urban areas, and there are 404 passenger cars per 1,000 people. Intense urbanization has also led to an increase in the rate of carbon dioxide emissions per capita metric tons from 5.2 in 1980 to 8.3 in 2002.

The Framework Law on the Environment and the Protection of Nature provides a foundation for all environment policy in Cyprus. Specific legislation includes: Control of Water Pollution, Control of Atmospheric Pollution from Industrial Sources, Agrochemicals, and Pollution of Public Spaces. The Ministry of Agriculture, Natural Resources, and Environment is the governmental agency responsible for promoting sustainable development and resource protection and management. This ministry coordinates the environmental activities of the Council of Ministers that are involved with implementing policies and monitoring compliance in the areas of responsible water use, water conservation, waste storage and treatment, water development, desalinization, pesticide and fertilizer control, air and water quality control, environmental impact assessment, industrial pollution control, and the protection of wetlands and biodiversity.

Cyprian commitment to global environmentalism is demonstrated through participation in the following international agreements: Air Pollution, Air Pollution–Persistent Organic Pollutants, Biodiversity, Climate Change, Kyoto Protocol, Desertification, Endangered Species, Environmental Modification, Hazardous Wastes, Law of the Sea, Marine Dumping, Ozone Layer Protection, and Ship Pollution.

Czech Republic

AFTER WORLD WAR II, Czechoslovakia, a member of the Austro-Hungarian Empire before WWI and an independent state in the inter-war period, came into the sphere of the Soviet Eastern Block. In 1968, a liberalization effort was stymied by Soviet invasion, leading to political protests and, ultimately, to harsh repression. After the collapse of the Soviet Union in 1989, the so-called velvet divorce resulted in the creation of the Czech Republic and Slovakia as separate entities. The Czech Republic is a small (30,450 square miles [78,866 square kilometers]) landlocked nation with a varied topography. The country is subject to flooding that is often detrimental to the environment. In July 1997, for instance, in the eastern part of the country, the entire Moravian area was flooded, including agricultural areas and industrial and municipal landfills along the Morava River. As a result, toxic substances were released into the environment. Unlike the hilly Moravian area, Bohemia in the western section of the Czech Republic is made up of rolling plains, hills, and plateaus set amidst low mountains. Economically, the Czech Republic has progressed much faster than most of the former Soviet satellites, and growth has been fostered by extensive trade with Germany and strong domestic and foreign investment. Czech natural resources include: hard coal, soft coal, kaolin, clay, graphite, and timber. With a per capita income of $18,100, the Czech Republic is ranked as the 58th richest nation in the world. The quality of life is predictably high in the Czech Republic, and the United Nations Development Program (UNDP) Human Development Reports rank the nation 31st in the world.

Extensive air and water pollution in Bohemia and in northern Moravia currently threaten the health of the Czech people, and acid rain has damaged the forests. With a heavily urbanized population (84 percent) and 357 passenger cars per 1,000 people, carbon dioxide emission is high at 11.6 metric tons per capita. Since the Czech Republic joined the European Union (EU) in 2004, the country is in the process of bringing industrial practices in line with those of other EU nations, a move that is predicted to reduce pollution. Despite existing problems, a 2006 study by Yale University ranked the Czech Republic fourth in the world in environmental performance, placing it above most other countries in its geographic and income groups. The Yale ranking was particularly high in the fields of water resources (96.7), natural resource protection (97.9), and overall environmental health (97.3). Approximately 16.1 percent of land in the Czech Republic is protected. Of 161 bird species endemic to the country, only two species are threatened. Mammal species are at greater risk, however, with eight of the 81 species threatened.

Because of extensive industrial growth, the government of the Czech Republic has been forced to deal with environmental problems and promote sustainable development without curtailing economic growth. In 1995, the government adopted the State Environmental Policy, a revision of an earlier law, and charged the Ministry of the Environment with implementation of environmental protection laws that included the National Policy on Mineral Resources, the National Strategy of Regional Development, the National Strategy for Industry, the State Energy Policy, the State Program of Support for the Use of Renewable Resources of Energy, the State Program for Energy Savings, the Strategy for Agricultural Policy, and the National Program for Health and the Environment. The Czech government also implemented Environmental Impact and Strategic Impact Assessments to evaluate environmental policies. Additionally, the Council for Sustainable Development was created under the Ministry of the Environment.

At the local level, the Czech Republic has established the Network of Healthy Cities and the Association of Municipalities to promote environmental responsibility. Internationally, the Czech Republic has participatied in the following agreements: Air Pollution, Air Pollution–Nitrogen Oxides, Air Pollution–Persistent Organic Pollutants, Air Pollution–Sulfur 85, Air Pollution–Sulfur 94, Air Pollution–Volatile Organic Compounds, Antarctic Treaty, Biodiversity, Climate Change, Kyoto Protocol, Desertification, Endangered Species, Environmental Modification, Hazardous Wastes, Law of the Sea, Ozone Layer Protection, Ship Pollution, and Wetlands.

Dams

FEW TECHNOLOGIES HAVE had more significant and persistent ecological impacts than dams. Almost every major river in the world has at least one large dam obstructing its flows. China alone has built over 22,000 large dams on rivers within its national territory, most of which have been constructed over the past three decades, and is nearing completion of the largest human-made structure in the world, the Three Gorges Dam. While varying in size and type, all dams share the goal of obstructing the flowing water of a river or stream in order to provide an array of perceived benefits to human communities. The most important of these include the conversion of flowing water into electricity (hydropower), the storage of water for irrigated agriculture, and the control of floods. Dams also engender an array of social and environmental consequences. Depending on size and location, dams create reservoirs, cause massive displacements of people, block fish migration routes, and significantly alter the hydrology and ecology of flowing rivers.

While the construction of dams to divert or block a river's flows is a technology dating back 5,000 years, the 20th century witnessed an unparalleled expansion in the scope and size of impoundments. The construction of Hoover Dam, a 220 meters high hydroelectric project built on the Colorado River in the western United States in the 1930s, ushered in the era of large dams. Over 40,000 large dams—defined as those with height of 15 meters or more—have been constructed on the world's rivers, the vast majority since 1950. In total, the water stored behind dams in reservoirs amounts to 10,000 cubic kilometer (roughly five times all the volume of the world's rivers combined) and covers an estimated land area of 400,000 square kilometers (about the size of California). There are three primary types of impoundments—embankment, gravity, and arch dams—that are designed based on the local geology and topography of a dam site. Most dams (80 percent) are earth and rock embankments, typically built across wider river valleys where dam fill materials are readily available.

As the scale of a dam increases, the scope, duration, and intensity of its social and environmental impacts also become amplified. The largest dams—such as the massive Itaipu impoundment on the Paraná River in South America, the Columbia River's Grand Couleee in the western United States, the Volga's Kuibyshev Dam in the Russian state of Samara, the Volta's huge Akosombo Dam in Ghana and, most recently, the Three Gorges Dam on the Yangtze River in China—have collectively displaced millions of people, inundated thousands of hectares of land, and brought about host of other socioecological effects. However, numerous dams and accompanying systems of weirs, barrages, and levies have for centuries served important roles in flood control, enhanced agricultural production, and urban water supply in nearly every region of the world.

In terms of human–environment relations, it is difficult to separate dams' social and ecological impacts. Both are closely intertwined, especially in those regions of the world where people remain partly or wholly dependent on the resources conferred by unobstructed rivers. In the equatorial zones such as the Amazon and Congo Basins and parts of monsoonal Asia such as the Mekong basin, millions of livelihoods remain crucially dependent on freshwater fisheries and floodplain agriculture, practices whose sustainability and integrity are in turn intimately linked to annual riverine flow cycles. The social and biophysical impacts of dams, particularly larger dams that produce significant reservoirs of stored water, can be usefully organized into (1) those effects experienced primarily near the dam site, the dam's reservoir, and related upstream regions, and (2) those effects experienced primarily downstream of the dam, oftentimes extending to a river's delta and estuarine regions.

An initial and obvious impact of river impoundment is the inundation of vast hectares of riverine lands and the consequent displacement of people living in these areas. While state agencies in charge of dam construction often pledge dam-affected peoples compensation in the form of new housing structures, agricultural lands, and cash payments, numerous relocation programs throughout Africa, Asia, and Latin America have failed to deliver on promised compensation plans. Official resettlement areas are typically inferior to traditional riverine lands in terms of agricultural productivity, and the long-term inhabitants living in these areas resent displaced peoples. This was the experience of the more than 100,000 Nubians resettled due to construction of the Aswan High Dam on the Nile River. The resettlement communities lacked basic amenities, exposed the displaced people to new diseases, and were agriculturally inferior to their previous lands.

A reservoir also represents a radical alteration of a river's hydrological and ecological functioning. While retaining some of the biophysical characteristics of a river, a reservoir essentially causes a shift

Dam Busters

The film *The Dam Busters* (1954), based on the book of the same name by Paul Brickhill (1951), highlighted the World War II Operation Chastise on May 17, 1943, in which British planes bombed the German dams using "bouncing bombs."

The British had been keen on bombing the German dams in the Ruhr to disrupt their enemy's war efforts, with the initial plan to drop a 10-ton bomb from 40,000 feet. However it was not yet possible to achieve, and large heavy nets in the reservoirs by the dams meant that torpedoes would not be effective either. This led the British scientist Barnes Wallis to come up with the idea of a "bouncing bomb" after seeing boys skimming pebbles over pools of water.

The breaching of the dams was planned not only to destroy them as a source of hydroelectric power, but more importantly to prevent the flow of water to industry and nearby cities, as well as flood some of the factory areas nearby. When the bomb was designed, it was decided to launch the air raid in May, when the water levels would be at their highest.

With only a few technical problems, Guy Gibson led the first formation of the "Dam Busters" over to Germany, with two others following. The Möhne dam was successfully breached; the Eder Dam was breached with the last bomb of the attacking formation, but the bombs were not able to breach the Sorpe and Ennepe Dams. In all, 53 of the 133 British air crew involved were lost, with three bailing out and becoming prisoners of war. The value of the operation was flooding much arable land, killing large numbers of livestock and showing the Soviet Union that Britain was prepared to launch risky operations to harm the German war effort.

from a flowing to a standing water environment. The shift from flowing water to largely stagnant water results in a host of hydrological, biological, chemical, and ecological transformations. Levels of dissolved oxygen and other key water chemistry parameters are irrevocably altered within reservoirs. The species composition and numbers of fish and other aquatic organisms shift to reflect a more lake-like ecosystem, resulting in the drastic reduction or extirpation of those species adapted to riverine environments. Dams can virtually eliminate migratory fish species whose routes from ocean to spawning grounds are blocked. The annual run of adult salmon and steelhead trout in the Columbia River Basin in the United States' northwest region has declined from a population of 10–16 million in the mid-19th century to an estimated 1.5 million in 2006, due almost entirely to the basin's 130 dams. France's runs of Atlantic salmon on many of its rivers suffered a similar fate due to dams built throughout the latter 19th century.

In many tropical reservoirs, such as Lake Kariba on the Zambezi River in southern Africa, invasive or undesirable plant species such as the water hyacinth and giant salvinia have proven difficult to manage. In addition, the filling of a reservoir after dam construction, which can take any where from several months to two or more years before completion, can have serious ecological consequences in terms of habitat destruction. In the case of the Kariba and Cahora Bassa dams on the Zambezi River in southern Africa, built in the late 1950s and early 1970s, respectively, dam authorities and governments undertook efforts to capture and relocate indigenous fauna (particularly large mammal species) prior to inundation, but numerous animals drowned during the filling period.

Reservoirs also produce economic and recreational benefits for some social groups. In the western United States, for example, massive reservoirs on the Colorado River (such as Lake Mead and Lake Powell) are important sites of recreational activity such as sport fishing and boating. Dams and reservoir levels are frequently managed to allow for downstream recreational activities such as rafting. In many tropical areas, the damming of flowing waters has resulted in very productive reservoir fisheries. However, many of these fisheries have proven a mixed blessing to local communities. At the Ubolratana reservoir in Northeast Thailand, constructed primarily as a hydroelectric facility in the 1960s, a lack of management and unsustainable harvesting rates have led to over fishing and relative poverty for reservoir communities dependent on fisheries for their livelihoods.

The social and ecological impacts of dams are closely intertwined, especially where people are dependent on rivers.

The water storage functions of dams also engender a host of social and ecological consequences, particularly impoundments designed to promote irrigation development. Throughout the 20th century, numerous governments—particularly those presiding over arid regions—perceived dams' water storage function as a crucial means of promoting irrigated agriculture and, eventually, boosting agricultural production. Massive investments in irrigation systems—consisting of a series of smaller weirs, barrages, and channels downstream of the primary impoundment to divert water to nearby agricultural lands—accompanied the so-called Green Revolution in agriculture in much of the Third World in the 1960s and 1970s. While the result of these investments has in many areas boosted overall agricultural production, irrigation development has also contributed to environmental degradation and social disruption.

One of the most serious environmental impacts of irrigation systems is salinization, or the increased presence of salts in agricultural soils associated with irrigated agriculture. The evaporation of water from reservoirs, canals, and fields can lead to increased concentrations of salts in irrigation water, which in turn increase the risk of adding salts to farming areas. Farmers often deliver more irrigation water to flush out saline soils, but this runs the risk of increasing the salinity of ground water. If improperly drained—poor drainage has been a dilemma for irrigated agriculture for decades—salts tend to accumulate in the groundwater below agricultural fields, adding to the problem. Saline water from irrigated fields, when returned to river channels, also contributes to degraded water quality in downstream reaches. Salinization has plagued the extensive irrigation systems built first by the British and later expanded by post-independence governments in northwestern India.

In addition, dams and irrigation systems often create favorable conditions for the genesis and spread of vectors (such as snails or insects) for debilitating diseases like schistosomiasis and malaria. Increased incidence of both diseases, which have a direct impact on human health and indirect economic impacts in terms of reduced labor availability, has followed the construction of water development infrastructure in many parts of North and West Africa, south Asia, and southeast Asia. Among communities living near the gigantic Volta Reservoir in Ghana, rates of people infected with urinary schistosomiasis skyrocketed in the years immediately following construction of the Akosombo Dam in 1965.

Itaipu Dam

The Itaipu Dam on the Parana River in Paraguay, South America, has been listed as one of the Seven Wonders of the Modern World by the U.S. magazine *Popular Mechanics* in 1995.

Generating power for Paraguay and Brazil from the dam's hydroelectric plant, the company that controls it is Itaipu Binacional, taking its name from what was originally an isle that was in the river close to the construction site.

Planning for the dam started in the 1970s with Sapena Pastor, the Paraguayan foreign minister, and Juracy Magalhaes, the Brazilian foreign minister, signing the "Ato do Igacu" (Igacu Act) on July 22, 1966, allowing them joint exploitation rights for the resources generated by the hydroelectric plant. Work on the dam began in 1970, and on October 14, 1978, the route of the Parana River was changed to allow the riverbed to dry so that work could begin on the dam itself. The reservoir for the hydroelectric plant was formed in October 1982, and on May 5, 1984, the first electricity was generated from the plant.

The undertaking had been vast. The reservoir was the largest in Paraguay and the seventh-biggest in Brazil. About 40,000 workers labored on the project. The electricity generated for Brazil was the equivalent of 434 thousand barrels of petroleum being burned every day. Following the success of the Itaipu Dam, the Yaciretá Dam was constructed on the Parana River on the borders of Paraguay and Argentina, with power gradually coming on tap, with the hope that it might be completed by 2008.

State-sponsored irrigation projects typically demand a series of reforms in the way that agricultural production is organized and managed. Irrigated agricultural demands an entirely different set of practices and technologies than rain-fed agriculture, and recipient communities are typically ill prepared to adopt these new techniques. Furthermore, the expenses associated with training farmers in new techniques and maintaining functioning irrigation infrastructure frequently outweigh the economic benefits associated with such projects. Such has been the case with numerous large-scale irrigation schemes such as the Mahaweli project in Sri Lanka, the arid regions of northern Mexico, and Kenya's Bura irrigation project on the Tana River.

While the impoundment of rivers generates significant biophysical changes in the area immediately upstream of the dam site, downstream hydrologic and ecological alterations are equally significant. Dams, by removing the fine and coarse sediment normally transported by flowing rivers, often result in significant morphologic adjustments to the river channel. The increased scouring of sediment-free waters can lead to downstream bank erosion and ultimately, to changes in river channel morphology, gradient, and sinuosity. Dams' blockage of sediment and nutrient flows can also significantly alter downstream water quality. Depending on factors such as the location where water is extracted and delivered to the channel below a dam and the relative volume of flows allowed downstream, a dam can produce major effects on river temperature, concentration of heavy metals and minerals, dissolved oxygen and other gases, turbidity, and nutrient load.

Perhaps most significant in terms of human–environment relations, dams can profoundly alter the timing, duration, and magnitude of seasonal flooding. In those regions where floodplains constitute important sites of agricultural and fisheries production, in particular the tropical and monsoonal zones of Asia, Africa, and Latin America, the disruption of annual flooding cycles has disrupted farming schedules, dried out floodplain forest ecosystems, and destroyed important fish habitats. Formerly productive floodplains that provided fish, plant materials, and other economically important resources to nearby communities in the southern United States' Mississippi River Delta, have been devastated as a result of upstream water projects.

Large dams can also have significant impacts on the delta and estuarine regions of a river system. In estuaries, many aquatic species have adapted to specific salinity gradients where the fresh water of the flowing river meets the tidally influenced saline water of the ocean. Moreover, numerous marine species depend on the tremendous amount of nutrients delivered by rivers to their estuaries. Dams cut off this important food source. Egypt's productive sardine fishery—dependent on annual plankton blooms spurred by floods that brought nutrients to the mouth of the Nile—in the Mediterranean Sea went into a precipitous decline in the years following closure of the Aswan Dam in the early 1970s on the Nile River.

EXPRESSIONS OF POWER

Dams are also expressions of political, economic, and symbolic power. Dam building is a big business, with an annual expenditure of between $32 and $42 billion during the 1990s. Despite these enormous investments, many, if not a majority, of the world's large dams constructed in the 20th century have been plagued by large cost overruns, construction delays, and unrealized economic benefits due to less than expected electricity production or water storage capacity. Beyond their potential economic benefits and costs, dams often serve a symbolic role, as representations of nationalism and humanity's ability to control nature. For dam promoters and builders, they are magisterial testaments to economic development and scientific progress. Prime Minister and nationalist leader Jawaharlal Nehru famously declared in the early 1950s that dams were the "temples of modern India" that would fuel agricultural development and industrialization. Similarly, the Akosombo Dam on the Volta River in Ghana and the Cahora Bassa Dam on the Zambezi in Mozambique both became important symbols of national economic development in post-independence Africa.

Dams have emerged as important foci in local and global struggles over environmental degradation and livelihood disruption. Northern-based nongovernmental organizations (NGOs) such as the U.S.-based International Rivers Network (IRN) and the Canada-based Probe International have formed coalitions with numerous NGOs and people's organizations across the globe to oppose a host of specific dam projects. Dam-affected peoples and their advocates have pointed out the disproportionate social and environmental costs borne by those communities whose fisheries-based and agricultural livelihoods are destroyed by the construction of large dams. These struggles culminated in the creation of the World Commission on Dams (WCD) in the late 1990s. The WCD—an organization founded by the World Bank and the World Conservation Union (IUCN) and made up of representatives from states, the dam industry, and dam critics—published a comprehensive report in 2000 calling for a more participatory approach to the construction of large dams. The report was highly critical of many of the world's large dam projects over the past half century, noting that many had failed to achieve their stated objectives in terms of electricity generation and irrigation coverage and had resulted in profoundly negative impacts on displaced communities without providing just compensation.

Dandelions

THE DANDELION, *TARAXACUM officinale,* is one of the most common plants in the world. Its Latin name, *Taraxacum,* derives from the Persian word for "bitter herb." *Officinale* implies that the plant has some beneficial or pharmaceutical value. The dandelion is probably better known by its many common names, including *Blowball, Puff-Ball, Clock Flower, Cankerwort, Lion's Tooth, Irish Daisy, Monk's Head, Priest's Crown, Swine Snout, Wild Endive,* and *Sin in the Grass.* The Spanish refer to it as *diente de leon*; the French as *pis-en-lit*; the Chinese as *pu gong ying*, or "earth nail," because of its deep taproot; and Native Americans as *Chicoria*.

Considered an "invasive weed" by many, the ubiquitous dandelion can be found in virtually every corner of the earth, due to its ability to survive in a wide range of climates and poor soil conditions. Easily identified by its yellow flower perched atop a tall stalk and its round, fluffy ball of white down and seeds, which are easily dispersed by the wind, the plant has been cursed by those who want to remove them from their lawns and praised by others

Dandelions have a checkered past, but throughout history humans have used it for food and medicine.

who boast about its nutritional and medicinal qualities. The plant is especially attractive to children, who like to blow the fluff ball of seeds into the air.

Dandelions have a checkered past, but throughout history, humans have employed the plant primarily as a source of food and medicine. Many believe that the plant originated in Asia, where it was initially used as a medicinal herb. During the 10th and 11th centuries, Arab physicians were praising the plant for its medicinal qualities. The dandelion was also present in ancient Europe. According to myth, Theseus ate a dandelion salad after killing the Minotaur. The Romans, as well as the Gauls and Celts, used the plant as a source of food. The Anglo-Saxons and the Normans used it for both food and medicine. It could also be found cultivated in monastery gardens. In Medieval times, the French referred to the plant as *dent-de-lion,* or "lion's tooth," in reference to the jagged, curved points on the leaves that resembled the predator's teeth. Saxon serfs soon corrupted the name to "dandelion."

European explorers and colonists brought the plant to the Americas for a variety of reasons. Dandelions came to Mexico and the Spanish hinterlands with the conquistadors, who used it for food and medicine. English colonists planted dandelions in their gardens to use as a "salet." German settlers carried the plant to Pennsylvania and used it as an early spring source of vitamins and nutrition. In Canada, the French brought dandelions to use as a food and health remedy. In time, Native Americas began to use the plant in a variety of ways. The Iroquois used it for stomach problems and water retention; the Cherokee made tea from the root to calm the nerves; and the Pillager-Ojibwa employed the plant as a cure for heartburn.

Medicinally, the dandelion has many important benefits, but its most common application is as a strong diuretic, hence the French name, *pis-en-lit,* or Piss-in-the-Bed. As an edible plant, dandelion is high in vitamin A and C and also copper and iron. All parts of the plant (leaves, flowers, and root) can be consumed. The leaves contain about 4 percent potassium, which is more than either broccoli or spinach. The roots can be roasted and used as a coffee substitute. Many species of wildlife, including deer, elk, bear, and geese, as well as several species of songbirds, depend upon the dandelion for food.

Although dandelions have historically benefited humans, today they are largely considered a nuisance, especially in Europe. The U.S. Forest Service lists the dandelion as an "invasive and exotic" weed.

Danube River

THE DANUBE RIVER is the second longest in Europe, at 1771 miles—only the Volga River is longer. It has been an important international waterway for many years, and in the ancient world represented the northern border of the Roman Empire as the river Danuvius.

The catchment area for the river is in southern Germany, where two streams, the Breg and the Brigach, combine to form the river near Donaueschingen, a small town on the eastern slopes of the Black Forest. The river then passes through the Swabian and Franconian mountains, passing the Bavarian plateau and then reaching its northernmost point at Regensburg, the capital of the Upper Palatinate. It then flows south through Passau into Austria, passing through Linz to Vienna, where, to reduce the threat of flooding, the river is diverted through a man-made canal. From there it goes into Slovakia, passing through Bratislava, Slovakia's capital. From there is flows through Komarom, Estergom and Budapest across the Great Alfold Plain until the Iron Gate Gorge, where a massive hydroelectric scheme was developed during the 1970s.

In eastern Hungary, it joins with its tributaries, the Drava, the Tisza and the Sava, with the Lower Danube flowing through Vukovar, in Croatia, then to Novi Sad, capital of the Serbian province of Vojvodina, then passes through Belgrade. It then goes between the Walachian Plain of Romania and the Danubian Plain of Bulgaria. It later splits into three channels heading into the Black Sea. According to legend, this delta region is one of the possible burial grounds for Attila the Hun.

The Danube has long been an important route of commerce through Europe, with large numbers of ships transporting produce and letters. Many barges now transport supplies, and there are also a number of tourist cruises. The Rhine-Main-Danube Canal now connects with the Danube, enabling ships to travel from the English Channel to the Black Sea; and in 1994, the river was declared one of the ten Pan-European transport routes.

Since Roman times, many battles have taken place along the Danube. The river protected Vienna from attack during its siege by the Turks in 1683. Napoleon's capture of Ulm on October 20, 1805, allowed the French to cross the river, and the battle of Wagram on July 5–6, 1809, was fought on the east bank of the river. During World War I, Austrian soldiers held most of the river. In World War II it provided a route for German supplies. The breakup of Yugoslavia saw fighting in Vukovar in 1991; and in 1999, NATO planes bombed the bridges over the Danube.

As well as hydroelectricity at places such as the Iron Gate Gorge, some ten million people in Europe get their drinking water from the Danube. Although in medieval times, many people lived from fish caught from the river, this only continues in the delta region.

The Danube has also been associated with the Danube School of landscape painting from the sixteenth century, and the subject of the musical waltz by Johann Strauss the Younger (1825–99), *An der schönen blauen Donau*, better known in English as the "Blue Danube." There is also *The Waves of the Danube* by the Romanian composer Ion Ivanovici (1845–1902).

The river is now protected by the International Commission for the Protection of the Danube River; and the Danube Delta became a UNESCO World Heritage Site in 1991.

Darwin, Charles (1809–82)

CHARLES ROBERT DARWIN (1809–82) was born on February 12, 1809, at Shrewsbury, England, the son of Robert Waring Darwin, a physician, and Susannah Wedgwood, daughter of pottery manufacturer Josiah Wedgwood. His grandfather was Erasmus Darwin, a respected physician and active naturalist who had published a theory of evolution (*Zoonomia*) in the 1790s, which as a boy Darwin discussed at length with his grandfather.

Darwin studied medicine at the University of Edinburgh and theology at Cambridge University, from which he graduated with a bachelor's degree. Abandoning his plan to become an Anglican priest, he joined a scientific expedition on board the *H.M.S. Beagle* on a voyage circumnavigating the globe.

Between 1831–36 Darwin served as a naturalist on the Beagle. In 1839 he published *Voyage of the Beagle* (*Journal and Remarks*). The book described research travels in Brazil, Uruguay, Argentina, and Chile, collecting specimens of plants, animals, and minerals while the survey crew on board the *Beagle* was preparing naval charts.

As Darwin collected data on the natural world, he was forced to conclude that the world was much older than about six thousands years. After visiting the Galapagos Islands, he began to develop the theory of evolution. He was influenced by Charles Lyell's theory of uniformitarianism in *Principles of Geology* and by Robert Malthus' *Essay on the Principles of Population* and its view of a struggle for existence among individuals competing for food and reproductive opportunity.

Darwin published his theory of evolution as the theory of the mutation of species in *Origin of the Species by Means of Natural Selection, or the Preservation of Favoured Races in the Struggle for Life* (1859). He argued that species of fauna and flora have developed from a common ancestor. The mechanism for the mutation of the members of a species into another species is natural selection that was similar to the way breeders or growers utilize certain species for selective breeding. Natural selection takes place among the enormous numbers of individuals in a species struggling for survival. Eventually, enough changes take place that new species emerge. Geographic isolation and genetic drift are two mechanisms that make the development of species change possible.

The publication of *Origin* was met with approval by some and disapproval by others. Darwin, who was constantly ill after his return to England, was publicly defended by his "bulldog," Julian Huxley.

Darwin had not discussed human evolution in the *Origin*; however, he did in *The Descent of Man and Selection in Relation to Sex* (1871). His last major work was *The Expressions of the Emotions in Man and Animals* (1872).

Darwin died at Downe, Kent, England on April 19, 1882. He was buried in a state funeral at Westminster Abbey.

Lord Alfred Russel Wallace

Although Darwin is the man credited with the theory of evolution, Lord Alfred Russel Wallace independently formulated his theory on natural selection which predated that of Darwin.

Alfred Wallace was born in Monmouthshire, Wales, in 1823, and attended a one-room school for six years, forced to leave for financial reasons. The young Wallace read voraciously, and at age fourteen, he became an apprentice for his brother who was a surveyor. It was a period when many landowners required accurate maps, and Wallace spent many years mapping the county of Bedfordshire and also parts of Wales. He became upset by the social injustices he saw, and also became heavily influenced by men like Charles Darwin and Alexander von Humboldt. Their books encouraged him to become interested in natural history.

In 1848, Wallace had the opportunity to go to Brazil with a naturalist friend, Henry Walter Bates. Wallace spent four years in Brazil; Bates was in the region for eleven years. Wallace wrote his first books on the Amazon and then headed to the East Indies.

Wallace was in the Malay Archipelago from 1854 until 1862, traveling from island to island, collecting zoological specimens and formulating his own views about the origin of species. His first work on the East Indies was published in 1855, and included his view that "every species has come into existence coincident both in space and time with a pre-existing closely allied species." In 1858, a paper published under the names of Darwin and Wallace was entitled "On the Tendency of Species to Form Varieties; and on the Perpetuation of Varieties and Species by Natural Means of Selection." There have been subsequent academic disputes over whether or not Wallace came up with the ideas before Darwin. It was soon after that Wallace developed what became known as Wallace's Line—the boundary that separated Australian fauna from that in Asia.

In 1862, having collected 125,000 animal specimens, Wallace returned to England and started writing about his experiences, his major works being *The Malay Archipelago* (1869), and *Contributions to the Theory of Natural Selection* (1870). Wallace went on lecture tours and later received many awards from scientific bodies; he died in 1913, at age 90.

DDT

DDT IS AN organochlorine insecticide used mainly to control mosquito-borne malaria and as an agricultural insecticide. It is available in several different forms: aerosols, dustable powders, emulsifiable concentrates, granules, and wettable powers. It is a colorless crystalline substance that is practically insoluble in water, but highly soluble in fats and most organic solvents. For many years it was one of the most potent and widely used pesticidal chemicals. It was first synthesized in 1874 by Othmai Ziedler. In 1939, Swiss scientist Paul Herman Muller discovered its use as an insecticide, for which he was awarded the 1948 Nobel Prize. The United States began to produce large quantities of DDT (dichlorodiphenyl-trichloroethane) to control vector-borne diseases such as malaria and typhus abroad. It was widely used by the Allied forces in malaria-prone jungles of southeast Asia. After 1945 it was extensively used as an agricultural insecticide. DDT was popular because of its low cost, effectiveness, persistence, and versatility.

DDT was largely responsible for eradicating malaria from Europe and North America. In countries like India, where millions used to die of malaria, its use almost eradicated the disease by the mid-1960s. A resurgence of the disease has occurred there and in many other tropical countries, however. DDT was less effective in tropical regions due to the continuous vigor in life cycle of mosquitoes and poor infrastructure; also because of the microbial resistance to drug treatment, the spread of the deadly malarial variant called *plasmodium falciparum,* and mosquito resistance to DDT. Currently, in Africa, about a million people die of malaria every year.

Since 1991, a number of researchers have been able to detect elevated levels of 1, 1, 1-trichloro-2, 2-bis (P-chlorophenyl) ethane (DDT) and its isomers in the air close to South Haven, Michigan. DDT is slightly to moderately toxic to mammalian species when it enters the digestive system through the mouth. In animal tests, it was found that DDT causes chronic adverse effects in the liver, nervous system, kidney, immune systems, and reproductive system. Its carcinogenic effects show increased liver and lung tumor production. As in other animals (including humans), birds are exposed to DDT through food chain. Fish and other aquatic animals obtain DDT from contaminated water bodies, the result of runoff from agricultural use. Because of the adverse effects of DDT, its use has been banned in developed countries; Sweden and Norway in 1970, followed by the United States in 1972. As of 2006, DDT has been used in tropical countries where mosquito-borne malaria and typhus are serious health problems.

Death of Nature

THE DEATH OF nature is an evocative metaphor that has been deployed by a number of writers and political activists in order to capture the form of modern social relations with the natural world. In his celebrated book, *The End of Nature: Humanity, Climate Change and the Natural World* (1989), Bill McKibben implicitly suggested this process of death in his argument that nature has somehow ceased to exist.

Of course, when McKibben talks about the end of nature, he is actually referring to the end of a specific way of understanding nature. This mode of understanding depicts nature as a pristine realm that is somehow separate from society and cut off from human control and intervention. According to McKibben, in the modern industrial era—an era of nuclear weaponry and DDT, of elevated carbon dioxide in the atmosphere and holes in the ozone layer, of genetic engineering and animal cloning—the notion of a timeless, unspoiled nature has become redundant.

While McKibben's work illustrates how industrialization has led to the elemental, or material, death of nature, it is Carolyn Merchant's *The Death of Nature: Women, Ecology and the Scientific Revolution* (1980), that provides the definitive account of how nature has *died*. Carolyn Merchant is professor of environmental history, philosophy, and ethics at the University of California–Berkeley. According to Merchant, the nature (or world) that has died is an organic one, and recognizes the necessary interdependencies that exist among humans, animals, and the entire physical universe. The organic worldview—suggesting as it does social dependence on the environment—is synonymous with cultures of care and respect in human dealings with nature. This type of understanding of, and disposition toward, the natural world has its antecedents in ancient and medieval scientific frameworks and belief systems, but has recently experienced a resurgence within deep-green thinking and politics.

Merchant's compelling account of the death of nature charts how the organic view of the world has been usurped by the more *mechanical* understandings of nature promoted within modern science and industrial society. According to Merchant, the rise of classical science and commercial capitalism have provided new knowledge about and metaphorical frameworks for understanding nature—knowledge and frameworks that have facilitated a belief in human independence from and dominance over the environment.

On Merchant's terms, the death of nature is not so much an absolute condition (or elemental change) in the condition of nature, but a new, rationally inspired way of understanding and experiencing the natural world. Consequently, while Merchant does chart how nature has been physically transformed by modern science and industrial urbanization, she is primarily concerned with how these material processes were (and continue to be) enabled by cultural and metaphorical practices that serve to *deaden nature,* and in so doing expose the environment to unchecked socioecological exploitation.

The idea of the death of nature remains a potent metaphor for understanding the profound ways in which human society has changed its ideological apprehensions of the environment, and how this has in turn led to the widespread physical transformation of the natural world. As with all metaphorical devices, however, many now writing about environmental history and the philosophies of nature are keenly aware of the dangers associated with claiming the death of nature. These concerns are based upon the realization that to talk of the death of nature suggests the existence of a natural world that can be dominated, totally controlled, and somehow separated out from human history. The search, it appears, is now on for new ways to understand nature as a simultaneously threatened entity of, and dynamic force within, human history.

Death Rate

THE DEATH RATE, also commonly known as the mortality rate, refers to the number of deaths within a population, most typically expressed by the number of deaths per 1,000 individuals of the population per year. While the mortality rate offers a general level of mortality, it can also be used to act as a measure of deaths in relation to a specific cause, such as natural disasters, incidents of a particular disease, age or gender groups, or infants and mothers. Therefore, a number of death rate measurements are in existence, each with their own distinct nuances. These include: the crude death rate, that is, the total number of deaths per 1,000 of the population; the infant mortality rate, a measure of the number of deaths of newborns (less than one year old) per 1,000 live births; the perinatal mortality rate, which counts the number of neonatal deaths per 1,000 births; and the maternal mortality rate, that is the number of maternal deaths from childbearing per 100,000 live births. Other detailed mortality rates exist, including the standardized mortality rate (SMR). The SMR refers to the total number of deaths per 1,000 of the population of a distinct age group, such as those aged over 65 years, or aged between 16 and 65.

INFLUENCES OF DEATH RATE

Within a country or a region the level of the death rate, just like the birth rate, is subject to numerous influences. These include dramatic events such as wars and armed conflicts, occurrences of natural disasters (such as typhoons, earthquakes, or floods), levels of poverty, levels of economic development, dietary habits, and the size and scope of healthcare services. Thus, in nations that experience high death rates, such as those within the African continent, it is not unusual to find that the health care infrastructure is lacking in comparison to those found within developed nations. However, even within developed nations, the death rate for social groups can differ due to their ability to afford comprehensive medical care and insurance.

Even in an affluent society such as that of the United States, the death rate is much higher for members of the laboring classes than white-collar workers; they are less able to afford health afford premiums and expensive medical care. Moreover, in societies like the United States, where people often eat fatty fast food, levels of heart disease inflate the national death rate. Consequently, national governments attempt to educate and encourage more balanced dietary habits and healthier living, aiming to lower the death rate among particular social groups most at dietary risk, and society as a whole.

One of the most significant influences upon the death rate is the infant mortality rate. In nations like Angola, Afghanistan, and Sierra Leone, places with the three highest levels of infant mortality in the world, their death rates are much greater than the worldwide average (about 8.9 per 1,000). In Angola, for instance, the death rate is about 25 per 1,000, and in Afghanistan about 21, a result of armed conflicts, poverty, and a lack of adequate medical care outside of urban areas. However, in both places the infant mortality level is also above the global average, with about one in five Angolan children and one in six Afghani children dying before their first birthday.

The factor that has the greatest influence upon any nation's death rate is disease, especially those of a cardiovascular, infectious, or respiratory nature. Access to medical care is therefore vital in ensuring the death rate remains low, and it is common to find low death rates in nations that are economically developed, where healthcare provision for both children and adults is mandatory and easily accessible. Diseases such as cholera, malaria, influenza, and typhoid have little impact within places like Europe and North America, but remain potent killers in Africa and other poverty-stricken regions of the world where healthcare is minimal. However, economic development does not mean a nation becomes immune from death by disease. In recent years, HIV/AIDS has had an impact upon many developed world nations' death rates, although the greatest impact of the disease is also within areas of the world where education of disease, and not just medical care, is not widely provided. Diseases like HIV/AIDS have profoundly impacted the death rates of nations in Africa. However, with wealth come incidents of disease with the potential to increase nominally the death rate, such as deaths from road traffic accidents and liver cirrhosis from alcohol abuse, a significant factor on rates of death in places like Russia.

Debt

DEBT IS GENERALLY defined as a sum of money or some other valuable that is owed by one individual (or group) to another. Debt is created when a person or company turns over a sum of money to be repaid at a later date, usually with interest.

The recorded history of private debt can be traced back to the second millennium B.C.E., although debts between individuals almost certainly date back much further than that. The existence and rules for dealing with debt appear in the Torah (all debts must be erased every 7, and every 50 years) and are subsumed into both Christianity and Islam, together with prohibitions on "usury," which at least initially simply forbade the charging of any interest. However, the need for ready cash to pay for raising armies and maintaining royal lifestyles drew monarchs into taking out loans from wealthy banking families when they were unable to raise sufficient tax revenues to meet their immediate needs. These private debts, together with the needs of the trading houses of northern Italy, created a demand for a new kind of financial service that both encouraged enterprising individuals to find ways to circumvent the usury laws and created new financial institutions that were to become essential for large-scale public borrowing.

By the 12th century, bills of exchange were in use in Genoa, and negotiable bills that were transferable to a third party appeared by the 14th century. These instruments, together with predictable revenue streams from taxation, allowed the earliest public debts to be taken out by the Venetian state in the 12th century, using future revenue from the salt taxes to guarantee the loans. In northern European city states a different system developed that involved selling redeemable, life or perpetual annuities. These loans were generally secured on some immovable asset such as the town itself, and interest was designated as a "gift" to avoid charges of usury. The monarchies of Europe began to imitate these urban loans by the 16th century, with the nascent state bureaucracies taking over the role of issuing annuities and ensuring reliable repayment of the loans. The creation of public banks in the 16th century and of chartered trading companies in the 17th provided new forms of public borrowing, secured by shares in trading companies or government issued bonds.

PUBLIC DEBT

Public debt is also known as government debt and occurs when any level of government (national, regional or local) takes out a loan. Generally, governments borrow money by issuing securities or bonds, although governments that are considered high risk may turn to commercial lending institutions and international lending institutions such as the IMF or World Bank. Government bonds are generally issued in the national currency if that currency has a strong track record of stability. Government bonds are gen-

Many societies view personal debt as immoral, but some modern economists see it as beneficial to the economy.

erally regarded as "risk-free" because governments have the power to raise taxes, reduce spending, and even print money to pay the bond when it matures. The primary risk associated with such bonds is that of fluctuations in the value of the currency over the life of the bond. Consequently, countries in which the currency is not stable may be forced to issue "sovereign bonds" in a more stable foreign currency. While this makes the bonds more attractive to borrowers, there is the risk that the government may not be able to purchase sufficient foreign currency to redeem the bonds when they mature.

The accumulation of pubic debt, particularly in a state with limited assets or poor economic prospects, can lead to the threat of default on the loans. In the 18th century, the Spanish government defaulted on its loans seven times, and in 1917 the revolutionary government of Russia repudiated the debts of the previous Imperial regime. More recently, the very high levels of debt accumulated by many developing countries have resulted in the intervention of intergovernmental organizations such as the IMF to prevent default and restructure the loans.

Tolerance for relatively high levels of government debt arises largely from Keynesian economic theory which asserts that government borrowing in times of economic slowdown provides capital for increased government spending. That spending in turn supports employment and fuels consumption, creating an economic recovery. At that time the loans can then be repaid. These theories became very popular in the 1930s and 1940s and had great influence on the Bretton Woods institutions (the IMF, the World Bank, GATT and the gold standard), which were created at the end of WWII to manage and stabilize global finances in the wake of the war and the Great Depression.

The problems associated with high levels of public debt largely depend upon the financial stability and economic strength of the government involved. In absolute terms, the world's largest debtor nations are in the developed world; however, strong economies, stable governments and substantial real assets make these debts manageable. During the 1990s the Clinton administration in the United States proved that even very large public debts could be paid off during periods of sustained economic growth. The greatest danger to developed countries with high levels of public debt occurs when much of that debt is external, leaving the country vulnerable to political and economic decisions made by foreign governments. For developing countries, high levels of public debt pose a rather different problem. If the ratio of interest payments (debt servicing) to government income becomes too high, it drains revenue from domestic public services, infrastructure, and industrial development. This depresses economic prospects and makes future loans riskier. In addition, as these countries generally have loans in foreign currencies, poor economic prospects lower the value of the domestic currency relative to the currency in which the loan was made and thereby increases the size of the loan (see Debt Crisis).

PRIVATE OR CONSUMER DEBT

Private debt as a transaction between two individuals has been around for a long time, but like public debt, it did not become a widespread phenomenon until the advent of public banking. Private debts can either be unsecured, in which case the ability to secure a loan will depend upon the creditworthiness of the individual; or they can be secured loans, where another asset owned by the borrower is used as security for the loan. Real property such as houses, land, and business assets are the most common forms of security. Secured loans tend to be offered at lower interest rates than unsecured loans, and interest rates also rise as the credit worthiness, determined by previous credit history, of an individual declines.

Historically, personal debt has been viewed by many societies as immoral, but modern economic perspectives often see consumer debt as beneficial to the economy as it increases domestic production and enhances economic growth. Governments may even encourage debt through tax relief for certain types of interest payments, if the loans are used in ways that encourage consumption of domestic products (for example mortgage interest relief in the United States).

The most common forms of secured personal debt are mortgages. However, there has been a large increase in unsecured personal debt in most developed countries over the past few decades, and the rising use of credit cards, payday loans, tax rebate loans, and consumer financing has led to record levels of private debt in many developed countries.

THE DEBT CRISIS

The most serious debt-related problem in the modern global economy, however, is the debt crisis afflicting many developing nations. Public borrowing by developing governments became common in the post-WWII period as international organizations such as the IMF and World Bank provided a secure framework for infrastructure and development loans. By 1970, the 15 mostly heavily indebted countries owed an average of 9.8 percent of their GNP in international loans. However, these loans were at preferential rates, made only for projects that were judged necessary for economic development and were held by non-profit organizations. By 1987, those same countries owed an average of 47.5 percent of their GNP. The 1970s saw radical changes in the international financial markets that were to greatly affect not only access to loans, but also the terms on which those loans were granted.

The initial impetus to increased borrowing by developing nations was the oil crisis of 1972–74, when the price of oil quadrupled over a two-year period. This increased price put tremendous pressure on the industrialization programs of countries that relied heavily on oil imports and at the same time sent a huge volume of "petro-dollars" into the coffers of the international banking community. Eager to recirculate this money, the banks began to offer low interest loans to even relatively high-risk borrowers, including many developing nation governments. For oil-importing countries, this provided capital to continue the development programs regardless of the increased cost of oil, and for those few countries that were oil exporters, the money was borrowed on the basis of the oil revenue bonanza to come. However, the second oil crisis of 1979–80 closely followed by the interest rate hikes of the early 1980s, and the deep global recession of 1981–82 left many developing countries with insufficient income to pay back their loans on schedule. These loans, often made for current consumption rather than to build economic capacity, also came at a time when the global economy had been destabilized by the ending of the Bretton Woods system and when there had been an overall decline in the terms of trade for products from the developing world. As countries came increasingly close to defaulting on their loans, the IMF emerged as the guarantor of creditworthiness for developing countries regardless of the lender. Part of the new guarantee process involved countries undergoing IMF structural adjustment programs, which were designed to address balance of payment problems generated by internal problems such as high inflation, structural inefficiencies, and large budget deficits. The IMF program was designed to reduce current consumption so that capital could be invested in future economic growth.

However, in the case of heavily indebted countries, it merely freed money to flow out of the country and back to the lenders, and led to austerity programs at home that had potentially devastating effects on human and physical capital as food and transport subsidies were reduced, health and education programs cut back, and taxes raised, even as public sector employees were laid off. In addition, requirements for increased export income often shifted agricultural production from local food supplies to export crops, increasing local food costs. Since the 1980s, the focus of the international financial community has been to restructure this debt to reduce the chances of large scale default. A wide variety of programs, including debt for nature swaps; debt for asset swaps, which give creditors the ability to buy physical assets in the debtor country at a deep discount; and cash buy backs, which allow the creditor to buy back the loan at a deep discount. More recently, as it has become apparent that such programs are only having a minimal impact on debt reduction, particularly in the poorest countries, the concept of debt forgiveness through programs such as the Millennium Development Goals is becoming increasingly common.

Debt-for-Nature Swaps

DEBT-FOR-NATURE SWAPS OCCUR when a creditor reduces or forgives a country's external debt in exchange for the debtor country redirecting a portion of its debt repayment to conservation and other environmental projects. In commercial swaps, a commercial bank donates or sells at a discount a country's debt to an international nongovernmental organization (INGO). The INGO (most commonly Conservation International, World Wildlife Fund, and the Nature Conservancy) separately negotiates a contract with the debtor government. The INGO cancels the original debt, and the debtor government pays a percentage of the original debt toward conservation projects.

A bilateral swap operates similarly, except that the creditor is a country. INGOs play a role either as an intermediary in the debt transaction or by designing conservation projects. In both commercial and bilateral swaps, resultant funds for conservation are paid in local currency and managed by an in-country NGO or conservation trust fund. Although multilateral lending institutions are prohibited from participating as creditors, the World Bank provides technical assistance.

HISTORY OF DEBT

Debt-for-nature swaps are part of a larger history of debt renegotiations that became necessary in the early 1980s, when debt-ridden third world nations were unable to meet repayment schedules. The first debt-for-nature swap occurred in 1987, when Bolivia owed $650,000 to a commercial bank. Conservation International purchased this debt for $100,000 with funds provided by the U.S. Agency for International Development (USAID). In return for cancellation of the original $650,000 debt, Bolivia created a $250,000 endowment to support the Beni Biosphere Reserve. A Bolivian foundation managed the endowment.

The Paris Club, a consortium of 19 creditor countries that sets debt restructuring policies, first permitted bilateral swaps in 1990. Creditor countries in North America and Europe, including Germany, Holland, Finland, and Canada, have participated in bilateral swaps. Also in 1990, the Enterprise for the Americas Initiative endorsed U.S. debt-for-nature swaps with select Latin American countries that met financial austerity and democratic governance criteria. In 1998, the Tropical Forest Conservation Act promoted U.S. swaps with countries containing significant tropical forests, including the Philippines, Bangladesh, and Latin American and Caribbean nations.

Debt-for-nature swaps are touted as beneficial for creditors, debtors, and nature. However, they do incur high transaction costs and require cooperation among multiple governmental agencies. To date, commercial and bilateral swaps have provided over $117 million and $1 billion for nature, respectively. The majority of beneficiary countries are Latin American, such as Costa Rica, Belize, and Ecuador. Swaps in Peru alone have endowed $57 million for conservation. Other beneficiaries include Madagascar, Vietnam, Jordan, and Moldova. Thirty beneficiary countries have created conservation trust funds. The largest swap provided $570 million for environmental restoration in Poland.

One justification for swaps is that external debt causes deforestation, since debtor nations attempt to repay debts via commercial agriculture and logging. Thus, reducing debt decreases environmental threats. However, concrete links between external debt and deforestation rates are inconclusive. Moreover, swaps to date have diminished total third world debt by less than 1 percent.

Another justification is that debt-for-nature swaps provide funding for on-the-ground management of "paper parks." Yet creditors worry that beneficiary nations depend too heavily upon external funding for parks. Debtor countries, on the other hand, express sovereignty concerns because of the broad role of INGOs in swaps; these intermediaries are seen as an external (and even neocolonial) authority, beyond the control of both the state and local people. Moreover, though swaps involve complex contracts, their enforceability is often unclear. So while swaps have put a tangible value on nature and have provided significant funding for the environment in countries that otherwise have little, questions still remain.

Deciduous Forest

DECIDUOUS FORESTS ARE dominated by tree species that drop their leaves and become seasonally dormant in response to challenging environmental conditions. Broad-leaved tree species of temperate deciduous forests drop their leaves in autumn to avoid the tissue-damaging winter temperatures and water stress of frozen soils. In the dry tropics, deciduous tree species shed their leaves to avoid the drought stress and injurious high temperatures associated with the dry season.

Temperate broad-leaved deciduous forest largely occurs in the northern hemisphere, chiefly eastern North America, western and central Europe, and eastern Asia. A small region of the southern Andes supports the southern hemisphere's only occurrence of temperate deciduous forest. Evergreen coniferous tree species, like pine (*Pinus*), spruce (*Picea*), fir (*Abies*), and hemlock (*Tsuga*) also grow in most temperate deciduous forests. Tropical deciduous forest, also called tropical dry forest, occurs in Central and South America, India and southeast Asia, and Africa, comprising 42 percent of tropical forests worldwide.

Temperate deciduous forests of the northern hemisphere are composed of closely-related tree species in general, such as oak (*Quercus*), maple (*Acer*), beech (*Fagus*), ash (*Fraxinus*), basswood or lime (*Tilia*), birch (*Betula*), and elm (*Ulmus*). Temperate deciduous forests, especially those in eastern North America, are noted for their structural and taxonomic diversity. European deciduous forests are lower in richness of tree species than are eastern North American and Asian deciduous forests due to past glacial history. The east-west tending mountains of Europe formed a barrier to the tree species migrating from the glacial advance, differing from the generally northeast-southwest tending Appalachian Mountains of eastern North America, which did not impede migration. The temperate deciduous forests of the Great Smoky Mountains of eastern North America, near the southern terminus of the Appalachian Mountains, support 130 species of flowering trees and 11 species of conifers, more in total that grow in all of Europe.

Temperate deciduous forests are vertically stratified, separated into four or more distinct vegetation layers from canopy to forest floor. The uppermost canopy or *overstory* stratum consists of the dominant trees of the forest. Immediately below the overstory" is the *understory*, stratum containing "overstory replacements and subdominant species that do not recruit to the overstory. A shrub stratum of woody, non-arboreal species may occur beneath the understory stratum. Finally, an *herb* stratum—consisting of small-stature vascular plants and mosses—rises to a meter or so above the forest floor. The herb layer, among all the vegetation strata in temperate deciduous forests, supports the highest diversity of plant species in the forest. Diverse vegetation also supports diverse animal life, including birds, mammals, amphibians, reptiles, and insects. Insects, especially caterpillars that feed on leaves of deciduous trees, form an important food base for neotropical migrant bird species in eastern North America. Neotropical migrants, like warblers, typically overwinter in tropical forests of Central and South America but nest and rear young in temperate deciduous forests where insect food is abundant.

Human impact on deciduous forests has been heavy. Tropical deciduous forests have been largely degraded or converted to agriculture and rangeland. Temperate deciduous forests have been converted to agriculture or urban and suburban land use. These forests are further impacted by stressors such as acid precipitation and nitrogen deposition, root causes of forest decline.

Decision Science

DECISION SCIENCE (DS) originated in Great Britain during World War II, when mathematical or quantitative approaches were used to solve logistic problems during military operations. Since then, it has evolved to be applicable to the management of all aspects of a system, product, or service. It is now considered an important input to decision-making in a wide variety of applications in business, industry, and government. The growing complexity of management since the 1940s has necessitated the development of sophisticated mathematical techniques for planning and decision-making. DS involves the quantitative evaluation of alternative policies, plans, and decisions and has become centered in the structured decision-making process cycle. It may also be called Operations Research (OR, American), Operational Research (OR, United Kingdom), Systems Science, Mathematical Modeling, Industrial Engineering, Critical Systems Strategic Thinking, Success Science (SS), and Systems Analysis and Design.

The study of DS involves the application of mathematical methods and tools for solving problems relating to the allocation of scarce resources subject to certain constraints. It contributes to the understanding of human decision-making as well as the development of methods and tools of analysis. Usually the problems deal with determining the least cost or greatest profit, subject to constraints such as some required quantities, capacity to manufacture or store, and available resources over a large number of variables.

The fundamental part of DS modeling is the "systems approach" to problem solving that indicates that the context of organizational problems is as important as the stated problem. The modeling process helps to improve operations through the use of scientific methods and the development of specialized techniques. It often involves defining a problem, collecting information, making decisions based on them, taking action, monitoring and evaluating the results of the implementation, and checking for new problems iteratively. There are two approaches to the decision process—sequential model or nonsequential model. The sequential model requires following certain linear steps, while the nonsequential model has certain phases that have a circular relationship. Orville G. Brim and others proposed one of the early sequential models in *Personality and Decision Processes, Studies in the Social Psychology of Thinking* (1962). They proposed following six steps as part of the methodology: Identification of the problem, obtaining necessary information, production of possible solutions, evaluation of such solutions, selection of a strategy for performance, and implementation of the decision.

However, a more realistic model should allow the various parts of the decision process to vary in order. One of the most accepted nonsequential models was proposed by Mintzberg, Raisinghani, and Théorêt in 1976 in "The Structure of 'Unstructured' Decision Processes," *Administrative Sciences Quarterly*. They identified the decision process to have three phases: identification, development, and selection. In this model, one may cycle through one or all of the phases in any order until an acceptable solution is found.

IDENTIFICATION AND DIAGNOSIS

The identification phase consists of identifying the problems or opportunities (decision recognition routine) and diagnosis routine—using the existing information and identifying new information to clarify and define issues. The development phase defines and clarifies the options and involves two steps—a search routine to find ready-made solutions and a design routine at developing new solutions or modifying existing ones. The selection phase involves three routines: a screen routine, to eliminate subobtimal alternatives; an evaluation-choice routine, to evaluate different alternatives and use judgment, bargaining, and analysis; and an authorization routine, to gain approval for the solution selected.

Most of the environmental problems are complex in nature; this makes the DS approach appear the most suitable for achieving suitable decisions. In the context of the environment, DS involves methodical procedures for integrating information about physical and social phenomenon, environmental processes, available options, the effects of different options on environmental and social conditions, and human values. Decision science often helps to improve the decision process as it helps in making explicit judgments about information (environmental policy) that involves diverse, conflicting, and changing values with scientific uncertainty. It involves participants in making the decisions, and therefore makes it potentially more acceptable and causes less contention among the participants.

Conversely, however, since many or most environmental decisions explicitly or implicitly involve reallocation of control or rights to environmental goods or services, or the control or shifting of externalities, benefits, or risks, critics charge that DS merely creates a depoliticized gloss for inherently political decisions. So too, as the science of risk analysis and perception has evolved, the importance of effective or emotional components of decision-making have become better understood. Their incorporation into DS remains somewhat unclear. For these reasons, while DS remains a potentially important component for environmental decision making, its role is not without concern or controversy.

Decomposition

DECOMPOSITION IS THE process by which organic matter and its associated nutrients and minerals are recycled through the biosphere by soil organisms. Three-fourths of all terrestrial carbon is present in soil, and various soils have different levels of carbon storage and decomposition rates.

Put simply, decomposition is the breakdown of complex organic molecules into simpler organic molecules by soil organisms, particularly bacteria and fungi. Decomposition begins when dead organic material such as plant leaves, roots, and wood, soil animals, soil microbes, plant root exudates, and soil animal excretions are deposited onto and into soil. Plant material accounts for the majority of organic matter, and thus carbon, added to soil organic matter pools in most ecosystems. Soil animals such as worms, insects, and small mammals mix the surface litter with deeper soil layers. This physical mixing breaks the fresh organic matter into smaller pieces in a process termed *comminution*, which increases the surface area available for microbial attack. Decomposer bacteria and fungi then become more active on the organic matter fragments, and decomposition proceeds more rapidly. The bacteria and fungi release specialized enzymes that cleave (depolymerize) bonds between complex organic molecules. Depolymerization breaks complex carbon compounds into simpler molecules such as single glucose units that are more easily metabolized by the microbes as energy and carbon sources. Some common decomposer bacteria include *Bacillus*, *Pseudomonas*, and *Clostridium*, which are active in decomposing cellulose. The brown and white rot fungi (*Basidiomycetes*) are common fungal decomposers that specialize in decomposing celluloses and lignin, respectively. Microbes also decompose organic molecules in soil that are not derived directly from plant matter, such

Decomposition is the breakdown of complex organic molecules into simpler organic molecules by organisms.

as organic compounds exuded from soil animals, dead bacteria, and fungal hyphae, or carbon stored as humus (described below). Soil animals such as earthworms that ingest organic matter aid in decomposition by inoculating organic matter with decomposer microbes, and by dispersing microbial inocula to organic matter hotspots.

The simpler organic compounds that result from decomposition may be used by microbes for energy or growth, mineralized by other microbes into inorganic nutrients and minerals, or incorporated into highly complex organic carbon compounds called *humus* that decompose very slowly. The byproduct of microbial decomposition under aerobic (sufficient oxygen) conditions is carbon dioxide (CO_2), which may remain in soil pores, dissolve in soil water to form carbonic acid, or diffuse from soil into the atmosphere. Thus, the rate of gaseous CO_2 released from soil is often used as a proxy to estimate microbial decomposition rates.

Decomposition rates vary seasonally and across scales from landscapes to biomes. The rate of organic matter decomposition depends upon organic matter quality (which influences how easily it is decomposed); community composition and activity of decomposer microbes and other soil organisms; and soil physical conditions, particularly temperature and moisture. Decomposition generally proceeds faster in warm, moist climates with deciduous vegetation, and slower in cooler, drier climates with evergreen vegetation. Recent scientific studies suggest that warming of the global climate may speed up the decomposition of organic matter stored in soils of high-elevation and high-latitude ecosystems such as boreal forests and tundra.

Deep Ecology

NORWEGIAN philosopher Arne Naess coined the term *deep ecology* in the short essay "The Shallow and the Deep, Long-Range Ecology Movement: A Summary" (1973). As the title of the paper suggests, this was at once a positive formulation of a new, deep ecology and a critique of what he disparagingly termed *shallow ecology*. These divergent "ecologies" were not divisions within scientific ecology, but branches of the environmental movement. Consumed with the search for piecemeal solutions to particular issues such as pollution and resource depletion, shallow ecology failed to ask deeper questions about the causes of ecological problems and therefore could never hope to solve the ecological crisis itself. Deep ecology, on the other hand, offered a wholesale normative critique of human society, and particularly the human relationship with nonhuman nature.

The bookends of Naess's philosophy of deep ecology are *self-realization* and *ecocentrism*. These two ideas are interrelated and arise out of the (scientific) ecological understanding of the living (and nonliving) world as comprised of interrelated, interdependent, and mutually constitutive beings. The philosophy of deep ecology is thus at once *naturalistic* in that it is derived from ecological science, and *holistic* as it appeals to the relationships between all beings, constituting a whole, living earth. Deep ecology offers a corrective against the (related) dominant Western, modern views that the human species is separate from nonhuman nature and that human individuals are in any sense separate from other living beings (other humans included). "Self-realization," for Naess, is the logical conclusion of any truly deep ecological questioning—when we realize the interconnectedness of all things, it becomes evident that any concept of the self must expand beyond the individual to include all things. Promoting Naess's ideal of self-realization, Fox states that:

> When we realize we are related to the whole, alienation drops away and we identify more widely with the world of which we are a part. Another way of expressing this is to say that we realize a larger sense of self; our own unfolding becomes more bound up with the unfolding of other entities.

So while deep ecology purports to offer a planetary-scale solution to the ecological crisis, the locus of normative change is the human individual.

ECOCENTRISM

Ecocentrism, the second key component of Naess's deep ecology, is a logical derivation of self-realization. Once an individual realizes that he or she is not a narrow, enclosed self and properly identifies with all of nature, anthropocentric (human-centered) thought or action becomes illogical.

Although Naess never writes in a polemical tone, the rhetoric of deep ecology is incontrovertibly divisive and dualistic. The most prominent example is the binary ecocentric/anthropocentric division, which maps directly onto the deep/shallow ecology division. Environmentally-sensitive individuals either possess deep ecological understanding or they do not; they either practice deep ecology or they do not.

Deep ecology was relatively unheard of in North America until 1985, with the publication of Devall's and Session's *Deep Ecology: Living as if Nature Mattered*, which presents a platform for the deep ecology movement. Unlike Naess's earlier work, the platform was intended to be less an *ecophilosophy* and more a set of principles that deep ecologists could rally around, regardless of philosophical or religious positions. The platform was based on the fundamental tenet that nature has "intrinsic value … independent of the usefulness of the nonhuman world for human purposes." Beyond this fiat of intrinsic value, which is basically a restatement of the deep ecology commitment to *nonanthropocentrism*, the platform called for a reduction in human population, a decrease in human interference in the natural world, a change in policies, and a personal "obligation directly or indirectly to try to implement the necessary changes." So the deep ecology platform at once codified a new grounding for many American environmentalists (ecocentrism) and recalled resonant themes within the movement (overpopulation, leaving "nature" to its own devices, and direct political action).

Although summarizing Naess's early writing on deep ecology is a relatively straightforward task, the same cannot be said of its American derivatives. Once deep ecology took root in North American literature, it quickly erupted into a diverse and rather amorphous catchphrase, summoned by different writers to mean quite different things. Although it is impossible to say exactly where it has had the strongest influence, deep ecology has made an indelible mark on the contemporary North American wilderness preservation movement.

Mick Smith argues that American deep ecologists rely on increasingly "scientistic routes" to arrive at their normative proposals, employing biologically determinist explanations of human behavior. This is due largely to the influence of Paul Shepard, who over the course of three decades wrote volumes of work speculating on the biological basis for human attitudes and behaviors toward nature. Sessions approvingly paraphrases Shepard's thesis:

> Humans are genetically programmed for wild environments, and…modern urban humans who have not bonded with wild nature are ontogenetically stuck, remaining in some ways in an adolescent stage of human development.

Smith finds that a culture of hubris and unreflexive scientism has inhibited the growth of a self-critical, pluralistic politics within the deep ecology movement.

Problematic as it may be, the North American variety may be truer to the spirit of Naess's intent than the more scholarly European deep ecology. As Katz, Light, and Rothenberg observe, "Naess has often stressed that he is more interested in deep ecology as a political and social *movement* than as a philosophy."

Deer

MEMBERS OF THE *Cervidae* family, deer are ruminant animals—meaning they are hooved and digest their food through a process of *rumination* on regurgitated cud; and possessing antlers, rather than horns. Indigenous to most of the world, some of the more than 30 species of deer can be found on every continent.

Throughout human history in North America, white-tailed deer and mule deer have been closely tied with human land use, economic activities, and cultural values. Unlike many other wildlife species, deer thrive in human-managed landscapes, and their populations have fluctuated with changing human practices. The tendency of deer to live near human settlements stems from their preference for a fine-grained mosaic of fields and forest, which provides an ideal combination of abundant food and ready access to shelter. Today, a variety of constituencies disagree sharply over how to manage growing numbers of deer.

Aboriginal North Americans across the continent considered deer an important resource for their meat, their versatile skins, and in many cases for other body parts that could serve as tools. Many groups, for example the Ojibwe of the Great Lakes region and the Navajo of the Southwest, expressed the importance of this game species through prayers recited upon killing a deer. Native American groups in the northeast and Great Lakes regions understood the deer's ecological preference for patchy landscapes; they burned areas of forest to create an edge habitat and encourage game.

The activities of Europeans upon their arrival in North America in some ways favored deer, but in other ways reduced their numbers. Though the eradication of predators eliminated one ecological control on deer, human hunting pressure increased; in the colonial period both Native Americans and Euro-Americans overexploited deer, particularly for their skins. In the 19th century, venison assumed an important place in the American diet as market hunters kept pressure on deer populations. Also, agriculture and timber extraction left little forest and therefore little edge habitat for deer near human settlements. Increasingly restrictive hunting laws throughout the late 19th and early 20th centuries helped deer populations recover.

Human communities today provide deer with ideal food sources by planting gardens, ornamental trees and shrubs, and agricultural crops. Typical suburban landscapes offer the mix of forest and field that deer prefer, and to a much greater extent than did burning by Native American communities. Deer populations have grown throughout the 20th century, reaching numbers and densities that many see as problematic. State conservation agencies have loosened hunting rules as a management strategy, but to limited effect. Farmers consider deer pests because of the toll that they take on fruit, vegetable, and ornamental crops; deer also damage gardens and landscaping in residential areas. Car crashes with deer cause injury, death, and increasing insurance costs. Deer ticks have increased with deer numbers, and human communities living near these populations have been exposed to Lyme disease, a poorly understood but debilitating illness. High deer populations and population densities are also associated with starvation during winter and chronic wasting disease (CWD). Deer alter vegetation communities through overbrowsing, and this has had cascading effects on other wild species such as songbirds.

In many U.S. regions, however, the cultural and economic significance of deer makes it politically difficult to enact wildlife management policies to reduce their populations. For hunters, deer are the center of important recreational activities as well as cultural identity. Hunters are often suspicious of official estimates of deer numbers, accusing wildlife officials of exaggerating populations; many choose to limit their own takes in order to ensure future abundance of deer. Deer are worth billions of dollars to the communities that bring in out-of-town hunters. Meanwhile, management agencies have also proposed culling campaigns, but concerned citizens and animal rights organizations have protested publicly funded killing of deer. Relocation and sterilization are costly and rarely effective.

Nova Foresta

Deer hunting in England had long been a royal prerogative, and in 1079, William the Conqueror established the New Forest in southern England as a royal forest. Covering the southwest of the county of Hampshire and a small part of the county of Wiltshire, the creation of the New Forest—called *Nova Foresta* in the Domesday Book of 1086—saw the inhabitants of 36 villages dispossessed. This allowed the deer to breed without having to worry about poaching, and the King to hunt freely. William the Conqueror died in 1087 and was succeeded by his son William “Rufus” II.

William Rufus also enjoyed hunting deer in the New Forest, and on one of these hunting expeditions, on August 2, 1100, he was hit by an arrow, allegedly fired in accident. Others have suggested that it was more likely part of an assassination plot organized by William’s younger brother and successor who became Henry I, nd who was, conveniently, in the hunting party. The site of William II’s death is marked by what is known as the Rufus Stone Memorial.

The forest laws ensured that interfering with the King’s deer and its habitat was severely punished, and these rules operated throughout the Middle Ages. Some 90 percent of the New Forest is still owned by the Crown, and is managed by the Forestry Commission. In June 1999 the New Forest was proposed as a UNESCO World Heritage Site, and in 2005 became a National Park. Several different species of deer still live in New Forest, most of them fallow deer, but also roe deer, red deer, and sika deer.

Deforestation

AT LOCAL, REGIONAL, and global scales, deforestation is significantly altering land cover, perhaps at an accelerating pace. According to the Food and Agriculture Organization and the United Nations Environmental Program, tropical forests are disappearing at a rate of 7.6 million hectares per year (as of year 2000): 4.4 million hectares a year in Latin America, 1.8 million hectares a year in Asia, and 1.4 million hectares a year in Africa. Trends suggest that deforestation of tropical forests is occurring at the greatest absolute rate in history. This transformation of the earth's surface is linked to a variety of scientific and policy issues that revolve around the human dimensions of land use/land cover change and the causes and consequences of such changes. As forests are converted to alternate land uses and/or degraded, forests and their ecological services also are profoundly transformed. Further, deforestation changes the nature of population-environment relationships and alters the feedback mechanisms that subsequently influence human decision-making and future trajectories of land use dynamics. On a global basis, forests are essential as a major carbon sink. They regulate climate and mediate greenhouse gases, influence the natural flora and fauna and protect the land and their regenerative properties, as well as impact human behavior and agency in fundamental ways.

PROBLEMS OF DEFINITION

At a fundamental level, deforestation is the transformation, or conversion, of forested areas to non-forested areas. Depending upon the space-time relations, the context of scale, and the particular circumstances of the transformation, the definition and determinants of deforestation are subject to a considerable degree of complexity. The mediating effects of indirect (through perhaps ultimate causes, such as, market forces) and proximate (direct modalities of change, such as access to chainsaws) influences further contextualize the definition, description, and explanation of deforestation.

Forested areas are converted to a variety of alternate land uses, including a change to subsistence or commercial crops; agro-forestry; grasslands for pasture; impoundments of water for lakes, ponds, and reservoirs; human settlements of households and communities; and shifting agriculture. Often, the loss of biodiversity and ecological services are associated with environmental degradation and deforestation. Forests also evolve through secondary forest succession and other mechanisms that influence forests over space and time. *Successional* forests can sequester carbon, possibly at a higher rate than the forests they replace, depending upon species, age structure, and site conditions; but the ecological services that successional forests provide are substantially different than what they replaced. Sustainable forestry offers context to deforestation, as timber management practiced relative to conservation goals, versus development scenarios, yield very different outcomes for population and the environment. Forest habitat fragmentation and the edge-effects of remnant forests also mediate the impacts of forest disturbances, for instance, through logging and fire.

INTEGRATED AND COMPLEX PROCESSES

Deforestation can be viewed, not as a single action or event, but as a set of integrated and complex processes and feedback mechanisms. For instance, deforestation can occur through natural and/or anthropogenic processes that exhibit sets of spatial patterns and time scales. Ecological disturbances, such as insect infestation, wildland fire, wind blow-down, and snow and rock avalanches can shape the composition, age structure, density, and spatial pattern of forests, as well as the timing, type, and degree of ecological services that they provide. Large-scale forest fires, more severe in the tropical regions during El Niño events, have severe implications for forest degradation and the release of carbon through forest fire emissions. Human actions and policies also affect forests and forest resources, through the conversions of forest to agricultural land uses, protection of forests in designated conservation areas, and the maintenance of riparian corridors through laws and regulations.

In addition, the direct and indirect effects of deforestation suggest other confounding issues, at least in the processes as well as the dichotomy of natural vs. anthropogenic factors of forest change. The distinctions between natural versus anthropogenic forest disturbance factors are becoming at times blurred and indistinct, such as in the case of the emerald ash borer that arrived in the Great Lakes region of the United States in wooden pallets from Asia, and are now rapidly decimating the ash tree population. Clearly, human agency has worked inadvertently to initiate a natural (through "exotic") disturbance process. In another instance, anthropogenic fires are significant in newly colonized, frontier areas such as the Amazon Basin, where positive feedback mechanisms between forest fragmentation, forest fires, and selective logging impact the probability of large and severe fires. Exogenous factors such as climate change, air pollution originating locally or over remote regions, environmental policies set by distant groups and organizations, international market prices for local commodities—these factors and others influence the driving forces of deforestation, the space-time lags of the interactions, as well as the scale and spatial context of forest conversions. Endogenous considerations such as land tenure systems, private vs. common property, resource endowments of sites, and culture and context further serve to mediate the description and meaning of forest and deforestation.

TIME

Time is also a central element in the debate over deforestation and in its description. In tropical forests, as well as other biomes of the world, deforestation is occurring at an alarming rate, but land change has commonly and consistently accompanied human developments. In the Amazon Basin, for instance, deforestation is occurring over broad geographic areas and at a staggering rate, driven by the complex interplay of socio-economic, demographic, and geographic factors that are distal and proximate to the basin. Many places around the world have experienced change with a distinct environment and time signature. The deforestation of the U.S. Great Lakes region in the early part of the 20th century is one example of land use/land cover patterns that have shaped today's land use, as is the deforestation in southeast Asia, which is driven by factors such as the expansion of upland field crops—primarily cassava—to meet the demands for high-calorie animal feed in Europe beginning in Thailand in the late 1960s and early 1970s. Other factors include fuelwood consumption, commercial logging, shifting cultivation, and forest degradation through grazing and fire. Within southeast Asia more broadly, population increase—affects the direct and indirect impacts of deforestation. Clearing land for grazing also contributes in important ways to deforestation in this region; for example, by destroying or degrading undergrowth and seedlings that succeed mature trees that are cut for fuelwood.

The grain and extent of deforestation also enters into the understanding of deforestation. *Grain* is the ecological, or *areal* dimension, of the measurement unit (measured at a 10-meter or 1-kilometer cell), whereas the *extent* is the dimension of the geographic context (a farm, province, national park, or a watershed). These concepts help to contextualize gaps in forests that may be caused by an individual tree-fall, or by the transformation of extensive forest tracts leaving only forest remnants.

The relative degree of connection between forest patches or remnants through ecological corridors is often used to describe the spatial organization of forest that has been transformed within a spatial-ecological context. Forest patch dynamics is a useful approach for appraising forests over space and time by considering forest resilience in the face of disturbances. In many definitions of deforestation, plantation forests are excluded, as they suggest a periodicity to the land transformation and the notion of a forest "crop" with an implied cycle of harvest and re-growth. Forest plantations offer very different ecological services than the forests that they may have replaced.

COMPLEX CAUSES

The causes of deforestation are aslo complex and varied. Most of the deforestation caused by anthropogenic actions has been related to the direct and indirect affects of agricultural land conversion, including the cultivation of crops, grazing of cattle, and fire. Land conversion may vary from peasant farmers who generally influence relatively small geographic areas (although their collective effects are substantial) to intensive, highly-mechanized agriculture that affects substantially large geographic areas, and often in a more profound way. Commercial logging is another common process of deforestation. The mode of timber harvest (e.g., selective cutting vs. forest clear-cutting) has severe implications for the environment. An interconnected and competitive global economy can further challenge forest resources, as they are often exploited to meet the demands of national and international markets and a consumptive population. Selling logging concessions, population in-migration into restricted or inaccessible areas, nonsustainable forest practices, mining, and urbanization alter the forested landscape slowly or suddenly and continuously or episodically. Some deforestation is deliberate, such as associated with urbanization, or unintentional, related to uncontrolled grazing of animals. Deforestation also occurs through wildland fire, volcanism, desertification, hurricanes, tornadoes, and other natural catastrophes. Feedbacks between natural and human processes such as air pollution, soil erosion, depletion of ground water, and over-use of forests further affect forests and the processes of change.

Fuelwood consumption, commercial logging, and shifting cultivation into forests all contribute to deforestation.

The influence of direct and indirect effects on forest resources is important. Direct effects include the removal or degradation of forests through fire or logging, whereas indirect effects are seen when forest remnants are overly fragmented, resulting in loss of subsequent forest habitat; reduction in the ability of the forest to provide critical ecological services such as biodiversity; and land degradation, further aggravating hydrological processes and carbon sequestration. Conversely, forest practices that sustain and rehabilitate a forest are important to the health, density, and structure of the forest and its overall resilience. From a social perspective, deforestation can influence human cultures, such as the practice of traditional subsistence agriculture and the hunting and gathering of forest resources by indigenous people.

LAND USE OR LAND COVER

Deforestation is also influenced by whether the forest resource is considered a land use or a land cover. Land use implies a "use" of the land for some sort of activity. An example is the retention of trees to provide shade from the hot tropical sun for farmers and their animals. In this case, the isolated trees of small patches of trees are considered a component of the pasture. Land cover implies a "cover" unrelated to its use, such as a community forest or trees retained near settlements to provide firewood, shade, and related forest resources. Furthermore, if forests are assessed using remote sensing technology, images representing a single "snapshot" in time offer a time-dependent characterization of the landscape, whereas time-series images can be used to examine intra- or inter-annual changes, rates, and patterns of forest change, degree of deforestation and reforestation, the nature of forest succession, and the historical context of deforestation. Comparing vegetation and landscape change patterns across different sensor systems with varying resolutions and design specifications can introduce bias and uncertainties in the forest change reports, so caution is urged.

A number of studies have examined the causes and consequences of deforestation at the local, regional, and global levels. The deforestation of tropical forests has received considerable attention from the science community, as well as government and non-governmental organizations. Case studies have relied upon fine- and coarse-grained sensor systems, country reporting of the forest area, and percent of forest area within political borders and ecological strata, as well as the change in forest conditions over time and space. Studies have also addressed the expected composition of landscapes and the spatial patterns of forests for future time periods using empirical and process models. Spatial simulation models are aslo being used to consider land change scenarios and the integrative effects of people and the environment on deforestation patterns and estimates for subsequent periods and landscape strata.

OTHER FACTORS

In these analyses, no single variable has accounted for the total observed or expected deforestation rates, patterns, and magnitudes. It is widely accepted that deforestation is the product of a host of ecological, socio-economic, demographic, and geographical factors that are linked in diverse ways. Poverty is often an important underlying cause of deforestation, as well as land tenure, plight of landless people, social inequalities, uncontrolled industrialization, globalization and transnational factors, consumptive use patterns, population migration, national debt, consumerism, and environmental policies and institutions.

Other important factors have included colonization and agriculture; infrastructure improvements; more access to markets, capital, and credit; a commercial economy; cattle raising; conversion of mangrove forests to shrimp farms; and oil and gas production. Secondary effects of these factors are important and numerous. For instance, greater participation in the commercial economy as a consequence of oil exploration in a region, and more access to isolated areas on roads built for oil exploration and to lay pipelines, is a story of frontier environments that has been well told.

What is clear is that forests are changing at an alarming rate, and deforestation's causes are social, biophysical, and geographic in origin. Feedback mechanism and nonlinear system dynamics explain many of the compositional and pattern-oriented changes affected by the interactions of people, place, and environment.

A case in point is the land use/land cover change in the northern Ecuadorian Amazon. In this region, evolution, conflict, and adaptation of social and natural systems have spatially-explicit responses and feedbacks that influence land use/land cover patterns and trajectories. Agricultural expansion, urbanization, land use intensification, deforestation, natural resource exploitation, dynamics of protected areas, and indigenous market integration and acculturation are among the most important ongoing processes of deforestation resulting from complex socio-economic, demographic, and biotic interactions between different stakeholders occurring at different scales.

STUDIES IN THE AMAZON

Studies in this region use an assortment of data drawn from theories and practices across the social, natural, and spatial sciences: imagary (to characterize land use/land cover change patterns and trajectories; ecological pattern metrics to describe the spatial structure of land change; a geographic information system to characterize geographic accessibility, resource endowments, and site suitability of land parcels being transformed from forest crops, pasture, secondary forest, and urban uses; longitudinal and cross-sectional, socio-economic and demographic survey data to characterize communities; statistical methods to link distal and proximate causes and consequences of deforestation; and spatial simulation models to examine deforestation, agricultural extensification, secondary forest succession, and urbanization for historical, contemporary, and future periods. Among a great many others, these studies have examined the questions:

What are the rates, patterns, and mechanisms of deforestation, and how do they compare and contrast across space and time scales?

What are the linkages between people, place, and environment on the Ecuadorian Amazon frontier, and what are the feedback mechanisms between population and the environment that influence deforestation patterns?

How are demographic and other aspects of human behavior changing frontier settings? Do properties emerge from local nonlinear feedbacks that constrain the evolving patterns of land use?

While the fundamental causes of deforestation in the humid tropics vary, small farmers are the primary direct agents of forest change in Ecuador. In Ecuador, rapid deforestation has occurred initially as poor farmers clear small areas for annual subsistence crops and to plant perennial cash crops. Then, as they accumulate savings and soil fertility declines, they plant pasture and acquire a few head of cattle. In Ecuador, there has been virtually no abandonment of plots as land degrades; instead, farmers sell off parts of their plots to newcomers, who initiate their own pattern of land clearing. However, their plots are smaller, so they have less land for raising cattle or even to support themselves, and as a consequence, resort more to off-farm employment, often in nearby towns. These towns have been growing very rapidly, so there are close linkages between land use/land cover change and urbanization. It is not only the level of deforestation in the Amazon that is important to understand deforestation, but also changes in the spatial patterns of deforestation and agricultural extensification, and more recently, urbanization that will shape the future trajectories of change.

NATURAL RESOURCE EXPLOITATION

Natural resource exploitation in the region primarily consists of oil prospecting and extraction and, to a lesser degree, African palm plantations. These activities produce large-scale economic impacts and widespread direct and indirect effects on deforestation dynamics. Both activities are mainly controlled by exogenous forces, in the case of the oil, by international and national market forces (oil exportation provides almost half of Ecuador total revenues); and in the case of African palm, by the national market for domestic cooking oil.

These industries directly modify land use/land cover, but their main effect is indirect change. They create demand for employment and services that triggers internal migration to the area and spontaneous agricultural settlement, creating a strong nonlinear relationship between national economic development and local demographic and agricultural processes.

The deforestation that is taking place in the Ecuadorian Amazon is relatively recent. About four decades ago, this landscape was used mainly by indigenous people and very few colonists for subsistence agriculture. The discovery of oil in 1964 triggered infrastructure development and spontaneous agricultural colonization. Rapid land cover changes in the region contributed to Ecuador's rank in 2001 as the country with the highest deforestation rate in Latin America over the last decade. Ecuador's ranking as the country with the third-highest oil reserves in South America and the development of additional oil infrastructure in the region suggests a future of road building, community expansion, and off-farm employment, and as a consequence, more deforestation.

GROWING HUMAN POPULATION

The ultimate driving force of deforestation throughout the world continues to be the growing human population, which is expected to stabilize at around 11–12 billion by the middle of the 21st century. It is not simply the demand human populations create for new agricultural lands that drives forest degradation and clearing. As the economies of the developing world mature and standards of living increase (e.g., China), demand for goods and services linked directly and indirectly to forests increases, usually in a nonlinear fashion (e.g., the U.S. per capita resource consumption trends in the 20th century).

One important growing concern relates to geopolitical circumstances and globalization pressures associated with energy supplies, in particular, fuel oils. Increasing petroleum scarcity due to declining reserves, growing demand, and regional conflict and political instability in areas of production is increasingly driving worldwide growth in alternative energy development.

The African palm is a case in point, as creation of plantations of this species dedicated to the production of biofuels is driving tropical deforestation in Southeast Asia, and is expected to do the same in Africa in the near future. Another example is the link between sugarcane-based ethanol production and deforestation in Brazil, a country that is rapidly decreasing its dependency on foreign crude oil imports through this strategy. Other nations are likely to follow Brazil's path in the coming decades.

Another important complicating factor influencing humanity's ability to understand and manage deforestation processes is global climate change, a phenomenon that is altering environmental gradients and ecotones across space-time scales, leading to greater unpredictability of the response of social and ecological systems to deforestation's affects. Hence, it is imperative that people, from individuals to communities and nations, act proactively to effectively understand, manage, and mitigate the process of deforestation before forest ecosystems are permanently degraded and altered on a global scale.

Delaney Amendment

THE DELANEY AMENDMENT that was introduced in 1958 to the Federal Food, Drugs, and Cosmetics Act outlawed the use of any food additives that might lead to the causing of cancer, specifically: "the Secretary [of the Food and Drug Administration] shall not approve for use in food any chemical additive found to induce cancer in man, or, after tests, found to induce cancer in animals." This amendment was clearly aimed at protecting consumers from the negligent or malevolent actions of food producers who may include such dangerous elements in their products and make them liable to prosecution if they should do so.

Delaney's argument was that no level of safety in terms of carcinogenic substances could be tolerated. The only safe level, therefore, was zero. Consequently, if in laboratory experimentation conditions test animals could have cancers induced through often large-scale introduction of a particular substance, then that substance was forbidden for use in food of any sort. Rep. James Delaney, D-N.Y., had served on a committee investigating food safety and additives issues that held two years of hearings around 1950. The Delaney Amendment was supplemented by others, notably the 1960 amendment concerning coloring additives, aimed at increasing consumer protection through the same policy of zero inclusion, as was a provision for animal feed.

Clearly, this amendment was considered to be antithetical to the interests of business and to some extent contradictory to existing legislation, which stipulated a legal dose for the inclusion of pesticide residuals, for example. Industry lobbyists spent a great deal of time and effort trying to have the Amendment repealed, and attempted to publish research intended to show that the zero-tolerance policy was inappropriate.

The amendment was repealed in 1997 after years of investigation, led by Monsanto and other corporations and beginning during the Clinton administration, and replaced by a package of legislation aimed at addressing issues that had arisen through scientific research in the intervening years. The concept of tolerable risk replaced the Delaney principle. Clearly, it is impossible to eliminate risk altogether, and technology does provide solutions to problems previously observed. This principle operates with respect to other consumer goods and services, and it would be inconsistent to maintain dual standards.

Further, recent research suggests that changing environmental conditions is leading to changes in allergic response to certain kinds of food, and it would be unfair to hold manufacturers to an unsustainable principle. Even so, it is true that the amendment was ended during a period of politics in which business interests were favored. Continued application and policing of strong regulations remain necessary to protect consumer interests.

Democracy

A DEMOCRACY IS a political system in which all adult citizens have the opportunity to participate in decisions affecting their interests. The more significant and comprehensive these opportunities are, the greater the level of democracy: political theorists discuss, in these terms, the "widening" or "deepening" of democratic decision-making. Ultimately, this extension of the democratic principle can lead to the questioning of the "political" category itself and its relationship to social choices determined by a market economy. However, within widely shared conceptions of *liberal democracy,* the economy is not a realm of civic self-determination, while the polity itself comprises decision-making by representatives elected by a form of majority voting among the population. Representative liberal democracy describes the overwhelming majority of political systems in the world today, in which the central institutions of government claim to provide equitable opportunities for citizens to shape the exercise of power, and in which that influence is facilitated by competing political parties.

Environmentalism, for all its organizational and ideological diversity, has presented a number of core challenges to the liberal democracies. Its central charge is that these political systems fail adequately to represent ecological interests, notably those of future generations and nonhuman species. Ecological sustainability is viewed as a critical condition for long-term planetary (including human) survival and well-being, but democratic political procedures are seen as limited in their capacity to deliver this. In the first place, the concerns of citizens, and hence politicians, are routinely centered on short-term material gains; environmental groups must compete for agenda-setting attention with organized interests promoting economic wealth creation regardless of ecological costs. The political and administrative institutions of liberal democracy are claimed to be ill-equipped to master ecological problem solving; there is a clear mismatch between the hierarchical, sector-based structures of policymaking within representative democracies and the dynamic, complex pathways of much ecological harm.

In recent years there has been substantial interest by political theorists in deliberative understandings of democracy, which dwell on the processes of shared communication by which political preferences are shaped. Proponents of *deliberative democracy* find too restrictive the liberal representative view that the essence of democracy is the aggregation of votes, arguing that reasoned discussion and debate on what are publicly justifiable choices is as important. The deliberative perspective has appealed to environmental political theorists for what they judge to be its potential for greening democracy. Given their open decision-making processes, deliberative political institutions are claimed to promote the recognition of environmental protection as a public interest by exposing citizens to other arguments about ecological sustainability. This civic openness is also seen as conducive to solving complex ecological problems inasmuch as deliberative institutions spread the cognitive burden of decision-making among the cooperative efforts of many individuals.

Environmental scholars have identified various institutional forms as promising vehicles for deliberative democracy. At the locus of representative power in parliamentary lawmaking, including its interpretation by the judiciary, the stress is on increased opportunities for articulating and defending ecological interests; for example, constitutional environmental entitlements and legal rights to public participation in project-based and strategic environmental assessment.

At the level of administrative decision making, deliberative designs can expose regulatory actions to citizen scrutiny and environmental values. Institutional designs already realized in practice include deliberative opinion polls, consensus conferences, stakeholder forums, and citizen juries. The appropriateness of a particular design rests on such contextual factors as purpose, issue, and scale; but the intention is always to enhance democratic participation and justification. It should be noted that the academic literature on the environmental credentials of deliberative democracy has focused on North America and Europe: the applicability of this research to younger democratic states remains to be seen.

Proponents of deliberative democracy generally view it as a complement to existing representative institutions, although debate continues about how the two can best be integrated in pursuit of environmental protection. In contrast, advocates of *direct democracy*, such as Murray Bookchin, flatly reject liberal democratic structures in favor of political self-determination by local communities. Inspired by the classical Athenian polis, where sovereignty is exercised directly by (free) citizens, the proposal is for decision-making by face-to-face assemblies, with coordination and administration entrusted to delegated municipal councils. Ultimately, both liberal states and markets would be replaced by communal political and economic structures. While these ideas have found support within radical green activist groups and networks, they remain, not surprisingly, outside mainstream environmental policy discourse.

Demographic Collapse

DEMOGRAPHIC COLLAPSE IS a term used to describe the decline of population or part of a population, especially its size, growth, density, or distribution. The term is connected to and often synonymous with *societal collapse* and is sometimes expressed simply as *collapse*.

Societal collapse is the broad decay or long-term decline of a specific culture and its institutions. Societal collapse frequently describes plagues, sudden and massive loss of human life, and the resulting breakdown of a civilization. The term is frequently attributed to William McNeill's *Plagues and Peoples*.

The 14th-century Black Death of Europe and the death of large numbers of indigenous peoples in the Americas from smallpox, measles, and typhus transmitted by the arriving Europeans are the most commonly cited examples of demographic collapse. Other examples of collapse in North America include the Cahokia and the Anasazi; in Central America, the Maya; in Africa, the Great Zimbabwe; in Asia, the Angkor Wat and the Harappan Indus Valley cities; in South America, the Tiwanaku and Moche societies, and in the Pacific Ocean, Easter Island.

Many societies can have a decline in one or more of their cultural systems, and a collapse is a sustained decline. However, it is sometimes arbitrary to distinguish between a decline and a collapse. Some authors argue against the term *demographic collapse* used as a euphemism for *genocide*. Sometimes, as in the case of Haiti in the 16th century, historians can't agree on the degree of death that resulted from disease and the amount of death that resulted from war, slavery, and forced labor in mines. Some historians say the massive loss of Haitian population was due to natural causes and diseases, and others say the population was intentionally starved and worked to death and thus it was genocide. There are frequently multiple causes in a case of civilization collapse, and it is sometimes difficult to detect primary from secondary.

Authors such as Joseph Tainter maintain that while disease, crop failures, invasions, and environmental degradation may be apparent causes of collapse, the ultimate cause is "diminishing returns on investments in social complexity" and the subsequent abandonment of or failure of the civilization. Jared Diamond follows this multivariable model of describing collapse and accents the environmental variables as being most important. He defines collapse as "a drastic decrease in human population size and/or political/economic/social complexity, over a considerable area, for an extended time."

He maintains that the factors leading to, or more usually, combining to create collapse are usually rising hostile relations with neighboring civilizations, decay of friendly allies and trading partners, climate change, and environmental damage. When cultural systems break down, starvation, war, and disease commonly occur. Collapse frequently occurs slowly, and historians and anthropologists wonder why members of various civilizations seem unable to change the direction of a culture in order to survive. Sometimes, however, collapse happens suddenly and with little warning. The Soviet Union in the 20th century is a good example of sudden collapse.

Beyond plagues and invasions, paleontologists, historians, climatologists, and anthropologists believe environmental problems frequently lead to collapse. Accidental ecological suicide, or *ecocide*, appears to have led several civilizations to collapse. The categories of these environmental problems are often related to overfishing, overhunting, deforestation, soil problems, water depletion, human population growth, and the effects of invasive species. In modern times, besides all of these usual difficulties with the environment, humankind must deal with the large-scale effects of industrialization on the environment: human-caused climate change, nuclear and chemical waste, greenhouse gases, ozone depletion and energy shortages.

Researchers write that our globalized society is perhaps more vulnerable to collapse than civilizations in the past, because a collapse in part of the global system could lead to a collapse of civilization all over the planet. Understanding why civilizations of the past have collapsed promises insights about avoiding a collapse in the future.

Demographic Transition Model

DEMOGRAPHIC TRANSITION IS a useful, if flawed, framework for understanding how human populations respond over time to particular types of social and economic change. Within this framework, the scale of analysis is typically that of a single country (of any size), and the key elements of population change are birth and death rates, which determine the pace at which a population grows—that is, its rate of natural increase.

Demographic transition models are most often depicted graphically. Birth and death rates are plotted on the y-axis; both are measured as a number per 1,000 population per year. On the x-axis, a unit of time—whether years, decades, or centuries—proxies for a country's level of economic development, or modernization. Four stages are then identified from left to right that correspond to particular ways the population changes as the country modernizes.

TRANSITION MODEL PHASES

In Phase I, pre-industrial, pre-transition populations are characterized by high birth rates and high death rates. Births are high at this stage because the economy is largely agriculture-based, and children's labor is valued. Further, because state social security systems are weak, children represent old age security. Couples may also overshoot their ideal family size because they expect some children to die young. Death rates are high because clean water is scarce and medical care is rudimentary or inaccessible, and death from hunger, infectious and parasitic diseases, and epidemics is common, particularly among children. Because birth and death rates are high, populations in Phase I grow slowly, if at all. These conditions have characterized human populations for most of history.

Phase II is catalyzed by the development of an early industrial economy. Machines replace agricultural workers, and the rural labor force moves to cities in search of jobs. Improvements in technology and national infrastructure enhance food production, storage, and supply; hunger becomes uncommon. Health is also enhanced by basic improvements in clean water provision and hygiene, and by medical treatments (such as vaccines and antibiotics) that reduce the incidence of disease. Death rates therefore drop dramatically. Meanwhile, birth rates remain high. Although children's labor is less needed than before, society is relatively slow to change deeply ingrained notions about the benefits of large families. Because the death rate falls much more quickly than the birth rate, populations undergoing early industrialization typically experience a dramatic population boom (sometimes exceeding three percent per year).

In Phase III, a fertility transition begins. As a new generation grows up in the city and as technological and industrial economies develop and grow, former ideals regarding family size are dropped. More importantly, employment opportunities for women mean that there is an economic cost associated with staying at home to care for children. Educational opportunities also become more widespread; women who stay in school longer typically marry later and are better skilled at ensuring the survival of existing children, as well as availing themselves of contraceptive technologies. For all of these reasons, birth rates begin to decline noticeably in Phase III, and begin to approach the still-declining death rate. Because births continue to outnumber deaths, however, population growth continues, but at a much slower rate (usually well under two percent per year).

Birth and death rates finally align again in Phase IV. By this stage, the economy is no longer dominated by industrial jobs; there is widespread access to good medical care and education, and employment is characterized by service industry jobs. In short, the economy is deemed developed. Small nuclear families of about two children are the culturally celebrated norm. Highly developed medical and sanitation systems mean that fatal infections have all but disappeared, and life expectancies are at an all-time high. Life-threatening conditions are more likely to be heart disease, cancers, and diseases associated with affluence, such as diabetes. Because birth and death rates are low, post-industrial, modernized economies have very low, and even negative, rates of natural growth.

CRITICISMS OF THE MODELS

The basic tenets of the demographic transition model were originally proposed in the late 1920s as a means to model the early-to-modern demographic history of Europe. The model was then elaborated and popularized by demographer Frank Notestein in 1945. He showed how European populations had changed since the early 18th century in response to the Industrial Revolution in ways that were later repeated in North America and other industrialized nations. He also showed how post-war Japan and other populations might be expected to change with increasing economic development.

His model was quickly adopted by demographers as a predictive tool with which to anticipate—even recommend—how a country's population would, or should, change under particular types of social and economic transformation. Its popularity spread as it was found to fit the mid-20th century demographic trajectories of most countries, particularly in the less developed world. In many Latin American and southeast Asian nations, for example, peak growth rates were generally synchronized with massive rural-to-urban migration stimulated by industrialization policies during the 1950s and 1960s (as in Phase II); subsequent entrenchment of the urban labor force led to greater employment and educational opportunities for women, and a correspondingly sharp drop in birth rates was noticeable from the 1970s on (as in Phase III).

By the 1970s, the model was also firmly established as a guide for population policies. Countries whose populations appeared to be lagging behind were prescribed programs to accelerate them to the next stage—usually through family planning programs designed to reduce birth rates. At the same time, academic demographers began to hone the generic model to suit the unique cultural or political contexts of different populations. Post-classic versions of demographic transition therefore incorporated attention to the role of religion, cultural practices, and political–economic arrangements.

But while it was widely recognized that different factors might, in different places, influence the rate and pace of fertility and mortality transitions, for most of the 20th century few scholars or policymakers questioned that the standard sequence of demographic stages through which Europe once passed should hold for all countries. Only recently has this Eurocentric model been seriously challenged. Some point out that Europe's demographic history cannot be a template for countries whose economies have been severely impacted by European colonization. For example, Europe's population would not have changed as it did if millions of rural Europeans had not emigrated to North and South America, thus relieving considerable pressure to absorb this labor force at home. But the demographic transition model, which rests on the problematic assumption that a country's population dynamics can be examined in isolation, does not consider international migration processes.

Other research is also showing that the demographic transition's unilinear, step-wise pattern is not inevitable. In Kenya, for example, researchers have shown that severe economic crises in rural areas—or the absence of economic development—have in fact stimulated a fertility transition. In Sub-Saharan Africa generally, the HIV/AIDS epidemic is also accelerating mortality rates (average national life expectancies below 45 are common) and slowing population growth at a stage of economic development where death rates should be declining. The post-socialist societies of eastern Europe appear to be Stage IV because of their extremely low birth rates, but in fact their economies still incorporate large agrarian elements, and death rates are rising due to economic deprivation and alcoholism.

Dendrochronology

DENDROCHRONOLOGY IS A method of dating through the analysis of tree rings. While it has broad applications for geologists, historical environmentalists, and dendroecologists, dendrochronology has proven especially helpful to archaeologists. Prior to the 1930s, archaeologists could assign only relative dates to their material, using, for example, artifact typologies, an object's position relative to artifacts in other stratigraphy, or the artistic tradition with which the object was ornamented. Relative chronologies, however, are especially problematic for pre-historic sites, which often lack any written corroboration not only of the site in question, but also of the civilization.

Dendrochronology emerged from the American Andrew Ellicott Douglass's master chronology of yellow pine in the 1920s for the dating of prehistoric Indian cultures (such as the Anasazi) in the southwestern United States. Other scientific dating methods (archaeometry) soon followed. Thermoluminescence dating, for example, can be used for nonorganic material (stone and pottery), but it is still in its developmental stage, and radiocarbon dating (C-14), which has a functional dating range to 50,000 B.C.E., only has an accuracy of more or less 200 years. Dendrochronology, therefore, is the only archaeometric process through which it is possible in both theory and practice to date to within a range of one year. One drawback, however, is that dendrochronology can date objects no older than the oldest samples of its regional tree-ring scale. Even with the oldest tree-ring scale in the world (south Germany), therefore, it is only possible to provide dates no older than 10,000 years B.C.E.

Dendrochronology is based on the practice of ring-width pattern matching. Each year, most trees grow a new layer, or ring, of wood. The thickness of the ring (ring-width variability) depends on external environmental factors, including temperature, aridity, and soil types. Trees in temperate zones generally display more ring-width variability than trees growing in semiarid regions. In constructing tree-ring scales, dendrochronologists choose trees indigenous to their region of study because they must compare the patterns of living trees with ancient samples. Core samples are collected from old living trees and compared with ring-growth patterns among several tree cross-sections. Missing years can be supplemented with wood from old buildings (such as medieval churches) or ancient charcoal and preserved wood. By overlapping the cross-sections of a large number of samples, dendrochronologists will arrive at a scale with which scholars can date archaeological contexts with preserved wood.

In addition to the American southwest, master chronologies have been developed for the American Midwest and eastern coastal regions, much of Europe, the Aegean, and the Near East. Chronologies are emerging as well for China and parts of South America. Dendrochronology's contributions to early history are many, including uncovering a climatic regression c.540 C.E. that affected the entire northern hemisphere. Archaeologists excavating waterlogged medieval cities (London, Dublin, Bergen, Stockholm, and Novgorod) in northern Europe use the preserved wooden foundations of buildings to reconstruct precise tree-ring chronologies spanning hundreds of years. And dendrochronologists have dated many of the thousands of painted oak wood panels that artists north of the Alps, especially in the Netherlands, favored during the Renaissance. In addition to the dates, the provenance of many of the panels signed by such artists as Rubens and Rembrandt has been traced to Gdansk (Danzig), Poland, thus shedding significant light on the commercial underpinnings of the Renaissance. The science of measuring tree time, therefore, continues to demonstrate applications extending far beyond the absolute dating of pre-historic sites.

Denmark

DENMARK OCCUPIES 16,602 square miles (43,000 square kilometers) and is a flat, highly industrialized country, surrounded by 4,500 miles (7,245 kilometers) of coastline. As of 2003, 61 percent of the Danish land area was cultivated, 19 percent was covered by roads and buildings, 11 percent were forests, and 9 percent was registered as nature.

Some government acts regulating wastewater pollution in Danish cities can be traced back to the 19th century. Furthermore, a comprehensive act on nature conservation was enacted in 1917. It was not until the 1960s and 1970s, however, that the environment became the subject of intense public

Danish energy production is increasing, but importance of oil has been decreasing, from 50 percent to 40 percent.

and political interest, and environmental problems became the object of more coherent public regulation. A Ministry of the Environment was established in 1971 and a comprehensive act on environmental protection was passed in 1973. The act regulated industrial pollution, but the agricultural sector succeeded in avoiding strict regulation.

During the 1980s, interest in environmental matters peaked on the electorate's agenda, and the most important environmental interest organization, the Danish Society for Nature Conservation, achieved an impressive number of members (245,000), representing one in 20 Danes. Several acts regarding environmental matters were passed during these years. One of the most important was the first Plan for the Aquatic Environment (1987), which, in particular, regulated pollution from the agricultural sector. The plan was enacted after Denmark experienced several incidents of severe eutrophication. The target was to reduce total discharge of nitrogen by 50 percent and total discharge of phosphorous by 80 percent. The phosphorous goal was fulfilled in the mid-1990s, the nitrogen goal in 2003. In general, the environmental conditions in watercourses, lakes, and fjords have improved. However, this is still not considered to be enough by the authorities, whose aim is to reduce the pollution further.

The 1980s and 1990s saw the development of new instruments—economic instruments and voluntary agreements. Denmark was among the world's pioneers, when introducing a green tax reform (1993), shifting the tax burden from labor toward natural resources. For instance, Danes now pay carbon dioxide taxes, waste taxes, and a plastic bag tax. Furthermore, these decades saw the development of a new active nature restoration policy.

Internationally, Denmark is under a range of obligations according to European Union (EU) directives and United Nations treaties and conventions.

Today, industry and services are the most important sectors for the Danish economy, while the agricultural, transportation, and energy sectors exercise the largest negative influence on nature and the environment. However, industry still represents a source of environmental problems, for instance, by emitting heavy metals into the air and by using a range of chemical substances that are damaging to human health and the natural environment.

In the agricultural sector, consumption of pesticides has fallen. Overall, consumption of these has decreased by 58 percent since the beginning of the 1980s. However, the sector's emission of ammonia continues to create local problems for sensitive natural areas as well as odor problems for neighbors—especially where emissions stem from large pig farms. Denmark is the world's largest exporter of pigs.

Danish energy production is increasing, but the relative importance of oil has been decreasing, from 50 percent (1985) to 40 percent (2004). On the other hand, natural gas and renewable energy (e.g., from waste and windmills) have increased their share. Sulfur emissions have fallen by 98 percent, and emission of nitrogen oxides by 50 percent, but emission of greenhouse gases in the energy sector has increased. Transportation is growing, but emissions of nitrogen oxides and hydrogen carbons have fallen. On the other hand, traffic is still one of the main sources of noise pollution, and the emission of particles has started rising again in the 21st century due to private diesel cars becoming more popular. The emission of fine particles is having a considerable impact on human health. Furthermore, the emission of greenhouse gases has also increased in the transportation sector.

In general, Denmark has one of the world's highest levels of emissions of greenhouse gases per inhabitant. In the EU's strategy to implement the targets of the Kyoto Protocol, Denmark has committed itself to reducing greenhouse gases by 21 percent in the period from 1990 to 2008–12. Despite the carbon dioxide–reducing policy instruments implemented, Danish emissions were 10 percent above the 1990 level in 2003. Some of the predicted effects of a warmer climate are changes in Danish biodiversity and agricultural crops. Furthermore, a need for better protection of the coastline is likely.

Denmark is well known for effective environmental regulation and the development of cleaner technology. On the other hand, the very high level of consumption in Denmark is having a negative environmental impact. Denmark's National Board of Health has suggested that around 10 percent of all cases of cancer in Denmark are due to negative environmental effects. Denmark's newest strategy for sustainable development (2002) is to decouple economic growth and environmental impact, so the relationship between economic growth and environmental damage can be weakened.

The Copenhagen Fire, 1728

The fire in Copenhagen in October 1728 was the largest ever in Denmark's capital, destroying about 28 percent of the city (including just under half of the medieval city), and leaving a fifth of the population homeless.

The cause of the fire, which started in the evening of Wednesday, October 20, 1728, was carelessness by the family of a restaurant manager Peder Rasmussen.

Night watchmen sounded the alarm, but the streets around Rasmussen's house were too narrow for the fire equipment. With a strong wind, the fire spread to nearby buildings with many people working in relays using buckets of water to try to douse the flames. Later that evening, another fire started at a brewery. This caused a diversion of manpower, causing both to consume many houses.

Early on the following morning, the artillery were using cannons to demolish already-burning buildings to create "fire breaks" to try to stop the flames spreading. At about 9 a.m. the bishop Christen Worm, fled his burning residence, only able to save three prayer books. It was not long before the City Hall was destroyed. During the late morning, embers from the other fires ignited new conflagrations, and that evening the Trinitatis Kirke ("Church of the Trinity") was burned down, resulting in the destruction of the University library that was stored there. Some 35,000 books perished, along with the archive of the Zealand Diocese which had been transferred to the library on the previous day.

On Friday with the wind shifting, firefighters made some progress, and on Saturday when the winds died down, the fire was eventually stopped. The Danish king, Christian VI, introduced October 23 as a public holiday but this was abolished in 1770. New fire regulations ensured that the city had wider main streets, and initially that only brick houses could be built along them. However this latter regulation was lifted three years later.

Deoxyribonucleic Acid (DNA)

DEOXYRIBONUCLEIC ACID (DNA) is the complex organic molecular structure that is responsible for encoding information that passes on genetically inherited traits in living creatures. DNA is part of all eukaryotic and prokaryotic cells, in addition to a number of viruses. Although the presence of DNA had been detected in the middle of the 19th century, it was not until 1953 that the Nobel Prize-winning scientists Francis Crick and James Watson determined the characteristic double helix spiral of DNA. DNA strands consist of a chain of nucleotides, which are composed of a sugar molecule (deoxyribose) attached to which are nitrogenous bases known as pyrimidines and purines, as well as a phosphate attachment. The strands are bound to each other covalently and according to a complex, but systematic set of rules. This makes for a stable arrangement in which the DNA can replicate itself by dividing the strands. Portions of each strand contain information known as genes, and these are passed on to the daughters of DNA division as a form of inheritance. The divided DNA consists of one original strand, and one newly created strand, which provides for some variation and evolution within a stable framework that reduces the possibility of entropy.

DNA double strands are combined in proteins within cells intensively, and these form chromosomes of a nature determined by the type of cell. Chromosomes reside within the nuclei of eukaryotic cells and within the cytoplasm of prokaryotic cells, which do not have a nucleus confined within a membrane. DNA also resides in other parts of eukaryotic cells and may also be part of plasmids, which are self-replicating bundles of genetic material found in organisms such as bacteria. The DNA within viruses differs in that it can take either single or double-stranded forms or else may be based on ribonucleic acid (RNA). Since DNA necessarily varies between individuals through carrying genetic material from parents, it is possible to identify unique configurations in people (and animals) and create a database of DNA fingerprints. This would be of considerable assistance in forensics, although it opens up a number of civil liberties issues. Similar technology is also being used to identify people who may be at risk of genetically transmitted diseases and medical conditions.

The number of genes within the DNA chains ranges from 20,000–25,000. Identifying all of these, together with the billions of combinations of chemical base pairs that help to construct them, has been the task of the human genome project that was completed in 2003 and represented a triumph of international scientific research collaboration and organization. Even so, progress toward solving technical issues has outstripped public awareness of and ability to understand the relevance of the work.

There has been considerable research and development aimed at identifying and exploiting the commercial possibilities of DNA and its related technologies. Hundreds of possibilities have been identified, although the complex laboratory techniques and testing processes have ensured that few profitable projects have yet been placed on the market. However, the potential for products that may assist in oncology, for example, provides an enticing prospect that has led to the ongoing availability of investment in science.

There remain a number of ethical issues in terms of manipulating and altering DNA sequences. For a variety of reasons, including religious and political reasons, some people believe that such manipulation is problematic and should not be permitted. The issues are complex and yet to be fully tested in legal systems around the world or in societal discourse. States that seek to inhibit such research will find leading pharmaceutical companies relocating to other regions where their activities are considered legally acceptable.

Department of Agriculture (U.S.)

THE UNITED STATES Department of Agriculture (USDA) is an executive department of the government of the United States. It has a multi-pronged mission to maintain an adequate supply of food in the country, promote agricultural research, promote the marketing of American farm products at home and abroad, and seek fair prices for farmers and consumers. The secretary of agriculture, the USDA's chief operating officer, is a member of the president's cabinet, and is appointed by the president and confirmed by the Senate. It has been common in the past for presidents to make appointments to the post of agriculture secretary as a reward for farm interests that supported the president's election; however, the president can ask for the secretary's resignation at any time. The deputy secretary of agriculture is the secretary's assistant. In addition, there are two undersecretaries, seven assistant secretaries, an inspector general, and a general council.

EIGHT MAJOR GROUPS

The UDSA is organized into eight major groups. The undersecretary for small community and rural development directs the Farmers' Home Administration, Federal Crop Insurance Corporation, and the Rural Electrification Administration. The undersecretary for international affairs and community programs directs the Agricultural Stabilization and Conservation Service and the Foreign Agricultural Service. The assistant secretary for marketing and inspection services directs the Agricultural Cooperative Service, Agricultural Marketing Service, Federal Grain Inspection Service, and other agencies. The assistant secretary for natural resources and environment directs the Forest Service and National Resources Conservation Service. The Forest Service manages the cutting of timber on federal lands. The National Resources Conservation Service was formerly known as the Soil Conservation Service. The assistant secretary for food and consumer services heads the Food and Nutrition Service and the Human Nutrition Information Service. The assistant secretary for administration directs the Office of Operations and other offices. The assistant secretary for economics supervises the National Agricultural Statistics Service and the Economic Research Service. The assistant secretary for science and education directs the Agricultural Research Service and other agencies. In addition, there is an assistant secretary for governmental and public affairs.

Because food is a permanent concern of the U.S. government, Congress and President Abraham Lincoln created an agricultural agency in 1862 with a commissioner at its chief operating officer. In the 1860s, about 60 percent of Americans were farmers. They were in constant need of good seed, information, and other help in order to maximize their productivity. In 1889, Congress elevated the original agency to department level with a secretary in charge. From its beginning, the USDA has worked with land-grant colleges, universities, and others with cooperative programs for agricultural research. It has an extension service covering rural areas, with resident farm agents who aid farmers with information. Educational programs for school children ensure there will be future farmers. Other programs aid college educational programs of students studying agriculture at the undergraduate and graduate level. The USDA serves farmers, ranchers, and the public through its programs in a variety of ways that go beyond just farming. As crop yields increased from the use of improved farming methods, the USDA expanded its activities to marketing the growing farm surplus at home and abroad.

The work of the USDA from its beginning has also promoted the adoption of new crops. The USDA encouraged soybean production early on, which has become a very important crop.

The sale of American rice, corn, wheat, soybeans, beef, and other products is promoted by the USDA's open markets program. It also seeks ways to encourage the consumption of all American foodstuffs to the world. The meat, poultry, and egg supplies consumed by Americans are delivered safely because of the USDA's vast inspection programs. It seeks to protect consumers from animal diseases that could affect humans such as foot and mouth disease, mad cow disease, or bird influenza. It also inspects grain supplies to prevent the sale and consumption of grains with diseases that could be harmful to human or animals.

The poor in America are aided by the USDA's participation in federal anti-hunger programs. These programs include Food Stamps, School Lunches, School Breakfasts, and WIC. USDA research also encourages proper nutrition, investing millions into nutrition research. It has developed and continues to modify its nutrition food pyramid. Because rural areas have often been impoverished, the UDSA has promoted rural housing, rural electrification, and supplies of safe drinking water. A number of programs focus on aiding the development of rural infrastructure. The Housing and Community Facilities Programs (HCFP) promote rural development. The Department also plays a very important role in the delivery of food aid to millions of people globally.

The USDA is also a steward of about 200 million acres of national forests and rangelands, providing the opportunity to encourage conservation and promote wildlife. The USDA is also America's largest conservation agency. It promotes environmental projects on vast areas of privately owned lands by encouraging the protection of soil, water supplies, and wildlife.

The research activities of the USDA extend to increase yields using less water and pesticides. It also encourages the development of new strains of seed that are resistant to emerging diseases. Other environmental protection activities of the USDA include dealing with the impact of animal waste, nutrients in water supplies that promote the growth of algae, pesticide runoff onto wetlands, and the development of wildlife habitat. The department's resource economists engage in a wide range of studies that seek answers to the best stewardship techniques for resource management. The laws administered by the USDA cover a wide range of subjects. These include environmental and conservation regulations; food production, safety, and distribution; foods marketing at home and abroad; and responses to natural disasters affecting crops or to terrorist threats to food supplies.

Department of Energy (U.S.)

THE U.S. DEPARTMENT of Energy (DOE) was created in 1977 under the administration of President Jimmy Carter, following the oil crises of the early 1970s, when the OPEC countries suddenly increased the cost of oil and caused economic difficulties around most parts of the world. However, the DOE traces its history back to at least the Manhattan Project. The DOE was designed to bring under one federal agency (the 12th cabinet level department) a variety of agencies and organizations that separately dealt with nonnuclear and nuclear sources of energy and their regulation.

In common with all governmental agencies, the actions of the DOE are subject to criticism from those who believe government should do less to regulate economic and social activities, and those who believe it should do more. Denial of climate change and the role of human actions in promoting it have intensified this criticism.

The DOE also considers very urgently the threat of terrorism and the possibility that energy institutions will be targeted for attack. As a consequence, the DOE's overarching mission is described as "… to advance the national, economic, and energy security of the United States; to promote scientific and technological innovation in support of that mission; and to ensure the environmental cleanup of the national nuclear weapons complex."

The DOE has four strategic goals: the Defense Strategic Goal, to protect national security by applying advanced science and nuclear technology to the nation's defense; the Energy Strategic Goal, to protect national and economic security by promoting a diverse supply and delivery of reliable, affordable, and environmentally sound energy; the Science Strategic Goal, to protect national and economic security by providing world-class scientific research capacity and advancing scientific knowledge; the Environment Strategic Goal, to protect the environment by providing a responsible resolution to the environmental legacy of the Cold War and by providing for the permanent disposal of the Nation's high-level radioactive waste.

Consequently, the DOE is involved in sourcing and supplying energy for the nation, subject to the interests of individual states and their rights; dealing with environmental issues arising from the uses of energy; and the provision of and support for science and research and development activities aimed at such subjects as energy conservation, new forms of energy generation, and the recycling of obsolete materials and equipment.

Its success in managing these diverse goals may be seen in that its research and development has won more than any private sector organization and more than twice as many as the total of all other federal agencies. Nevertheless, since elected officials motivate many of its decisions, some of the DOE's policies are subject to criticism on ideological grounds. On February 1st, 2005, Samuel Wright Bodman was sworn in as the 11th secretary of the DOE; his responsibilities include managing a budget in excess of $23 billion and with more than 100,000 employees and contractors. The DOE's activities are likely to become increasingly complex as more data become available on the impact of energy use and, consequently, how it should be regulated, as well as the fraught intersection between international politics and the securing of stable energy sources globally.

Department of the Interior (U.S.)

IN 1789, THE U.S. Congress established three executive departments: Foreign Affairs (later called the State Department), the Treasury, and Department of War, and with them, created the positions of attorney general and postmaster general. Although these three departments were created to accommodate and maintain complicated interior and external affairs, they had to administer most domestic matters as well. The proposal for a department of internal affairs continued for a half-century, supported by many presidents, including Madison and Polk. The Mexican-American War of 1846–48 gave the proposal new support as the responsibilities of the federal government increased. President Polk's treasury secretary, Robert J. Walker, became one of the most vocal advocates for such a department. This idea of forming a separate department to handle domestic issues wasn't realized until March 3, 1849, when a bill was passed that created the Department of the Interior (DOI) to oversee the nation's internal management.

This new department had a wide range of responsibilities, including the management of all public parks, settlement of freed slaves in Haiti, management of hospitals and universities, overseeing all Washington, D.C., jails, and the administration of all patents and pensions. Natural resource management, land use and classification, wildlife conservation, Native American affairs, and territorial affairs remained within the scope of the DOI; however, many of the original domestic concerns for this new department were gradually transferred to other new departments such as the Bureau of Agriculture, which later became the Department of Agriculture. Additional agencies were created, such as the Home Department, which consolidated the General Land

Office into the Department of the Treasury, the Patent Office into the Department of State, the Indian Affairs Office into the War Department, and the military pension offices with the War and Navy Departments. Subsequently, DOI responsibilities expanded to include the census, regulation of territorial governments, exploration of the western wilderness, and management of the D.C. water and sewer system.

In its early days, the Bureau of Education was placed under the DOI, but later transferred to the Department of Health, Education, and Welfare. Since the 1870s, the DOI made important advances that would keep its work crucial to this day. Between 1887–89, the Interstate Commerce Commission (ICC) was established within the DOI, and the Dawes Act authorized property allotments to Native Americans.

Nearly 400 national parks, monuments, seashores, and battlefields are managed via DOI's National Park Service.

In addition, agencies within the DOI were established to oversee most federal lands and issues involving rock and water. Since the department began its geological survey of the American West in 1869, it would ultimately lead Congress to the creation of the U.S. Geological Survey in 1879. In 1910, the Bureau of Mines was established to oversee mine safety and disseminate rock, ore and mineral information, while ten years later, the Mineral Leasing Act would be created to impose mining land rental fees and royalties on oil, gas, rock, ore and mineral production in 1920. In 1977, the Office of Surface Mining Reclamation and Enforcement would be set up to oversee the regulation of federal and state strip coal mining and environmental damage mitigation. In 1982, the Minerals Management Service was established to assist in the collection of ore and mineral revenues and to oversee all offshore sites beyond the near continental shelf areas. Finally, in 1996, all "interior science and technology functions" were consolidated within the U.S. Geological Survey under the DOI.

The department also administers and enforces environmental protection policies for federal lands. Congress established Yellowstone as the first National Park in 1872, but it was President Woodrow Wilson who would sign the Act that created the National Park Service under the National Parks Organic Act in 1916. Currently, national parks and monuments cover more than 83 million acres across 49 States, the District of Columbia, American Samoa, Guam, Puerto Rico, Saipan, and the Virgin Islands. President Teddy Roosevelt established the first National Wildlife Refuge at Pelican Island, Florida, in 1903.

WILDLIFE, RANGELANDS, AND LIVESTOCK

The protection and management of wildlife, livestock, and rangelands would also become a department focus. From 1902–10, the Bureau of Reclamation was established within the DOI to oversee the construction and management of dams and water systems in the west with the construction of Hoover

Dam completed in 1935. Currently, the Bureau of Reclamation supplies water to about 20 percent of the West—or about nine million acres—with dam-based hydroelectric generation using 56 power plants on-line, generating 35,000 megawatt hours (MWh) of electricity in 1996. In fact, energy projects administered within the DOI on federal lands and offshore areas supply nearly 30 percent of our nation's energy production.

The Taylor Grazing Act would follow in 1934 to regulate the economic use of public lands with a special focus on farmland and range management, mostly due to the disaster of the Great Dust Bowl in the Midwest. During the Great Depression of the 1930s, numerous agencies within the department would utilize thousands of workers employed by the Civilian Conservation Corps (CCC) and Works Progress Administration (WPA) to build and/or improve the infrastructure of over 50 national parks and monuments, wildlife refuges, fish hatcheries, and protected areas.

In 1940, the U.S. Fish and Wildlife Service was created by uniting the Bureau of Fisheries and the Bureau of Biological Survey. The department's General Land Office and the Grazing Service were later merged into the newly organized Bureau of Land Management (BLM) in 1946.

The DOI increasingly implements protection policies for nonmainland lands and territories, but that are still under federal protection or administration. In 1873, all U.S. territories were transferred from the Department of State to the DOI, including Alaska, Hawaii, the Virgin Islands, and Puerto Rico (before their conversion to state status). In 1950, the department assumed jurisdiction over American Samoa, Guam, and the Trust Territories of the Pacific Islands; in 1980, the Alaska National Interest Lands Conservation Act was enacted, which added more than 47 million acres to the National Park System.

In 2006, the DOI managed more than 500 million acres (or 2 million square kilometers) of surface land, or about 20 percent of the United States. It manages nearly 500 dams and 350 reservoirs through the Bureau of Reclamation; nearly 400 national parks, monuments, seashore sites, and battlefields through the National Park Service; and more than 500 national wildlife refuges through the Fish and Wildlife Service.

Subordinate agencies include the National Park Service, Geological Survey, Bureau of Indian Affairs, Fish and Wildlife Service, Bureau of Land Management, Minerals Management Service, Office of Surface Mining, Bureau of Reclamation, and Office of Insular Affairs.

Dependency Theory

DEPENDENCY THEORY IS a school of thought that emerged mainly in Latin America in the 1960s and 1970s to explain sustained patterns of poverty and low growth rates in Latin America, Asia, and Africa after World War II. Dependency theory inverted neoclassical development economics, which assumed that economic growth was eventually beneficial to all, even if the benefits were not equally shared. Neoclassical theorists argued that Latin America, Asia, and Africa were underdeveloped because they had not been sufficiently integrated into a global economy. On the contrary, dependency theorists argued that "developing" countries had been integrated into the world capitalist economy since the beginning of European capitalist expansion starting in the 16th century. Long-term poverty and low growth rates in "underdeveloped" regions were the result of the nature of the interactions between developed and underdeveloped countries, which were characterized by relations of dependency. Underdevelopment was therefore the outcome of a process, rather than being an initial condition from which various stages of "development" ensued.

While all dependency theorists share the view that unequal economic and political relations characterize the interactions between developed and underdeveloped regions, there are many differences between them. Dependency theory can be divided into liberal, neocolonial, and neo-Marxist trends. Raul Prebisch (b.1901), an Argentinean economist, exemplifies the liberal school. He argued that poor countries export primary commodities to the rich countries that manufacture the products that are resold to the poorer countries. This "value added" through manufacturing is captured by the developed countries. He advocated import substitution policies, including tariffs and quotas to protect domestic industry and solve these problems. These policies were followed by many developing countries until neoliberal economic philosophy became dominant in international financial institutions in the 1980s.

The neocolonial approach is identified with Andre Gunder Frank (1929–2005). A refugee from Nazi Germany as a boy, he spent much of his early teaching career in Brazil and Mexico. Gunder Frank's earliest work to deal with dependency was *Sociology of Development and Underdevelopment of Sociology* (1967). There, he not only critiqued most ideas associated with mainstream development theory, but also presented an influential theory of satellite-metropolis relations, which was one of exploitation, as surplus value in the form of profits was appropriated from the satellite regions by the metropolis. Satellite-metropolis relations also existed within developing countries. Urban financial centers functioned as metropoles for the agricultural hinterlands that provided the primary products that were sold by commercial elites to developing countries. His case studies on Brazil (1963), Chile (1964), and Mexico (1965) showed how the most seemingly isolated and impoverished regions of these countries, such as northeast Brazil, had been intricately linked to global capitalism since the 1600s.

Gunder Frank's theory of metropolis-satellite relations was partially criticized by Ernesto Laclau, who argued that the existence of market ties between metropolis and satellite did not mean that the satellites were capitalist. Rather, forms of unfree and servile labor that were characteristic of feudal relations often marked their relations. Hence, dependency theorists should also examine the nature of class relations in the countryside in order to understand the dynamics of underdevelopment. However, Immanuel Wallerstein (1974) ignored this distinction, developing a world systems approach that incorporated many of the ideas of the dependency school. He further added the concepts of core, periphery, and semi-peripheral regions, and differentiated between an economic system and a world empire. The core and periphery regions were similar to Gunder Frank's metropolis and satellite, while the semi-periphery had the function of buttressing the core ideologically and politically.

Dependency theory has a major influence on the field of political ecology, since it helps to show how unequal economic and political relations create poverty, which often produce ecological degradation as a result. So too, economic development programs built around notions of dependency, especially import substitution programs, have environmental impacts since they tend to employ subsidies for industry at the expense of the agricultural sector, with implications for farm product prices, soil exhaustion, and overuse of chemical inputs.

Deposit-Return Charges

DEPOSIT-RETURN CHARGES ARE fees paid by consumers, typically for containers of liquid or powdered substances. Companies hope to encourage consumers to recycle the containers by repaying the deposit-charge when they are returned to the retailer, who is asked to administer the system of fees on behalf of the manufacturer. The system is particularly useful when the containers are of comparatively high value compared to the contents, as is the case with many carbonated soft drinks in the developing world, when consumers frequently prefer to take away the product in plastic bags for a slightly lower cost and leave the deposit-bearing item in the hands of the retailer, who is thereby able to achieve a modest profit. The system is also important when the containers are environmentally hazardous, and represent a good use of resources if recycling is encouraged, instead of paying the higher costs associated with cleaning the resulting hazard.

In many developed states, the financial incentive is reinforced by information and persuasion, and in some cases, people respond better to such an approach. However, willingness to participate in recycling schemes can decline over time, which can have important implications for industries that rely on recycling for their raw material inputs. Millions of people scavenge for a meager income from rubbish dumps in poorer countries, or scour urban residential and industrial areas for salvageable items. That so many people are able to extract a living this way, no matter how meager, indicates the extent to which so much recyclable waste is needlessly thrown away or consigned to dumps that may then lead to further environmental problems.

The United Nations estimates that some 2,000 million tons per year of waste are generated in Europe alone, which includes 40 million tons per year of hazardous waste. A significant amount of this waste can be eliminated through such measures as encouraging retailers not to distribute free plastic carrier bags, and through greater use of financial incentives to eliminate needless waste. Nevertheless, when the containers are of some economic value, perhaps more than returning them can provide, there is an incentive for retailers to divert them to other purposes. It is estimated, for example, that between 750,000 and 1 million steel beer kegs go missing annually in the United Kingdom at a cost of more than 22 million, because of global demand for steel. Consequently, industry suppliers may levy substantial deposit charges on the items in the future. This is opposed by those retailers who consider themselves innocent of losing or selling the kegs, and resent having to tie up their money in this way. When the waste products involved are hazardous and of little value to the manufacturers, as in the case of mobile (cell) telephone batteries, then government regulation is necessary to ensure that appropriate recycling takes place.

Deregulation

DEREGULATION IS THE work that governments do to remove regulations that restrict business, individuals, or other institutions. The regulatory restrictions may be related to economic development, changes in environmental protections, changes in the political philosophy that organizes a nation, or for a number of other reasons. Removing regulations can come for a number of reasons, including changing political philosophies, changing technologies or demographics, or the successes of regulatory policies that render them obsolete.

Until the New Deal’s regulatory legislative program that began in 1932, the United States had historically followed an economic policy of *laissez faire* taken in part from the writings of Adam Smith, author of *The Wealth of Nations* (1776). The goal was to allow free enterprise the maximum amount of room for creating businesses, exploiting the nation’s natural resources, and for providing goods and services to the county. Economically, the country prospered under a policy of *laissez faire,* except that on an almost regular basis, overexpansion of farmland or of other business activities led to economic panics or depressions during the 1800s, and finally in 1929 with the Great Depression.

With the election of Franklin D. Roosevelt in 1932 as President, a major program of regulatory legislation was instituted under the name *New Deal*. This program was really a development of regulatory activities that had begun in the 1800s under the influence of the Progressive Movement, which was opposed to the Robber Barons, as the most successful and aggressive businessmen of the day were known. Antitrust legislation was used to curb the control of John D. Rockefeller's Standard Oil Trust. Soon, legislation was adopted to help the growing conservation movement being encouraged by President Theodore Roosevelt.

However, it was the entry of the United States into World War I that for practical purposes changed the economy from *laissez faire* into a command economy. The end of the war and a "return to normalcy" meant dismantling the regulations used to direct the economy during the war. However, many of the entry and midlevel government bureaucrats in the federal government under Wilson were to become the leaders of the New Deal, including Franklin Roosevelt, who had been Assistant Secretary of the Navy.

During Roosevelt's first term (1933–37), the United States Supreme Court declared many of the laws of the New Deal, such as the National Recovery Act (NRA), unconstitutional. The Four Horsemen—Justices George Sutherland, James Clark McReynolds, Pierce Butler, and Willis Van Devanter—were conservatives who sternly opposed the New Deal legislation. Influenced by Social Darwinism and the Gospel of Wealth, they along with defeated President Herbert Hoover favored a policy of not intervening in the economy, which was supported by Roosevelt. By 1937, the Court began upholding the policies of the Roosevelt administration. The result was that not only was the economy regulated, but so were many new areas of life. The policies of President Lyndon Johnson and others supporting the Environmental Movement after the 1970s promoted a regulatory state.

Regulatory policies aim to protect, promote, or provide, through some form of redistribution, goods and services to the people and even to the environment. Policies, once adopted, do not always last forever. Because of developing technologies, improvements in scientific understanding, changes in lifestyle or any number of reasons, policies may need to be changed or in some cases repealed.

An important deregulation in American history is found in the repeal of the Eighteenth Amendment to the United States Constitution, which sought to impose a public policy to end alcoholism and drunkenness. However, the policy failed to do either and instead fostered criminal empires and lawlessness because of the significant number of people who opposed the policy. The Twenty-First Amendment repealed the policy of federal regulation of all manufacturing and sales of alcoholic beverages and returned regulations to the state. The repeal was a major act of deregulation.

SUCCESSES AND FAILURES

Deregulation may be an indication that a policy has been successful. The prohibition policy was a general failure, but the conservation laws adopted in the 1960s and 1970s have had some notable successes. Among the animals listed in regulations used to administer the act was the American alligator. When the hunting of alligators ceased for a decade or more, their numbers swelled to a level that led to their removal from the endangered species list. However, as their numbers increased to the point that dogs, children, livestock, and sometimes even adults were killed, wounded, or maimed, deregulations were necessary to encourage the hunting of wild alligators. Today there are estimated to be at least one million alligators in the wilds in Florida alone. There are more in other states from Texas to Virginia.

With the return of the alligator in the wild and successful alligator farms, alligator skins are again being used in belts, books, and bags and other products such as alligator meat. Today, alligator farms are an important conservation resource that provides jobs and income to a growing number of people in Florida and other states. The same story of successful recovery can be told about deer herds in the United States as well as other species brought back from the brink of extinction.

In other situations, deregulation has been unsuccessful. In the 1970s, Savings and Loans were financial institutions that had developed into savings banks. They offered similar but different services

Russia's electricity sector and other industries were deregulated after the collapse of communism in 1989.

from traditional banks. Both the banking industry and the savings and loan industry were heavily regulated in response to the many bank and savings institutions failures that had occurred during the Great Depression. However, with inflation and a growing need for amassing huge amounts of capital for big projects, voices were raised to deregulate the savings and loan industry.

For a while, it seemed that deregulation was going to be an enormous success. However, these federally insured institutions, in their rush to make loans, used lending practices that led to very financially insecure loans. Lending competition pressured lending officers into ever less well-secured loans. The appropriate capital resources needed for collateral were weak if not imaginary. By the 1980s, the savings and loan industry collapsed. In response, Congress reregulated the industry.

MODERN DEREGULATION PHILOSOPHY

The philosophy behind much of modern deregulation was developed as an economic philosophy applicable to public policy. Milton Friedman, Alfred E. Kahn, and other economists at the University of Chicago developed the theories of Ludwig von Mises, Friedrich von Havek, and other economists. Among their ideas was the view that government had, in the New Deal and the Cold War, overregulated the economy and society. They taught that businesses were so inhibited by restrictions that markets were rendered inefficient. They also sought to remove the restrictions that hindered competition and that thereby reduced productivity. A major expectation that was offered for adopting deregulation policies was the claim that prices for goods would decrease significantly.

President Jimmy Carter made deregulation an important party of his legislative agenda, seeking the advice of Alfred Khan. Congress passed for Carter's signature three major pieces of legislation deregulating the transportation and shipping industries in the United States. The Hart-Scott-Rodino Antitrust Improvements Act, the Emergency Natural Gas Act, The Airline Deregulation Act, the Staggers Rail Act and the Motor Carrier Act of 1980, and The Depository Institutions and Monetary Control Act were adopted in the last two years of Carter's administration. They have had an enormous impact on the economy since.

Deregulation continued in the administration of President Ronald Reagan. Adopted were the Garn-St. Germain Depository Institutions Act (1982), the Bus Regulatory Reform Act (1982), the Natural Gas Wellhead Decontrol Act (1989), and the National Energy Policy Act of 1992.

Of enormous importance for deregulation during the presidency of Reagan was the breakup of the American Telephone & Telegraph Company (AT&T) by federal court order. The company was split into AT&T and seven "baby bells." The breakup initiated an era of telecommunications growth, as MCI and other companies gained competitive ground. However, new technologies such as cellular phones and fiber optics, along with cable companies competing in the phone business, led to a range of regulations and deregulations that have had a variety of effects.

During Bill Clinton's presidency, more regulatory reforms were adopted. Besides efforts at reducing the size of the federal government, legislation was adopted to deregulate the telecommunications and other industries. The Telecommunications Act of 1996 and the Gramm-Leach-Bliley Act of 1996 had major effects on the future of the United States and the world. The Telecommunication Act provided for enormous competition between the telecommunications manufacturers and communications companies.

However, by the second term of President George W. Bush, a number of actions to deregulate had met with mixed results. An electricity crisis in California, the collapse of energy trading companies such as Enron, and the communications giant MCI all exposed a number of fraudulent practices that required closer scrutiny of the respective industries if investors and the public were not to be cheated by the corrupt few. Other markets deregulated in the United States by 2006 included the media market and the natural gas industry.

Deregulation is not the same as liberalization. Deregulation seeks fewer regulations in order to promote competition, productivity, and market efficiencies. Liberalization allows more competitors into a market. However, it may not necessarily result in fewer regulations. It may be that the market with more competitors is increasingly regulated to protect consumers. It may also be that liberalization leads to the rise of oligopolies or monopolies.

The arguments made by Friedman and others in favor of deregulation were supported by observation of political scientists that the agencies that regulated industries were often subject to "regulatory capture." Theoretically, regulatory bodies are independent and free to regulate according to their mission. However, no matter how independent a regulatory body is when it begins, it is subject to annual budget renewals.

As Congress works on budgets each year, it has members who are more attuned to the interests of industries in their districts than they are to conservation or environmental interests. Eventually, members may be appointed by administrations that are also more sympathetic to industry than to the environment. The regulatory body may be staffed with dedicated people, but unless the agency is constantly in the news as a saving champion of the environment, the agency will be faced with the possibility of budget cuts, appointments of leadership who are opposed to rigorous enforcement of environmental policies, or to the possibility that the agency may be completely eliminated in the budget process. In the end, the politics of the budgetary process and the appointing process facilitate the "capture" of the agency by opponents of rigorous enforcement. Deregulation has promoted at times regulatory capture.

DEREGULATION IN OTHER COUNTRIES

Following the success of some of America's deregulation activities, a number of countries have also attempted deregulation. Some of the deregulation projects have been success and some have been disappointing. In Latin America in 1973, Chile experienced a *coup d'etat,* when the late General Augusto Pinochet overthrew the government of President Salvadore Allende. After the coup, reforms were instituted. These were essential actions to deregulate the economy following the Socialist regulations instituted by the Allende government. In recent years, another Socialist government has been elected; however, it has yet to try to undo the successful economic revolution that deregulation instituted in Chile. To re-regulate the Chilean economy would very likely cause economic collapse and starvation.

Also in Latin America, Argentina was deregulated by the Menem administration during the period between 1989–99. The success of these reforms has been debated. There is no doubt that eventually, massive deindustrialization occurred along with unemployment and severe financial difficulties. Eventually, the United States and some European countries offered aid to Argentina and Brazil.

Other counties that have engaged in deregulations have included Japan and Australia. Japan's economy since its collapse early in the 1990s has been in a period of slow or negative growth. Its tradition of cartels and its huge interaction between government and private industry have made deregulation necessary, but due to Japanese nationalistic ideas, it has been resisted.

In Australia, deregulation has brought mixed results as it also has in New Zealand and in other countries. In southeast Asia, the countries that have gained the most from deregulation have been China and India. Both of these economic giants have experience enormous growth gains after they moved from a Socialist- or Communist-regulated economy to economies that encourage entrepreneurship while lightening the hand of regulation.

For economists, the gains in China and India have been wonderful. However, for environmentalists, the gains have been expensive because of the absence of concern for the environment. Pollution, destruction of habitat, destruction of watersheds and farmlands through dam building projects, and, in the case of India and even quietly in China, significant population growth despite efforts to restrain family sizes to only one or two children.

In Russia and the former Soviet Union, the economic picture has been less favorable than it has been in India and China. The economy of Russia has been weak, primarily due to its legislative failures. In the old Soviet Union, all economic activity was directed by the state and the Communist Party. However, the ecological facts of life in the old Soviet Union were such that the zeal for industrialization and the quest for economic development suppressed concerns for environmental protection.

The case of Chernobyl's nuclear power plant's disastrous meltdown and the resulting pollutions of a vast area were more than matched by destruction of habitats, pollution of the environment, and the ruinous exploitation of many areas under communism. The goal was industrialization and not ecological integrity. The end of Communism has not led to a prosperous period of deregulation. Rather, the absence of organized regulations as well as settled business laws has created uncertainty that stymies development and ecological protection.

One industry to be deregulated in Russia since the collapse of Communism in 1989 was the energy industry. Its electricity sector and other industries were deregulated along with the natural gas sector.

In Great Britain, deregulations have come and gone as the Labor and Conservative governments have waxed and waned. Efforts at deregulation have sought to establish a system that works for the country's economic benefit rather than to placate its political ideologues. Deregulation of environmental laws usually means a return to the destruction of the environment. Human nature is such that the desire for gain usually wins over the zeal to protect the planet.

Desert

DESERTS COVER ABOUT 35 percent of the earth's surface and are mainly located between the latitudes of 5–35 degrees north of the equator. They are regions characterized by high aridity, little vegetation cover and large surfaces of bare soil, and highly adaptable plants and animals that can survive long droughts. According to bioecological definitions, the world's deserts represent all ecoregions of the world that harbor desert vegetation, identified by xerophilous life forms and the general desert-adapted physiognomy of the dominant plants.

Among these, aridity is the most prominent indicator, commonly measured by the Aridity Index, an estimator for the ratio between mean annual precipitation and mean annual potential evapotranspiration, which is less than 1.57 inches (–40 millimeters) for arid deserts and –.79 inches (–20 millimeters) for semideserts. Aridity is highest in the Saharan and Chilean-Peruvian deserts, followed by the Arabian, East African, Gobi, Australian, and South African deserts, and lower in the Thar and North American deserts. Desert climate can be hot or cold. Among the hot deserts, there are two that have two rainy seasons—Somora and Karoo. Three have one rainy season: Northern Sahara, Mohave, Middle-Asian. Deserts with summer rains include southern Sahara, inner Namib, and Atacama. Central Australia is a desert characterized with few rains during any season. Coastal deserts that have fog but no rain include the North Chilean Coastal desert and outer Namib. Finally, deserts without any rain or vegetation include the Central Sahara.

PRECIPITATION

Desert climate is characterized by precipitation of less than 9.84 inches (250 millimeters) with high variability, high diurnal variations of temperature, and strong solar radiation. The high aridity as well as typical pulse-type variations in desert environments are caused by global atmospheric and oceanic phenomena, such as the position of the jet streams, the movement of polar-front boundaries, the intensity of the summer monsoon, El Niño southern Oscillation events, and even longer-term ocean cycles, such as the Pacific Decadal Oscillation. Driven by these large-scale forces, the intensity of midlatitude continentality, ocean upwellings, and rain shadows—the major factors modulating the distribution of arid lands—the intensity and frequency of rain pulses on a local scale may vary substantially with time, and in a seemingly unpredictable fashion. This structures desert ecosystems in a way that requires a physical and behavioral adaptation to the patch dynamics of primary production, water, and nutrient cycling in scales of space and time. During pulses of bounty, the fragile seedlings of desert plants can germinate, establish, and prepare for long droughts by burying their roots deep in the desert soils. To a large extent, it is the heterogeneity of pulses that drives the high biodiversity of desert ecosystems.

Among the hot deserts, the Mohave is one of only three deserts that have a rainy season.

Typical desert soils are aridisols, characterized by little weathering of the maternal rocks and low organic matter in the surface layer, formed under the typical influences of desert conditions by strong winds, scattered but torrential rains, and high temperatures. The materials in these soils are often cemented together, forming water-impervious hardpans, sometimes containing salts or gypsum. The low soil cover exposes deserts to much more wind and water erosion than any other environment as a result of steep slopes.

Humans living in deserts undergo considerable dehydration, and therefore have learned to cope with the dry environment for their survival with a panoply of behavioral, cultural and technological adaptations. Traditionally, desert livelihoods were made of three types—hunter-gatherers, pastoralists, and farmers. To adapt to the patchiness of the desert ecosystems, for instance, the movements of pastoralists mimic the variability and unpredictability of the landscape, and range reserves provide saving banks and buffers against periods of scarcity in food, water, and money. Desert agriculture occurs mostly around oases and desert rivers, which often provide silt and nutrients through flooding cycles. These ways of life, however, are changing rapidly, from hunter-gatherers to cattle ranchers, and from nomadism and transhumance to tourist-targeted activities. In recent times, extraction of minerals, use of vast spaces for military facilities, energy-intensive urban developments, and tourism have increasingly changed the ways of life for some desert populations.

However, due to the extremely slow rate of biological activity in deserts, these ecosystems take decades, if not centuries, to recover from even slight damage. Moreover, because traditional livelihoods in deserts require large areas, they are particularly vulnerable to political and environmental changes. Irreversible damages have been caused in previously good agricultural grounds in deserts by large-scale modern developments, such as dam constructions for water and energy supplies. Finally, the specific aesthetic features and atmospheres of deserts, their silence, wideness, beauty, bareness and emptiness, have always created an intimate spiritual relationship between humans and the desert landscape. All three monotheistic religions have roots in desert regions, where they still remain places of spiritual inspiration and meditation.

Desertification

THE TERM *DESERTIFICATION* was coined in 1949 by A. Aubreville, a French scientist working in West Africa. Aubreville introduced this umbrella term to describe several ecological processes in tropical Africa, in particular the progressive transformation of tropical forests in savanna and drier ecosystems. In advancing this term, Aubreville was attempting to describe the way in which the Sahara Desert was expanding to engulf desert-marginal savanna grasslands. The term was further popularized in the 1970s because of the prolonged Sahelian drought. Since then, *desertification* has aroused intense debate in the scholarly community about the extent, definition, causes, and how to control this phenomenon, which has led to multiple definitions. In 1983, Michael Glantz and Nicolai Orlovsky reported encountering more than one hundred definitions of desertification in related literature, signifying its complexity.

However, what is certain is that desertification is nothing new; it has been with humanity since the beginning of civilization. *The World Atlas of Desertification,* published by the United Nations (UN) Environment Program (UNEP), offers the following definition: “Land degradation in arid, semiarid, and dry subhumid areas resulting from various factors, including climatic variations and human activities.” Land in this context stands for soil, local water resources, land surface, and vegetation, including crops. Degradation is defined as the reduction of resource potential by one or a combination of the processes acting on the land, while arid, semiarid, and dry subhumid climatic zones are collectively referred to as the susceptible dry lands. On the other hand, true deserts (hyperarid zones) are not seen as susceptible to desertification as they are already biologically unproductive.

A more comprehensive definition of desertification was offered by the 1977 UN Nairobi Conference, which served to draw attention to the phenomenon, particularly in terms of its destructive force on people’s livelihoods. This conference defined desertification as:

> ...the diminution or destruction of the biological potential of the land, (which) can lead ultimately to desert-like conditions. It is an aspect of the widespread deterioration of ecosystems, and has diminished or destroyed the biological potential, i.e. plant and animal production, for multiple use purposes at a time when increased productivity is needed to support growing populations

in quest of development. Important factors in contemporary society—the struggle for development and the effort to increase food production, and to adapt and apply modern technologies, set against a background of population growth and demographic changes—interlock in a network of cause and effect.

The UN Nairobi conference attempted to explain the causes desertification. The blame for the deterioration of productive ecosystems was squarely placed on the quest for ever-greater productivity, which has in turn intensified exploitation of fragile environments. Overexploitation was seen to give rise to degradation of vegetation, soil, and water, the three elements that serve as the natural foundation for human existence. The fear was that in exceptionally fragile ecosystems, such as those on the desert margins, the loss of biological productivity through the degradation of plant, animal, soil, and water resources could easily become irreversible, and permanently reduce their capacity to support human life. It was argued that desertification is a self-accelerating process, feeding on itself, and as it advances, rehabilitation costs rise exponentially.

URGING IMMEDIATE ACTION

The Nairobi conference urged immediate action to combat desertification, and a world map of land degradation by desertification and many case studies from all over the world were presented. These case studies clearly illustrated that desertification was not only happening in Africa, but was a worldwide problem. Since then, several other maps of land degradation have been produced, facilitated by improving technologies such as Geographic Information Science and Remote Sensing. These technologies have yielded important data on desertification. It is now estimated that more than 23.6 million square miles (6.1 billion hectares)—47.2 percent of the earth's land surface—is dry land. About 3.9 million square miles (1 billion hetares) of this area are naturally hyperarid (true) deserts, with very low biological productivity. The remaining 19.7 million square miles (5.1 billion hectares) are made up of arid, semiarid, and dry subhumid areas. It is the latter part that has been degraded by human activities and adverse climatic conditions such as prolonged drought. According to UNEP, about one-fifth of the world's population depend on these lands for their livelihood, hence the importance of combating desertification.

Glantz and Orlovsky identify two major factors of desertification: climate and human activities. Climate refers to climate variability, climate change, or drought. Climate variability is defined as the naturally occurring fluctuations in precipitation, temperature, wind speed and direction, evaporation, and so on for a given period of time. Climate change refers to the view that desertification is primarily a result of natural shifts in climate regimes. Prolonged periods of drought are also a major cause of desertification. These three climatic factors often result in the degradation of an ecosystem, thereby affecting the livelihoods of people who depend on it.

The impacts of different types of human activities on the environment form the second set of factors. Activities such as cultivation, livestock herding, and wood gathering have all been cited as major causes of desertification, particularly in fragile environments. Cultivation of marginal climatic environments, poor soils, or the use of inappropriate cultivation techniques such as reduced fallow time, improper tillage, drainage, and water use have all been implicated in the expansion of desertification. Overgrazing is another problem that leads to land degradation, especially in poorly managed rangelands. In many developing countries, people depend on firewood or charcoal for cooking and heating purposes. In some parts of Africa, the production of charcoal to satisfy urban energy needs has resulted in wholesale environmental degradation.

The controversy on defining desertification and attempting to extricate the major factors that lead to this condition has arisen because of disagreements on how it should be considered. Some researchers think of desertification as a process of change, while others view it as the end result of a process of change. For example, World Bank economists have been at the forefront in sounding the alarm about deforestation and environmental degradation in Africa. World Bank economists Kevin M. Cleaver and Gotz A. Schreiber have vehemently argued that Africa is engaged in a downward spiral of population growth leading to environmental degradation and, therefore, poor agricultural performance. They see land degradation as the end result of a process of change with population explosion as the cause. On the other hand, other scholars offer evidence of the opposite, and see land degradation or desertification as a process of change, not the end result. For example, Thomas J. Bassett and Koli Bi Zueli counter the assertions of Cleaver and Schreiber by noting that it is dominant perceptions of environmental change, rather than concrete evidence, that lie behind the widely held belief that Africa is engaged in an "environmental crisis of staggering proportions." These scholars argue that there is only shaky evidence to support the perception of Africa as physically disintegrating due to the destructive practices of its inhabitants. In recent years, a number of books and articles have been written to counter the dominant view that Africa is facing rapid desertification. These include the 1998 work of James Fairhead and Melissa Leach, the 1996 work of Melissa Leach and Robin Mearns, and the 1998 work of Michael Mortimore.

The ways to combat desertification therefore also depend on the understanding of this process. Those who believe it is an end result of several causes such as population growth and overgrazing often suggest population control, reforestation programs, and placing restrictions on pastoralists to make them sedentary and to reduce the numbers of their livestock. On the other hand, those who believe that this is a process in which one species, such as trees, may replace another species, such as grass, do not consider desertification a major problem. However, trees replacing grass may in itself be considered degradation by those who depend on livestock for their livelihood. The case study of northern Cote D'Ivoire, by Bassett and Zueli, clearly points out that the positive perception of afforestation is erroneous. In the Ivorian savanna, the increase in woody species may actually be undermining the health of grasslands, which may, ironically, lead to policy prescriptions that exacerbate grassland degradation, resulting in the loss of an important resource that pastoralists depend on.

Design (and Ecodesign)

DESIGN IS THE process of planning, initiating and/or laying out a new product, service, piece of equipment, landscape, building, plan, policy or the like, typically in an artistic, technically proficient, or skillful fashion. It is a future-oriented act of envisioning and creative problem-solving.

Typically, design involves sketching, drafting, computer-assisted manipulation of three-dimensional spaces, and artistically or accurately representing and arranging forms and materials for new functions and purposes. Design by its very nature embraces ideas about utility, aesthetics, convenience, efficiency, and practicality. In architecture, for example, design ideals can be traced to Vitruvius, who espoused durability, convenience, and beauty as the tenets of design. Design involves the manipulation of technologies, from simple instruments such as drafting pens and paper to sophisticated technologies such as Computer Assisted Design (CAD) and Geographic Information Systems (GIS). Design practitioners include architects, planners, landscape architects, instrument-makers, interior designers, artists, engineers, environmental scientists, computer scientists, and chemists, among others. Much design literature is underpinned by environmental determinism (the notion that the environment directly affects human behaviors and actions) and encompasses a set of values whereby humans are seen to legitimately manipulate the environment to produce outcomes that benefit our species over others.

DESIGN IN HISTORY

Throughout history, various civilizations have practiced elements of design. Stonehenge in England, for example, is a Neolithic design innovation, presumably allowing for the accurate forecasting of crop sowing and harvest times. Some commentators have argued that the ability to design is a unique property of our species, enabling humans to produce environmental modifications and transformations from stone tools to metropolises like Chicago. Feminist historian of science Donna Haraway has even asserted that in many ways humans have become cyborgs—biomechanical entities that are dependent upon, and have merged with, our technologies.

Western society in particular has inherited a fractured system of thinking centred upon the instrumental value (use value) of nature. Since the Industrial Revolution, modern design practices have resulted in the large-scale metabolization of nature into canals, bridges, buildings, automobiles, and the like. The perception that humans are outside of nature has led to environmental impacts seldom being factored into design processes (e.g., the production of toxic substances such as dioxins or radioactive waste). More recent design applications, including the use of nano-technology in the design and assembly of tools at a molecular level, and genetic engineering (the manipulation of an organism's DNA to produce new features within that organism or even new organisms), perpetuate dualistic thinking about nature–society relations and the concomitant risk of adverse environmental impacts.

ECODESIGN

Ecodesign entails "designing with nature" for the benefit of the wider environment. Contemporary applications of ecodesign include the development of new technologies as a transition to ecological sustainability—what Slessor characterizes as a movement from "high tech" to "eco tech." Water-sensitive urban design, nature's services approaches, ecological restoration, permaculture, green buildings, biotechnology, wind farms, and hybrid cars are all examples of ecodesign. Ecodesign combines environmentally benign philosophies, technologies, materials and legal standards to meet current needs in ways that create lower levels of environmental impact while preserving biodiversity (natural capital).

Ecodesign advocates strategies that will result in a net environmental gain, both social and ecological. The underlying premise is to emulate biophysical and ecological processes—recognizing interdependencies, and in so doing, improve the ecological sustainability of products and services. Ecodesign seeks to overcome the "utopian ideals" inherent in traditional design practices, such as order and beauty, which inevitably produce "sterile environments," replacing them with sensibilities grounded in the chaotic "messiness" of biological systems. Industrial ecology, for example, seeks to mimic ecosystem processes by metabolizing waste. The waste outputs of industries are used as the raw material inputs for other industries—thus closing material and energy loops.

From an environmental planning perspective, perhaps the most influential work on ecodesign was Ian McHarg's *Design with Nature* (1967). In this book, McHarg sketched out a new way of designing human settlements working with, rather than against, natural processes and recognizing natural limits. Possibly the ultimate expression of ecodesign can be found in Jennifer Wolch's 1998 "Zoöpolis,"a new kind of socially and ecologically inclusive city built around environmental processes and acknowledging plants and animals as legitimate urban residents.

Developed “First” World

THE FIRST WORLD, now known as the *developed, industrialized,* or *Western world*, are terms used to describe countries that have collectively attained a good standard of living, a high per capita gross national product and a strongly diversified technology base. The United Nations (UN) state that “developed countries tend to have high gross domestic products, high literacy rates, minimal spread of poverty, and are technologically advanced.”

Standard of living describes the quality and quantity of goods and services available to people in any given country. It is generally measured by real (i.e., inflation adjusted) income per person, and the Gross Domestic Product (GDP) of a country is defined as the total value of final goods and services produced within a country's borders in a year, regardless of ownership. Neither standard of living nor GDP are the same as “quality of life,” which takes into account a variety of other factors that determine social well being such as recreation, safety, cultural diversity, social life, mental health, and environmental quality issues. The UN Human Development Index (HDI), identifies countries with an HDI measurement of over .8 as falling within the developed world category. Categories within the HDI include life expectancy, poverty, literacy, and healthcare.

According to the UN, Economic Division countries—including Japan, Canada, the United States, Australia and most countries in the European Union—are First World countries. While statistical analyses can be useful in differentiating between the social and economic status and welfare of nations, the term *First World*—like *Third World*—is essentially a political term that has many other connotations attached to its use.

The term was first used after the end of World War II, when the parties to the North Atlantic Treaty Organization and the Warsaw Pacts became known as the western and eastern blocs. Many countries did not fit into either category, with the remaining often referred to as belonging to the Third World. The countries belonging to the First and Third Worlds have changed with the political times, and today, the terms *developing* or *First World* are often derided for being too Western and paternalistic in focus, presuming superiority by one group of nations over others.

This does not hide the fact that inhabitants of First World countries do enjoy a substantially higher standard of living than do those living in the Third World. The socio-economic advantage that the First World has gained over the Third World has come at a significant environmental cost. Raven notes that “there is an important linkage between such factors as human population density, rate of growth, consumption and the choice of particular technologies on the one hand, and the state of the environment on the other."

Approximately 25 percent of the world's people reside within developed countries, yet consume 80 percent of the world's nonfuel minerals. The United States, while comprising only five percent of the world's population, consumes up to 30 percent of the worlds resources. Environmental impacts from the consumption of resources by the First World is having a major impact on the world's environment and climate with most of the largest emitters of greenhouse gases being those countries in the developed world. Australia, for example, has the highest emissions of climate changing gases by any country on a per capita basis, and they are equal to six times more than those emitted by China. For context, Australia's population is 20 million, whereas China's is 1.3 billion.

The impact of high consumption of the Earth's resources by the developed world is being felt more acutely in the environments of the developing world. Consumer demand in Japan for timber has resulted in the deforestation of parts of southeast Asia, while in East Africa, forests have been cleared to grow tea, coffee and other cash crops for export to Europe. In South America, the pampas grasslands have been cleared in favor of serving the market for meat in Europe and North America.

High consumerism levels in the First World have created a major non-organic waste problem compared to that of the Third World. *The Atlas for Population and the Environment* notes that more than 500 million tons of waste is generated each year in the First World, of which some 30 percent are mineral wastes, 20 percent industrial, 40 percent agricultural and 5 percent municipal. By contrast, research has identified that throughout the developing regions of the world, such as Indonesia or India, 73–96 percent of local waste consists of food and biodegradable material. The importance of the link between affluence and waste is further highlighted by the fact that a 40 percent increase in GDP of countries belonging to the Organization for Economic Cooperation and Development has been accompanied by a similar increase in waste generation.

Given the global nature of our economy and the global reach of environmental issues such as climate change, significant equity challenges exist for the rights of developing countries to also provide for their citizens a similar lifestyle to that enjoyed by people in developed nations. The challenge is how to support these rights, while minimizing the major environmental impact this will cause. Estimates show that if all of the world's people attained the standard of living comparable to that in the United States, three more planets—comparable to earth—would be needed to support them. This is clearly not an option.

The impact of globalization has meant that now, more than ever, we live in an interdependent world connected by mutual need for natural resources, through the relations of a global economy and the movement of people across countries. This need has been partially recognized in meetings such as the Earth Summit in Rio in 1992, the development of the Millennium Goals, and the formation of many international institutions that attempt to address the conjuncture of population, technology and environment in both the developed and developing worlds. Such institutions include the World Bank, the International Monetary Fund, the World Business Council for Sustainable Development, the UN Development Program, Consultative Group on International Agricultural Research (CGIAR) and formation of international environment groups such as World Wildlife Fund or Friends of the Earth, who focus on the equitable relationship between people and the environment.

Development

THERE ARE FEW ideas more contested than development, which involves a complex history of competing understandings of terms as varied as *progress, geopolitics, gender, culture,* and *environment*. There is general consensus that the development era began at the end of World War II and was tied to European Reconstruction and shifting geopolitics. Colonialism had been the central organizing practice prior to this period and was gradually receding with the increasing independence of former colonial outposts. Colonialism involved the political, economic and spatial control of various regions for the benefit of colonial empires. The colonies were established for the removal of raw materials and human labor, while being promoted as part of a larger imperial mission. In an example of this sentiment, writer Rudyard Kipling argued that the development of other regions was part of the "white man's burden," which spoke to a paternalistic responsibility that came with being supposedly more advanced. In addition to the decline of colonialism, a speech by President Harry Truman in 1949 helped usher in the development era by arguing that colonialism would be replaced by "a program of development based on the concepts of democratic fair dealing." Rather than colonial empires and colonies, the globe would be divided into independent nation-states that would set the terms for political and economic engagement. Also important at this time was the establishment of new international institutions to facilitate the rebuilding of Europe and global exchange. A series of meetings at Bretton Woods, New Hampshire, in 1944 resulted in agreements on the rules for commercial and financial systems between the world's major industrial states. These meetings are also remembered for establishing the International Monetary Fund (IMF) and the World Bank, which have become two of the leading institutions in promoting international development.

Development has always involved politics as much as economics. This can be seen by the labeling of countries under the development lexicon. Durign the rising tensions between the United States and the Soviet Union, developing countries were viewed as strategic pawns. The United States and its allies were classified as members of the First World, the Soviet Union and its allies were the Second World, and all the other countries became the Third World. Although there are tremendous variations between countries labeled Third World, this became a commonly used classification. Third World or developing countries tend to rate low on development indicators that assess their socio-economic characteristics. Commonly used indicators include Gross Domestic Product (GDP) and Human Development Index (HDI). GDP is a measure of all the goods and services produced within one year. HDI assesses life expectancy, education measured as adult literacy and average years of schooling, and purchasing power. Development indicators can be problematic, however, since they often overlook differences within specific countries and regions. GDP, for example, is helpful in understanding the overall economic output for a particular country, but does not show income inequalities or variations between urban and rural areas. Critics have also argued that GDP increases positively with some negative environmental conditions such as the clean-up of an oil spill. Indicators such as these provide only a limited picture and can also contradict each other. Several countries rate fairly high according to their GDP but much lower based upon their HDI because of socio-economic inequality. As such, the classification of countries for the purposes of development should be treated carefully.

MODERNIZATION THEORY

The focus of much early development thinking was the diffusion of Western characteristics to facilitate the perceived necessary evolution of countries in the Third World. This was known as modernization theory. The best example of this was Walt Rostow's "Stages of Economic Growth," which positioned each country in a particular stage that required technical and cultural transformation to facilitate its development. The five stages were traditional society, preconditions for take-off, take-off, drive to maturity, and high mass consumption. These stages were an ideal path, involving a linear evolution realized through increased manufacturing and industrial organization, infrastructure development, and the emergence of a social elite. Rostow argued that countries could move along the trajectory once they acquired certain economic, political, and cultural characteristics that resembled the developed world. Modernization was firmly linked with the goal of Soviet containment, as the United States and its allies believed economic development would resist the spread of communism throughout the Third World. As such, development aid was often directed toward countries with strategic benefits to lending countries.

THE ROLE OF THE STATE

Another important element of early development thinking was theorizing the role of the state. Supported by influential economist John Maynard Keynes, the state was believed to play a large role in facilitating economic growth for developing countries. An example of this applied in practice was import-substitution industrialization (ISI). ISI was an approach adopted by a number of Latin American countries in the 1950s and involved strong state intervention to encourage domestic production for domestic markets. ISI utilized the state and market manipulation to facilitate its goals. Import tariffs were instituted to make foreign products more expensive and were eliminated on needed inputs for domestic production.

ISI was generally unsuccessful for a number of reasons. It had little impact in reducing imports, and in some cases increased them since more inputs were needed to support local industries. There was little diversification of the sectors supported by ISI beyond the industries producing sophisticated goods. In responding to market indicators about which products to create, ISI tended to reproduce economic inequality by manufacturing goods that were unaffordable to the majority of the population. The failure of ISI helped propel arguments that economic growth was best achieved through the utilization of the market, which would reach ascendancy in the 1980s with neoliberal theory. Other perspectives about international development emerged as well, including the dependency school, which argued that global integration and trade worsened—rather than improved—economic conditions in the developing world. To the dependency theorists, ISI was evidence that the global system was primarily designed to benefit wealthier countries.

The 1970s were a volatile period for geopolitics, global finance, and development. The Organization of the Petroleum Exporting Countries (OPEC) instituted an oil embargo that dramatically increased the price of gasoline. This produced an energy crisis that had ripple effects throughout the world. Poorer countries found it more difficult to manufacture basic commodities and were forced to pay more as imported goods increased in price. Revenues from high gasoline prices—or "petrodollars"—were funneled into the Third World by private banks. The result was that developing countries took out more loans to stay afloat.

The debt crisis was further exacerbated by U.S. policies in the late 1970s to strengthen the value of the dollar, which resulted in increased interest rates. Finance markets were tied to changes in international markets and as the prices of primary commodities declined in the early 1980s, the income generated by developing countries was reduced. Between 1973–83, the outstanding debt owed by developing countries increased fivefold, to $810 billion. This resulted in a number of countries, beginning with Mexico, announcing that they would be unable to service their debt. In order to halt a potential global financial crisis, the IMF and World Bank stepped in as brokers, thereby expanding their influence within the developing world.

ASIAN TIGERS

During this time, development began to experience shifts in regards to economic theorizations of the role of the state and the market. Neoliberalism became more pronounced and asserted that the state was a hindrance to effective economic growth. One of the mechanisms for advancing neoliberalism was structural adjustment, which attached specific conditions upon loans to developing countries. Structural adjustment goals included the reduction or elimination of a balance of payments deficit, the resumption of higher rates of economic growth, and the achievement of structural changes that would prevent future payments and stabilization problems. State-owned businesses were sold and budgets were often directed away from supporting environmental and social services. The legacy of structural adjustment, and lending conditionality more generally, remains one of the most contested issues in development policy today.

Neoliberalism gained further prominence in the 1980s with the seeming explosive economic growth of several Asian countries. Labeled the *Asian Tigers,* these newly industrializing countries (NICs) demonstrated success in establishing a viable manufacturing sector through export processing. As opposed to ISI, export processing involved the establishment of manufacturing not for domestic production but for foreign export. Countries such as South Korea, Taiwan, and Singapore were able to attract foreign capital to establish manufacturing bases within their borders. Utilizing a number of incentives such as reduced tax rates and low labor costs, export processing became frequently cited as a model for successful economic growth. It is worth noting that critics of this strategy argue that export processing results in significant social and environmental costs as foreign firms show little concern for local conditions. Additionally, it has been argued more recently that, rather than relying exclusively on the market to achieve economic growth, the national governments of the NICs were quite aggressive in suppressing labor costs and unions.

CONCERNS ABOUT ENVIRONMENT

A shift in development accompanied increasing concerns in the 1970s about environmental problems including deforestation, desertification, population and famine. Neomalthusian ideas of population growth surfaced, which asserted that famine and other environmental issues were the product of a rapidly increasing global population living beyond its means. Influential scholars such as Paul Ehrlich argued that human population was increasing exponentially while the ability to sustain the population through environmental resource consumption was more limited. In *The Population Bomb*, Ehrlich argued that human population growth would result in the deaths of hundreds of millions of people. Also in the 1970s, the Club of Rome published a report entitled *The Limits to Growth* that asserted that major changes in geopolitical relations would be needed to stem an environmental catastrophe and population collapse. These events pushed environmental concerns onto the forefront of development debates and contributed in a wave of interest in merging environment and development. This popularized the idea of *sustainable development,* which generally attempts to combine economic development with concerns for environmental sustainability.

Sustainable development has been influenced by a series of key meetings and reports that helped frame its central tenets. One event was the United Nations (UN) Conference on the Human Environment, which was held in 1972 in Stockholm, Sweden. This was the first major summit on environment and development and was attended by representatives from 113 nations. Conference attendees agreed to a number of principles, including the idea that development and environmental protection were not mutually exclusive and could actually support each other. This seemingly upended the idea that environmental protection would always come at the expense of economic growth. The Stockholm Conference was followed by the World Conservation Strategy (WCS) of 1980, which attempted to integrate development goals with conservation planning. The three central objectives of the WCS were maintaining essential ecological processes, preserving genetic diversity, and ensuring sustainable utilization of species and ecosystems.

A watershed moment for sustainable development was the World Commission on Environment and Development (WCED) *Our Common Future* report of 1987. The WCED defined sustainable development as "[meeting] the needs of the present without compromising the ability of future generations to meet their own needs." The WCED Report identified a number of critical areas for sustainable development, including reviving growth, changing the quality of growth, meeting essential needs, ensuring a sustainable population level, conserving and enhancing the resource base, reorienting technology and managing risk, and merging environment and economic in decision making. Most important was its continuation of earlier statements that sustainable development could reconcile economic growth and environmental sustainability.

Subsequent international gatherings attempted to build upon these developmental principles. Foremost among them was the UN Conference on Environment and Development, which was held in Rio de Janeiro, Brazil, in June 1992. The Rio Summit received significant international publicity and produced *Agenda 21*, a lengthy document that outlined 27 principles for sustainable development. The World Summit on Sustainable Development was held in Johannesburg, South Africa, in 2002 and attempted to further expand upon some of the goals established in Rio. Specifically, the WSSD resulted in an *Action Plan* that included halving the proportion of people without access to sanitation and drinking water, deal with climate change, and stop biodiversity loss by 2010. As a result of these meetings and reports, sustainable development has become a buzzword that has sparked a significant amount of attention in professional and academic circles while becoming a paradigm for institutions as diverse as the World Bank, corporations, and nongovernmental organizations (NGOs) throughout the developing world.

ISSUES IN DEVELOPMENT

Development has continued to expand to involve a number of concerns. One of these is development and gender, which assists in understanding the impacts of development processes upon men and women. Informed by feminist theory, scholars have shown that development differentially impacts women who are often overlooked by development agencies. Women have been shown to contribute differently to the public and private spheres, and possess different knowledge about local conditions. The UN established the Women in Development decade to focus attention upon the relationships between gender and development and various institutions have worked to include women as full stakeholders in development planning.

A second issue has been the localization of development and interests in participation. Participatory rural appraisal (PRA) involves a number of techniques to include local communities as participants in development. PRA and participatory development represent a critique of large-scale development that is blueprint-oriented and ignores the nuances of local context that often shape the effectiveness of development. A wave of interest in NGOs and social capital suggest an intention to direct attention toward local processes, communities, and actors. The growth of microenterprise lending, which provides small loans to poor groups, also fits within this trend. Microenterprise lending began when the Grameen Bank in Bangladesh began giving out small loans, called microcredit, in the 1970s. The high repayment rates, coupled with the ability to assist the very poor, have generated a great deal of interest in microenterprise lending.

The belief that we are increasingly living in a globalized world has focused attention upon global finance, flows of exchange, global environmental processes, and cultural change. Countries continue to position themselves within regional trading blocks to access new markets and protect themselves from foreign competition. The North American Free Trade Agreement (NAFTA) connected Canada, Mexico and the United States, while the expansion of the European Union (EU) links countries from eastern and Western Europe. There has been continued movement toward other regional associations, as represented by the Free Trade Area of the Americas (FTAA) and the rebirth of the African Union (AU).

Development remains a hotly contested and challenging set of ideas and goals. This is evidenced by recent assessments of the state of international development. The UN has proposed its own Millennium Development Goals that challenge the global community to meet the following by 2015: eradicate extreme poverty and hunger; achieve universal primary education; promote gender equality and empower women; reduce child mortality; improve maternal health; combat HIV/AIDS, malaria and other diseases; ensure environmental sustainability; and develop a global partnership for development. Unfortunately, recent evidence indicates that for many countries, particularly in sub-Saharan Africa, these goals will not be achieved. Even while economic and political relationships expand at the international scale, development is increasingly the site of protests and resistance within various locations. Protests have accompanied the World Trade Organization (WTO) meetings from outside, and from within as a bloc of developing countries, derailed recent agreements because of their concern for agricultural subsidies in the United States and Europe. Reactions to neoliberal economic theory have appeared particularly in Latin America as countries such as Bolivia nationalize certain industries. These events suggest that development will continue to be challenged and reworked in the 21st century.

University of Texas at Austin

Diamond, Jared

JARED DIAMOND IS Professor of Physiology and Geography at the University of California, Los Angeles. He is an important academic, both in his own right and as a lightening rod for renewed debate over the merits and dangers of what is most commonly called environmental determinism. Jared Diamond was trained as a physiologist, but is well known for his ecological investigation of avian evolution in Papua-New Guinea and more recently for his work as an environmental scientist, historian, and geographer. He is probably most popularly known for his 1997 book, *Guns, Germs, and Steel,* which won a Pulitzer Prize in 1998. Both the arguments in the book and its success make it important for an understanding of contemporary environment–society relations.

The argument is simple: Diamond attributes the enormous differences worldwide in income, welfare, and stability to a single ultimate cause: environmental conditions. He argues that "[three] factors—time of onset of food production, barriers to diffusion, and human population size—led straightforwardly to the observed intercontinental differences in the development of technology."

Diamond positions his argument as a denial of genetic or cultural explanations for the differences between contemporary societies. Instead, the societies with greatest access to cultivable food supplies and domesticable animals were able to develop powerful military tools (namely, steel tools, weapons, and deadly germs) that enabled them to conquer the world. Diamond called the transition from hunting and gathering to settled agriculture the greatest mistake human society ever made.

There have been many critiques of Diamond's work, but the best is by geographer Jim Blaut, who argues that Diamond's science is inaccurate and marshaled selectively, particularly with regard to Asia. In addition to critiques of his science, Blaut (and others) challenge Diamond's understanding of the relationship between history, culture, and the environment. The environment is clearly an important historical actor, but it works in conjunction with economic relations, politics, cultural beliefs, and even historical contingency. Within geography, the most severe critiques of environmental determinism (generally pre-dating Diamond) are to be found in the subfield of political ecology.

ENVIRONMENTAL DETERMINISM

Aside from the specifics of Diamond's science, the success of *Guns, Germs, and Steel* is important in the context of a revived environmental determinism. Several prominent academics such as Jeffrey Sachs, David Landes (1998), and Ricardo Hausmann (2001) have criticized geography for casting aside explanatory models that causally link the environment and economic development. They have articulated a sort of "politically correct" environmental determinism in which poverty is not a product of history, culture, or politics—it's a case of "bad latitude."

There are several factors that facilitate the revival of this determinism: first, the failure of development economics to deal with inequalities between human societies has transformed the optimism of the early post-war period into a certain fatalism; second, the possibility of multiple superpowers has gradually been replaced by the military and economic dominance of a small handful of countries—primarily those European countries blessed with the most "favorable" environment; third, there is a new awareness of—and respect for—the ability of the environment to effect not only localized conditions, but the well-being of human life on this planet.

Diffusionism

DIFFUSIONISM IN THE social sciences of anthropology and cultural geography is a theory about the spread of ideas, technologies, and practices from one culture to another. Human beings invent things or behaviors. It has been long noted that some cultures use similar tools, art techniques, or cultural practices. The question has naturally arisen whether these similarities are due to the spread (diffusion) of ideas, or whether they arose spontaneously as independent inventions in different locations. In diffusionism, features of one culture spread to another culture over geographic distances because of mutual contact. An example of cultural diffusionism is the use of the hammock. For centuries, European sailors slept on the decks, piles of ropes, or on whatever could be tolerated in the ships they sailed. Christopher Columbus's first voyage to the New World brought his sailors into contact with the use of the hammock. The idea spread to other

European sailing nations and soon was a standard way to sleep.

Social scientists from the Heliolithic and culture-history schools of thought represent the most extremes advocates of the theory of diffusionism. Functionalists like Bronislaw Malionowski opposed their theories. In England, G. Elliott Smith was a leading English diffusionist. In Germany and Austria, the Kulturkreis School was an advocate of diffusionism among pre-Bronze Age humans. Cultures diffuse geographically as they spread things such as foodstuffs, music styles, items of clothing, and technological developments. Diffusion can also include the spread of religion. It is well known, for instance, that religions in India have spread along the Grand Trunk Road that runs from Calcutta along the Ganges River, through the Punjab to the Khyber Pass. Those who have spread their religions on this road include warriors, merchants and prisoners, as well as innumerable monks, priests, preachers, and other religious teachers.

Diffusionism is often described using biological models. The model of the spread of a disease can be used to describe the contacts needed to spread tools, technologies, and theories. For example, the spread of syphilis began with the return of Columbus from his First Voyage. Among the six Indians and sailors who returned, several carried the disease. Contact with prostitutes in Spain and then their contacts with a unit of French soldiers gave rise to the name *French Pox*. Tracing the vectors of many diseases is an exercise in medical detective work. Anthropologists conduct the same detective work to trace the spread of ideas from one culture to another. Types of diffusion include: relocation, expansion, hierarchical, contagious, and stimulus.

Relocation diffusion occurs when the same individuals or groups move from place to place spreading their culture. The Puritans of New England moved to spread their religion to a new land. Expansion diffusion describes the spread of a newly adopted cultural feature into an ever-growing population. The result is a dramatic increase in the number of people who have accepted the new cultural feature. Hierarchical diffusion occurs when cultural ideas leapfrog from elites in one central area to others in another city by passing rural or poorer areas. The spread of eating sushi in the United States has followed this pattern. Contagious diffusion spread like diseases. In fact, this is descriptive of the spread of diseases in cultures. The spread of HIV/AIDS has exhibited this pattern. Stimulus diffusion occurs when one culture applies the general idea(s) of one culture in a new way in their own environment. The adoption of reindeer by Siberian peoples is an example of stimulus diffusion. Diffusion can be slowed, delayed, or blocked by a number of factors. Time and distance have, until the advent of modern travel, often muted the spread of cultural factors. In some cases, cultures may outlaw the adoption of cultural changes in an attempt to prevent their spread.

Dioxins

DIOXINS ARE A class of 75 chlorinated aromatic hydrocarbons that vary widely in their toxicity to humans. Dioxin toxicity is measured by Toxic Equivalent Factor (TEF) for which the standard of 1.0 is TCDD, or *tetrachlorodibenzo–p–dioxin*, one of the most toxic substances known. Dioxins are chemically and toxicologically related to chemicals known as furans, and some of the polychlorinated biphenols, or PCBs. Dioxins have no commercial application and can be produced as byproducts of manufacturing processes involving chlorine or fire in the presence of chlorine and complex carbon molecules.

Dioxins are more soluble in fat than water, meaning they bind to organic matter and bioaccumulate. Human exposure to dioxin is generally through consuming animal-based foods like meat, dairy, and eggs, making exposures widespread. Dioxins are very persistent in the environment and do not migrate easily through groundwater or vaporize into the air. Much is unknown about the causes and effects of dioxin toxicity, but it appears it influences endocrine function affecting fetal development, the reproductive system and the liver, and is associated with some cancers. Dioxin is believed to act through binding to a receptor protein that enters the cell nucleus and affects gene expression. In acute doses, dioxin can cause a skin condition known as chloracne, and its hormonal effects can be evident in extremely tiny doses of parts per trillion.

The sources of dioxin are almost entirely anthropogenic. The EPA estimate conducted in 2003 found that the vast majority of releases in the United States were into the air, and about half of those from medical and municipal waste incinerators. Most of the remainder came from backyard burning of trash, cement kilns, and fuel combustion.

SCIENCE AND POLITICS OF DIOXIN

The science and politics of dioxin have been marked by a series of controversies related to where dioxin comes from, what it does to people, and what constitutes an acceptable level of risk, punctuated by periodic environmental justice flashpoints centering on dioxin exposure. Industrial accidents involving dioxin provided contested evidence of dioxin's dangers. The involved corporations found no link between dioxin exposure and illness in the studies they paid for and conducted, while independent studies found significant increases in cancer in exposed people.

A series of broad-scale dioxin exposures that occurred in the 1960s and 1970s made dioxin a major environmental justice issue. From 1962–71, the U.S. Air Force sprayed large areas of South Vietnam with *Agent Orange,* a mix of herbicides including 2,4,5–T and 2,4–D, organochlorine chemicals that contained substantial amounts of dioxin byproducts. American veterans' health problems from Agent Orange led to a series of studies that found many veterans' health conditions were due to their exposure to dioxin.

Love Canal was a site where tens of thousands of tons of chemical waste containing dioxin was dumped and subsequently leached into groundwater, mobilizing the dioxin that readily diffuses through oily solvents. The health problems faced by Love Canal residents made public in the late 1970s accelerated attention from the environmental justice movement, government, and corporations on dioxin. Other dioxin hotspots were the Alsea river valley in Oregon where 2,4,5–T was sprayed, causing widespread birth defects; and Times Beach, Missouri, where dioxin-polluted oil was sprayed to keep down dust on roads and subsequently contaminated the town.

Around this time Dow Chemical Company, a manufacturer of many products linked to dioxin, came out with a paper entitled "Trace Chemistries of Fire" that contended dioxin came not from human activity, but was produced naturally from forest fires. This theory was quickly refuted, but the role of natural combustion in global dioxin production continues to be promoted by spokespeople for industries tied to dioxin pollution.

The EPA made its first assessment of dioxin's public health implications in 1985, and has issued three reassessments since: in 1988, 1994, and 2003. The magnitude of exposure and its consequences remains much disputed. Although EPA reported in 2003 that dioxin emissions fell about 75 percent since 1987 (mostly due to reductions in incinerator emissions) and dioxin concentrations in food have declined considerably since 1970, the EPA admits that the cancer risk from dioxin to the general U.S. public may exceed 1 in 1,000. This level is three magnitudes greater than the generally accepted one in a million acceptable risk. The average body burden of dioxin in the U.S. public approaches the minimum level at which harm may result.

Disasters

A DISASTER IS a serious disruption of society that causes human suffering, and damage to built and natural environments so extensive that the affected communities cannot recover through the use of their own resources. Disasters have traditionally been divided into two groups: natural and man-made. They can also be classified according to their speed of onset, as either sudden or slow.

Man-made disasters are the direct consequence of human action and involve some aspect of human intention, negligence, or error. Technological disasters include transport, industrial, and structural accidents. Two of the greatest man-made industrial disasters occurred in the 20th century: the Bhopal gas tragedy in 1984 and the Chernobyl nuclear disaster in 1986. Man-made disasters may also include ecological disasters in which human actions damage ecosystems, often in a way that threatens human communities, and disasters caused by wars and civil conflict.

Natural disasters occur when a vulnerable community suffers casualties or damages from a natural hazard. These are normally–occurring events in the environment which have the potential to harm human communities. They can be divided into meteorological and hydrological hazards (cold waves and heat waves, extreme storms, hurricanes, tornadoes, drought, flood), geological hazards (earthquakes, tsunamis, landslides, volcanoes) and biological hazards (epidemics and infestations).

NATURAL OR MAN-MADE?

The distinction between natural and man-made disasters has become increasingly blurred as it is recognized that there is a strong human component in all disasters. Some hazards are clearly "natural," such as earthquakes, tsunamis, or volcanic eruptions. Their negative impact on communities, however, can be aggravated by human actions. An earthquake can trigger a disaster only if communities are built in seismic zones and if building construction is not adapted to earthquake activity. The loss of lives and property and the social dislocation caused by Hurricane Katrina in August 2005 was exacerbated by a range of human actions. The primary aggravating factor in the losses suffered in New Orleans, for example, was the historical development of large sections of a city in an area two meters below sea level.

Other disasters can be the indirect consequence of human action. Flooding can be caused or intensified by deforestation and the destruction of wetlands. Droughts and the famines that follow them are caused by global variations in climate but also by deforestation, overgrazing, and the excessive use of rivers and aquifers for irrigation.

Disasters have social and environmental consequences. The direct economic costs of a disaster are generally measured in the number of casualties and the expense of re-establishing property and infrastructure. The intangible social costs include the disruption of societies caused by the exodus of evacuees from a disaster zone or intensified competition for limited resources.

The poor and disenfranchised in a community are more likely to suffer the adverse effects of disasters because they lack the resources to effectively prepare for them or recover from them. Similarly, wealthier countries have more resources with which to respond to disasters within their borders than do developing countries. Disaster impact comparisons based on insured losses can be misleading, as poorer nations have less infrastructure and capital exposure. Slow-onset disasters, such as drought or famine, sometimes do not appear in such analyses at all.

The ecological losses that can result from disasters, such as the destruction of habitats or the loss of wildlife, are not easy to quantify and are seldom factored into impact studies of disaster events. *Disturbance ecology* teaches that floods, fires and other natural disruptions are essential to the dynamics of ecosystems. Naturally occurring fires are part of the life cycle of forests and maintain a vigorous biodiversity. River ecosystems require periodic flooding to remain healthy. The natural capacity of ecosystems to withstand or even thrive after such natural disruptions can be severely diminished by human actions. Degraded forests are more prone to fire and insect infestation. Removing wetlands, dunes, and mangroves from coastal areas increases the damage caused by ocean storms and tsunamis. Eroded hillsides are more vulnerable to flooding.

One of the prime reasons why statisticians show an increase in the number of disasters in recent decades is the massive increase in human populations living in hazard areas. Global warming may also increase the frequency and intensity of extreme weather events and cause increased flooding and ocean storm surges, as well as fatal heat waves. Recent research suggests a possible correlation between sea surface temperature in the key areas of cyclone birth in the North Atlantic and the annual intensity of cyclones.

Discount Rate

THERE IS AN ongoing discussion in environment-related fields about the practice of discounting in economic analysis. The need for discounting arises when economists seek to compare the costs and benefits of a project or policy that occurs over a number of years. Economists do not treat future costs and benefits the same as current ones, because the value of a dollar tomorrow is less than the value of a dollar today. This argument is theoretically related to two factors. First, this money can be invested, and interest earned, between now and the future. If the dollar is not received until the future, than such an investment opportunity is foregone. In practice, this foregone rate of return is often calculated at the prevailing interest rate (or the average productivity of capital) in a particular context. Second, economists argue for a positive rate of time preference for at least two reasons. First, the underlying level of impatience assumption suggests that people have a time-bound conception of their own self-interest that leads them to favor consumption in the present over that in the future. It generally has been assumed that poor households have a higher rate of time preference than wealthier ones as satisfying basic needs in the present is paramount. Second, a positive rate of time preference is suggested based on the belief that future generations will be better off than those in the present. According to this argument, current generations may reasonably weight a unit of consumption in the present more heavily than the same unit in the future, where it is assumed to be a proportionately smaller piece of an ever-expanding pie.

Projects in the private sector often rely on the opportunity costs of capital (or the interest rate) to establish a discount rate. It is disputed whether the discount rate for public sector projects should be based on the opportunity cost of capital or a social discount rate that is more closely associated with the rate of time preference. In the past, the World Bank has recommended that the standard opportunity cost of capital be used as the discount rate. Development economists typically have suggested a discount rate of 10 percent for projects in developing countries based on this opportunity cost criterion. Others argue that it is better to go with the social rate of time preference, as government and individuals are different than corporations in that they must consider a wider range of issues than just profit.

In practical terms, the discount rate enters project calculus when it is used to determine the net present value of all future benefits and costs. When all such costs and benefits are expressed in present terms, analysts may undertake a cost benefit analysis to determine if it is worthwhile undertaking a project. The formula for calculating net present value is (B minus C) divided by (1 plus r)$^{\text{year}}$, where "B" equals benefits, "C" equals costs, "r" equals the discount rate, and "year" refers to the number of years into the future from the present.

The choice of an appropriate discount rate for the cost-benefit analysis of public sector projects is highly controversial. First, some assert that the use of a high discount rate, or any discount rate at all, leads to short-sighted assessment of costs and benefits, especially longer-term environmental costs and benefits. The higher the discount rate, the more significantly future costs and benefits will be progressively reduced each year in relation to current costs and benefits. Projects that affect environmental quality over the longer term, such as soil conservation efforts that will not yield results for ten years, do not appear to be remunerative investments when future benefits are highly discounted. Second, many have suggested that high discount rates have negative implications for inter-generational equity because this practice dissuades public entities from investing in projects that only generate significant benefits for future generations. Finally, there is an emerging body of scholarship that suggests poor people do not necessarily have higher rates of time preference than their wealthier counterparts. For example, recent empirical research in Zimbabwe found that poor subsistence farmers often demonstrate future bias in their decision making. The behavior of poor households under famine conditions in others parts of Africa also suggests a very low rate of time preference. The implications of this for discounting practice in the public sector are potentially significant. If one accepts that the rate of time preference may be a more appropriate determinant of discount rates for use in the cost-benefit analysis of development projects in the poorest countries, then it would seem reasonable to re-examine standard discount rates given that time preference rates for the poor may not be as high as previously thought.

Discourse

DISCOURSE IS A term used by social scientists and theorists to refer institutionalized habits of thinking, talking, and narrating, which both reflect, reproduce, and impose understandings of the world. The most prominent theorist influencing nature–society studies that incorporate or adopt the idea of discourse is Michel Foucault, whose social theory directs attention at normal ways of speaking about and categorizing the world; the degree to which they are inherited, imposed, and enforced socially; and the limits and bounds they place on seeing nature and society. As Norman Fairclough explains, for Foucault,

> the objects of discourse are constituted and transformed according to the rules of some particular discursive formation, rather than existing independently and simply being referred to or talked about in a particular discourse.

Discursive practices, in other words, guide what can and cannot be said in particular places and times. In modernity, the "rules" of discourse are increasingly tied to institutions such as governments, schools, hospitals, and prisons. These institutions, by design, are in the business of producing normative proposals for (individual and collective) social conduct. Accordingly, Foucauldian analyses tend to be highly anti-institutional and particularly skeptical of the norms that arise within discourse.

FOUCAULTIAN DISCOURSE

Methodologically, Foucaultian discourse analysis tends to focus on the textual aspects of discourse, rather than the institutions themselves. From various texts, the "rules" of discourse can be extracted, and the silences and displacements inferred. Discourse analysis offers the opportunity to "rewrite" the discourse, laying bare that which was previously disallowed or disavowed. Discourse analysis is thus an openly political maneuver, designed to "destabilize" primary or authoritative texts.

As many "discourses of nature" (biodiversity conservation) are associated with large-scale institutions and also tend to proffer normalizing programs, nature-discourses have come under increased scrutiny from poststructuralists. As Noel Castree explains, "'Deconstructing' [discourses of nature] entails 'denaturalizing' them: that is, showing them to be social products arising in particular contexts and serving specific social or ecological ends that ought to be questioned."

There is an assertively normative component to discourse analysis as well: discourses of nature "ought" to be deconstructed. This is representative of a radical "nature-skepticism." The task at hand is not just to call into question the naturalized discourses, but also to effectively denaturalize them, and so make them harder to take for granted, and easier to unseat. As so much environmental discourse relies to a great degree on the efficacy of statements regarding nature or "the natural," an effectively denaturalized text is stripped of much of its authority.

Bruce Braun and Joel Wainwright hail this approach as "a departure from existing work in the field which assumes nature to be an unproblematic category, in the sense that it is a thing that is self-present to knowledge." They argue instead that the object of environmental studies and politics, nature is an effect of power. To make sense of this last statement, it is necessary to examine Foucault's theorization of *power*.

For Foucault, *power* is not something which the state or a dominant group has or possesses. Rather, it is diffuse and omnipresent: people (through discourse) are always operating within a "field of power." This concept of power was at least partially formulated in an attempt to replace the unrealizable utopian goal of revolution (the overthrow of a singular, oppressive, sovereign power) with one of resistance, where individuals and groups regain a positive political presence within (rather than against) oppression through everyday acts of destabilizing authoritative discourses (as texts, rules, ways of acting). Specifically in terms of knowledge, Foucault argues that there can be no knowledge outside of power, so the concept of *knowledge* is replaced by *power/knowledge*.

Conceptualizing nature as a discourse and an "effect of power," then, is to make a claim that the what we take for granted as "nature" is historically produced, enforced and made to appear normal through power relations. In such a formulation, some ecological advocates, among others, understand nature as unproblematic and unconstructed, even while statements about nature are always inherently political. Such advocates, however well-meaning, fail to recognize the political character and effects of their discourses, assuming them instead to be "natural" or given.

Braun's writing on the temperate rainforests of British Columbia is representative of this sort of discourse analysis at work in nature-society studies. In his analysis, he reveals that struggles between the forestry industry and environmentalists, though they appear dramatically opposed to one another, actually adopt common frameworks by inheriting discourses that hold the forests of the region to be natural (and therefore nonhuman). All the while, their tacit discursive consensus render indigenous people, and their claims to the forests of the region, essentially invisible, disallowing their voice in the debates over the use and protection of the forests. This marks an important intervention into the debates over these forests. More generally, the post-structuralist intervention signals important lessons for any critical or reflexive analysis of environmental problems and politics.

Disease

WHILE THE CONCEPT of disease might appear to be straightforward, it is actually highly complex. Its definition varies across geographic and temporal context and it must be considered in relation to how health and illness are also defined. In its simplest form, disease is a condition that has been diagnosed by a medical practitioner. In the West, biomedical practitioners, also called allopathic physicians, generally determine how a particular disease is defined. A disease, then, is something that can be operationalized biomedically, where the link between a cause and effect might be known. Illnesses, on the other hand, may manifest themselves without any clear cause or disease etiology. It is common to have a cold without the presence of a disease. Disease is often contrasted to health, which is even more difficult to define or measure. There is no ideal time when someone is in a total state of health. So, social and physical scientists tend to focus extensively on disease causation, effects, distributions, and diffusions.

EPIDEMIOLOGY

The study of diseases in human communities is called *epidemiology*. Epidemiologists investigate the biological, social, historical, or geographical relationships between a disease and its consequences. In any epidemiological study, the focus is on mortality (death) and morbidity (disease and/or illness) and the causal links between the two. The goal of epidemiology is twofold: to understand why morbidity or mortality rates may rise or fall; and to try to understand how and why a disease may wane and how to control future spread. The factors leading to increased morbidity and mortality rates may be biophysical, social, or environmental. Epidemiologists examine different diseases in their biological, social, or environmental contexts to determine how to reduce the spread and effects of particular diseases. Moreover, epidemiologists seek to identify new illnesses and place them into disease categories.

Many diseases fit into two broad categories: chronic or acute. Chronic diseases (or illnesses) are long-term conditions that may or may not require medical intervention, such as heart disease or high cholesterol. Acute diseases (or illnesses) are intense, short-term conditions, such as influenza or strep throat. Some chronic diseases are differentially intense, causing periods of decreased mobility or feelings of ill health. Depending on the person and their current state of health and the broader circumstances, both chronic and acute diseases can be the cause of mortality. Some diseases are also considered infectious, spreading from one person or animal to another person or animal, or even through one animal or insect to another animal or insect, and then to a human. Often, epidemiologists are interested in understanding the vector of an infectious disease, the subject through whom a disease passes as it spreads. Some infectious diseases can be carried from an insect to a human (such as malaria), while others are purely human-to-human (such as HIV).

When studying the spread of diseases, it is important to examine a multitude of factors, including the overall population that is impacted by a particular disease, the environmental context (broadly conceived) in which that disease is spreading, and the individual or community-based behaviors or practices that might intensify or mitigate the diffusion of a particular disease. It is impossible to partition one of these areas out from the rest, and so social scientists must consider the interrelationships among the multitude of factors that intensify certain disease distributions and limit others. Moreover, it is critical that those studying diseases take into consideration the broader socio-cultural and political-economic contexts that play a crucial role in determining how certain diseases spread and why others may be stopped. As an example, malaria eradication programs have been very effective in a number of highly industrialized economies, while this particular disease, spread via mosquitoes, remains a leading killer of people in many parts of the developing world. There is thus a geography that underlies any disease distribution or pattern, a geography based in the context of human–environmental and social relationships.

Often misunderstood by the general public, therefore, are the social power dynamics that impact disease distributions. This is because biomedicine often constructs diseases as spread through germs (or other microbes), focusing our attention on the microbiology of disease dynamics. While the biological is always important, the political and economic context may play an even more significant role in the daily lives of those at risk for disease. Some social scientists have thus turned to the subdiscipline of political ecology as a framework for explaining the complex intersections between humans and their environments and the emergence of diseases. A political ecology of disease suggests that scientists must examine the environmental as well as the human factors of diseases in tandem, since there is no way to divest disease causation from its broader human context.

POLITICAL ECOLOGY

In taking a political ecology approach, the distribution and diffusion of diseases as emerging out of the dynamic environment can be investigated, much of which is based in human-induced change. As an example, recent studies have shown that the use of certain pesticides in agriculture found throughout many areas of Latin America might cause long-term neurological, gastrointestinal, or physiological diseases (or illnesses). Over time, extensive exposure can lead to long-term problems, including the onset of certain cancers.

As another example, shrimp farming can produce, in areas with endemic malaria or dengue hemorrhagic fever, such as Vietnam or Eritrea, new, large sites of standing water ideal for the breeding of mosquitoes. These mosquitoes have the potential to further spread malaria or dengue fever. Recent studies have also shown that schistosomiasis, a parasitic infectious disease that develops in water-based snails and spreads to humans, has become endemic in new flood areas around dams. The most recent example is that of the Three Gorges Dam area in China, where the expansion of water on the land has been linked to the potential for this disease to spread to multiple communities. This is similar to what happened along Lake Volta in Ghana, a human-created lake that was linked to an increase in cases of schistosomiasis.

Susceptibility to these diseases, based in changes to the environment, are not without socio-cultural and political–economic links. It is often the case that extended exposure to pesticides, malarial exposure via shrimp farming, or contact with the parasites that cause shistosomiasis are more common among the working poor. In fact, in all three cases, the root of transmission is as much a product of the political–economic context as it is the biological one. For example, in industrialized agricultural economies, regulations have been put in place to mitigate the use of certain toxic pesticides. Such regulation is less likely in developing economies. The daily operation of industrialized shrimp farms is often left to the working poor, who are more likely to see day-to-day exposure to the mosquitoes breeding in these farms. And, those who must use water from rivers or man-made lakes that might contain high levels of parasites because they have no running water, are much more likely to encounter schistosomiasis.

INTENSIFIED URBANIZATION

There are other ways, however, that shifts in the ecology of certain places might lend themselves to the expansion of diseases. For example, intensified urbanization. Proximity to freeways, ports, or industrial parks might increase the likelihood of having asthma. Diseases of the skin and regular rashes are also common among those living close to these hazards. Crowded urban areas, particularly in poorer neighborhoods, can intensify the rate of tuberculosis or whooping cough infections, which are spread via the human respiratory system. The outbreak of SARS (severe acute respiratory syndrome) was concentrated in major metropolitan areas, such as Hong Kong and Singapore, and was linked to wind flow patterns in certain high-rise complexes in Hong Kong, in particular.

As an airborne disease, SARS spread quickly and was quite dangerous to the most vulnerable, particularly children and the elderly. The close proximity of urban living and the built environment of the high rise partially accounted for the rapid spread of this particular disease. This means, as well, particularly in countries such as the United States, that certain ethnic and racial communities are more susceptible to certain diseases. The rates of respiratory infection are particularly high among poor African Americans in heavily polluted urban areas in proximate location to factories and freeway systems, for example.

Throughout history, diseases have also spread from one population to the next via the ever-increasing interconnections present in the economy.

In historical context, the Silk Road was not only a vehicle of dynamic economic exchange and socio-cultural diffusion between the Mediterranean and East Asia; it was also a vehicle for the transportation of diseases from one place to the next. Smallpox, measles, and the bubonic plague spread throughout the regions of the Silk Road. These diseases spread to areas where people lacked any immune experience to deal with their spread, and this held dire consequences for those who came into contact with these diseases. On occasion, diseases have been used intentionally as weapons, thus also facilitating their global spread. Syphilis also traveled via an expanded global network of trade. The intensified sexual and drug-using networks made available by modern-day air transportation, which linked cities such as New York and Port-au-Prince in the 1980s, facilitated the spread of diseases such as HIV. SARS was identified as having moved from Asia to Canada via the air transportation system, which led the World Health Organization to briefly recommend the quarantine of the Toronto area and its airport.

The distribution of diseases and the fear attached to them often has dire political–economic consequences. Take, for example, Bovine Spongiform Encephalopathy (BSE) or "mad cow disease." This disease, which can spread from a cow to a human who ingests that cow, significantly impacted the British beef market. Travelers from the United Kingdom are asked to report if they have been in a rural area when entering the United States as a way to mitigate the spread of BSE in the United States. Despite these efforts, there have been a few cases of BSE reported in the United States, prompting the Japanese government to stop the import of U.S. beef into their country. This debate over the link between an economic import and the spread of a deadly disease has led to an intense economic struggle between these two trading partners. In another case, Haiti in the 1980s was identified as a key site for the spread of HIV, leading to the decimation of their tourist economy. Fear of SARS and Avian Bird Flu has similarly hurt the tourism economies of Hong Kong and Thailand.

Ironically, there are also potential consequences when the biological environment is intentionally modified to reduce certain diseases. The recent controversy over the link between heavy metals (particularly mercury or thimesoral) in vaccines and autism among young children is an example. Despite protestations from the pharmaceutical and medical communities, thimesoral has been removed from many vaccines in the last five years because of the intense scrutiny it has received. Mercury has been replaced with aluminum, which is sometimes linked to Alzheimer's and dementia, although no link has been made about the long-term effects of aluminum-based vaccines. So vaccines, despite their widespread use and high rates of success for stemming the diffusion of certain diseases, are not without controversy or concern. The hope that penicillin and other medicines more generally would put an end to infectious diseases in the 1970s, for example, has not come to fruition. Scientists underestimated the mutability of diseases.

Some of the most significant problems today stem from the fact that new forms of old diseases

Ryan White

There is a high degree of social stigma attached to the people and places thought to be diseased. Examples of this can be found throughout history with the development of leprosy colonies and asylums meant to house those who were thought to have mental diseases. Seen as unproductive economic citizens, the plan was to quarantine these populations to minimize their impact on the larger society. Stigma is also often fueled by misconceptions of how certain diseases are spread in the first place, leading many to conflate the causes of one disease with the spread of another.

Such confusion may have significant social implications, as people are made marginal because of misunderstanding. This is most classically seen in the case of Ryan White, a young boy who contracted HIV in the United States from a blood transfusion while treating his blood disorder known as hemophilia. Ryan White fought the stigma and isolation and became an important representation of how HIV was and was not transmitted.

are emerging that are resistant to the prophylactics meant to stem their spread. Newly developed malarial medications have not been able to keep pace with the mutation of malaria. It is quite possible to contract a strain of malaria that is drug resistant. Antibiotics, once seen as a panacea for all diseases, have been given in such large quantities for viral infections (where they are ineffective because antibiotics fight bacterial infections) that they are becoming ineffective against bacterial infections as well. In some cases, antibiotics have also destroyed the good bacteria in the body, giving rise to a new regime of medications called probiotics, designed to promote bacterial growth in the body; for example, in digestion. More generally, vaccine and other pharmaceutical developments are also controversial because they often pit individual rights (the right to vaccinate or not) against the larger public good (the right to be protected from various diseases).

Disease is not simply the absence of health, because a person can live a perfectly healthy (and long) life with a chronic illness. But, diseases are processes that lessen how a person might live. It is thus valuable to consider how diseases manifest themselves, how and why they might spread, where they spread, and how they might be contained. At the same time, diseases are not simply the responsibility of individuals; they are often tied to the dynamic changes taking place in socio-cultural, political–economic, and environmental contexts. Moreover, diseases are not isolated from one another. In fact, co-infections or co-factors are common and can exacerbate the consequences of having certain diseases. Malnutrition diminishes the body's capacity to fight off com-

Susceptibility to diseases is not without socio-cultural and political–economic links. For example, the daily operation of industrialized shrimp farms is often left to the working poor, who are more likely to be exposed to mosquitoes.
